Meteorologisches Observatorium
Lindenberg –
Richard-Aßmann-Observatorium
Lindenberg, Germany
frank.beyrich@dwd.de

Frank Beyrich has been Head of the Boundary Layer Processes Group at the Meteorological Observatory Lindenberg of the German Meteorological Service (DWD) since 1997. He organized the LITFASS field experiments in 1998, 2003, and 2009 that focused on the area-averaging of energy fluxes over a heterogeneous land surface. He has been performing atmospheric research with scintillometers since 1994, when he received his PhD at Freie Universität Berlin.

Oscar K. Hartogensis

Environmental Sciences – Meteorology
and Air Quality
Wageningen University
Wageningen, The Netherlands
oscar.hartogensis@wur.nl

Oscar Hartogensis works as a researcher at the Meteorology and Air Quality Group of Wageningen University in the Netherlands. He received a PhD in Meteorology in 2006 and works in the field of (turbulent) exchange processes between the atmosphere and the land surface. He has a special interest in developing new measurement methodologies for estimating fluxes at the land–surface interface, in particular related to the scintillometry technique.

**Henk A.R. de Bruin**

Bilthoven, The Netherlands
hardb@xs4all.nl

Henk de Bruin obtained his MSc in Physics at the University of Amsterdam and his PhD in Agricultural Sciences at Wageningen University. In 1985 he was appointed as Associate Professor at Wageningen University and worked there until his retirement. His research focused on micrometeorology with a special emphasis on turbulence and evapotranspiration. In the 1990s, he was one of the initiators of the "renaissance of scintillometry", which led to a broader application of scintillometers in many countries around the globe.

**Helen C. Ward**

Department of Atmospheric and
Cryospheric Sciences
University of Innsbruck
Innsbruck, Austria
helen.ward@uibk.ac.at

Helen Ward studied physics at Oxford University and received her PhD in urban micrometeorology from King's College London (2013). She carried out postdoctoral research at the Centre for Ecology and Hydrology, Reading University and Yonsei University and is currently based at Innsbruck University, Austria. Her research focuses on improving understanding of turbulent exchange, particularly in complex environments (e.g., urban areas and mountainous terrain), through measurements (eddy covariance, scintillometry) and modeling.

Acoustic Tomography

Armin Raabe , Manuela Starke , Astrid A. Ziemann 

Remote sensing techniques supply valuable observations from distant regions, which should not be disturbed or cannot otherwise be monitored. These observations often provide integrated information along the whole signal path. Thus, particular data analysis is necessary in order to generate a spatial mapping of the observed quantities. If a sufficiently large number of line-integrating or beam-integrating observations is available, tomographic techniques can be applied to combine these quantities to a spatially resolved two-dimensional or three-dimensional field according to output data of numerical atmospheric models. That way, for example, atmospheric temperature and wind fields can be derived by a special application of tomography presented in this chapter: acoustic travel-time tomography. This method uses the propagation speed of acoustic waves in air to estimate temperature and wind fields within the atmospheric surface layer.

The basic setup for acoustic travel-time tomography is a configuration of sound sources and sound receivers that are placed around an area under investigation. Knowing their exact positions, travel-time measurements provide information on the speed of sound along the acoustic propagation path between the sources and receivers. A subsequent joint analysis of the sound wave travel times, the tomographic inversion, gives the spatially resolved temperature field and the wind field. The technical setup of the method is described together with the required calibration and quality control procedures. Furthermore, selected results and an estimate of the achieved quality are presented.

Tomography is a noninvasive measurement technique combined with a special analysis algorithm and an imaging method. It is used to remotely monitor distributions of physical quantities without installing sensors in the area under investigation. For this purpose, influences on a probing energy, for example electromagnetic or acoustic waves, are analyzed. The waves

pass through an area under investigation along different paths and are changed by the properties of the medium. In most tomographic applications, the energy used for investigation is emitted and received by transducers which are placed around the area or volume of interest. It must be ensured that sources and receivers are arranged such that the signals pass through all parts of

the measurement domain on crossing paths. On their way they encounter different physical conditions of the medium. Thus, all recorded signals carry information about the medium from their individual ways through it. The observed modifications along all propagation paths are then used, to draw conclusions about the spatial distribution of properties within the investigation area. To do this, tomographic inversion algorithms are used. The mathematical algorithms used for this inversion aim at generating spatial distributions of physical quantities

within the measurement domain, which enable computation of synthetic signals that match optimally with the observed values.

Tomographic techniques require an enormous amount of measured data, which must then be handled and processed. The development of computer-based tomography is closely linked with an increase in the computing capacity which, in turn, leads to an increasing number of tomographic applications in science and technology.

35.1 Measurement Principles and Parameters

One special implementation of tomography for meteorological applications is the acoustic travel-time tomography (A-TOM). This technique is based on the dependency of effective sound speed on air temperature and the flow field (Tables 35.1–35.3). The values of the relevant physical constants (R_a , γ) can be found in Chap. 5. The warmer (and moister) the air is, the faster acoustic signals travel through it. Furthermore, the effective speed of acoustic signals that travel in the wind direction is increased, while it is decreased in upwind direction (Table 35.3). Sound speed measurements, which are based on the travel-time measurements between points whose positions relative to each other are known, contain information about the air temperature and the wind vector component along the sound propa-

gation paths. If sound sources (speakers) and receivers (microphones) are placed around the measurement area or volume in such a way that acoustic signals travel along different directions through this region, it is possible to reconstruct the spatial distribution of wind and temperature in the region spanned by the sound paths using tomographic inversion algorithms.

The A-TOM method is scalable and thus suitable for observing wind and temperature distributions at several spatial scales and application areas (e.g., over natural landscapes, detecting the flow conditions in a wind tunnel, or controlling the air conditioning in rooms). Subsequent descriptions concentrate on tomographic measurements within the atmospheric surface layer.

35.2 History

The theoretical basis for tomographic reconstruction techniques is connected with *Johann Radon's* (1887–1956) derivation of what is now called the Radon transform (1917) [35.1], a special form of the Fourier transformation. The Radon transform mathematically describes the line-integrated value of a function at a plane if this function changes spatially along the considered line. The result of the integral is called a projection. If one knows several projections from different imaging directions, one can inversely recalculate the distribution of this function.

35.2.1 Tomography in General

The Radon transformation is one important mathematical basis for the development of technically applicable tomographic reconstruction algorithms. Tomographic techniques are used to estimate cross sections of an object from line-integrated measurements [35.2]. Such methods are widely used in medicine, for example, to examine the interior of the human body without surgical intervention. For the development of x-ray computer-assisted tomography (CT, *Allan M. Cormack* (1924–1998), *Godfrey Hounsfield* (1919–2004)) and magnetic resonance tomography (MRT, *Paul C. Lauterbur* (1929–2007), *Peter Mansfield* (1933–2017)), the Nobel Prize was awarded in 1979 and 2003, respectively.

Since the development of the CT, tomographic techniques are developing and becoming more and more attractive for several applications in science and technology. Consequently, sonic tomography devices have also been developed for medical purposes (e.g., [35.3]).

Compared with developments in medicine (CT overview, e.g., in [35.4]), geophysics, (overview in [35.5, 6]) and oceanography (overview [35.7]), where acoustic tomography methods have been standardized and used routinely for many years, acoustic tomography in meteorology is still at a research state. Tomography of the atmosphere focuses on analyzing boundary layer structures (overview, e.g., in [35.8, 9]) and depicting flow and temperature fields in fluid dynamics [35.10] (see also Chap. 36).

35.3 Theory

Even if the mathematical tomographic method can theoretically reconstruct a temperature or flow field from an observed sound speed field, a reasonable reconstruction is only possible if the measurements are able to observe this velocity distribution with

35.2.2 Tomography in Air

The experiments of *Spiesberger* and *Fristrup* around 1990 [35.11] provided the basic ideas underlying recent developments in acoustic tomography for meteorology. At the time, they combined acoustic measurement methods with tomographic algorithms to improve the accuracy of location of chirping birds in complex surroundings. A few years later, *Wilson* and *Thomson* [35.12] used an acoustic array of loudspeakers and microphones to record wind and temperature fields over a homogeneous flat terrain. Similar developments were done by *Raabe*, *Arnold* and *Ziemann* [35.13, 14] to observe the structure of turbulent transport over a nonhomogeneous landscape. Special experiments and observational campaigns were implemented (e.g., [35.15]). The observed datasets are used to apply different tomographic algorithms [35.16, 17] that employ statistic, algebraic, or filter-procedures to invert the line-integrated information to a two-dimensional (2-D) or three-dimensional (3-D) distribution of meteorological quantities, which affect the sound propagation. An assessment of the meteorological potential of acoustic tomographic methods for atmospheric research is given in [35.9]. Note that signals of sound propagating through the atmosphere have long been used to obtain information about vertical and horizontal structure of the atmosphere within the troposphere up to the stratosphere, using natural and artificial sources of sound [35.9].

In our case the measurements use artificial sound sources and they are positioned within the atmospheric surface layer. The size of investigation areas or volumes includes scales of >100 m down to some meters. Acoustic tomographic methods are also used in wind tunnels [35.10] or inside of rooms to detect flow and temperature fields [35.18, 19]. An air stream tomograph, which was tested in laboratories [35.20], is another example of actual developments. The applications go down in spatial extent to record turbulent structures at the scale of an acoustic anemometer [35.21]. A newly developed tomographic application is the use of unmanned aerial vehicles as a sound source at different heights of the atmosphere, and an array of receivers at the surface, to reconstruct vertical structures in the boundary layer [35.22].

sufficient accuracy. The tomographic inversion techniques provide a useful result only if the measurement of the parameters are performed in sufficient spatial density and sufficient temporal sampling.

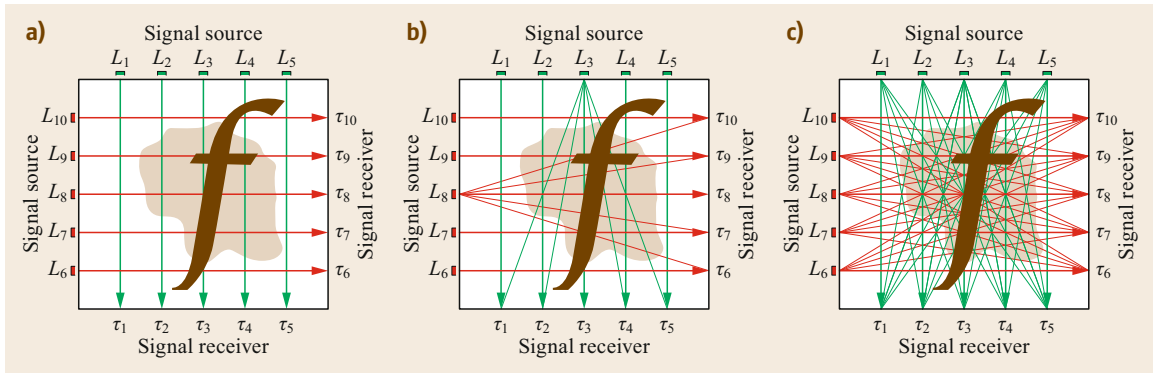

Fig. 35.1a–c Schematic view of a simultaneous or successive observation of signal travel times $\tau_i(1-10)$ at different paths $L_j(1-10)$, which cross the area characterized by a field f which in turn influences the propagation times and paths. The first example (a) shows schematically a single sound path between one fixed source and one fixed receiver. The number of paths throughout the field f increases due to the fact that the signal of one sound source can be detected by several receivers (b,c). With an increased number of sound paths a spatially higher resolved tomographic reconstruction of the field f is possible

35.3.1 General Procedures

The tomographic reconstruction of a spatial distribution of a quantity within a region, which can be described by a model function f , is based on measurements taken along different paths L through the medium (theoretically first described in [35.1]). The measurements take place along certain propagation paths, which are characterized by the position of the signal sources and signal receivers, and by the properties of the medium. Because such measurements contain information about the integral conditions along the entire propagation path, the measured data are referred to as line integral values or projections. The tomographic inversion is then an algorithm that can deduce the distribution f from the knowledge of the line integral values illuminating the medium from different view directions.

In the case of acoustic tomography described here, these line-integrated values are travel-time measurements. The observed quantity is the signal travel time τ between the transmitter and the receiver, which is related to the propagation medium by the line integral

$$\tau = \int_L f dL, \quad (35.1)$$

where L is the signal path length through the medium and f is a scalar field that describes the speed of the propagating wave in the medium. For acoustic waves in a non-moving medium, $f = s = 1/c_L$ is the slowness, the reciprocal of the Laplace sound speed c_L . In refractive media, the signal path is in general a curved path, which depends on the field f . The observed travel time τ does not provide information about the exact signal

path L or the distribution of f along L and is therefore a nonlocal path-integrated quantity.

The basic idea of atmospheric tomography is to combine a large number of travel-time observations that scan the investigated region from many directions in order to obtain a well-resolved approximation of the field f . For a given set of observations τ_i , a set of equations

$$\tau_i = \int_{L_i} f dL_i, \quad (35.2)$$

has to be solved for the unknown function f (scheme is shown in Fig. 35.1). As the corresponding curved signal paths L_i depend on f , this is a nonlinear inverse problem. It is also an ill-posed problem as (1) there may be no solution in a strict mathematical sense, especially if real noisy observations are considered, (2) the solution is usually not unique, and (3) the solution is not stable (Chap. 36). In real applications, the problem is also globally underdetermined as the number of observations is in general insufficient to describe the field f .

The extension of field f is determined by the propagation paths between the positions of the signal sources and signal receivers. In the case of acoustic tomography, the source is a sound transmitter and the receiver is a microphone. The reconstruction of the f field is possible because different paths cross different parts of the field leading to different travel times, when the signals interact with different parts of f . An inversion algorithm searches for such a distribution of f that the observed travel times can be reproduced. To solve this inverse problem, numerous algorithms have been developed. These can be subdivided into four main groups. A solu-

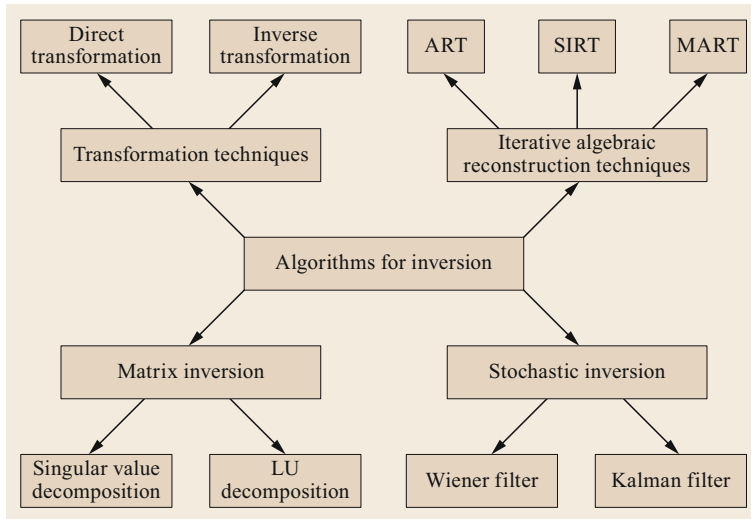

Fig. 35.2 Classification of inversion techniques (ART – algebraic reconstruction technique, SIRT – simultaneous iterative reconstruction technique, MART – multiplicative algebraic reconstruction technique, LU – lower-upper matrix decomposition) (after [35.23] © G. Fischer, with kind permission of the author). In the literature, examples for all the methods can also be found in the field of meteorology (Sect. 35.10)

tion method cannot be favored and should be chosen depending on the specific application of tomography (Fig. 35.2).

35.3.2 Sound Speed in Air

If the composition of air is constant, the effective speed of sound in air depends on the air temperature and the wind vector. In nature, the composition of air is constant for the ratio of nitrogen, oxygen and argon, but it is variable with respect to the proportion of water vapor. That means, the sound speed is influenced by water vapor concentration which is accounted for by use of acoustic virtual temperature instead of air temperature (Table 35.2). Under average conditions, the sound speed increases by 0.6 m s^{-1} if the absolute air temperature increases by 1 K. In the same manner, the sound speed increases by 0.1 m s^{-1} if specific moisture increases by $10^{-3} \text{ kg kg}^{-1}$.

Under normal atmospheric conditions, the air temperature can vary in time or from position to position by $\approx 10 \text{ K}$ over a day (a moderate value). Hence, the sound speed changes by $\approx 6 \text{ m s}^{-1}$. The moisture can vary maximally by 10 g kg^{-1} (a very big value) followed by sound speed changes by 1 m s^{-1} . That is the reason for the assumption applied in the following: the sound speed based on the acoustic virtual temperature is only slightly influenced by air moisture variability. Of course, the individual gas constant and specific heat ratio must be known for another gas composition to calculate the sound speed (Table 35.3).

Regardless of the exact composition of the air mixture, the movement of the medium always influences the speed of sound as follows. The sound speed decreases if sound waves are traveling against the flow

direction (i.e., against wind direction), increases in downwind direction and does not change under cross-wind conditions. This statement is limited to a flow speed $|v|$, which is much smaller than the sound speed c_L (Fig. 35.3). This limitation must be taken into account when describing the propagation of sound waves in a moving medium.

In a medium at rest, the sound wave propagates with a speed c_L in a direction \mathbf{n} normal to the acoustic wave front

$$c_L = c_L \mathbf{n} .$$

The sound velocity along the sound propagation in a moving medium point in a different direction \mathbf{s} tangent to the sound ray path

$$c_{\text{ray}} = c_{\text{ray}} \mathbf{s} .$$

Fig. 35.3 Velocity of acoustic signals propagating in a moving atmosphere illustrated by a relocated wave front (dashed lines) at time t and $t + \Delta t$ (after [35.10] © IOP Publishing, reproduced with permission, all rights reserved)

The sound energy propagates along this vector, which results from the vector sum of the speed of sound vector in the wave front direction and the velocity \mathbf{v} of the moving medium

$$c_{\text{ray}} = c_L \mathbf{n} + \mathbf{v}.$$

Of interest is now the magnitude of the sound speed

$$c_{\text{ray}}(\mathbf{s} \cdot \mathbf{s}) = c_L(\mathbf{n} \cdot \mathbf{s}) + \mathbf{v} \cdot \mathbf{s}.$$

Only under assumption $|\mathbf{v}| \ll c_L$ the direction of \mathbf{n} and \mathbf{s} are near the same.

The resulting sound speed is called effective sound speed

$$c_{\text{ray}} = c_L + v_r = c_{\text{eff}}.$$

A detailed description of the physics of sound propagation in moving media can be found in [35.24, 25]. In history, *J.W.S. Rayleigh* [35.26] introduced this concept of effective sound speed for a small wind speed in comparison to the magnitude of Laplace (adiabatic) sound speed c_L in air, which only depends on acoustic virtual temperature T_{av} , (Tables 35.2 and 35.3). The effective sound speed is then determined by the component of the wind vector, which acts in or against the propagation direction of the sound wave. Using this approximation, methods developed for a motionless medium can be applied to a moving medium. In practice, the applicability of the effective sound speed approximation should be investigated for the individual application [35.27].

35.3.3 Acoustic Travel Time

Measuring sound speed is described in the following from the perspective of a propagation of known sound signals over greater distances (order of magnitude: 50–500 m). The approach was proven in practice with several applications of acoustic tomography inside the atmospheric boundary layer.

The speed of sound between a source and a receiver is estimated as the quotient between the geometric sound path length D and the elapsed time of an acoustic signal, which travels along this path. The assumption of straight-line sound propagation is thereby used, i.e., it is assumed that the influence of spatial sound speed variability is primarily in first order in comparison with the influence on the sound path length due to sound refraction. To neglect the influence of refraction on the sound path, the actual sound speed gradients, especially in the vertical direction, have to be checked and the length of the sound path must be limited.

The distance between transmitter and receiver can be determined relatively simply, e.g., with an electronic

tachymeter, even at distances of > 100 m with an uncertainty of a few millimeters. It is important that the geometric distance also coincides with the positions of the transmitted and received signal, which are not so easy to determine, because of the finite dimensions of the transmitter and receiver.

To analyze the travel time using the record of sound signals between sound source and receiver, a successfully used technique is based on cross correlation between the transmitted and received signal [35.12].

The travel time of the acoustic signals between a sound source and a receiver corresponds to the time delay of the received signal relative to the time of its emission at the source. Assuming that the signal is not changed along its propagation path, the received signal $y(t)$ corresponds to a time-delayed version of the transmitted signal $x(t)$: $y(t) = x(t - \tau_0)$. The time delay τ_0 is estimated by analyzing the cross correlation function $r_{x,y}(\tau)$ between the transmitted and the received signal

$$\begin{aligned} r_{x,y}(\tau) &= \int_{-\infty}^{\infty} x(t)y(t + \tau)dt \\ &= \int_{-\infty}^{\infty} x(t)x(t - \tau_0 + \tau)dt. \end{aligned} \quad (35.3)$$

The cross correlation function reaches its maximum for the delay $\tau = \tau_0$, which corresponds to the travel time of the acoustic signal. This cross correlation technique for estimating the travel time requires special properties of the generated signals. From information technology so-called pseudorandom sequences (MLS: maximum length sequences) are known whose autocorrelation is characterized by an impulse-like function [35.28]. In such a signal, however, all sound frequencies are included similar to white noise, which may not fully be transmitted by the sound sources. Furthermore, the air absorbs sound energy, especially for higher sound frequencies. Hence, it then cannot be ensured that the signals are transmitted along the sound propagation paths without any changes in their signals' signature. However, it should be noted that such MLS signals have been successfully applied for short distances up to a few meters [35.10, 18, 28].

For applications of the method with distances between the sources and receivers of several decameters up to a few hundreds of meters in the atmospheric boundary layer, signals with a fixed sound frequency, two wave trains with a defined number of oscillation periods, and a pause between them are used [35.29, 30]. The chosen frequency has to be adjusted to the hardware (speakers) and a possible high-pass filtering of the received signal has to be taken into account. This,

Fig. 35.4 (a) Normalized signal amplitude (nsa) of a theoretical acoustic signal (out) consisting of 2×2 sine periods with a frequency of 7 kHz interrupted by a break, (b) the normalized signal amplitude of the received signal (nsa (input)), and (c) the normalized cross correlation function (nccf) between the generated and the received signal. The nccf maximum is marked with a filled circle. The associated time lag corresponds to the travel time of the acoustic signal (adapted from [35.29])

in turn, is recommended in noisy environments (street noise) to enhance the signal-to-noise ratio (SNR). An upper limit for the sound frequency is given because atmospheric absorption of sound increases for increasing frequency [35.31], which is especially important for long-range sound propagation. The sample rate of the device has to be high enough to ensure that the signal frequency could be represented properly with respect to the sampling theorem, which states that the sample rate has to be at least twice as high as the signal frequency.

It is possible to synthetically increase the sample rate by interpolating the signal to estimate interim values within the sampling time of the data logger using a sinc function. With such a method it is possible to increase temporal resolution by a factor of ≈ 10 [35.28]. This leads to a sharper detection of the maximum using the cross correlation method described above.

Successful experiments have been carried out with sound frequencies of 1 kHz [35.14] and 7 kHz ([35.29, 32], cp. Fig. 35.4). Wilson and Thomson [35.12] worked with a swept-frequency signal (Table 35.4).

Table 35.4 Examples for used sound signal structures to detect travel times by the cross correlation technique

Reference	Data logger sampling rate (kHz)	Sound signal	Interpolation after cross correlation
[35.30]	10	1 kHz double burst of 4 ms duration with a 14 ms pause between the bursts	–
[35.29]	51.2	2×2 sine periods with a frequency of 7 kHz with a break of ≈ 1 ms	Using sinc
[35.12]	16	Sine wave sweep 100–1000 Hz, duration 0.1 s	–
[35.10]	51.2	Pseudorandom sequences (MLS)	Using sinc
[35.18]	51.2	Pseudorandom sequences (MLS)	Using sinc

35.3.4 Separation of Temperature and Flow from Sound Speed

If the distances between transmitters and receivers in the measuring area are known, then the observed sound travel times over the distances between transmitter and receivers can be used to calculate an effective sound speed. This velocity reflects the path-integrated influence of the acoustic virtual temperature and of the wind vector. Because the observed effective sound speed is influenced by temperature and the wind vector, the measurement method itself or the analyzing algorithm must allow to distinguish between temperature and wind if one is interested in the meteorological quantities.

There are examples of the use of bidirectional sound paths, which may be spatially separated in the measurement field [35.33]. In practice the measuring sections do not necessarily have to be arranged at right angles to record the full information for the calculation of the horizontal wind; however, this can be advantageous depending on the inversion scheme (Fig. 35.5) [35.28, 34].

Other methods use stochastic inversion, which is designed from the outset to generate two separate distributions of the direction-independent temperature field and the direction-dependent flow field from the sound speed data. Such procedures have to specify some parameters, which describe the turbulent nature of the underlying meteorological fields of temperature and flow velocity [35.20, 35, 36].

Some methods firstly separate influences of temperature and wind included in the effective sound speed. In a second step, these separated datasets are converted into spatial distributions of wind vector and temperature using inversion algorithms. The most favorable method is probably the use of reciprocal transmission paths.

Examples with consistently reciprocally arranged sound paths are analyzed in [35.37].

In the following, we describe the application of the reciprocal method to separate datasets of temperature-dependent and wind-dependent sound travel time from

the measurements. These data are used after the separation as input data for tomographic algorithms.

This method for separating is based on the fact that scalar temperature influences the speed of sound independently of the direction of sound propagation, while the influence of flow depends on the direction. A flow component in the direction of sound propagation yields an increase of the effective sound speed, while it leads to a decrease in the opposite direction, as is obvious from $c_{\text{eff}} = c_L(T_{\text{av}}) + v_r$ (Table 35.3, Fig. 35.5).

To separate the vectorial and scalar influences, an arrangement consisting of two transmitter–receiver pairs is used in which they are facing each other in opposite directions at a defined distance D (Fig. 35.5).

Two sound sources (loudspeakers) and two receivers (microphones) are mounted at a distance D . Along both directions the travel time of an acoustic signal τ is measured. The effective sound speed in the direction of the flow component along the sound ray path v_r is given as a sum of the adiabatic sound speed c_L and v_r : $c_{\text{eff},1} = c_L + v_r$. In the opposite direction the effective sound speed is given as a difference $c_{\text{eff},2} = c_L - v_r$.

The indices mark the forward (index 1) and backward (index 2) direction. Consequently, c_L or T_{av} as well as v_r along the straight propagation paths between the transmitter–receiver pairs can be calculated

$$c_L = \frac{1}{2} (c_{\text{eff},1} + c_{\text{eff},2}) = \frac{D}{2} \left(\frac{1}{\tau_1} + \frac{1}{\tau_2} \right) = \sqrt{\gamma R_a T_{\text{av}}}, \quad (35.4)$$

$$v_r = \frac{1}{2} (c_{\text{eff},1} - c_{\text{eff},2}) = \frac{D}{2} \left(\frac{1}{\tau_1} - \frac{1}{\tau_2} \right). \quad (35.5)$$

This approach is also used, at a very small scale, by sonic anemometer/thermometer (for an overview see Chap. 9 and [35.38]).

Fig. 35.5a,b Scheme of bidirectional (a) or reciprocal sound propagation (b) used to separate scalar temperature and the vectorial flow influence on the effective speed of sound (sound source: loudspeaker; receiver: microphone)

In this result, two datasets of simultaneous observations exist:

1. A dataset of Laplace sound speed values for each transmitter–receiver pair
2. A further dataset for the wind speed component along the sound propagation path, which influences the speed of sound between each transmitter–receiver pair

A distribution of several such pairs enables probing through an area or volume of air from different directions. Therefore, it is possible to obtain information from mostly all parts of a measuring area or volume. This information consists of averages along lines, which must be understood as projections for using tomographic reconstruction methods. Such precisely recorded datasets create the requirements for the technical developments of acoustic tomography and the experimental setup to reconstruct air temperature and velocity fields.

35.3.5 Uncertainty

The basis for accurate tomographic reconstruction of temperature and flow fields in air is a proper estimation of the speed of sound along different paths through the area. In order to calculate the speed of sound (Table 35.3) between a source and a receiver precisely, the transmission path length and the travel time along this path must be measured or known. Several issues, e.g., technical and signal-dependent, influence the travel-time determination leading to uncertainties due to sampling and signal analysis as well as to possible errors in recalculated wind speed and temperature values [35.29].

To detect the signal within the environmental noise, the SNR should be as high as possible. Thus, sound attenuation effects in air should be minimized. The measured sound pressure level at a microphone depends on the effects of spherical spreading, i.e., geometrical sound attenuation, and attenuation due to air absorption. Atmospheric absorption is primarily dependent upon sound frequency and secondary on air temperature and humidity [35.31]. Additionally, interference from environmental sounds near the microphones should be avoided. Unfortunately, the wind itself creates flow noise on the microphones. Windscreens for microphones are a useful tool to avoid this noise contamination.

The travel-time measurements require application of an acoustic multichannel device, which uses a common temporal basis for all output and input channels. The digital record of a continuous acoustic signal is im-

plemented with an analog digital converter (ADC). The ADC provides discrete values with a time resolution (sampling interval or sample period Δt) that depends on the sampling frequency or sampling rate f_s of the device: $\Delta t = f_s^{-1}$. Thus, an increasing sampling rate results in a decreasing uncertainty of the travel-time estimates. On the other hand, an increasing sampling rate is followed by higher demands on storage space and data processing capacity. Furthermore, a reduction of the time intervals between successive data points can be achieved by interpolating, e.g., using the sinc function [35.28].

The sampling rate f_s must be high enough to record the complete sound frequency range $f_{\text{sound}}^{\text{max}}$ contained in the used sound signal. Here, the sampling theorem and the resulting Nyquist frequency f_v must be kept in mind: $f_s = 2f_v \geq 2f_{\text{sound}}^{\text{max}}$ [35.39].

Further, it is important to take into account that the electronic transmission and reception of the sound signals requires a certain amount of processing time in the electronic device itself. This period is not part of the sound travel time; nevertheless, it must be determined separately to include the inertia time of the electronics in the process of analysis.

Additional uncertainties with respect to travel-time estimation arise from the properties of the signal analyzing method, e.g., of the cross correlation function. The most certain results can be achieved for signals with an impulse-like autocorrelation function, i.e., for an impulse-like signal or white noise. However, both signals are inappropriate for acoustic travel-time applications with path length of more than several meters. Impulse-like signals would require an enormous excitation energy in order to generate a signal. A single impulse is not suitable to drive a speaker appropriately (without any damage). On the other hand, white noise is not bandlimited, which, in turn, would require an infinite sampling rate. Thus, signals are used which hold a special signature as shown in Fig. 35.4 and whose autocorrelation function is characterized by a clearly distinguishable maximum. At the very least, one must estimate the uncertainty of the travel-time measurement $\Delta\tau$, which is $\Delta\tau \geq \Delta t$.

For an estimation of the effective speed of sound, not only the travel-time measurements have to be implemented with a small uncertainty, but also the positions of the sound sources and receivers have to be known exactly. Thus, the measurement of positions should be put into practice using a device, which reaches a very high accuracy, e.g., an electronic tachymeter. With such a device, the geometric distances D along all sound travel paths can be measured within an uncertainty dD of only a few millimeters up to path lengths of several hundred of meters.

Fig. 35.6 Uncertainty of the derived temperature and wind speed along the propagation path as dependent upon the uncertainty in the determination of acoustic travel time normalized by the distance between the sound source and receiver, applying reciprocal sound propagation. The uncertainties associated with various experiments are marked (red STINHO-1, -2 [35.30]; blue SQuAd [35.29], green [35.12])

When employing reciprocal sound paths, one assumes sound wave propagation along straight rays with measured geometric distances between sources and receivers. However, the geometric distances and the sound path lengths are not identical in any case due to gradients of temperature and wind along the sound propagation path, which cause a refraction of the sound wave. Generally, in the atmosphere, vertically increasing wind speed prevails, while air temperature can decrease or increase with height. In the horizontal direction, all conceivable gradients can exist. As a result, the sound propagates along curved lines. These deviations from the geometric distances produces a systematic uncertainty in the sound speed measurement, which results in uncertainties in determination of temperature and wind speed [35.29, 32].

For practical applications, it is possible to measure with absolute or relative accuracy.

Absolute accuracy means that the distances between all sources and receivers are measured with an uncertainty dD and that acoustic travel times are measured with an uncertainty of $d\tau$. Thus, the resulting uncertainty of the estimated speed of sound depends on both, dD and $d\tau$. Relative accuracy refers to measurements of acoustic travel times, where positions of sources and receivers are calculated using an alternatively measured temperature and wind distribution as an initial calibration of the system. After doing this calibration, changing travel times are only attributed to variations in temperature and wind speed with regard to the initial conditions at the calibration time. Consequently, uncertainties of the positioning of sources and receivers can

be neglected, resulting in higher accuracies of relative measurements. Nonetheless, this approach requires precise knowledge of temperature and wind distribution within the area under investigation at the calibration time.

Ziemann et al. [35.29] show the complete derivation of temperature and wind uncertainty assuming an exact sound path determination for reciprocal sound propagation. The analysis indicates that the uncertainty of the temperature is given by

$$\Delta T_{av} = 2\sqrt{\frac{T_{av}}{\gamma R_a}} \Delta\tau \left[\frac{(\gamma R_a T_{av}) + v_t^2}{D} \right], \quad (35.6)$$

$$\Delta v_t = \Delta\tau \left[\frac{(\gamma R_a T_{av}) + v_t^2}{D} \right]. \quad (35.7)$$

As an illustration, for a travel-time accuracy of $78 \mu\text{s}$ (SQuAd-Project, spatially resolved quantification of the advection influence on the balance closure of greenhouse gases [35.29]) and a path length of 50 m (i.e., travel-time uncertainty normalized by distance of $1.6 \times 10^{-6} \text{ s m}^{-1}$), a maximum temperature uncertainty of $\approx 0.3 \text{ K}$ results for the instantaneous single path measurement (Fig. 35.6). The uncertainty of relative wind measurements depends only on the uncertainty of travel-time measurements. Assuming again a path length of 50 m, a maximum wind uncertainty for the instantaneous single path measurement of $\approx 0.2 \text{ m s}^{-1}$ results. For other experiments (e.g., STINHO, structure of turbulent processes under inhomogeneous surface conditions [35.15, 30]) in the past, a travel-time un-

certainty of $300\ \mu\text{s}$ was achieved applying path lengths of $\geq 200\ \text{m}$ (i.e., normalized, by distance, travel-time uncertainty of $1.5 \times 10^{-6}\ \text{s m}^{-1}$) resulting in similar temperature and wind uncertainties. With increasing path lengths, the uncertainty of temperature and wind components decreases. Otherwise, for a constant distance between sound source and receiver, the uncertainties are lower for a lower uncertainty in the travel time (Fig. 35.6).

35.3.6 Experimental Setup

A tomographic measurement setup using reciprocal sound propagation (Sect. 35.3.4) is based on measurements that determine the speed of sound along one and the same propagation path in the backward and forward directions. This is similar to a sonic anemometer which spans long distances (Chap. 9). Conversely, a sonic anemometer can also be understood as a tomographic array [35.21].

For tomography, a number of transmitter/receiver stations must be distributed within the area of investigation (Fig. 35.7). Some experimentally realized transmitter/receiver distributions are presented in Sect. 35.8. To prepare a measuring configuration the following topics are helpful.

Spatial Distribution

Sound paths must pass through all parts of the area spanned by the positions of the transmitter/receiver stations. In order to obtain information about the spatial

distribution of sound velocities within the area of interest, several sound sources and receivers have to be positioned around or inside the area. To reconstruct temperature and flow field using an inversion algorithm, the resultant sound paths should cover the area of interest as homogeneously as possible. The length of sound paths must be known as exactly as possible. Applying reciprocal sound propagation and algebraic reconstruction techniques (Sect. 35.3.7), positions of sources and receivers have to be chosen in such a way that a separation of the influences of temperature and flow on the speed of sound is possible. It would be advantageous if the distance between the transmitter/receiver positions at the border of the measuring field (red line) are chosen in such a way that the sound path lengths differ as far as possible between all positions. In such a case, the sound signals reach the receiver at different times, and the single signals can be easily identified.

Identification of Sound Signals

Sound sources and receivers situated close to the ground make sound propagation more complex. Besides direct sound waves between loudspeaker and microphone, there are also ground-reflected waves [35.40]. This reflected wave integrates the conditions of the air layer between the ground surface and the source/receiver. Additionally, the interference between those sound reflections can lead to considerable effects within the received signal, which should be estimated before starting with the experimental setup.

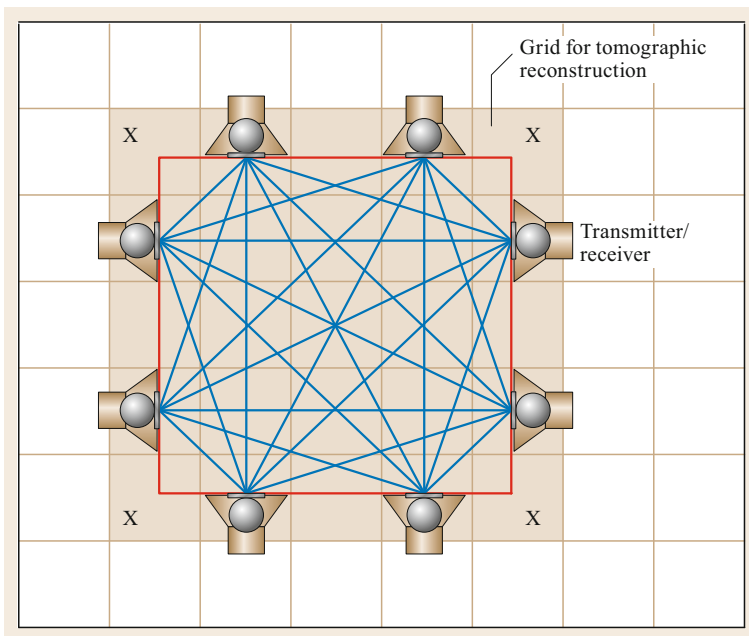

Fig. 35.7 Schematic representation of the measuring principle of acoustic travel-time tomography. An area is scanned along various paths by sound signals (blue lines), which are sent (received) from loudspeakers (microphones) at different locations. The determination of travel times of the signals along known propagation paths allows the calculation of the effective speed of sound and thus provides information about the temperature and flow along the propagation path (X: grid cells without any crossing sound ray)

Furthermore, it has to be ensured that the acoustic signals, which reach the receiver from different transmitters, can be clearly assigned to the source of origin. This can be implemented using a different signal signature for each transmitter or by choosing the distances between all transmitters and receivers in such a way that all paths have different lengths (i.e., clearly distinguishable travel times). In the latter case, a time window can be defined for each sound propagation path, in which the signal is expected to arrive at the receiver. The time window size must be selected so that, during the measurement time, possible wind and temperature changes leading to travel-time changes can also be recorded. By specifying a detection range for air temperature or wind, the time window size can be set.

Resolution of Field Reconstruction

Especially for algebraic reconstruction (inversion) techniques, the area under investigation must be subdivided into distinct grid cells. Within each grid cell, the physical properties (both temperature and wind) are assumed to be constant. After separation of the influences of temperature and flow on the speed of sound (Sect. 35.3.4), the meteorological fields are reconstructed independently using various tomographic inversion methods.

In the example of Fig. 35.7, the area of investigation is divided in $5 \times 5 = 25$ cells. In this example, there is no sound path through the cells at the corners (X) of the tomographic grid. Hence, there is no information available for tomographic inversion within these grid cells (or voxels in 3-D case) and the available information has to be extrapolated from neighboring cells. In the optimal case, the sound paths are traveling through all parts, i.e., all grid cells, of the measuring area.

Before starting with a tomographic field experiment it is appropriate to test the arrangement of sound sources and receivers applying optimization algorithms. This is due to the fact that an acceptable reconstruction of the temperature and velocity fields in the measurement area strongly depends on the arrangement of the sound transmitters and receivers and their number. As a rule, a study area equipped with M transmitters and N receivers can ultimately be decomposed into $(M \times N)/2 = J$ subareas for which temperature and velocity can be identified. The denominator 2 results from the separation of wind and temperature as required for reciprocal sound propagation, which means that each two sound paths are identical. The prerequisite for the use of tomographic procedures is that the positions of the transmitters and receivers and their mutual position are known. The arrangement of transmitters and receivers is limited only by imagination. When

positioning, the above-mentioned influences on sound propagation should be considered.

35.3.7 An Example of Inverse Tomographic Reconstruction

In the following, the reconstruction of temperature and velocity fields from travel-time (sound speed) measurements is explained with an example. The example uses the simultaneous iterative reconstruction technique SIRT (Fig. 35.2), which has proven to be one of the most robust algebraic reconstruction techniques [35.41, 42].

SIRT presupposes that after recording the signal travel times along all paths between sound sources and receivers it is possible to divide the sound speed observation into two parts:

1. Travel times which are only influenced by Laplace sound speed along all paths
2. Velocities v_i that represent the influences of wind component on the sound speed along the paths.

Here we note that the time-dependent stochastic inversion (TDSI) [35.16, 35] exhibits comparable results, with the advantage that the datasets must not be divided into a Laplace sound speed part and a velocity part, but one has to know additional information of the turbulent field structure.

Reconstruction of (Air) Temperature Fields

The following information must be available (see Sect. 35.3.1):

For each transmitter–receiver pair $1 \leq i \leq I$: temperature-dependent travel time of acoustic signal τ_i

$$\tau_i = \int_{L_i} \frac{dL_i}{c_{L,i}} \quad (35.8)$$

and sound path length L_i to estimate the Laplace sound speed at the path $c_{L,i} = L_i/\tau_i$, or the so-called slowness $s_i = \tau_i/L_i$ along L_i .

For a tomographic reconstruction using SIRT the whole area of interest, through which the sound propagates, is subdivided into J grid cells. The path length between transmitter and receiver is then given by

$$L_i = \sum_{j=1}^J l_{ij}, \quad (35.9)$$

where l_{ij} is the path length of the i -th sound ray path through the j -th grid cell.

Each piece l_{ij} can be affected by the individual slowness s_j

$$\tau_i = \sum_{j=1}^J l_{ij} s_j. \quad (35.10)$$

The aim of the tomographic reconstruction is to estimate a set of slowness values for all grid cells $j = 1, \dots, J$ in such a way that, for a given geometry (course of sound paths through a defined grid cell structure), the measured travel-time values along all $i = 1, \dots, I$ rays are well represented.

The calculation of slowness values for all grid cells using algebraic reconstruction techniques requires the following steps [35.10]:

1. Presetting of an initial distribution for the slowness values (e.g., homogeneous distribution)
2. Calculation of travel-time values for all sound ray paths according to (35.10) (forward modeling)
3. Computation of deviations between calculated and measured travel-time values and subsequent calculation of corrections for slowness values within each grid cell
4. Calculation of an improved slowness distribution within the tomographic grid
5. Repetition of steps 2–4 until a termination criterion is reached (maximum number of iterations, maximum deviation between modeled and measured travel-time values)
6. Stop of iterative process, and calculate distributions of acoustic virtual temperatures from slowness values/Laplace's sound speed values using the physical relations from Tables 35.2 and 35.3

For the most applications presented here, SIRT is used to calculate the slowness distribution within the grid cell structure. Advantages of SIRT are its favorable convergence properties, its low computational requirements (which allows for online analyses), and also its low sensitivity with respect to small perturbations of the input data, i.e., the travel-time measurements [35.43]. Furthermore, no additional information on the properties of the distribution is required prior to the reconstruction using SIRT. In contrast to other algebraic methods, SIRT calculates corrections for the slowness values within each grid cell Δs_j but not before all modelled (τ_i^{calc}) and measured travel-time values (τ_i^{meas}) have been treated

$$s_j = L_j^{-1} \sum_{i=1}^I \left(l_{ij} \frac{\tau_i^{\text{meas}} - \tau_i^{\text{calc}}}{L_i} \right). \quad (35.11)$$

Here,

$$L_j = \sum_{i=1}^I l_{ij}$$

represents the length of all sound ray sections within grid cell number j . Hereafter, the new distribution of slowness values (superscript $t + 1$) within the grid can be calculated from the present distribution and correction (superscript t) by $s_j^{t+1} = s_j^t + \Delta s_j^t$.

Reconstruction of Wind Velocity Fields

In order to reconstruct the vector wind field within the area of interest, a vector tomographic algorithm has to be used. An overview on vector tomography is given in [35.44]. As consistent with the temperature reconstruction, an iterative tomographic algorithm is used for flow reconstruction [35.10, 37]. Basic information can be found in [35.45].

To reconstruct the flow field distribution, the area of interest is divided into J grid cells as it is done for temperature reconstruction. The measured flow values v_i along I different propagation paths serve as input data for the tomographic reconstruction of the flow field. Starting from an initial guess for the flow values within each grid cell j (e.g., for a three-dimensional wind vector $\mathbf{v}_j = (u_j, v_j, w_j) = (0, 0, 0)$ – calm) an iterative algorithm is used to improve the grid cell solution up to a termination criterion.

To improve the solution, the projection of the flow field on the i -th sound ray path $v_{r,i}^{\text{calc}}$ is calculated dependent on the grid cell values for the flow for each grid cell j and the fraction of the ray path length of the i -th sound ray within the j -th grid cell l_{ij} , where the total length of the i -th sound ray is L_i

$$v_{r,i}^{\text{calc}} = \frac{1}{L_i} \sum_{j=1}^J l_{ij} [(u_j \cos \alpha_i + v_j \sin \alpha_i) \cos \theta_i + w_j \sin \theta_i], \quad (35.12)$$

$$v_{r,i}^{\text{calc}} = \frac{\sum_{j=1}^J l_{x,ij} u_j + l_{y,ij} v_j + l_{z,ij} w_j}{L_i}. \quad (35.13)$$

In this equation, $l_{x,ij}$, $l_{y,ij}$, $l_{z,ij}$ denote the signed fraction of the i -th sound ray path within the j -th grid cell in the x -direction, y -direction, and z -direction, respectively. The flow vector within each grid cell j is given by its components $\mathbf{v}_j = (u_j, v_j, w_j)$ as before. The angles in (35.12) describe the geometry of the sound ray path within the volume, where α_i is the azimuth angle of the projection of the i -th ray path on the horizontal plane and θ_i is the elevation angle of the i -th sound ray path measured from the horizontal plane (Fig. 35.8).

Fig. 35.8 Geometry for the i -th sound ray path, which is defined as a straight connection between a sound source (S) and a receiver (R) within a Cartesian coordinate system. L_i is the total length of the sound ray path, while $L_{x,i}$, $L_{y,i}$ and $L_{z,i}$ are the orthogonal projections of the sound ray onto the x -axis, y -axis, and z -axis of a Cartesian coordinate system, respectively (from [35.10], © IOP Publishing. Reproduced with permission. All rights reserved)

A measure for successive improvements of the solution within all tomographic grid cells is given by

the difference between $v_{r,i}^{\text{calc}}$ and the measured velocity component along the i -th sound ray path $v_{r,i}^{\text{meas}}$

$$\Delta \mathbf{v}_j = \begin{pmatrix} \Delta u \\ \Delta v \\ \Delta w \end{pmatrix}_j = \left\{ \begin{array}{l} \left[\sum_{i=1}^I |L_{x,ij}| (v_{r,i}^{\text{meas}} - v_{r,i}^{\text{calc}}) \cos \theta_i \cos \alpha_i \right] L_{x,j}^{-1} \\ \left[\sum_{i=1}^I |L_{y,ij}| (v_{r,i}^{\text{meas}} - v_{r,i}^{\text{calc}}) \cos \theta_i \sin \alpha_i \right] L_{y,j}^{-1} \\ \left[\sum_{i=1}^I |L_{z,ij}| (v_{r,i}^{\text{meas}} - v_{r,i}^{\text{calc}}) \sin \theta_i \right] L_{z,j}^{-1} \end{array} \right\}. \quad (35.14)$$

In the preceding equation, $|\cdot|$ stands for the absolute value, e.g., $|L_{x,ij}|$ is the absolute length of the i -th sound ray path within the j -th tomographic grid cell in the x -direction and $L_{x,j}$, $L_{y,j}$, and $L_{z,j}$ are the total lengths of all sound ray paths within the j -th grid cell in the x -, y -, and z -direction, respectively.

35.4 Devices and Systems

Standardized equipment for applications of acoustic tomography in atmospheric sciences does not exist at present. Generally, a measurement system consists of a multichannel controlling and recording unit together with sound sources (loudspeakers) and sound receivers (microphones). Additionally, a procedure and a device (e.g., electrooptical device like a tachymeter) to locate the transmitter and receiver at exact positions within the area of investigation is needed (Fig. 35.9).

35.4.1 Travel-Time Recording

The electronic devices must be able to record the sound signal correctly. It is advantageous if the used sound signals have a signature to identify the artificial signal within the environmental noise recorded by the microphone unit. In several implementations (e.g., [35.14, 42]), the acoustic signal consisted of a defined repetition of short pulses. To derive the travel time of the received sound signal, a cross correlation method between transmitted and received signals was successfully used (Sect. 35.3.3). Transmission and reception of signals could be controlled by an acoustic spectrometer card, which has a common time base for all input and output channels. The sample rate of this device has to be

high enough to ensure that the signal frequency is represented properly with respect to the Nyquist sampling theorem (e.g., [35.39] Chap. 2).

35.4.2 Sound Sources and Receivers

Commercial loud speakers of different types are used as sound sources, which are designed for different frequency ranges and a wide angle of sound emission. The sound receivers are commercial microphones. Figures 35.10 and 35.11 show typical sound sources and microphones (with wind screen) that are used during different experiments like STINHO-1 and STINHO-2 [35.15]. Figure 35.10d also shows the distance of microphones and speakers in the landscape. The transmitter–receiver station shown in Fig. 35.11 corresponds almost for reciprocal sound transmission.

The volume of the hardware-generated sound signals has to be adjusted to enable a proper detection at the microphone. It is advantageous if the structure of the transmitted signals is so short that the human ear cannot hear their tonal structure. Long-lasting measurement campaigns with such a signal (Fig. 35.4) were mostly accepted by people in the surrounding neighborhood.

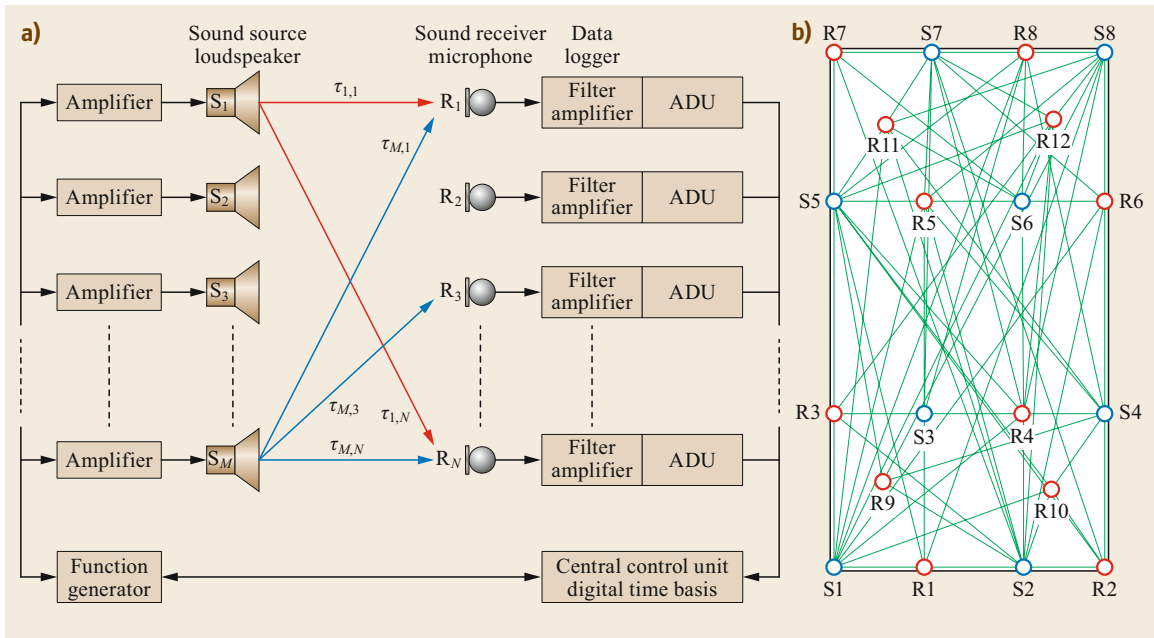

Fig. 35.9 (a) Scheme of a multichannel system to record travel times of sound signals using a bidirectional approach (similar to reciprocal sound propagation, but with a small spatial offset between transmitter/receiver pairs) consisting of M sound sources and N receivers. Each receiver can detect the signal from each sound source. (b) The measurement system records $N \times M$ sound travel times. Each travel time belongs to a different path (green lines) through the measuring area with receivers (R_*) and sources (S_*). These individual paths can be identified in a measurement setup which was realized, e.g., during the STINHO-2 experiment (after [35.15]). In this case, the system consists of 8 sources and 12 receivers distributed within an area of $300 \text{ m} \times 440 \text{ m}$

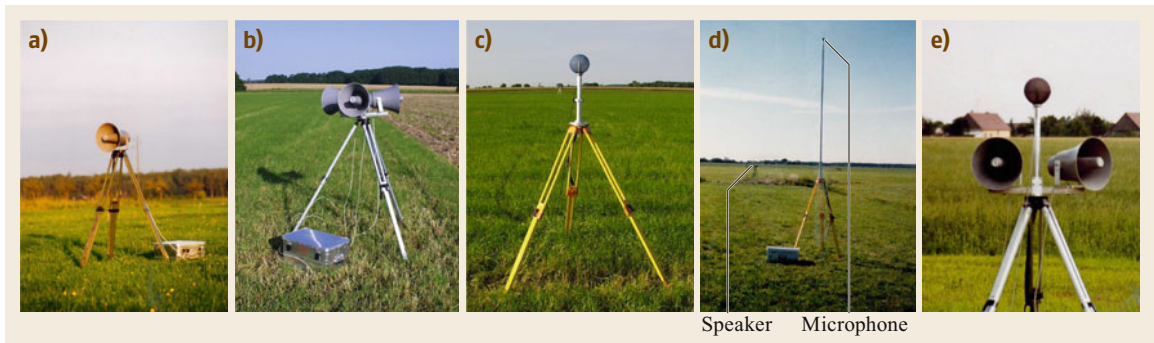

Fig. 35.10a–e Speakers, used as sound sources (a,b) and microphones (c,d) used during different experiments like STINHO-1 and STINHO-2. The equipment implements the travel-time measurement with 1 kHz signals. To obtain a wide angle of sound transmission up to 3° of such loudspeakers are combined into one station (b). A single microphone (a wind screen is necessary (c,d)) is used as a receiver station. To realize reciprocal sound speed measurements, transmitter and receiver must be combined into one station (e). Part (d) shows the distribution of microphones and speakers in the landscape (a) (after [35.30] with permission from © Acta Acustica united with Acustica); (b,c) (after [35.33]); (d,e) (photos © Arnold)

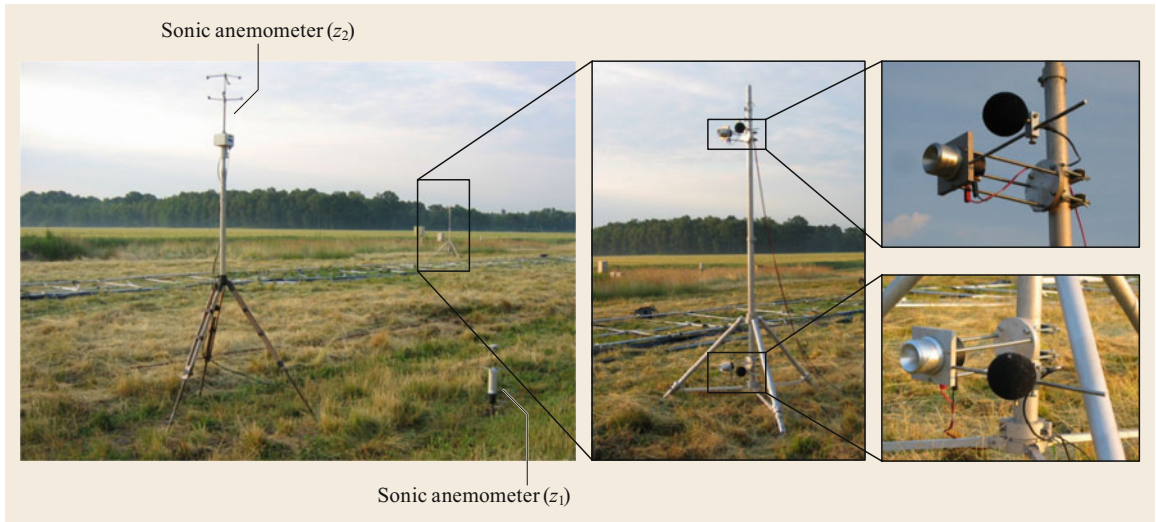

Fig. 35.11 Transmitter/receiver station equipped with Visaton loudspeaker and a 1/4-inch microphone under a wind screen. These travel-time measurements use 7 kHz sound signals. The picture also shows two sonic anemometers, which are used for comparison during the experiment (after [35.32] with permission from E. Schweizerbart'sche Verlagsbuchhandlung OHG)

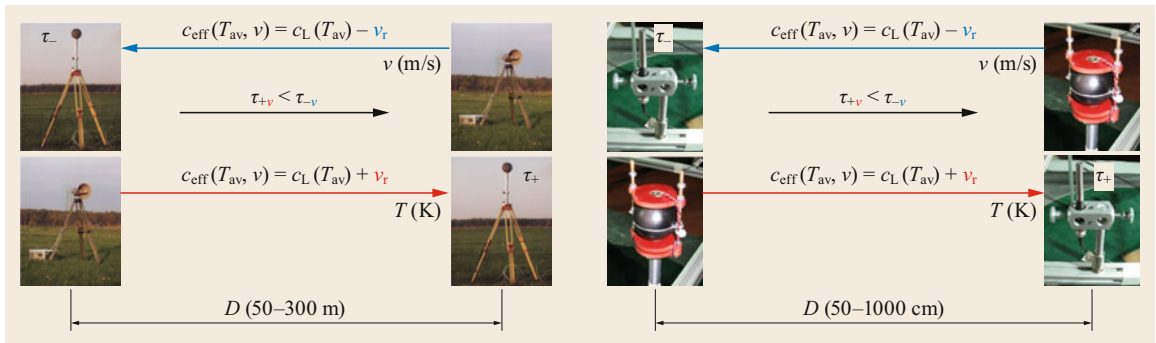

Fig. 35.12 Examples for the scalability of acoustic travel-time measurements

35.4.3 Scalability

An advantage of acoustic methods is their scalability. Depending on the geometric extent of the area of investigation, the physical data analysis methods do not change (Fig. 35.12). This property allows new components to be easily tested under laboratory conditions, as well as to investigate the interaction between an experimental setup, electronic signal transmission and numerical analysis. A change of the extent of the area under investigation may demand an adjustment of the

frequency of the sound signal as well as a corresponding choice of sound sources and receivers to fit to the measurement task. Here, the scalability is limited to measuring sections, for which a straight-line sound propagation under the given temperature gradients or flow gradients must be ensured. Small-scale laboratory setups are used to test types of sound signals [35.28] and tomographic inversion methods [35.20, 37]. The small-scale measurement setups are then again suitable for analyzing the structure of temperature and flow fields (e.g., in wind tunnels [35.10] or indoors [35.18]).

Table 35.5 Example characteristics for temperature and wind speed measurements (instantaneous values) at different spatial scales calculated using (35.6) and (35.7)

Reference	General conditions of the measurement		Uncertainty of target variables		
	Acoustic path length (m)	Travel-time uncertainty (μs)	Uncertainty of travel time ($\times 10^{-6} \text{ s m}^{-1}$) normalized by distance (Fig. 35.6)	Acoustic virtual temperature (K) (35.6)	Wind speed (m s^{-1}) (35.7)
[35.30]	≥ 200	300	1.5	0.3	0.2
[35.29]	50	78	1.6	0.3	0.2
[35.12]	100	100	1	0.2	0.1
[35.10]	1	2	2	0.4	0.25
[35.18]	5	2	0.4	< 0.2	< 0.1

35.5 Specifications

Tomography systems have to be designed to adapt to the structure of the sound signals, their frequency content, and the repetition rate of the measurements to the geometric configuration of the measuring field. Since higher sound frequencies are strongly attenuated over long distances, the use of ultrasound is infeasible when working on a micrometeorological scale. However, under small-scale laboratory conditions, ultrasound may well be the frequency range of choice. The tomographic experiments described in the literature thus also use sound signal structures adapted to the measuring conditions, which are intended above all to ensure unmistakable identification of the sound signal. Differing signal structure of the emitted sound from the various transmitters is to be regarded as an advantage. The

recording of the sound signals is done with data logger technology, which of course has to ensure a sampling rate that can record the frequency content of the used sound signals.

For different implementations of the technique, estimated uncertainties of derived temperature and wind values are given in Table 35.5. As described in Sect. 35.3.5, uncertainties strongly depend on the size of the measurement area as well as on the feasible temporal resolution of travel-time measurements. It is important to note that a maximum error calculation was applied. The received values of uncertainties are higher in comparison to an investigation of purely statistical uncertainties, which can be described, e.g., by the standard deviations of high-frequency measurements.

35.6 Quality Control

If the geometric structure of the measurement array is known, then the recording of the travel times of the sound signals must be controlled for the following reasons:

1. For plausibility of propagation time windows of the sound signals

2. For plausibility of variability of the sound speed field between successive measurements

An overview to parameters which must be controlled in preparation for and during acoustic tomographic measurements can be found in Table 35.6.

Table 35.6 Influences and uncertainties of sound speed measurements for acoustical tomographic purposes and tomographic reconstruction methods

Uncertainty	Influence on the speed of sound and its measurement	Consideration
Composition of the air, different water vapor content	Change of R_a ($\text{J kg}^{-1} \text{K}^{-1}$), γ	Measurement of the acoustic virtual temperature (acceptance of a small influence of moisture on the temperature measurement)
Geometric distance	Measurement of the distance between the transmitter and receiver and their mutual location	Estimation of uncertainty of distance measurements
Travel-time measurements	Time synchronization of electronic devices sampling frequency of received sound signals, used frequency of sound	Estimation of the uncertainty of travel-time measurements. The accuracy is limited at least by the digitizing frequency of the data logger and the frequency of the used sound signal.

Table 35.6 (Continued)

Uncertainty	Influence on the speed of sound and its measurement	Consideration
Deviation from straight sound propagation: curved rays	Vertical and horizontal gradients of wind and temperature Possible formation of acoustic shadow zones. The signal is not detectable (see Sect. 35.3.6, <i>Identification of Sound Signals</i>)	Limitation of the distance between individual transmitters and receivers Monitoring signal level/amplitude of the maximum of the cross correlation function to exclude measurements with insufficient signal strength
Reciprocal sound propagation	Different influence on the sound paths in the up and downwind direction	Determine whether differing path lengths in back and forth direction are a negligible source of uncertainty. The sound levels at these paths are different
Reflections	Reflections of sound signals on the ground (ground dip) or obstacles Superposition of direct sound signal and reflections	Definition of time windows in which the incoming signal is assigned to the known sound source–receiver path. Positioning of equipment in sufficient distance to reflecting obstacles (also to objects which belong to the measuring device)
Identification of the designed/emitted sound signals	Signal-to-noise ratio (SNR) Expected arrival times of the used sound signals at the receiver Signal amplitude too low (acoustic shadow due to refraction, upwind, damping) → cross correlation function no clear maximum → no clear travel time signal	Use of defined signal forms. Defining the time slots for the arriving times of sound signals traveling along the known distances between transmitters and receivers Time window size must be based on the possible signal travel time change during the measurement time (possible wind and temperature change in the study area and during the duration of measurements) Monitoring SNR (e.g., amplitude of maximum of cross correlation function relative to noise) Reduction influence of ambient noise (usually low-frequency) due to (high-pass) filtering of the received signals (corresponding selection of the sound signal frequency required for this)
Superimposition of (identical) sent sound signals	Distances between transmitters and receivers are identical	Measurement setup must be changed so that all distances between transmitters and receivers are of different lengths, so that the sound signals arrive separately at the receiver Not simultaneous emission of sound signals from all positions, but send out the signals at the different transmitters successively. Or each transmitter signal get its own identifier
Separation of wind and temperature influence in the travel-time data	Unfavorable arrangement of sources and receivers with respect to up and downwind	Altering the design of the measurement layout by changing the location of sources and receivers appropriately Use different sound signals to identify each individual sound source
Tomographic reconstruction	Sequence of iterative solution processes, abort criterion for iterative solutions Decomposition of the measurement area into subareas	The structure of the spatial resolution of the tomographic reconstruction must match the number of sound paths. When algebraic reconstruction algorithms are used, this can be determined by the number of transmitter–receiver pairs. The number of grid cells should not be greater than the number of sound paths that cross the study area in different directions
Duration of the measurement cycle or repetition rate of complete cycles of the sound propagation time measurement	Computer processing time Averaging successive measurements	Limits the resolution of temporal changes in temperature and wind field structure, making representation of turbulent structures more difficult
Turbulence	Turbulent structures of smaller spatial extent than the predetermined grid width of tomographic array	Fluctuations in travel time and sound level Adaptation of the repetition time of a measuring cycles to turbulence
Attenuation of sound waves	Sound frequency-dependent	Necessary volume, choice of sound frequency in relation to the distances between source and receiver

35.7 Maintenance

Tomographic arrays for characterization of micrometeorological conditions have so far been operated only during special measurement campaigns.

The aim of those campaigns was:

1. To ensure the comparability of the tomographic results to conventional measurement methods at several spatial scales.
2. To provide temperature and flow field data in a structure comparable to numerical models.
3. To validate various tomographic algorithms for their applicability.

Experiments over an extended duration of time require stability of the measurement equipment (no changes to the source and receiver characteristics unless it is possible to recalibrate the equipment regularly) as well as using speakers and microphones that are suitable for outdoor use. If the measuring positions are connected by cables, then the cable has to be protected from destruction for instance by rodents. It is to ensure that the measurements can be performed continuously, which may require a tremendous amount of storage media as well as a control of a sufficient amplitude of the received signals.

35.8 Application

Various arrangements of transmitters and receivers can be found in the literature.

The arrangement installed at the Larson Agricultural Research Center was aimed at reconstructing horizontal (2-D) wind and temperature fields [35.12]. Later, at the Boulder Atmospheric Observatory (BAO), an arrangement for 3-D A-TOM was installed (Fig. 35.15) [35.9]. Experiments such as STINHO

(Figs. 35.13 and 35.14) [35.15] attempt to capture the horizontal wind and temperature fields over relatively large heterogeneously designed landscape sections (max. $300\text{ m} \times 700\text{ m}$) [35.33], e.g., to apply the observed data for the validation of LES (large eddy simulation) models [35.15, 46]. Specially designed measurements can be found in [35.34, 47]. Integral information about temperature and wind along specific

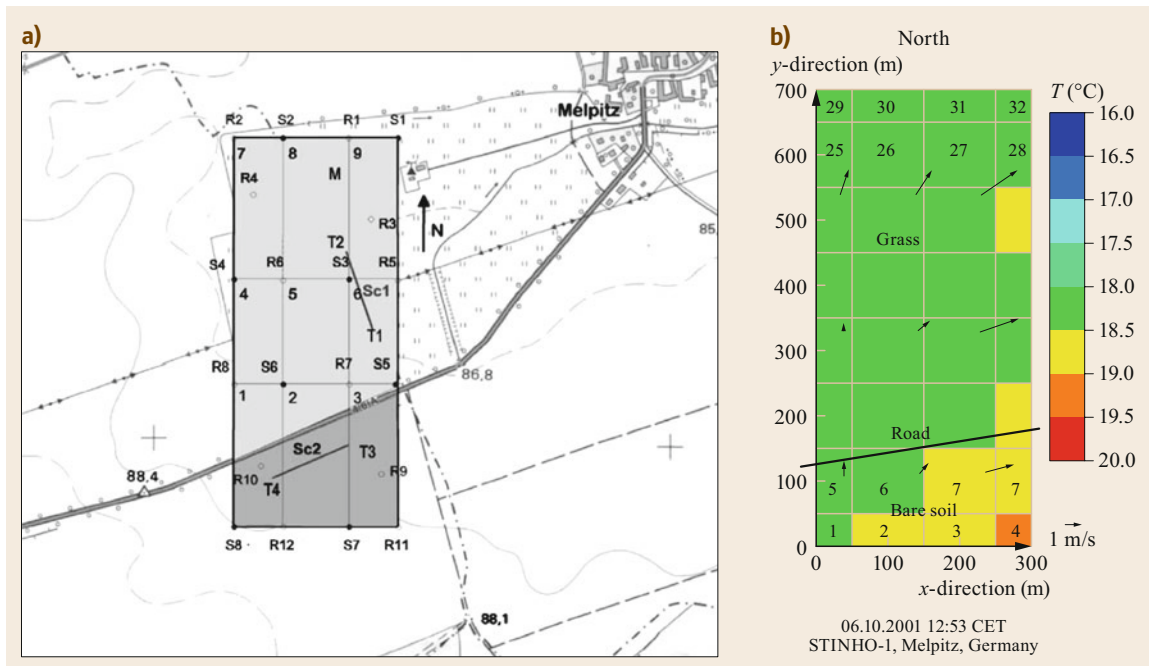

Fig. 35.13a,b STINHO-1: (a) Layout of the area under investigation ($300\text{ m} \times 700\text{ m}$) at the research station Melpitz (after [35.33]); (b) example of a single tomographic temperature and wind field measurement, which provides a grid structure comparable to numeric calculations

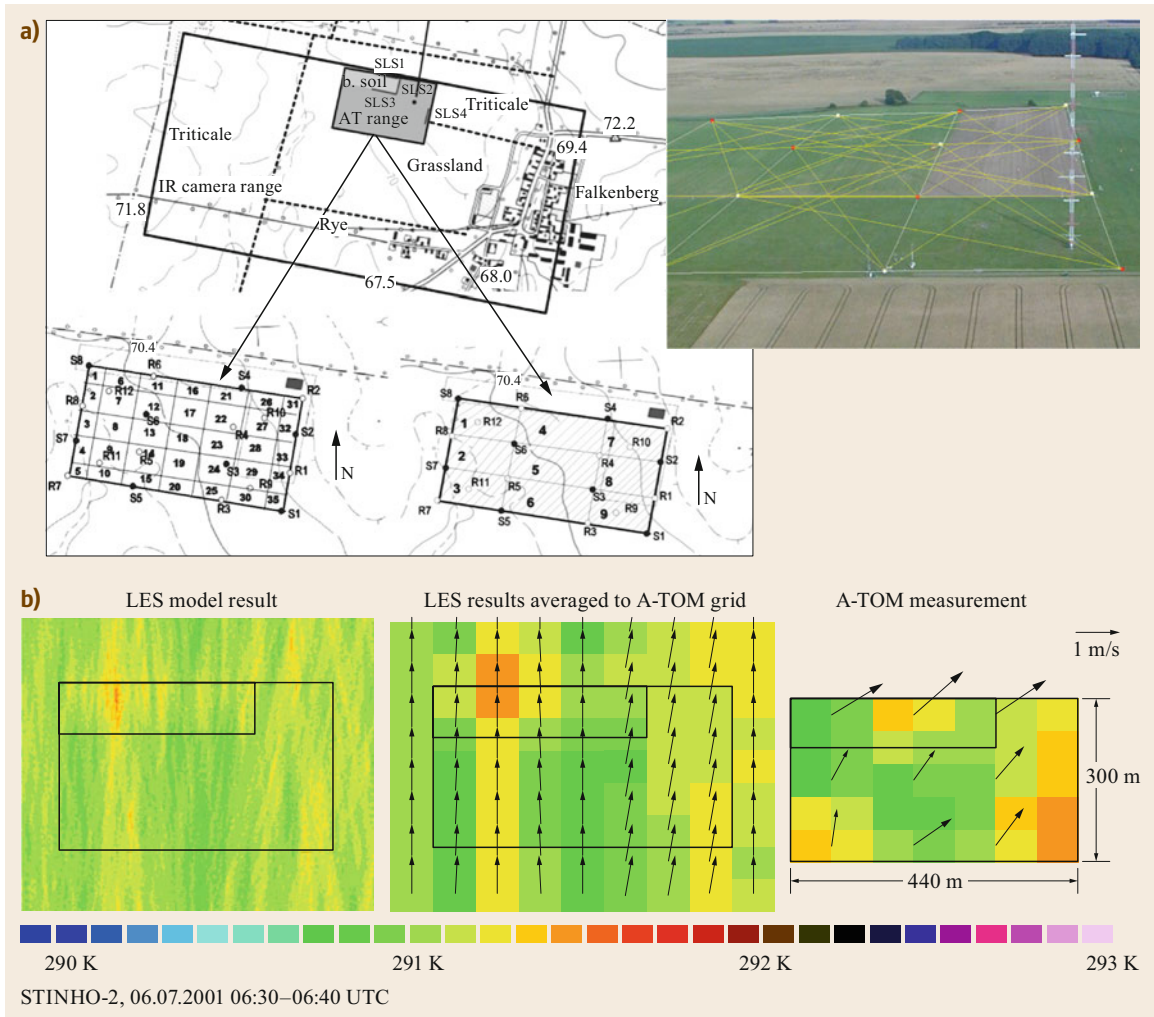

Fig. 35.14a,b STINHO-2: View of the experimental area around the boundary layer field site near the Meteorological Observatory Lindenberg of the German Meteorological Service (DWD). See text for further information. **(a)** Left: map of the measuring field near Lindenberg/Falkenberg: AT marks the area for acoustic tomography measurements. The area was divided for tomographic images into 35 grid cells for temperature and 9 grid cells for wind vector. Right: aerial photo of the landscape around the AT range: yellow lines show schematically the propagation paths of the sound waves between the sound sources and receivers (after [35.15] with permission from E. Schweizerbart'sche Verlagsbuchhandlung OHG.) **(b)** Large-eddy simulation of temperature and wind field (10 min mean) in comparison to the tomographic reconstruction of the acoustic travel-time measurements during this time of the day

propagation paths has been used to provide additional information, e.g., for path-integrated observations like FTIR (Fourier-transform infrared spectroscopy) procedures [35.29, 32]. In [35.22], UASs (unmanned aircraft systems) served as sound sources at different altitudes of the atmospheric boundary layer, with a microphone array on the ground. The aim was to visualize the vertical structure of the boundary layer using sound speed observations. To illustrate the spectrum of experimental designs, three examples are described in more detail.

The STINHO-1 experiment (Fig. 35.13) was carried out at the research station Melpitz of the Institute of Tropospheric Research (TROPOS) near Leipzig, Germany. At this site, a road cuts through the measuring area and separate areas of grassland (northern part) and bare soil (southern part). This indicates the aim to investigate the structure of turbulent processes under inhomogeneous surface conditions (STINHO). The positions of receivers are labelled R1 to R12, the sources S1 to S8. Not all transmitters and receivers are posi-

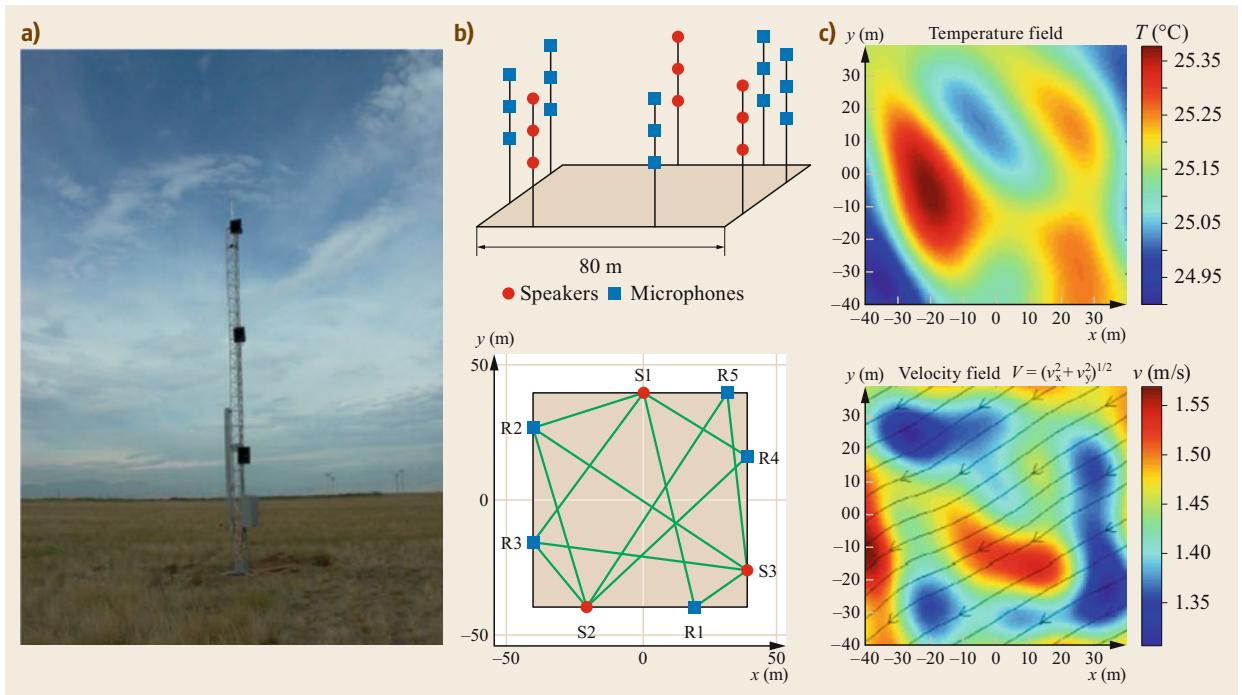

Fig. 35.15a–c The 3-D array for acoustic tomography research built at the Boulder Atmospheric Observatory (BAO), which was designed for reconstruction of 3-D temperature and wind fields. Shown are tomographic reconstructions of the temperature and velocity fields in one of the three levels at 09.07.2008 21:32:30 UTC. **(a)** Photography of arrangement of sound sources and receivers at one mast. **(b) Top:** scheme of experimental setup with 8 masts, 5 masts with microphones, and 3 masts with loudspeakers. **Bottom:** scheme of sound paths used for tomographic reconstruction (method of time-dependent stochastic inversion, TDSI). **(c) Top:** the reconstruction of temperature field using tomographic algorithm. **Bottom:** the reconstruction of wind field using tomographic algorithm (after [35.48, 49] Figure assembled)

tioned at the border of the measuring field. Because of the great distances between the transmitter and receiver positions and the desire to cover all parts of the measuring field with sound paths, some transmitters or receivers are inside the measuring area (e.g., S8, R6). T1 to T4 are positions of conventional temperature and humidity sensors, Sc1 and Sc2 are the scintillometer measurements and M marks the routinely working 12 m profile mast. These additional sensors were used to compare area-averaged measurements (A-TOM) with point or line measurements. All meteorological sensors and acoustic equipment were positioned 2 m above the surface. A horizontal slice of temperature (color scale) and wind (arrows) field at a height of 2 m above the ground on 06.10.2001 at 12:53 CET are shown as an example. This picture is reconstructed from one single measurement cycle, whose duration is given by the sound travel times and represents a snapshot of the temperature and wind field. The legend indicates the achievable resolution for the temperature as well as for the wind vector.

Because it is not entirely possible to have a reciprocal sound path distribution, the method of bidirectional sound paths was applied to obtain the wind field distribution. In this case, the resolution of wind field is reduced (9 cells, number 1–9 in Fig. 35.13a) in comparison to the resolution of temperature (numbering of temperature cells 1–32 in Fig. 35.13b).

The STINHO-2 experiment (Fig. 35.14) was carried out at the boundary layer research field Falkenberg, a part of the Meteorological Observatory Lindenberg (MOL) of the German Meteorological Service (DWD). Around the 99-m meteorological tower (foreground), the tomographic array was built up. To get different surface conditions, the measuring area covers grassland and a plowed field. The yellow lines symbolize the sound propagation paths for acoustic tomography, which covers an area of $300\text{ m} \times 440\text{ m}$ (AT range). Within the A-TOM range different observational systems (e.g., profile masts, eddy covariance, scintillometer) were distributed. The tomographic array is included in an area of an extension of $900\text{ m} \times 2000\text{ m}$ which was observed with an infrared camera to detect sur-

face temperature distributions. Figure 35.14 shows the arrangement of the twelve acoustic receivers (R) and eight sound sources (S) and the resulting temperature and wind cells for tomographic reconstruction. The investigated area is divided into 35 grid cells for the temperature with an extension of $70\text{ m} \times 70\text{ m}$ and nine cells for the wind vector. The lower partitioning of the wind field is due to the bidirectional separation algorithm. Figure 35.14 also shows a large-eddy simulation of an air temperature and wind field with a resolution on $2.5 \times 2.5\text{ m}^2$ aggregated to the grid structure of the tomographic reconstruction. In comparison to the simulation, the A-TOM shows a 10-min average for the same time 06.07.2001, 06:30–06:40 UTC.

The STINHO-2 experiment produced travel-time datasets, which were used by different publications to investigate the capability of tomographic reconstruction schemes [35.16, 36, 48]. The transmitter–receiver configuration used during STINHO only allows reconstruction of 2-D temperature and velocity fields.

In [35.30], a tomographic experiment with an acoustic array comparable to STINHO is introduced. In com-

parison to the STINHO experiment, microphones were positioned at two different heights above the ground. Subsequently, acoustic measurements from different heights were used to analyze horizontal and vertical gradients of temperature and wind fields.

The acoustic array built at the BAO (Fig. 35.15) is the only example of an outdoor tomographic measurement setup, which was used to investigate the 3-D structure of turbulent wind and temperature fields [35.9]. The 8 masts are equipped with 9 transmitters (speaker) and 15 microphones and enclose a volume of $80\text{ m} \times 80\text{ m} \times 10\text{ m}$. In order to represent turbulent structures in the wind and temperature field from the measurements, stochastic tomographic reconstruction methods were used. This acoustic tomography array was intended particularly for developing reconstruction methods suitable to the verification of LES schemes. In its version BAO 2.0, the array consisted of 8 combined transmitter–receiver stations at the positions shown above. With this distribution of the equipment, a perfect reciprocal sound transmission was realized only for one plane parallel to the surface [35.50].

35.9 Future Developments

Acoustic tomography (A-TOM) of the atmospheric surface layer (ASL) has been demonstrated through research as a viable and unique technique for remote sensing of the temperature and wind velocity fields. The method was developed to provide spatially averaged measurement data, e.g., to compare flow field models (LES) with experimental data, where model and experiment achieve the same resolution. All of the tools needed to include A-TOM in continuous monitoring of temporal changes in 2-D and 3-D temperature and wind velocity fields in the ASL were developed. However, currently a long-term monitoring site does not exist. Even tomographic arrays such as the BAO are not operated permanently at the present time. But new applications can always be envisioned. In its version 2.0, the BAO is operated close to wind turbines to measure the turbulent wake flow.

Permanent use of acoustic tomography is difficult because audible sound is typically used for the measurements, which at times can disturb local residents. Furthermore, the measurement positions must be permanently fixed in the landscape very accurately in order to ensure a high quality of sound speed observations. A conceivable solution would be the use of natural or existing sound sources. Such sources could provide information to reconstruct the structure of the velocity and temperature fields where the sound has

traveled through (e.g., sound of airplanes). Then, not only a part of the surface layer, but the entire boundary layer or troposphere, could be the subject of investigation [35.51].

An example of obtaining sound speed information from the entire atmosphere comes from infrasound and seismic stations used for verifying compliance with the Comprehensive Nuclear-Test-Ban Treaty [35.52]. For this purpose, a global observation network is maintained internationally, which also records infrasound [35.53] created by different natural sources (meteors, severe storms, mining explosions, and other human-caused or natural phenomena). By determining the velocities, angles of arrival, and, in some cases, travel times of these waves, one can attempt to solve the inverse problem of reconstructing the temperature and velocity fields in the atmosphere. Such monitoring could allow us to gain new knowledge about the spatial structure of these fields and their temporal evolution in different meteorological regimes [35.9, 48].

Presently, it is still a goal to include observed and analyzed sound field data in continuous and operational meteorological monitoring programs. But experiences with A-TOM provide a helpful example to extrapolate and upscale results of point-like measurements for special measurement campaigns and to deliver consistent data to numerical models across a range of scales.

35.10 Further Readings

Overviews of inverse techniques can be found in the following textbooks:

- For general description of inversion techniques see W. Menke: *Geophysical Data Analysis: Discrete Inverse Theory* (Academic Press, New York 1984).
- Mathematical basics for tomographic and inverse methods are introduced by F. Natterer: *The Mathematics of Computerized Tomography*. Classics in Applied Mathematics, Vol. 32 (SIAM, Philadelphia 2001).
- The fundamentals of computer tomography are summarized in A.C. Kak, M. Slaney: *Principles of Computerized Tomographic Imaging* (IEEE Press, New York 1988) and its specification to geophysics in T. Lo, P.L. Inderwiesen: *Fundamentals of Seis-*

mic Tomography. Geophysical Monograph Series, Vol. 6 (SEG, London 1994).

- Tomographic techniques in combination with oceanographic research are described by W. Munk, P. Worcester, C. Wunsch: *Ocean Acoustic Tomography* (Cambridge Univ. Press, New York 1995).
- Physical effects in atmospheric acoustics and the sound propagation through inhomogeneous, turbulent media are explained and illustrated by V.E. Ostashev, D.K. Wilson: *Acoustics in Moving Inhomogeneous Media*, 2nd edn. (CRC Press, Boca Raton 2016), as well as by E.M. Salomons: *Computational Atmospheric Acoustics* (Springer, Dordrecht 2001) and K. Attenborough, K.M. Li and K. Horoshenkov: *Predicting Outdoor Sound* (Taylor & Francis, London 2007).

Armin Raabe

Leipzig Institute for Meteorology (LIM)
University of Leipzig
Leipzig, Germany
raabe@uni-leipzig.de

Armin Raabe studied physics at Leipzig University and obtained his PhD in 1980. As a member of the Leipzig Institute of Meteorology he focused on mesoscale modeling of atmospheric and hydrological processes over a heterogeneous landscape. In 1994 he developed methods to observe temperature and air stream fields of landscape areas, as well as indoors using acoustic sound measurements, especially focusing on acoustic tomographic methods.

Manuela Starke

Chair of Meteorology
Technische Universität Dresden
Tharandt, Germany
manuela.starke@tu-dresden.de

Manuela Starke (Barth) studied meteorology at the University of Leipzig where she also obtained her PhD in 2009. The main focus of her work was the further development and optimization of a method for simultaneous measurements of spatially resolved temperature and flow fields in air using acoustic travel-time tomography. Further research topics include the modeling of atmospheric sound propagation and of atmospheric boundary layer processes.

Astrid A. Ziemann

Chair of Meteorology
Technische Universität Dresden
Tharandt, Germany
astrid.ziemann@tu-dresden.de

Astrid A. Ziemann is a research associate at the Chair of Meteorology at TU Dresden. She studied meteorology at the Humboldt-Universität zu Berlin and received her PhD at the Leipzig University in 2000 for a theoretical study of acoustic tomography. Current research topics include: wind energy, heat resilient cities in changing climate and outdoor sound propagation.

GNSS Water Vapor

36. GNSS Water Vapor Tomography

Michael Bender, Galina Dick

The spatial distribution of the atmospheric humidity is difficult to observe, especially for larger domains with dimensions of tens or hundreds of kilometers. The signals of satellite positioning systems like GPS or Galileo are modified by the atmospheric water vapor, and a combination of a large number of such signals provides an opportunity to observe the humidity distribution with high temporal resolution under all weather conditions. The positioning signals are collected by ground-based receiver networks and processed in a certain way in order to separate the humidity information. The information obtained in this way is a nonlocal path-integrated quantity, and tomographic techniques are required to obtain spatially and temporally resolved humidity fields. The whole processing chain from signal detection and signal processing to the final tomographic reconstruction of the atmospheric humidity distribution is presented.

The impact of the atmospheric water vapor on weather and climate, as well as its significance, were highlighted in many of the previous chapters, as were the relevance of reliable humidity observations. Satellite positioning was not designed as a remote-sensing system but is sensitive to atmospheric humidity and can contribute to large-scale humidity monitoring. The information contained in positioning signals and collected by ground-based receiver networks can fill the gap between in-situ observations, such as sensors at synoptic stations or radio soundings and satellite-based remote-sensing instruments. The signals propagate through large parts of the atmosphere and are modified by the amount of

water vapor along each signal path. If the density of the received signals is sufficiently high, tomographic techniques can be used to reconstruct the spatial humidity field from these path-integrated observations. The spatial resolution of such humidity fields is limited by the receiver density and is usually between 10 and 50 km horizontally and between 100 and 1000 m vertically. While the resolution is not very impressive at first glance, the fields extend across large areas of the atmosphere, which would not otherwise be covered. The extension of small networks is usually limited to some tens of kilometers while nation-wide networks are extended over several hundreds of kilometers. The

observations are available continuously for all weather conditions and can be processed within a rather short time. Currently, a near realtime processing with delays

below 30 min is possible, but realtime applications with delays below some minutes are currently under development.

36.1 Measurement Principles and Parameters

Global navigation satellite systems (GNSS) are based on a constellation of satellites that orbit the Earth and transmit navigation signals continuously. GNSS receivers at the Earth's surface decode the navigation messages from several GNSS satellites and compute the receiver position. As of January 2021, there are four GNSS: the US American Navstar Global Positioning System (GPS), the Russian GLONASS, the European Galileo, and the Chinese BeiDou. Each of these systems consists of at least 24 satellites. In total, about 100 satellites are operational, and up to 30 can be tracked simultaneously at any place on Earth.

GNSS was not designed as a remote-sensing device, however the impact of the Earth's atmosphere on the navigation signals deteriorates the quality of positioning and needs to be corrected for. The atmosphere corrections estimated in precise positioning carry valuable information on the atmospheric state, which leads to the special branch of GNSS atmosphere sounding.

GNSS signals are electromagnetic waves in the microwave range, i.e., $\approx 1\text{--}1.5$ GHz, and can be detected in all weather conditions. The Earth's atmosphere leads to a delay of the signals and to curved signal paths as the speed of light in the atmosphere is smaller than in vacuum. The major contribution to the atmospheric delay is caused by the free electrons in the ionosphere but can be corrected by an ionosphere-free linear combination of signals with different frequencies. The neutral atmosphere is a nondispersive medium for microwaves, and other strategies had to be developed.

GNSS determines the signal travel time from the GNSS satellite to the GNSS receiver and estimates the distance between satellite and receiver. The receiver position can be obtained if at least four satellites are in view. Signal delays due to the neutral atmosphere lead to wrong distances and positions. The delays depend on the satellite elevation, i.e., the angle of the satellite above the horizon, which determines the length of the signal path inside the atmosphere, and the atmospheric state. The former leads to a simple geometric expression and can easily be corrected, but the latter leads to a considerable uncertainty for positioning.

To overcome this problem the zenith total delay (ZTD) is estimated by most GNSS data processing techniques. The ZTD is the delay due to the neutral atmosphere obtained for a hypothetical GNSS satellite in

the zenith of the GNSS receiver. ZTDs are estimated using the signals of all visible GNSS satellites and represent the mean atmospheric state above the receiver at a certain time. The signal travel times are corrected with the ZTDs, thereby leading to improved positions, but the ZTD is also the basic quantity for GNSS atmosphere sounding.

The ZTD is related to the pressure, the temperature, and the humidity in the vicinity of the GNSS station. GNSS signals provide no information about the specific contributions of these quantities to the ZTD, and additional meteorological observations are required to get more specific information, e.g., about the humidity. The atmospheric humidity is highly variable in space and time and is less well known than pressure and temperature. Pressure and temperature observations at the GNSS station have, therefore, been used to separate the integrated water vapor (IWV) from the ZTD. The IWV is equivalent to the precipitable water (PW) in a column above the station but provides no information about the vertical profile. The IWV is expressed in kg m^{-2} , while the PW is given in mm (of liquid water). IWV observations from GNSS networks provide valuable information about the horizontal distribution of the atmospheric humidity, and IWV was the first GNSS-derived quantity widely used in meteorology [36.1–3].

ZTD and IWV are rather idealized and simplified quantities, and the true delays along each individual satellite-receiver axis would provide much more detailed information. In recent years, more advanced processing techniques have been developed, which estimate such slant total delays (STDs). Instead of 1 ZTD, about 10 (GPS) or 30 (all GNSS) STDs are now available for each GNSS station and each epoch. The atmosphere over dense ground-based networks of GNSS receivers is scanned by STDs from many directions, and the information about the spatial humidity distribution hidden in large path-integrated STD data sets can be acquired by tomographic techniques.

Tomography requires large data sets of path-integrated quantities observed along intersecting signal paths (Fig. 36.1). Because of the integrated character of the observations it is not possible to locate the information along individual signal paths. In the case of many intersecting paths, the information can to some degree be located near the intersection points. A combined

Fig. 36.1 GNSS signals propagating through a spatial grid. The refractivities at the grid nodes can be estimated by tomographic techniques if there is a sufficient number of GNSS signal paths near each node

Table 36.1 GNSS-specific parameters. Most quantities are defined in Sect. 36.3. Physical constants and humidity-related parameters can be found in Chaps. 5 and 8, respectively

Parameter	Description	Unit	Symbol
Parameters relevant for GNSS observations and processing			
Refractive index	$n = c/v$, vacuum speed of light to speed of light in gas	–	n
Observed GNSS parameter			
Optical path length	$t = \int_s n ds$, signal travel time transmitter–receiver	s	t
Output of the GNSS processing			
Slant total delay	$STD = 10^{-6} \int N ds$, delay by neutral atmosphere	m	STD
Slant hydrostatic delay	Approx. delay of dry atmosphere	m	SHD
Slant wet delay	$SWD = STD - SHD$, approx. delay due to water vapor	m	SHD
Integrated water vapor	Vertically integrated amount of water vapor	kg m^{-2}	IWV
Slant-integrated water vapor	Total amount of water vapor along signal path	kg m^{-2}	SIWV
Precipitable water	$IWV = \rho_w PW$ with the density of liquid water ρ_w	mm	PW
Final result of the GNSS tomography			
Refractivity	$N = 10^6(n - 1)$, equivalent to n	–	N
Wet refractivity	Atmospheric refraction due to water vapor	–	N_{wet}
Absolute humidity	Density of water vapor	kg m^{-3}	a

solution for all signals observed leads to a spatially resolved 3-D field, and techniques for solving such systems of equations are summarized under the term *tomography*.

Data sets of real observations are, in most cases, not sufficient to determine the entire field within the scanned volume. The reasons for this are insufficient numbers of observations, inadequate distributions of transmitters and receivers, or large observation errors. This leads to ill-posed inverse problems, which are difficult to solve. In the case of the GNSS tomography a very large vol-

ume, i.e., the whole atmosphere up to the tropopause over regions of several hundred square kilometers, is scanned by a rather limited number of STDs, and additional meteorological observations and some constraints are required to obtain stable tomographic solutions.

The physical quantities obtained by GNSS and some intermediate parameters provided by the GNSS processing are given in Table 36.1. The fundamental quantities for describing the atmospheric humidity are given in Chap. 8, and the physical constants are listed in Chap. 5.

36.2 History

The basic ideas of tomography were already developed at the beginning of the twentieth century, but widespread applications could not evolve until detector and computer technology reached a sufficiently high level. In the beginning of the 1970s, tomographic applications were developed in many different fields, such as radiology, materials science, geophysics, oceanography, and atmospheric science. Atmosphere sounding with acoustic tomography is described in Chap. 35.

The application of tomographic techniques to GPS signals seemed natural and was already suggested in an

early stage of the development of GPS [36.1, 4, 5]. First experiments in 1999 [36.6, 7] and 2000 [36.8–10] led to positive results with small networks of GPS receivers. As a consequence of these early results, many experiments were completed all over the world [36.11–13].

In the meantime, the geodetic agencies of most countries built up nation-wide networks of GPS receivers that could be utilized for the GPS tomography. Attempts were made to establish operational GNSS tomography systems that provide 3-D humidity fields in near realtime for nowcasting or data assimilation [36.14–16].

36.3 Theory

GNSS tomography is an approach to reconstruct large three-dimensional tropospheric fields from a rather limited number of path-integrated GNSS observations. This leads to a demanding inverse problem, which is discussed in Sect. 36.3.1. There is no direct interdependency between GNSS signals and the atmospheric state, and there is some freedom to choose from different GNSS-derived quantities as input to the tomography. The relationship between GNSS observations and different atmospheric quantities is described in Sect. 36.3.2, and some options for reconstructing humidity fields are discussed in Sect. 36.3.3.

36.3.1 Tomography and Inverse Problems

GNSS tomography is based on travel time measurements. The observed quantity is the signal travel time t between the transmitter and the receiver through the Earth's atmosphere with the refractive index n . In the case of electromagnetic waves, t is given by the optical path length

$$t = \int_S n \, ds, \quad (36.1)$$

where S is the signal path within the atmosphere. In refractive media, the signal path is, in general, a curved path that depends on the field n . The observed travel time t does not provide information about the exact signal path S or the distribution of n along S and is, therefore, a nonlocal path-integrated quantity. The basic idea of atmospheric tomography is to combine a large number of travel time observations that scan the investigated region from many directions in order to ob-

tain a well-localized approximation of the field n . For a given set of observations t_j , a set of equations

$$t_j = \int_{S_j} n \, ds_j \quad (36.2)$$

has to be solved for the unknown field n . As the corresponding curved signal paths S_j depend on n , this is a nonlinear inverse problem. It is also an ill-posed problem, as there may be no solution in a strict mathematical sense; especially if real noisy observations are regarded, the solution is usually not unique and not stable. In real applications, the problem is also globally underdetermined, as the observations are, in general, not sufficient to describe the entire field n . To overcome these limitations a number of approximations are made.

In a first step, the continuous field n is discretized by introducing a spatial grid with a discrete set of grid nodes. The field n is defined on the grid nodes only, and the set of equations (36.2) can be described in vector notation. The observations are combined to an observation vector \mathbf{y} , n_i are mapped to a 1-D state vector \mathbf{x} , and the integral equations are expressed by a vector operator \mathbf{F} , which acts on the state vector \mathbf{x}

$$\mathbf{y} = \mathbf{F}(\mathbf{x}). \quad (36.3)$$

Throughout this chapter it is assumed that all observations were taken at the same time and that the field n did not develop during the observation. To observe the temporal evolution of n , several sets of observations may be taken into account, which are processed consecutively but independently. This is equivalent to a temporal discretization of the problem.

The observation operator \mathbf{F} solves the line integrals on a discrete grid. As the signal paths depend on \mathbf{x} , this is still a demanding problem, and a second approximation is made by assuming that the signal paths are known in advance. This linearizes the problem, and the integral can be approximated by the sum

$$\int_S n \, ds \approx \sum_i n_i \Delta s_i. \quad (36.4)$$

The sum can always be rewritten as an array of weights, which are applied to the n_i , i.e., $w_i n_i$. For each observation, such an array is obtained and can be assigned to the row of a matrix \mathbf{A} . This leads to a discretized and linearized form of (36.2)

$$\mathbf{y} = \mathbf{A}\mathbf{x}, \quad (36.5)$$

with one row $y_j = A_{ij}x_i$ for each observation j and the grid nodes i . The properties of \mathbf{A} are defined by the implementation of the discrete observation operator, by the form of the grid, i.e., by the density and distribution of grid nodes, and by the number and distribution of observations; \mathbf{A} is, in general, not a square matrix, and \mathbf{A}^{-1} does not exist. Because of the ill-posed character of the problem, \mathbf{A} is a rank-deficient matrix. In the case of an insufficient number of observations or an irregular distribution of observations, \mathbf{A} may be a sparse matrix with lots of zero elements. The properties of \mathbf{A} are defined by the geometrical setup only, the shape of the field n and the quality of the observations do not affect \mathbf{A} . However, \mathbf{A} determines the amplification of observation errors and the quality of the reconstructed n field, i.e., the stability of the solution.

The properties of \mathbf{A} can be investigated by the singular value decomposition (SVD). For ill-posed problems, a limited number of large singular values and a large number of small singular values, which decay to zero, is obtained. The singular values are used to define the conditioning of the matrix and the degree of ill-posedness of the entire problem. The singular value decomposition of the $m \times n$ matrix \mathbf{A} is given by

$$\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T, \quad (36.6)$$

where \mathbf{U} is a unitary $m \times m$ matrix, \mathbf{V} is a unitary $n \times n$ matrix, and $\mathbf{\Sigma}$ is a diagonal matrix with the singular values σ_i of \mathbf{A} , usually given in descending order. The condition number of \mathbf{A} is defined by the ratio between the largest and the smallest singular value

$$\text{cond}(\mathbf{A}) = \frac{\sigma_{\max}}{\sigma_{\min}} \quad (36.7)$$

and determines the amplification of small variations $\Delta\mathbf{y}$ in the input data

$$\frac{\|\Delta\mathbf{x}\|}{\|\mathbf{x}\|} = \text{cond}(\mathbf{A}) \frac{\|\Delta\mathbf{y}\|}{\|\mathbf{y}\|}. \quad (36.8)$$

Ill-posed problems lead to ill-conditioned matrices \mathbf{A} with large condition numbers. The decay rate of the ordered singular values σ_i is used to define the degree of ill-posedness α [36.17]: if the singular values satisfy

$$\sigma_i = \text{order}(i^\alpha) \quad \text{with } \alpha \in \mathbb{R}^+, \quad (36.9)$$

the problem is mildly ill-posed if $\alpha \leq 1$ and moderately ill-posed if $\alpha > 1$. The problem is severely ill-posed if σ_i decay exponentially

$$\sigma_i = \text{order}(\exp(-\alpha i)) \quad \text{with } \alpha > 0. \quad (36.10)$$

The three-dimensional problem of the GNSS tomography with a highly variable transmitter-receiver geometry leads to moderately or severely ill-posed problems and strong constraints, and additional observations are required to obtain stable and meaningful results.

Because of the ill-posed character the usual linear algebra techniques for solving sets of linear equations, e.g., a least-squares solution, cannot be applied. There is a variety of different approaches for solving these kinds of problems [36.18–21], and it depends very much on the specific problem which ones lead to reliable results. The techniques applied in the GNSS tomography are described in the subsequent sections.

36.3.2 GNSS Tomography

The optical path length (36.1) describes the travel time between the GNSS transmitter on board the GNSS satellite and the GNSS receiver at the ground, which is about 70 ms in the zenith direction. For the GNSS atmosphere sounding only the impact of the atmosphere is important. The neutral atmosphere delays the signals about 10 ns in the zenith direction and up to 100 ns at low elevations. The slant total delay (STD) is the difference between the optical path length (36.1) and the geometric distance G between transmitter and receiver

$$\text{STD} = \int_S n \, ds - \int_G dg = \int_s (n-1) \, ds + (S-G). \quad (36.11)$$

The signal is delayed for two reasons: $n > 1$ along the signal path as described by the integral term, and the curved signal path S is slightly longer than G ,

i.e., $S - G > 0$. As the integral term is the major contribution to the STD it is usually possible to neglect the geometric delay $S - G$ in tomographic applications, and the STD can be expressed by

$$\text{STD} = \int_s (n - 1) ds = 10^{-6} \int_s N ds, \quad (36.12)$$

with the refractivity $N = 10^6(n - 1)$. It is rather cumbersome to deal with small delays on the order of some nanoseconds, and delays are usually expressed in meters by multiplying the delay with the vacuum speed of light. Following this convention, a delay of 7.7 ns is given as a STD of 2.3 m.

Each GNSS receiver tracks all GNSS satellites in view, i.e., all GNSS satellites above the horizon at a given position and a given time. In the case of GPS, about 8–12 satellites can be tracked simultaneously; multi-GNSS receivers can track up to ≈ 30 satellites. A ground network of GNSS receivers provides a large number of different views through the atmosphere, which contains spatial information about the atmospheric state. Due to the almost random distribution of the GNSS satellites and receivers there is no meaningful projection on a 2-D plane, and the full three-dimensional problem needs to be addressed.

The refractivity N can be expressed in atmospheric quantities pressure p , temperature T , and relative humidity R . For a mixture of gases like the Earth's atmosphere, empirical approximations for N are applied [36.22–24]. A widely used expression is the Smith and Weintraub formula

$$N = k_1 \frac{p_d}{T} + k_2 \frac{e}{T} + k_3 \frac{e}{T^2}, \quad (36.13)$$

where p_d is the partial pressure of dry air in hPa, e is the partial pressure of water vapor in hPa, and T is the temperature in kelvin. The empirical constants k_1 , k_2 , and k_3 were determined by several authors and are given in Table 36.2. For geodetic applications, the Rüeger constants are recommended [36.26], while the Bevis constants [36.25] quite often lead to better results in meteorological applications. The first term in (36.13)

Table 36.2 Atmospheric refractivity constants k_1 , k_2 , and k_3 according to different authors

Reference	k_1 (K hPa ⁻¹)	k_2 (K hPa ⁻¹)	k_3 ($\times 10^5$ K ² hPa ⁻¹)
Smith and Weintraub [36.24]	77.6	72.0	3.75
Thayer [36.23]	77.6	64.8	3.776
Bevis [36.25]	77.6	70.4	3.739
Rüeger [36.26]	77.689	71.2952	3.75463

describes the refractivity due to the dry atmosphere, i.e., all atmospheric gases without water vapor, the two remaining terms describe the contribution due to water vapor. The partial pressures p_d and e can be replaced by the ideal gas law

$$p_d = \varrho_d \frac{R^*}{M_d} T \quad \text{and} \quad e = \varrho_w \frac{R^*}{M_w} T, \quad (36.14)$$

where ϱ_d and M_d are the density and molar mass of dry air, ϱ_w and M_w are the density and molar mass of water vapor, and R^* is the gas constant (Chap. 5). This leads to an alternative form of (36.13)

$$N = k_1 \varrho \frac{R^*}{M_d} + \left(k_2 - k_1 \frac{M_w}{M_d} \right) \frac{e}{T} + k_3 \frac{e}{T^2}. \quad (36.15)$$

Here, ϱ is the density of moist air, i.e., $\varrho = \varrho_d + \varrho_w$. Using (36.15) and (36.1) the hydrostatic and the wet delay can be defined: the slant hydrostatic delay (SHD) is given by

$$\text{SHD} = \int_s k_1 \varrho \frac{R^*}{M_d} ds, \quad (36.16)$$

and the slant wet delay (SWD) can be expressed as

$$\begin{aligned} \text{SWD} &= \int_s \left[\left(k_2 - k_1 \frac{M_w}{M_d} \right) \frac{e}{T} + k_3 \frac{e}{T^2} \right] ds \\ &= \int_s \left[k'_2 \frac{e}{T} + k_3 \frac{e}{T^2} \right] ds \end{aligned} \quad (36.17)$$

by introducing a new constant k'_2

$$k'_2 = k_2 - k_1 \frac{M_w}{M_d}. \quad (36.18)$$

The specific form of the SHD was chosen as the integral can be solved in the case of hydrostatic equilibrium (Sect. 36.3.3).

Equation (36.13) can be combined with (36.12) and provides an expression that relates the observed STD to three atmospheric fields, i.e., p , T , and R . However, the GNSS observations provide no information about the individual contributions of these fields to the STD, and it is not possible to reconstruct all three atmospheric fields from STD observations. There are basically two strategies to address this problem. One is the tomographic reconstruction of the refractivity field using the STD observations. The humidity field can later be obtained using N , the p and T observations, and (36.13). Another strategy is the derivation of the SWD or the

Table 36.3 Different options for the application of observations and the tomographic reconstruction

Case	Observations	Tomography	Final field
1	STD \rightarrow	STD $\rightarrow N$	$+p, +T \rightarrow a$
2	STD + $p \rightarrow$	SWD $\rightarrow N_{\text{wet}}$	$+T \rightarrow a$
3	STD + $p, +T \rightarrow$	SIWV $\rightarrow a$	$\rightarrow a$

slant-integrated water vapor (SIWV). The meteorological observations at the GNSS site are used to separate certain contributions to the STD and to reduce the number of fields in (36.13). The GNSS tomography will lead to the wet refractivity, if SWDs are used and to the absolute humidity, if SIWV data are used. The different options to obtain the final humidity field are given in Table 36.3.

In all cases, pressure and temperature profiles are required. In cases 2 and 3 in Table 36.3, the profiles at the GNSS stations need to be known; in cases 1 and 2, one profile for each column of the tomography grid would be required. Usually, only surface observations are available, and attempts have been made to approximate the profile information from the surface data. The STD \rightarrow SWD \rightarrow SIWV conversion strategy is described in the next section. In the case of the grid columns, it is in most cases sufficient to compute profiles based on p_0 and T_0 using, e.g., the US standard atmosphere [36.27] or simple approximations from textbooks.

36.3.3 Wet Delay and Integrated Water Vapor

Most implementations of the GNSS tomography use slant wet delays (SWDs) or the slant-integrated water vapor (SIWV) as input, and a reliable method for converting STDs to SWDs and SIWV is required. These methods make use of the zenith delay, which can be obtained from the slant delay by integrating (36.12) for a vertical signal path, i.e., by replacing $\int_s ds$ with $\int_{h_0}^{h_{\text{sat}}} dz$. Here, the GNSS receiver is located at the height h_0 , and the GNSS satellite is assumed to be at the height h_{sat} above the receiver; z is the vertical coordinate. This leads to the zenith total delay (ZTD), the zenith hydrostatic delay (ZHD), and the zenith wet delay (ZWD).

The zenith hydrostatic delay can be estimated from the surface pressure. This is a standard technique [36.28] based on [36.29, 30], which solves (36.16) for a vertical atmospheric column in hydrostatic equilibrium

$$\text{ZHD} = \frac{0.0022768p_0}{1 - 0.00266 \cos(2\varphi) - 2.8 \times 10^{-7}h_0}, \quad (36.19)$$

where p_0 is the total atmospheric pressure at the antenna reference point in hPa, h_0 is the height above geoid in m, and φ is the geodetic latitude. With the observed ZTD, this leads to the wet delay $\text{ZWD} = \text{ZTD} - \text{ZHD}$. The ZWD can be mapped to the signal path using a mapping function, like the wet global mapping function [36.31]

$$\text{SWD} = m_{\text{wet}}\text{ZWD}. \quad (36.20)$$

In geodesy mapping functions [36.32, 33] are used to compute the projection of the zenith delay on a given signal path with a specific elevation. They are empirical functions that approximate the Earth's curvature at a given latitude and the atmospheric state at a given day of the year.

Regarding (36.16) the term *wet delay* is somewhat misleading. The SHD is not strictly the delay due to the dry atmosphere, as ϱ instead of ϱ_d is used. The SHD is, therefore, somewhat larger than the true dry delay, and the wet delay estimated with $\text{ZWD} = \text{ZTD} - \text{ZHD}$ is smaller than the true wet delay. The error is in the order of a few percent, and the ZWD estimated using (36.19) is a good approximation.

The SIWV is a linear function of the SWD [36.25, 34]

$$\text{SIWV} = \Pi \text{SWD}. \quad (36.21)$$

The factor Π depends on some constants and the temperature profile above the GNSS receiver. In most cases, the temperature profile is not known, and the water vapor weighted mean temperature T_m is used to estimate the impact of the whole profile from the temperature T_0 in kelvin at the GNSS antenna

$$T_m = 72.2 + 0.72T_0. \quad (36.22)$$

The factor Π is given by

$$\Pi = \frac{10^6}{\varrho_w R_w \left(k'_2 + \frac{k_3}{T_m} \right)}, \quad (36.23)$$

where ϱ_w is the density of water vapor, R_w is the gas constant of water vapor (Chap. 5), k_3 is the empirical constant given in Table 36.2, and k'_2 is given by (36.18). There are alternative approaches for estimating the SHD or SIWV, e.g., the Hopfield model [36.35, 36], but as there is no reference for water vapor observations in the free atmosphere, it is difficult to identify the best one.

The procedure described above is based on two assumptions. 1. Surface observations p_0 and T_0 are sufficient to approximate the impact of the pressure and temperature profiles above the GNSS receiver. 2. The

horizontal pressure and temperature gradients are sufficiently small to map the zenith delay on the signal path even at rather low elevations of $\approx 5^\circ$. The error introduced by (36.23) is much larger than the error of (36.19), and the SWDs are a more reliable input to the tomography than the SIWV. However, in severe weather conditions, even (36.19) can introduce serious errors [36.37], and the application of STDs might be the best option.

36.3.4 Discrete Spatial Grid

A spatial and temporal discretization is required to solve (36.5) numerically. Assuming that all observations in \mathbf{y} were taken at the same time is equivalent to temporal discretization, and the choice of the time step Δt depends on many parameters, which are discussed in Sect. 36.4.4. The spatial grid is used to describe the refractivity field on a limited number of grid nodes and defines the number of unknowns that have to be specified by the inversion. The shape of the grid and the distribution of grid nodes is not predefined by (36.5), and any irregular grid can be chosen. However, the GNSS receiver network, which provides the observations, constrains some parameters of the grid (Sect. 36.4.2), and a special grid structure might be recommended by the observation operator, e.g., a regular voxel grid. The grid nodes are usually defined by latitude, longitude, and height and need to be mapped on a vector \mathbf{x} . No specific order is required, but the mapping must be unique, and the same mapping needs to be used when the design matrix \mathbf{A} is defined.

36.3.5 Observation Operator and Design Matrix \mathbf{A}

The slant-delay observation operator computes individual delays based on the observation geometry and the discrete refractivity field defined on a spatial grid. The operator defines the signal path between the satellite and the receiver within the grid, interpolates the refractivities of adjacent grid nodes on the signal path, and estimates the delay by numerical integration of (36.12).

With the approximations described in Sect. 36.3.1, it is assumed that the signal path is known in advance and does not change during the inversion. The signal path might be a straight line between transmitter and receiver, but it could also be a more realistic curved signal path.

The simplest way to define the forward operator is a straight line in a voxel grid, i.e., a direct implementation of $\int N ds \approx \sum N_i \Delta s_i$, where the N_i are the refractivities within the voxels, and Δs_i are the subpaths in the corresponding voxels. This is rather similar to

a nearest-neighbor interpolation combined with a very basic numerical integration. While this can be implemented easily, it leads to a step function along the signal path and a very nonsmooth observation operator. Such an operator will lead to rather large operator errors and to a less stable inversion.

A much better observation operator can be obtained in a two-step approach. A set of supporting points for the numerical integration along the signal path is defined in a first step. A high-quality numerical integration algorithm [36.38, 39] provides the weights of each supporting point. In a second step, the refractivities from the spatial grid are interpolated on the supporting points. The interpolation algorithm determines the contribution of each grid point to each supporting point, i.e., a second set of weights. The observation operator is a combination of both weights [36.40].

An alternative approach is to implement the full nonlinear observation operator. The linearized operator, i.e., the j -th row of \mathbf{A} , is given by the derivatives of the STD operator with respect to N_j

$$a_{ij} = \frac{\partial \text{STD}_i}{\partial N_j}. \quad (36.24)$$

This is equivalent to the adjoint operator used, e.g., in the variational data assimilation. In the case of a voxel grid, the operator is already linearized by the approximation described above, and the derivatives of the sum are the subpaths in each voxel. For a more sophisticated STD operator with a nonlinear interpolation and a numerical integration based on higher-order polynomials, the derivatives must be computed explicitly.

The bending of the signal path needs to be taken into account if STDs at low elevations $\varepsilon \lesssim 30^\circ$ are used. Observation operators developed for numerical weather models show that the STDs computed for straight lines overestimate the delays systematically [36.41], leading to an operator error of $\gtrsim 5$ mm at $\varepsilon = 30^\circ$ and ≈ 100 mm at 5° . A raytracer [36.42] can be used to estimate the curved signal path in a previous refractivity state or even in the standard atmosphere [36.27], and (36.12) can be integrated along this curved path. As the vertical structure of the humidity field is to a large degree determined by STDs at low elevations, the application of a raytracer is recommended.

36.3.6 Inversion

There is a variety of tomographic techniques [36.19, 43], but most of them focus on the solution of isolated static problems. In the case of the GNSS tomography, a continuously developing humidity field is desired, and the atmospheric state needs to propagate in time. The

Kalman filter [36.44] is a reliable approach for estimating the state and the error of continuously developing linear systems. While the Kalman filter is not designed for solving inverse problems, it very often provides stable results. In the case of severely ill-posed problems, it can be combined with regularization techniques that lead to a well-conditioned matrix \mathbf{A} [36.45].

The Kalman filter uses a two-step approach. The forecast step propagates the system in time, and the update step combines the current state with the latest observations. The forecast step from time t_{k-1} to t_k with the previous state $\mathbf{x}_{k-1} = \mathbf{x}(t_{k-1})$, and the forecast $\mathbf{x}_k^- = \mathbf{x}^-(t_k)$ is given by

$$\mathbf{x}_k^- = \mathbf{F}\mathbf{x}_{k-1}, \quad (36.25)$$

$$\mathbf{P}_k^- = \mathbf{F}\mathbf{P}_{k-1}\mathbf{F}^T + \mathbf{Q}_k. \quad (36.26)$$

In the case of tomography, there is no model that propagates the state \mathbf{x} in time, and the forecast is just a copy of the old state \mathbf{x}_{k-1} to \mathbf{x}_k^- ; \mathbf{F} is the unit matrix \mathbf{I} , the forecast error covariance matrix \mathbf{Q} is not time dependent, and the equations simplify considerably

$$\mathbf{x}_k^- = \mathbf{x}_{k-1} \quad \text{and} \quad \mathbf{P}_k^- = \mathbf{P}_{k-1} + \mathbf{Q}. \quad (36.27)$$

The update step combines the forecast \mathbf{x}_k^- with the latest observations \mathbf{y}_k and provides the new state \mathbf{x}_k with the error covariance matrix \mathbf{P}_k . The Kalman gain matrix \mathbf{K}_k is used to compute the increments to \mathbf{x}_k^- and to update the error covariance matrix; \mathbf{K}_k depends on the observation operator \mathbf{A}_k , the forecast error covariance matrix

\mathbf{P}_k^- , and the observation errors \mathbf{R}_k

$$\begin{aligned} \mathbf{K}_k &= \mathbf{P}_k^- \mathbf{A}_k^T (\mathbf{A}_k \mathbf{P}_k^- \mathbf{A}_k^T + \mathbf{R}_k)^{-1}, \\ \mathbf{x}_k &= \mathbf{x}_k^- + \mathbf{K}_k (\mathbf{y}_k - \mathbf{A}_k \mathbf{x}_k^-), \\ \mathbf{P}_k &= (\mathbf{I} - \mathbf{K}_k \mathbf{A}_k) \mathbf{P}_k^-. \end{aligned} \quad (36.28)$$

A continuously running GNSS tomography system would start with an initial state \mathbf{x}_0^- and an error estimate \mathbf{P}_0^- . The state \mathbf{x}_0^- is updated using the latest observations \mathbf{y}_0 which leads to the best estimate of the state \mathbf{x}_0 , i.e., the state with the minimum error covariance \mathbf{P}_0 . The cycle continues with the subsequent application of the equations (36.27) and (36.28). The choice of the time step Δt depends on the respective application and is discussed in Sect. 36.4.4.

There are two fundamental problems with the application of the Kalman filter to GNSS tomography. A reliable estimate of the propagation error \mathbf{Q} is required to obtain a stable system; \mathbf{Q} is the error introduced by the assumption that the state does not change within a period Δt and can be estimated from climatological data. The conditioning of \mathbf{A} is crucial, as \mathbf{A} is not only used for updating the latest state but also for estimating its error covariances. In the case of severely ill-posed problems, the ill-conditioning of \mathbf{A} leads to an instable filter, which diverges quite fast to meaningless results. Regularization techniques like the truncated SVD or Tikhonov regularization can be used to improve the conditioning of \mathbf{A} and to stabilize the filter.

36.4 Devices and Systems

The GNSS tomography is the last step in a rather long and complex processing chain with three almost independent subsystems. The GNSS raw observations with the basic travel time information are collected by ground-based networks of GNSS receivers. The raw observations are processed by complex GNSS processing systems, which provide precise positioning information. The GNSS atmosphere processing is usually done in a second step and determines the STDs together with other tropospheric products. The STDs and some additional meteorological observations are used by the GNSS tomography system in order to estimate spatially resolved humidity fields. The only hardware components of the whole system are the GNSS satellites and receivers. GNSS processing and tomography are done by special software packages that run virtually on any computer and at any place with access to the data.

36.4.1 GNSS Systems

Navigation satellite systems were designed for precise positioning and consist of GNSS satellites that orbit the Earth twice a day at a height of $\approx 20\,000$ km and GNSS receivers at the ground or onboard other satellites. The GNSS satellites carry high-precision atomic clocks and GNSS transmitters that continuously broadcast GNSS signals with precise timing information. There is no communication between the GNSS receivers and the satellites, and there are no remote-sensing instruments onboard the GNSS satellites. Any receiver that can track at least four GNSS satellites is able to compute its position from the timing information coded in the GNSS signals [36.35].

The GNSS satellites and the supporting infrastructure are operated by space agencies that are responsible for guaranteeing continuous uninterrupted availability

of the positioning services. GNSS receivers are available from many companies and in a variety of product types, ranging from on-chip receivers for mobile devices to high-quality geodetic receivers. GNSS atmosphere sounding is based on the signal travel time information, and precise geodetic receivers with high-grade antennas are required to obtain observations of sufficient quality. Different GNSS use slightly different frequencies and special signals, which are not supported by all receivers. However, most geodetic receivers do now support all four GNSS.

Apart from the quality requirements, there are no special demands on receivers for the GNSS tomography. It is not the single receiver but an entire network of receivers that provides the basic data for the GNSS tomography and determines the quality of the final humidity fields.

36.4.2 Ground-Based GNSS Networks for Tomographic Applications

The GNSS tomography requires a large amount of observations from many GNSS receivers. The GNSS receivers and the supporting infrastructure are organized in ground-based GNSS networks. The distribution of the stations within the network has a large impact on the quality of the tomographic reconstruction and needs to be considered when the tomography system is configured.

The basic parameters of a GNSS tomography system are the region covered by the system, the horizontal resolution, and the vertical resolution of the solution. The vertical extension is given by the tropopause height, as almost all of the atmospheric water vapor needs to be considered for a reliable solution. These parameters are to a great extent predetermined by the receiver network.

GNSS delays are integrated along the whole signal path. To get a spatially resolved humidity field, a sufficiently large number of intersecting signal paths is required in order to locate the information on each path. For subsections without any intersecting paths, only some spatial mean value can be obtained. This is the case in the lowest part of the atmosphere, where the minimum elevation of the observed GNSS signals and the Earth's curvature prevent intersections between different signal paths. Another problem are the outer boundaries of the network, where the intersections with outward pointing signal paths decrease significantly.

The vertical resolution of the tomographic solution is limited by the mean interstation distances within the GNSS network. A receiver located at the position B in Fig. 36.2 cannot detect any signals below a given height H_2 at a point A in a distance S_{AB} . The atmosphere be-

Fig. 36.2 Geometric limitations for atmosphere sounding by GNSS slant paths. GNSS signals detected at a position B cannot cover the atmosphere below the height H_2 at a position A. The vertical range below H_1 is not visible due to the Earth's curvature, and the range between H_1 and H_2 cannot be scanned because of the minimum elevation $\varepsilon = \varepsilon_{\min}$ that is detected by the receiver

low the height H_1 is shaded by the Earth's curvature, and the range between H_1 and H_2 cannot be scanned because of the minimum elevation $\varepsilon = \varepsilon_{\min}$, which is usually between 5° and 10° . An estimate of H_1 and H_2 for a spherical Earth and without regarding the ray bending in the atmosphere is given by [36.46]

$$H_1 = R_0 \left(\sqrt{1 + \tan^2 \left(\frac{S_{AB}}{R_0} \right)} - 1 \right), \quad (36.29)$$

with the radius R_0 of the Earth and the distance S_{AB} between the points A and B. The contribution $H_2 - H_1$ due to ε_{\min} is

$$H_2 - H_1 = R_0 \tan \left(\frac{S_{AB}}{R_0} \right) \left[\sin \left(\frac{\pi}{2} + \frac{S_{AB}}{R_0} \right) \times \left(\tan^{-1} \left(\frac{\pi}{2} + \frac{S_{AB}}{R_0} \right) + \tan^{-1} \varepsilon \right) \right]^{-1}. \quad (36.30)$$

To estimate the vertical resolution it is helpful to compute the distance S on the Earth's surface where a slant with the elevation ε reaches the height H_2

$$S = R_0 \left(\frac{\pi}{2} - \varepsilon - \arcsin \left(\frac{R_0}{R_0 + H_2} \right) \right). \quad (36.31)$$

Some distances S obtained with $\varepsilon = 5^\circ$ are shown in Table 36.4. It turns out that signals below 1000 m can be expected only for stations within a radius of 11.3 km, and stations with distances exceeding 22.4 km provide data above 2000 m. Stations that are farther away than ≈ 100 km cannot contribute any information. The num-

Table 36.4 Station distances S for some heights H_2 according to (36.31) with $\varepsilon = 5^\circ$

H_2 (m)	1000	2000	5000	10000
S (km)	11.3	22.4	54.5	104.4

ber of stations that provide data increases with H_2 until the top height regarded by the tomography is reached. In the case of a large network with a homogeneous station density, the number of stations will grow with S^2 . If the tomography requires a certain number of signals within each layer, the vertical extension of the layers can be reduced, i.e., the vertical resolution increases with height.

The horizontal resolution in the lower troposphere is also limited by the mean receiver distances within the network, as there are almost no GNSS observations between the stations. The situation improves with increasing height, but more than 50% of the water vapor is located below 2 km and increasing the horizontal resolution with height brings no advantage.

Summarizing, there is a rather large gap in the lower troposphere where no intersecting slant paths can be expected and where the vertical resolution is very poor. Above a certain height, the vertical resolution begins to increase. This is exactly the opposite of the desired situation. To obtain a reasonable vertical resolution in the boundary layer, the minimum elevation can be decreased, but only very dense receiver networks will lead to substantial improvements.

So far, a flat terrain has been assumed. In mountainous regions, it might be possible to place some receivers along mountainsides that provide almost horizontal views at different heights and help alleviate the low resolution near the surface.

It depends very much on the density and distribution of GNSS receivers within the network whether the STD data sets are really sufficient for GNSS tomography. If the spatial coverage of the atmosphere by GNSS observations is insufficient, tomographic techniques will lead to instable solutions with many artifacts, and other strategies for combining all available observations might be more productive, e.g., data assimilation techniques [36.47] or least-squares collocation [36.48].

Modern GNSS networks consist of geodetic multi-GNSS receivers which track all visible satellites on several frequencies simultaneously [36.49]. High-quality multi frequency receivers are required to remove the impact of the ionosphere and to achieve the required precision. Existing networks can be further densified with less expensive single-frequency receivers [36.50, 51] in order to reach the high receiver density required by the GNSS tomography.

36.4.3 GNSS Processing

GNSS receivers are able to display their position. However, the coordinates computed by the receiver are rather inaccurate, with errors between ≈ 10 m for budget single-frequency receivers and ≈ 10 cm in the case of high-quality geodetic receivers. In order to obtain high-precision coordinates with sub-cm errors complex GNSS processing packages are required. GNSS atmosphere products can only be derived during the GNSS processing. An overview about GNSS processing in general can be found in [36.52, 53] and about GNSS atmosphere processing in [36.54, 55].

Processing of the GNSS raw data can be done in network mode using undifferenced phase observations [36.56] or double differences (DD) of phase observations [36.57]. The DD approach removes satellite and receiver clock errors by differencing simultaneous observations from two sites and two satellites. Because DD processing eliminates clocks and allows for ambiguity resolution, it is sensitive to small variations in the nonisotropic part of the troposphere. The technique to transform double difference residuals into line-of-sight residual delays (which can then be converted into non-isotropic slant water observations) for an individual ray path between a transmitting satellite to a receiving antenna is described by [36.58].

However, this approach has several disadvantages, especially for operating dense GNSS networks with more than 200 sites, where the processing time increases exponentially with an increasing number of sites/parameters. The disadvantage of DD for STD calculation is that the resulting residual is a combination of four observations instead of one.

The necessity of an efficient operation of large networks within short computation time was one of the main reasons for introducing the precise point positioning (PPP) approach [36.59]. The main idea of the PPP strategy is the processing of each site separately, fixing the high quality GNSS orbits and clocks. The advantage of PPP for slant calculation is that the line-of-sight observations from the receiving antenna to each transmitting satellite are individually modeled, and site specific effects can be investigated. This approach helps to avoid error propagation from poorly functioning stations within the network and even to avoid a complete failure of the solution in the case of problems with one of the fiducial sites of the network.

However, the main advantage of the PPP strategy is the processing time, which increases only linearly with the number of stations and solved parameters (e.g., ZTDs or gradients every 15 min). The possibility to process a large number of the stations in near realtime is of

significant importance for the tomography where dense networks are required.

The main disadvantage of the PPP analysis is that satellite orbit and clock estimates with high accuracy are required. Typically, satellite clock values are computed together with the satellite orbits from a global GNSS tracking network. Thus, the GNSS data processing for PPP has to be split into two steps. Step 1 includes the estimation of high-quality GNSS orbits and clocks from a global network, e.g., from a network of IGS (International GNSS Service) sites. This leads to the most accurate and consistent results and, consequently, to highly reliable STDs. Another possibility is to use accurate final orbit and clock products provided by IGS. However, this may lead to inconsistent results. Step 2 is the actual PPP processing of individual stations. An overview of the PPP strategy can be found in [36.60].

There is a number of software packages for GNSS data processing. The most widely used commercial GNSS software package is Bernese, which can handle both DD and PPP methods [36.57] and is based on a least-squares (LSQ) adjustment. Two other free packages that are typically used for research are GIPSY/OASIS, which is based on a Kalman filter and GAMIT/GLOBK, which uses LSQ. GIPSY/OASIS is often preferred because of its better computational efficiency associated with the PPP approach, while GAMIT/GLOBK does not support PPP and is restricted to DD. These three software packages are used by most GNSS analysis centers that provide tropospheric GNSS products for meteorological projects like E-GVAP (egvap.dmi.dk) or COST Action 1206 [36.61].

Another example of a noncommercial software package that is able to process the STDs automatically using the PPP strategy is the Earth Parameter and Orbit System (EPOS) software developed at the German Research Centre for Geosciences (GFZ). The EPOS software is based on a least-squares adjustment of undifferenced phase observations and makes use of the conventions defined by the International Earth Rotation and Reference Systems Service (IERS) [36.56, 62–64]. EPOS supports both the network mode and the PPP mode. The former is required to calculate high-precision GNSS orbits, clocks, and station coordinates, which are provided to IGS and are required by PPP. The latter is used to process large numbers of stations for different meteorological applications.

Operational GNSS data processing at the GFZ for meteorological applications has provided all kinds of tropospheric products, namely zenith total delays, integrated water vapor, slant total delays, and tropospheric gradients in near realtime for more than 15 years.

The automated processing of GNSS data in PPP mode with EPOS is split into two parts. Part 1 is the so-called *base cluster* analysis in network mode, where

the estimation of high-quality GNSS orbits and clocks from a global network of about 100 IGS sites is performed. Among the estimated parameters at this step are the GNSS orbits, satellite clocks, Earth rotation parameters (ERPs), and ZTDs for 4-h intervals. GFZ ultra rapid IGS products for orbits and clocks as well as GFZ ERPs are used as initial values.

The second part is the PPP analysis itself: estimation of all tropospheric products (ZTDs/IWV/STDs) using parallel processing of stations in clusters based on fixed orbits and clocks from the first step. EPOS adjusts for the ZTDs with a resolution of 15 min, for tropospheric east and north gradients with an hourly resolution, as well as for STDs with 2.5 min time resolution from a sliding 24-h data window. The station coordinates are fixed, once determined with sufficient accuracy within ITRF (International Terrestrial Reference Frame).

36.4.4 Setup of a GNSS Tomography System

A GNSS tomography system is basically a solver for (36.5), and its structure is quite simple. In a first step, the three components of the equation need to be set up for a specific case. The state vector \mathbf{x} is defined by the spatial grid, which is usually a predefined static grid. Equation (36.5) is solved for \mathbf{x} , however most algorithms require an initial state or background, and \mathbf{x}_{ini} needs to be specified, optionally together with some error characteristics or a full background error covariance matrix. All available observations, i.e., the delays and any additional observations that might be required to stabilize the inversion algorithm are mapped to the observation vector \mathbf{y} . In most cases, the observation errors are also required. The size of \mathbf{y} depends on the number of observations available at a certain time and may vary considerably. The linear operator \mathbf{A} maps the state vector on the observation vector. The rows of \mathbf{A} are the linearized observation operators for each observation in \mathbf{y} and need to be redefined for each specific situation. The second step is the numerical solution of (36.5) and provides \mathbf{x} , optionally together with some error estimates. As the problem is ill-posed, and \mathbf{A} is ill-conditioned, some strong constraints are usually required to obtain stable and meaningful solutions. The constraints are an important part of the whole system and need to be carefully tuned. In a last step, the results might be converted to a more convenient quantity, e.g., from a refractivity field to a field of the absolute humidity, and provided to potential users.

Discretization and Approximations

The numerical solution of (36.5) requires a discrete spatial grid. The grid defines the region that is covered by the tomography, and the horizontal and the vertical res-

olution. The total number of grid nodes is the number of unknowns in (36.5) and needs to be sufficiently large to implement realistic observation operators with reasonable operator errors but should be as small as possible, as the ill-conditioning of \mathbf{A} increases with the number of unknowns. The limitations of the grid resolution due to the receiver network were discussed in Sect. 36.4.2.

Another important choice is the kind of delays used by the tomography: STD, SWD, or SIWV. As discussed in Sect. 36.3.2, additional errors are introduced by the conversion to SWDs or SIWV, and it depends on the meteorological observations available at or near each GNSS station whether the conversion leads to reliable results.

In most cases, the signal paths do not cover the whole volume of the atmosphere spanned by the GNSS tomography. This leads to a sparse matrix \mathbf{A} . One strategy for reducing the sparsity of \mathbf{A} is to collect path delays over a longer period of time. Especially rising or setting satellites have a rather high angular velocity and scan different parts of the atmosphere if the period is sufficiently long, e.g., between 15 and 60 min. This leads to a better spatial coverage and more stable results at the expense of a reduced temporal resolution. Increasing the sampling rate of the GNSS receivers is usually not beneficial as signal paths separated by only 30–120 s propagate through almost the same parts of the atmosphere and do not provide additional information.

Modeling of the Observation Operator

The design of the STD observation operator is discussed in Sect. 36.3.5. The implementation used in a specific GNSS tomography system can affect the performance of the whole system, as the operator adds some error to the system of equations. The operator error at low elevations can exceed the observation error if no raytracer is used.

In general, it is a good idea to use all available meteorological observations to stabilize and constrain the tomographic solution. This might be synoptic observations, radiosonde profiles, water vapor radiometer data, satellite observations, or even other GNSS products like ZTDs or the vertically integrated water vapor (IWV). As the GNSS tomography works with just one field, e.g., the refractivity or absolute humidity, all these observations need to be mapped on this field. These observations are appended to the vector \mathbf{y} , and the linearized observation operators need to be in the corresponding rows of the operator \mathbf{A} .

Inversion Strategy

The inversion algorithm is the core of any tomography system and the choice of a specific algorithm has

a significant impact on the whole system. The inversion technique determines the solution strategy for the ill-posed inverse problem and the stability of the solution. It also controls the complexity of the system. A tomography system based on the algebraic reconstruction techniques (ART) can basically work with the observations and the corresponding operator \mathbf{A} . No error information is required or provided, and the iterative algorithm does not require any complex matrix manipulations or inversions. This leads to a much leaner system than, e.g., a Kalman filter, which requires detailed error information and is based on a much more complex and computationally demanding algorithm. A large number of inversion techniques has already been applied successfully to the GNSS tomography [36.11, 43]; some examples are given below.

The many variants of the ART family [36.43, 65] are fast iterative approaches that require little extra information [36.66, 67]. However, a good initialization is very beneficial. The mathematical justification is not very convincing [36.18], and a general criterion for stopping the iteration (index k in (36.32)) does not exist, which may lead to degrading or oscillating solutions. Usually it is possible to find a set of parameters for a specific configuration that leads to fast and rather stable results. Multiplicative ART (MART) is a particularly fast converging variant and was used in Sect. 36.8

$$x_j^{k+1} = x_j^k \left(\frac{y^i}{\langle \mathbf{A}^i, \mathbf{x}^k \rangle} \right)^{\frac{\lambda A_j^i}{\sqrt{\langle \mathbf{A}^i, \mathbf{A}^i \rangle}}}. \quad (36.32)$$

This equation describes three nested loops of the iteration algorithm. The innermost loop, index i , determines the factor that is applied to the j -th element of the state vector \mathbf{x} . The contributions of all observations y^i are added and applied to each single x_j^k . This is repeated for all elements x_j of the state vector, index j . These two loops are repeated until a stable state \mathbf{x} is reached, index k . The relaxation parameter λ determines the weight of the observations with respect to \mathbf{x} . The algorithm shows fast convergence if λ is large but also becomes less stable with an increasing number of artifacts. A large number of iterations k is required if λ is too small, which also leads to instable results. The optimal λ needs to be experimentally determined [36.15].

The pseudo inverse \mathbf{A}^\dagger is an approach to invert \mathbf{A} and to compute the new state \mathbf{x} with $\mathbf{x} = \mathbf{A}^\dagger \mathbf{m}$ [36.66, 68, 69]; \mathbf{A}^\dagger is estimated using the truncated SVD (36.6), i.e., the large number of small singular values that are typical for inverse problems are truncated at a certain threshold in order to obtain a well-conditioned matrix: $\mathbf{A}_p = \mathbf{U}_p \mathbf{\Sigma}_p \mathbf{V}_p^T$. There are algorithms for estimating the threshold, but the exact threshold remains somewhat ar-

bitrary. The solution is obtained in one step

$$\mathbf{x} = \mathbf{A}_p^\dagger \mathbf{m} \quad \text{with } \mathbf{A}_p^\dagger = \mathbf{V}_p \mathbf{\Sigma}_p^{-1} \mathbf{U}_p^T. \quad (36.33)$$

If an initial field \mathbf{x}_0 with some error characteristics \mathbf{B} is available, a weighted, damped least-squares solution leads to an optimal combination of the initial information and the new observations [36.70–72]. A similar approach is used in the variational data assimilation [36.73]. These techniques cannot update the error estimates and work either with a constant background error or need an additional strategy for estimating the errors of the solutions. The solution can be given in incremental form

$$\mathbf{x} = \mathbf{x}_0 + \mathbf{B} \mathbf{A}^T (\mathbf{A} \mathbf{B} \mathbf{A}^T + \alpha^2 \mathbf{R})^{-1} (\mathbf{y} - \mathbf{A} \mathbf{x}_0), \quad (36.34)$$

where α is the damping term, \mathbf{B} is the error covariance matrix of \mathbf{x}_0 , and \mathbf{R} is the observation error covariance matrix as in Sect. 36.3.6. By increasing or decreasing α the weight of the observations can be decreased or increased, which has an impact on the stability of the solution. For $\alpha = 1$, this is equivalent to the 3-D variational solution.

The Kalman filter (Sect. 36.3.6) might be the most consistent technique as long as no specialized inversion strategies that can deal with the highly variable degree of ill-posedness are available. The Kalman filter combines the latest humidity field and the observations using the corresponding error covariance matrices and provides not only an optimal solution but also an updated error covariance matrix for the solution. For numerical reasons, a square-root filter should always be implemented, which is more stable and avoids negative humidities that can easily appear if the original Kalman filter is used. Reliable error estimates are required but may be difficult to obtain.

Especially the error of the forward step, which in case of the GNSS tomography is just a copy of the previous state, is difficult to estimate. A climatology provides some mean error, but the true error of the humidity fields is highly variable in space and time and can lead to strong deviations from the true state. As there is no stabilizing physical model it is difficult for the system to recover from a wrong state, and it may get unstable. Another problem is the ill-conditioned operator \mathbf{A} that enters the Kalman gain matrix and has a degrading effect not only on the solution but also on the error characteristics.

The GNSS tomography systems developed up to now do not run continuously by updating the latest state with newly acquired observations. Even a Kalman filter can become unstable after some time and needs to be restarted from a reliable state. There are many rea-

sons for this. The system runs without a physical model and can easily get into a meteorologically meaningless state. The degree of ill-posedness depends on the satellite constellation and varies heavily, leading to an ill-conditioned operator \mathbf{A} that amplifies small errors to a varying degree. The inversion techniques described above cannot adapt to such a behavior and may become unstable [36.74].

Meteorological Observations, Constraints, and Pseudo Observations

In most cases, (36.5) has an infinite number of solutions \mathbf{x} , and most of them are meteorologically meaningless. Therefore, strategies are required to single out the most realistic humidity field. The best strategy is to add some extra observations to the system of equations. Especially well located observations, e.g., from synoptic stations or radiosondes, constrain the system to a realistic state and stabilize the inversion as the operator \mathbf{A} becomes less ill-conditioned. Especially whole profiles from radiosondes, radiometers, or lidars are very beneficial, but other integrated quantities like satellite data or the GNSS column-integrated water vapor are also helpful.

Synoptic observations can be used to constrain the surface layer to the observed humidities, and the top layer at the tropopause can be constrained to a very small humidity or even be set to zero. Such constraints guarantee that most of the humidity is located in the lower atmosphere. If only the slant delays were regarded, an upside-down atmosphere with most of the humidity near the tropopause would be entirely equivalent, at least in a flat geometry.

Constraints can, in general, be described as

$$c(p(\mathbf{x})) = 0, \quad (36.35)$$

where c is the constraining function, and p is some projection. Most constraints used in GNSS tomography are equality constraints that simplify to $c(\mathbf{x}) = 0$ and can be regarded as pseudo observations

$$\mathbf{y}_c = \mathbf{A}_c \mathbf{x}, \quad (36.36)$$

where the rows of \mathbf{A}_c are the linear(ized) constraints c and $\mathbf{y}_c = 0$. The original system of linear equations (36.5) can be extended by (36.36) and be solved in one step. However, there is also an error related to the constraints that needs to be considered if, e.g., a Kalman filter is used [36.75].

In most cases, the GNSS slant delays are available only for some parts of the atmosphere, while there is no information for other parts. This leads to strong and

unrealistic gradients within the solution. One way to smooth out such gradients are intervoxel constraints. One option is to constrain the humidity at each grid node to the mean humidity of the neighboring nodes, e.g.,

$$0 = x_i - \frac{1}{\sum_j c_j} (c_1 x_{r_1} + c_2 x_{r_2} + \dots + c_M x_{r_M}), \quad (36.37)$$

where the indices r_1, \dots, r_M select the neighbors of node i , the c_j are the weights assigned to each neighbor, and M is the total number of neighbors, e.g., $M = 26$ in a regular 3-D grid. Another option is a Gaussian filter, which takes all grid nodes within a given radius into account. As the humidity usually decreases with height, the weights should be vertically adjusted.

In most cases, the GNSS processing also provides the IWV above each GNSS station, and the vertically

integrated humidity at the corresponding grid columns can be restricted to the observed IWV

$$0 = \text{IWV}_j - \sum_r a_r, \quad (36.38)$$

where IWV_j is observed at station j , and the a_r are the absolute humidities in the grid column next to the station.

A well-tuned combination of these strategies is usually required to obtain a stable GNSS tomography system. Care must be taken to avoid too strong constraints or too much smoothing, as the solutions may look very convincing but are far from reality. An overconstrained system leads to some kind of mean humidity field with only minor fluctuations due to the observations and cannot represent the real atmospheric dynamics.

36.5 Specifications

The final product of the GNSS tomography is a field of the absolute humidity a . Some of the most relevant parameters are the horizontal and vertical resolution and the error of a . The resolution of the final field is to a large degree defined by the mean interstation distances within the GNSS ground network (Sect. 36.4.2) but also depends on the quality and density of the observations. It would be possible to increase the resolution if a large number of STDs, e.g., from multi-GNSS receivers, is available, or if meteorological observations from dense sensor networks can be utilized. The latter is especially important for the lower part of the troposphere, which can hardly be resolved with GNSS observations alone. As there are so many influencing variables, it is a demanding task to estimate the theoretical resolution even for an existing network, and no general statements can be made. However, applications with horizontal resolutions between 10 and 80 km and

vertical resolutions between several hundred meters and ≈ 2000 m exist.

To quantify the error of a is even more difficult, as a is obtained by solving an ill-posed inverse problem with highly variable input data. It is, in general, not possible to propagate errors beyond the solution of an inverse problem, and the validation of the results with independent observations is the only way to estimate the error (Sect. 36.6.2). The situation is comparable to the output of numerical weather models, i.e., analyses and forecasts, which are also provided without any error estimates and can only be validated using the observations.

The humidity fields provided by the GNSS tomography can be related to the requirements of the World Meteorological Organization (WMO) for the specific humidity (Table 36.5). The WMO threshold for the higher and lower troposphere can already be reached by most local GNSS networks and some dense national net-

Table 36.5 WMO requirements for the specific humidity according to the Observing Systems Capability and Review Tool (OSCAR) and feasibility of the targets by the GNSS tomography (<http://www.wmo-sat.info/oscar/variables/view/161>). The uncertainty ε , the horizontal resolution h_{res} , and the vertical resolution v_{res} as specified by the WMO are given

WMO target	ε (%)	h_{res} (km)	v_{res} (km)	GNSS tomography
High troposphere				
Goal	2	2	0.3	Future very dense local networks with additional profile information
Breakthrough	5	10	0.4	Dense (local) networks with interstation distances ≤ 10 km
Threshold	10	30	1	National networks with interstation distances ≤ 30 km
Lower troposphere				
Goal	2	0.5	0.1	Presumably out of reach
Breakthrough	5	5	0.2	Future very dense local networks with additional profile information
Threshold	10	20	1	National or local networks with interstation distances ≤ 20 km

works, if additional surface observations that constrain the profile in the lower troposphere are available. Tomographically reconstructed humidity fields with a horizontal resolution of 10 km are also available for some local networks; however, whole profiles with a vertical resolution of 400 m and a rather small uncertainty are very demanding. As discussed in Sect. 36.4.2, the vertical resolution is limited by the interstation distances and a resolution of 400 m, or even 200 m as required for the lower troposphere, can be obtained only for interstation distances below 2 km. A high vertical resolution with a small uncertainty can presumably be obtained only if

additional observed profiles are available. The temporal resolution and timeliness of tomographic products depend on the GNSS processing strategy and are almost independent of the spatial resolution. The delay due to the tomography is in the order of some minutes, and the tomographic products can be provided almost as fast as the original GNSS products. Most GNSS processing centers are already better than the WMO breakthrough with a 60 min observation cycle and a timeliness of 30 min. There are even some GNSS products that reach the WMO goal of a 15 min cycle. Future realtime products will be supplied significantly faster.

36.6 Quality Control

GNSS products cannot be regarded as true observations but are estimates from rather complex processing systems. Monitoring the quality of such products is a rather complex task. The most important atmospheric GNSS products are humidity estimates such as the IWV or 3-D humidity fields. As there is no high-quality reference system for humidity observations in the free atmosphere, the GNSS humidity products can only be compared to observations from other remote-sensing systems, which have their own peculiarities.

36.6.1 GNSS Processing Quality Control

The basic output of GNSS processing systems are the coordinates of the stations that are used in parallel for quality monitoring. The errors of several input parameters are estimated during the processing, such as the error of the GNSS satellite orbits, the error due to the ionosphere, signal multipath errors, antenna-related errors, and the uncertainties of mapping functions. These errors can be propagated through the least-squares adjustment of the atmospheric parameters and provide a per-epoch and station error of the ZTD and STD [36.55, 76]. While these error estimates to some degree depend on the process-

ing system, they provide valuable information on the temporal variation of errors and can complement the empirically determined errors derived in the next section.

36.6.2 Validation of Meteorological GNSS Products

The basic GNSS atmosphere products are the ZTD, IWV, and STD. These quantities are continuously validated by most processing centers in order to ensure a high quality of the products and to improve the processing strategies. There are few meteorological observation systems that provide these quantities, and additional observations are usually required to obtain comparable quantities, e.g., converting a radiosonde profile into a ZTD or the IWV. It should be emphasized that intercomparison studies provide the bias and standard deviation of the differences between both systems but do not reveal the true error of the GNSS products. It is always the error of both instruments plus the error of the data conversion that contribute to the standard deviation of the differences, and the error estimates can be regarded as an upper limit for the true error of one of the systems.

Table 36.6 Error of GNSS atmosphere products found in different inter-comparison studies. The typical range of the GNSS derived quantity is shown together with the standard deviation σ , the instruments which were used for comparison and references of recent studies. Radiosondes (RS), water vapor radiometers (WVRs), satellite systems like DORIS or geodetic techniques like VLBI are typically used for such studies

GNSS	Range	σ	Instruments
ZTD	1–2.7 m	3–6 mm	DORIS, RS, NWP [36.77, 78]
ZWD	0–250 mm	3–9.5 mm	VLBI, WVR, RS, NWP [36.79], WVR [36.80]
IWV	0–80 kg m ⁻²	0.9–2.7 kg m ⁻²	DORIS, RS, NWP [36.77, 81]
SIWV	0–300 kg m ⁻²	1.76–7.13 kg m ⁻²	WVR [36.82]
STD	1–25 m	10–12 mm	NWP, WVR [36.83]

The errors of some GNSS atmosphere products as found in recent intercomparison studies are shown in Table 36.6. A more comprehensive overview is given in [36.11]. Table 36.6 provides a range of errors because various GNSS products were validated with different instruments.

36.6.3 Validation of 3-D Humidity Fields from GNSS Tomography

The validation of large three-dimensional atmospheric fields is a demanding task because the errors vary spatially and temporally, and the entire quality of the fields is difficult to express. The fields of the wet refractivity or the absolute humidity provided by the GNSS tomography are usually compared to radiosonde profiles or fields from numerical weather prediction models (NWP), which requires a mapping to the observed quantities and also spatial interpolation.

Table 36.7 shows the results of some tomography validation studies. The errors are difficult to compare

Table 36.7 Errors of tomographically reconstructed humidity fields. The number of GNSS stations (N_{stat}), the reconstructed variable (var.), the observations used for validation (obs.) and the reported errors are shown. The error is expressed either by the root mean square (RMS) or the standard deviation σ

Reference	N_{stat}	Var.	Obs.	Error
Benevides, et al., 2018 [36.74]	17	N_{wet}	RS	0.5–3 g m ⁻³ RMS in a
Rohm, et al., 2014 [36.45]	45	N_{wet}	NWP	$\sigma = 4.2\text{--}12.4$
Shangguan, et al., 2013 [36.84]	272	N_{wet}	RS	RMS = 6.5–9.2
Troller, et al., 2006 [36.16]	43	N_{wet}	NWP	RMS = 1.8–6.5

because the tomography experiments differ in many ways. The number of GNSS stations, the extension of the network, the GNSS processing, the inversion strategy, and the regarded period of time vary in a wide range, and only a general impression can be provided.

36.7 Maintenance

The GNSS tomography depends on the STD products provided by GNSS processing systems, which themselves require raw GNSS observations from ground-based receiver networks. Consequently, the maintenance of a GNSS tomography system must take place on the corresponding levels, i.e., maintenance of the GNSS hardware and the data links to the processing centers, and operation and monitoring of the GNSS processing system and the tomography system.

In a strict sense, the GNSS satellites should also be mentioned here, but they are operated by space agencies that ensure almost unlimited availability.

36.7.1 GNSS Stations and GNSS Hardware

Depending on the application, existing permanent networks can be utilized or small temporary networks need to be installed. In the first case, the provider will keep the network up and running, and only the data link needs to be monitored. In the latter case, the major effort is to build up a new network (Sect. 36.4.2). GNSS receivers are basically radio receivers without any moving parts and usually run for many years but require

some infrastructure like power supply, data links, housing, etc., which need some attendance.

36.7.2 GNSS Data Processing and Tomography System

GNSS processing systems and tomography software are both rather complex applications that require continuous supervision, especially if they run operationally. Apart from the computer hardware, the data links and the availability of external products must be monitored. In both cases, data from external sources must be available, e.g., orbits and clocks for GNSS processing or STDs and meteorological observations for tomography. Up to now, the stability of tomographic solutions has been an issue, and continuously cycled tomographic systems require constant monitoring.

The processing of atmospheric products like STDs and the GNSS tomography are fields of active research, and continuous updates of the software systems are required in order to provide state-of-the-art results. The growing interest in GNSS atmospheric products leads to new user requirements, which need to be addressed.

36.8 Application

The GNSS tomography is a valuable tool for monitoring the spatiotemporal variation of water vapor in a specific region. The majority of the applications developed up to now is based on small regional networks with 20–30 receivers [36.12, 66, 70–72, 74]. Large nationwide geodetic networks were utilized to monitor the water vapor distribution on much larger scales of sev-

eral hundred kilometers. Attempts were made to run operational tomography systems that provide spatially resolved humidity fields for nowcasting and assimilation in numerical weather models [36.15, 16]. However, the stability of the inversion and the quality of the results is still an issue, and none of these systems is already operational.

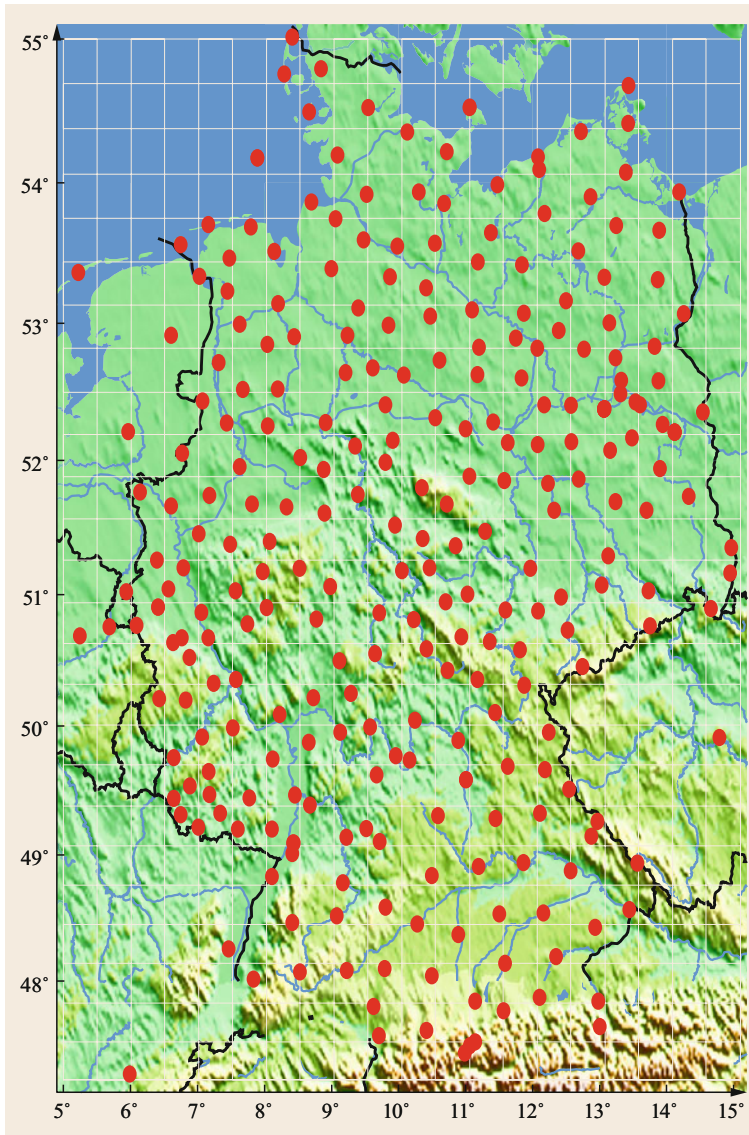

Fig. 36.3 German GNSS network of about 270 stations. Between 8 and 12 GPS satellites could be tracked simultaneously at each station, leading to 2100–3200 STDs. A horizontal 20×25 cell grid was used for the tomographic reconstruction (gray lines)

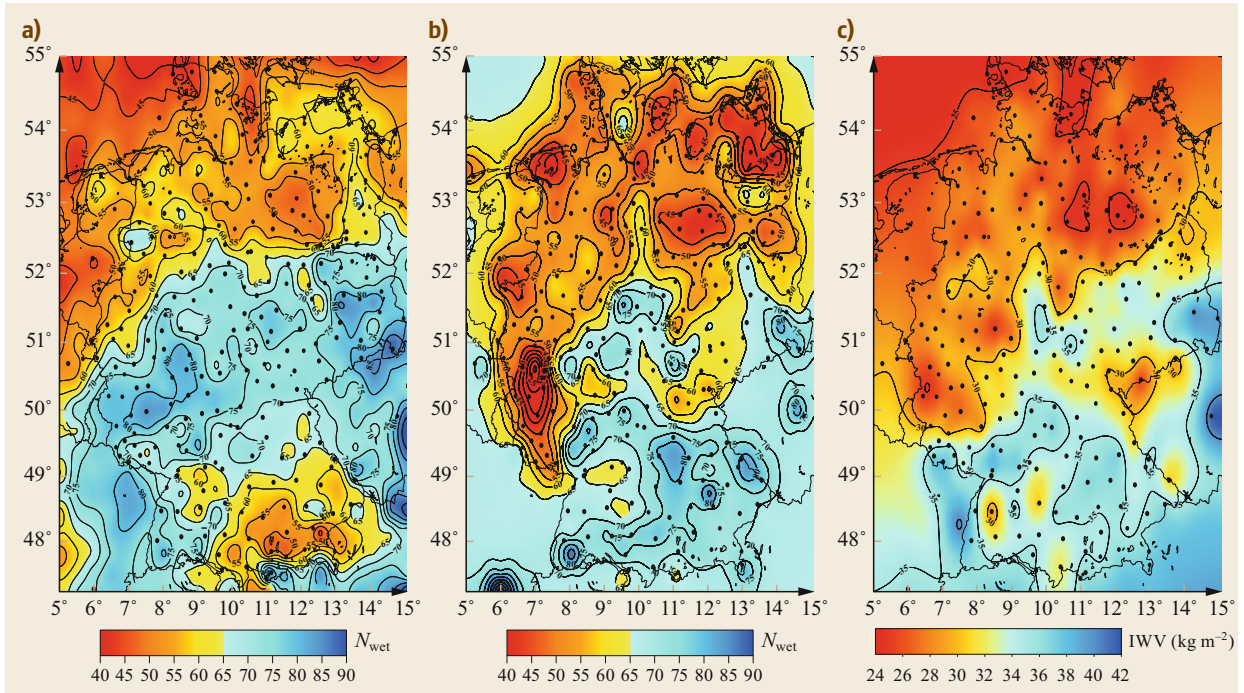

Fig. 36.4a–c Humidity fields from COSMO (a), the tomographic reconstruction (b) and GPS IWV (c) from 14.07.2009, 16:00 UTC and for the region shown in Fig. 36.3. The 1009 m layer of the model and the tomography is shown. The N_{wet} field computed from COSMO fields and interpolated on the tomography grid was used to initialize the tomography. The IWV field of interpolated GPS station observations is shown as a reference

As an example, some results of a German tomography system that was developed at the GFZ in Potsdam are shown [36.15]. The GNSS tomography was designed to run as a part of the near realtime GNSS processing, which already provides STD data from ≈ 300 German stations. Pressure and temperature observations from meteorological sensors at the GNSS stations and from the synoptic stations of the German Weather Service (DWD) were used to obtain SWD data sets (Sect. 36.3.3). A regular spatial grid with 20 grid cells in E–W direction and 25 cells in N–S direction covering 700×930 km was used. STD observations from 30 min were combined in each solution, leading to a total of 30 000–50 000 STDs, depending on the satellite constellation. The vertical range of 10 km was divided into 30 cells leading to a resolution of 35 km horizontally and 330 m vertically (Fig. 36.3). Several inversion algorithms were compared, e.g., different variants of ART, weighted, damped least-squares estimates, or the Kalman filter, but none of them proved to be superior, and most of the experiments used the fast MART algorithm.

The tomography was initialized using N_w fields computed from the surface observations and a simple exponential profile, which was scaled to the GNSS IWV observations or with analyses provided by the operational local weather model COSMO-DE of the DWD. The results shown in Fig. 36.4 were initialized by a COSMO field that differed considerably from the GNSS IWV field. The result of the tomographic reconstruction is much closer to the observed IWV field than the initialization but shows some clustering due to insufficient observations. Smooth areas without any structure are obtained at the outer borders, where no GNSS observations were available. The vertical N_w distribution shown in Fig. 36.5 also differs from the initial COSMO field. As the humidity distribution in numerical weather models is always somewhat uncertain, independent observations are required to validate the vertical humidity structure in the fields. The radiosonde profiles from 12 German radiosondes were compared to the columns of the N_w field near the radiosonde stations. Some results for 12 UTC are shown in Fig. 36.6. The

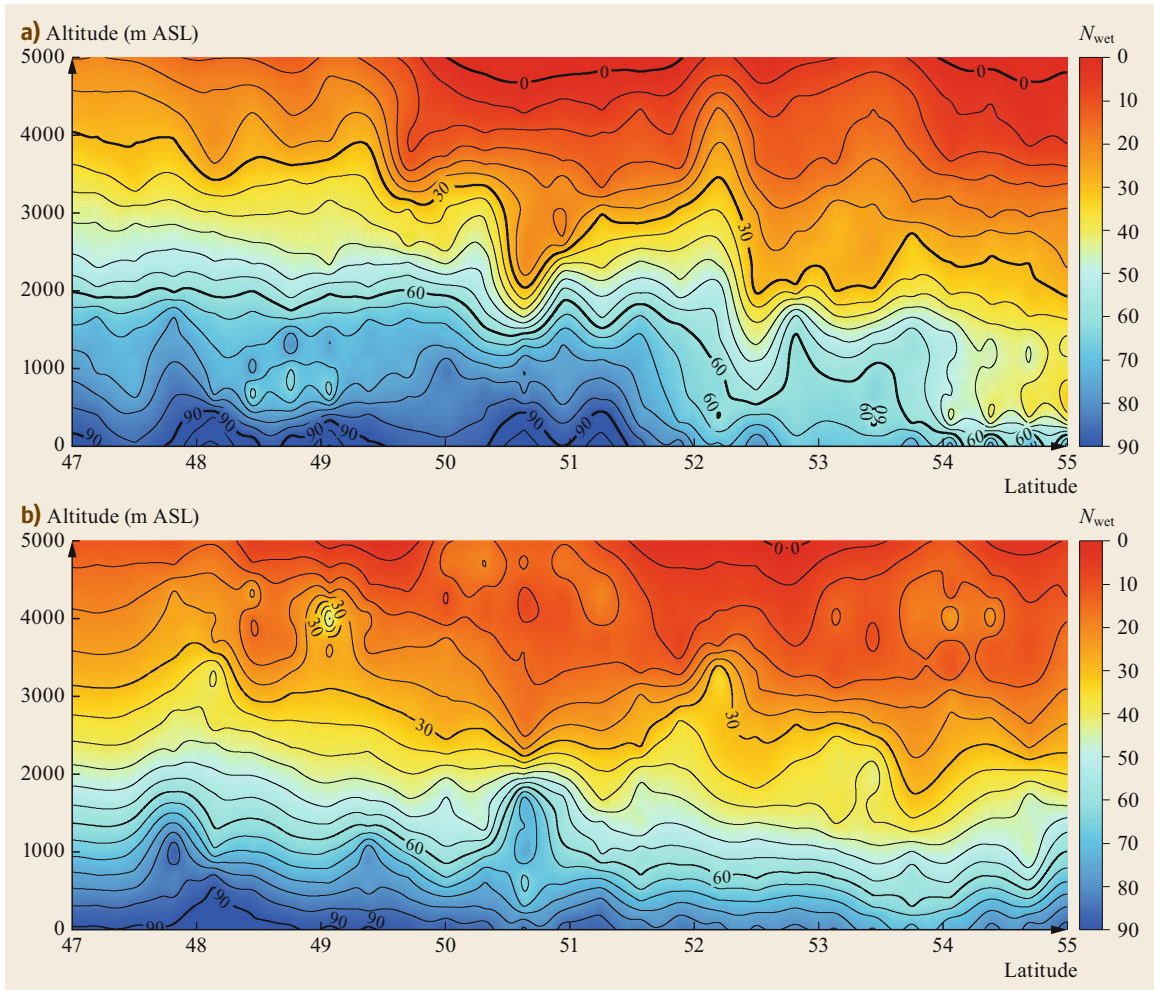

Fig. 36.5a,b Vertical N_{wet} distribution in COSMO (a) and in the tomographic reconstruction (b). The vertical humidity structure in N–S direction at a longitude of 10° is shown

results from the tomography were interpolated on the radiosonde profiles in order to preserve the high vertical resolution of the observations. The tomography solution is based on a spatial grid with a vertical spacing of 330 m and is much smoother than the observations. In general, the tomography profiles try to reproduce the observed vertical structure, but the quality of the pro-

files depends very much on the distribution of the GNSS observations and the initial conditions. While some profiles are in good agreement, others show strong deviations, especially in the lower part of the troposphere up to 3000 m [36.82]. As discussed in Sect. 36.4.2, such a behavior was to be expected because the interstation distances are much too large to obtain reliable results below 3000 m.

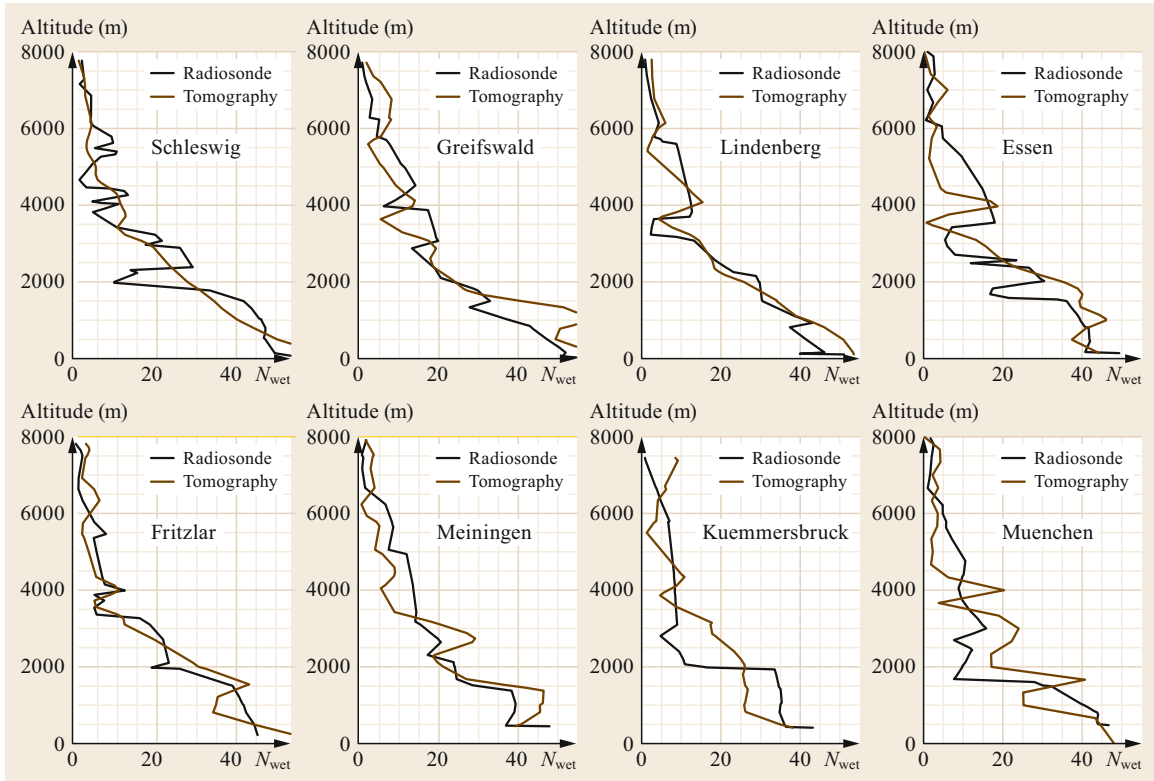

Fig. 36.6 Tomography profiles (brown) interpolated on the observations of some German radiosonde stations (black). The profiles were observed at 14.07.2009, 12:00 UTC

36.9 Future Developments

GNSS atmosphere sounding and GNSS tomography are fields of active research that are developing rapidly. Currently, four satellite positioning systems with more than 120 satellites are available. When Galileo and Bei-Dou become fully operational, more than 30 satellites will be visible at any time and any station. This will lead to about three times more STDs and a much better spatial coverage of the atmosphere than GPS alone. With the new satellites, additional frequencies and signals of improved quality became available and accelerated the development of advanced multi-GNSS receivers. In parallel, more sophisticated multi-GNSS processing techniques have been developed and will be further improved, leading to atmospheric GNSS products of increasing quality.

New processing strategies allow realtime processing of the raw GNSS observations, including atmospheric products, and STDs may in the near future be available within a few minutes. First realtime systems

are already running, and the quality is approaching the quality of currently operational near realtime systems with delays of about 30 min.

In the last decade, the number of national weather services that use GNSS atmosphere products increased constantly and created a common interest with geodetic research. Programs like E-GVAP (egvap.dmi.dk), which combine the efforts of meteorological and geodetic research to improve weather forecasts, are very successful and promote further cooperation. Up to now, the main focus was on cooperation with existing geodetic network providers in order to get access to the GNSS observations. In future, new GNSS networks especially designed for atmosphere sounding might be established.

A combination of these efforts might in the near future lead to nation-wide realtime tomography systems that provide 3-D humidity fields with a high spatial and temporal resolution.

37. Satellite and Aircraft Remote Sensing Platforms

Manfred Wendisch , André Ehrlich , Peter Pilewskie 

Instrumented satellites and high/mid-altitude research aircraft equipped with remote sensors are used to derive dynamic, thermodynamic, chemical, and radiative properties of the atmosphere, as well as to characterize atmospheric components (gases, aerosol particles, clouds, and precipitation) and surface properties (e.g., albedo, reflectivity, and temperature). This chapter provides an overview of these air- and spaceborne sensing platforms, especially those that are currently operational. The basic principles of satellite orbits are introduced, some historical milestones in the development of satellite and aircraft platforms for Earth observations are summarized, and special issues and requirements relating to spaceborne and airborne sampling are outlined. Two concise tables included in the chapter are particularly informative. As well as listing the agencies that currently operate Earth observation satellites, Table 37.2 provides detailed information on some of those satellites, such as their orbits and launch dates, selected remote sensing instruments carried

by the satellites, and parameters that are measured or retrieved by them. Furthermore, the table presents some links to more detailed information on current Earth remote sensing satellites. Table 37.3 provides similar information for research aircraft that are utilized to measure atmospheric and surface properties.

Satellites and aircraft can be used as platforms for instruments to observe the atmosphere and surface of the Earth. These instrumented airborne and spaceborne platforms have revolutionized Earth observations and driven the development of improved remote sensing instruments. The increased use of satellite observations has in turn created a demand for research aircraft with in-situ and remote sensing instruments that can supplement and validate the satellite observations. In this chapter, we present an overview of most of the currently operational spaceborne and aircraft-based measurement platforms equipped with remote sensing instrumentation that are used to derive atmospheric dynamic and state properties, radiative, chemical, and other atmospheric parameters,

and characteristics of the Earth's surface. We restrict our summary to facilities that provide a global view of the Earth system, so we do not discuss:

- Low-flying or ultralight aircraft (i.e., with a single seat, a weight of less than 120 kg, and a top speed of less than 100 km h⁻¹) with ceiling altitudes of less than about 4 km
- Tethered or free balloons
- Unmanned (remotely controlled) aerial vehicles
- Helicopters.

This allows us to focus on remote sensing platforms on satellites and high/mid-altitude aircraft.

Table 37.1 General characteristics of meteorological satellites and research aircraft

	Meteorological satellites		Research aircraft	
	Geosynchronous (e.g., geostationary)	Low Earth orbit (e.g., Sun-synchronous)	Pressurized	Unpressurized
Application	Operational weather forecasts and (increasingly) research	Research and operational	Mostly research; partly for data assimilation into synoptic models	
Altitude (km)	35 800	300–1000	≥ 4	< 4

37.1 Principles of Platforms

Satellites are essential for obtaining a global picture of the Earth system. Spaceborne observations of the Earth are performed from two primary types of satellite orbits: geosynchronous and low Earth orbits.

Geosynchronous satellites orbit the Earth at an altitude of approximately 35 800 km. Each orbit takes one sidereal day (23 h, 56 min, and 4 s), so the satellite moves at a speed that matches the Earth's rotation. Geostationary satellites, a special type of geosynchronous satellite, orbit the Earth in its equatorial plane or at a low angle of inclination (relative to the equatorial plane) above a fixed location on the Earth, so they are ideal for observing diurnal cycles in a specific region. Most currently operational meteorological satellites are geostationary and observe the Earth at different longitudes. They are mostly used to forecast weather, but they are increasingly being utilized in research too.

Low-Earth-orbit satellites are found at altitudes of 300–1000 km. In a special type of low Earth orbit called a *Sun-synchronous orbit*, the satellite passes over a given point on the Earth's surface at the same local mean solar time each day. Satellites in Sun-synchronous orbits circle the Earth in 90–103 min at high angles of inclination of 96–99°, meaning that they pass close to the poles (i.e., a Sun-synchronous orbit is almost a po-

lar orbit around the Earth). A Sun-synchronous orbit is characterized by constant illumination of the Earth on the day side of the orbit, which ensures repeatable solar illumination during specific seasons. Because a Sun-synchronous orbit does not pass directly over the poles, it is difficult for a satellite in such an orbit to acquire data for the central polar regions if it has fixed nadir-viewing instruments. For most Sun-synchronous satellites that perform 14–16 orbits daily, full Earth coverage is achieved anywhere from twice a day to once every 16 days, depending on the scan width of the sensor.

Research aircraft can be categorized into pressurized platforms (with a ceiling altitude of more than 4 km) and unpressurized platforms (low-flying; a ceiling of less than 4 km). Certain complications are encountered when installing sensors within a pressurized aircraft cabin; for instance, the instruments will need to be sealed to avoid drawing in cabin air that will contaminate samples of the free atmosphere. Our discussion of research aircraft is restricted to pressurized high-altitude (above 9 km) platforms and partially-pressurized mid-altitude (between 4 and 9 km) platforms. Table 37.1 lists some of the main characteristics of satellites and aircraft that are used for meteorological observations and research.

37.2 History

A comprehensive overview of the history of Earth observations by satellites is given in [37.1], and the history of aircraft-based measurements is provided in several chapters of [37.2]. The first aerial photographs were probably taken by the French photographer Gaspard Félix Tournachon (1820–1910) at an altitude of about 80 m over Paris on 23 October 1858. Tethered balloon observations were also performed for military purposes during the US Civil War (1861–1865). Airplanes were used to take photos of the Earth's surface during both World Wars. The first cloud photographs were obtained

at altitudes of 110–165 km using rockets built by the US military and the Soviet Union in 1947. Color infrared photography was used for the first time after World War II. The Soviet Union launched the first satellite (Sputnik 1, designed by Sergei Pavlovich Korolev) on 4 October 1957. The US followed with its first satellite, Explorer 1, launched on 31 January 1958. The first weather satellite, Vanguard 2, followed in 1959, although it had limited success. The Television InfraRed Observation Satellite (TIROS-I), launched on 1 April 1960, was the first low-Earth orbit, Sun-synchronous

meteorological satellite. Today there are hundreds of Sun-synchronous satellites in orbit [37.3].

The first geostationary satellite, the Applications Technology Satellite (ATS), was launched on 7 December 1966; it operated for six years. This was followed by a series of six spacecraft launched by the National Aeronautics and Space Agency (NASA) in collaboration with the National Oceanic and Atmospheric Administration (NOAA). In 1974, the Synchronous Meteorological Satellite-1 (SMS-1) became the first operational satellite for measuring meteorological conditions to enter geostationary orbit. SMS-2 followed in 1975 to complement SMS-1. The first Geostationary Operational Environmental Satellite (GOES-1) was launched on 16 October 1975. The first satellites of the GOES series were spin-stabilized and viewed the Earth only 10% of the time; they were in operation from 1975 until 1994. From 1994 on, the GOES series of spacecraft employed three-axis stabilization. GOES-8, the first of those spacecraft, was launched on 13 April 1994. GOES-9 through GOES-12 were launched between 1994 and 2001. These three-axis stabilized satellites were capable of viewing the Earth 100% of the time, continuously acquiring images and atmospheric soundings. GOES-13, launched on 24 May 2006, was the first of the subsequent generation of GOES spacecraft with an advanced attitude control system that uses star trackers and a spacecraft optical bench and has improved instrument pointing performance. Currently, GOES-15 (also called GOES-P) operates as GOES-West and GOES-16 (GOES-R) as GOES-East, in reference to continental North America. The latest in the series, GOES-17 (GOES-S), was launched on 1 March 2018. GOES-T and GOES-U are scheduled for launch in 2020 and 2025, respectively.

Landsat is one of the longest-running programs for acquiring Earth imagery from space. On 23 July 1972, the first Earth Resources Technology Satellite (ERTS-1) was launched. Follow-up satellites in this series were eventually renamed to Landsat. The most recent satellite in this series, Landsat 8, was launched on 11 February 2013.

In Europe, the European Space Agency (ESA) and the European Organisation for the Exploitation of Meteorological Satellites (EUMETSAT) operate geostationary satellites. METEOSAT-1 was launched in November 1977, and METEOSAT-2 was launched in 1981. METEOSAT Second Generation (MSG) is currently operational, and the fourth of the MSG series was launched in 2015. Data continuity will be ensured until the first METEOSAT Third Generation (MTG)

satellites enter service, which is expected to happen in 2022 and 2023. Russia operates the Geostationary Operational Meteorological Satellite (GOMS) series at a longitude of 76° E, first launched in 1994. Three new geostationary spacecraft are planned for operation at longitudes of 14° W, 76° E, and 166° E. Japan utilized the Geostationary Meteorological Satellite (GMS) series at 140° E; the first GMS was launched in 1977, and GMS-5 reached orbit in 1995.

Recent satellite missions by the ESA as part of the EU's Copernicus project include the polar-orbiting Sentinel satellite family. Sentinel-1A was launched in April 2014; Sentinel-1B followed two years later, in April 2016. Both include a C-band synthetic aperture radar (SAR) with a wavelength of 6 cm. Sentinel-2A and B were launched in 2015 and 2017, respectively. They carry a multispectral imaging instrument for high-resolution atmospheric and surface observations, and are considered a continuation of the Landsat program. Sentinel-3A and B (2016, 2018) include different sensors for characterizing land, ocean, and ice surfaces. Sentinel-4 and 5 focus on atmospheric composition measurements. For example, Sentinel-5P (launched in 2017) uses the Tropospheric Monitoring Instrument (TROPOMI) to quantify the atmospheric composition, air pollution, and the ozone layer.

In 1912, *Richard Assmann* (1845–1918) performed the first atmospheric measurements using an aircraft [37.4]. He recorded the atmospheric pressure and temperature up to an altitude of 1100 m. Near-daily temperature soundings by aircraft commenced in the 1920s and continued through World War II. Eventually, these quasi-regular measurements were replaced by routine radiosonde measurements. However, early aircraft profile data were shown to improve synoptic weather forecasts. In 1936, the first aircraft observations of turbulence and thermodynamic properties were carried out in France. In 1944, a series of temperature and humidity soundings of the lowest 300 m of the atmosphere over the ocean were carried out using an aircraft. Further aircraft-based turbulence measurements were conducted in the 1950s. *Wigand* was one of the first to perform cloud measurements from an airborne platform in the early twentieth century [37.5]. Ice crystals were sampled by *Weickman* in 1945 [37.6]. In the 1970s, *Robert Knollenberg* pioneered the development of optical spectrometers to measure the size distributions of cloud and precipitation particles [37.5]. With the development of imaging cameras and spectrometers, as well as radar and lidar, aircraft-borne remote sensing measurements became widespread by the 1980s, and have continued since then.

37.3 Issues and Instrumental Requirements

Spaceborne and aircraft platforms operate in harsh environments, often with rapidly changing conditions, which has consequences for the instruments and the measurements performed on the platforms, and perhaps even the subsequent data analysis. For example, vertical wind or solar radiation measurements from aircraft or satellites require extremely accurate time and position data that are obtained with high frequency in real time for data analysis and interpretation. Therefore, the movement, position, and angular attitude of the quickly moving platform must be measured precisely and then made available immediately during the flight. When performing thermodynamic measurements from an aircraft, corrections must be made for the compressibility of air and dynamic heating. The instruments used must be capable of handling large and sudden pressure variations, as such variations are common (e.g., they occur during take-off and landing). Dramatic temperature changes are possible. Humidification and icing of sensors may occur, especially in the presence of supercooled liquid water clouds. High winds and strong turbulence may occur. Aircraft operation at mid and high altitudes requires fast true air speeds that typically range between 100 and 200 m s⁻¹. As a result, the instruments must have fast response times. The remote sensing devices installed on aircraft need to be robust and insensitive to the mechanical shocks that may occur during take-off and landing; they also need to withstand instant accelerations, heavy vibrations, and sudden altitude and attitude changes. The requirements for satellite sensors are even stricter because they must survive the launch. There are advantages to constructing remote sensing instruments with low weights, volumes,

and power consumptions. This is true for both satellite- and aircraft-mounted sensors. The high measurement sampling rates needed (for both satellite- and aircraft-based instruments) mean that huge amounts of data must be saved.

Aircraft can deliver both in-situ and remote sensing measurements, unlike satellites, which can only provide remote sensing data. The in-situ data are obtained along the track of the aircraft (spaghetti-like or otherwise), but the remote sensing capabilities of an aircraft measurement platform can equal or improve upon (e.g., through better resolution) satellite measurements. Aircraft are also often used for dropping sondes, which are an essential part of both research and operational meteorology.

Aircraft platforms enable data collection at otherwise unreachable altitudes. They also have flexibility in all three spatial dimensions when choosing the flight path. Targeted sampling and Lagrangian measurements can be pursued. Furthermore, detailed process studies can be performed (e.g., characterizing the vertical distribution of cloud particles). Satellite remote sensing measurements can be validated using aircraft platforms. Thus, new satellite sensors are often developed and tested for airborne use before they are launched into space. Satellite sensors are far more sophisticated than aircraft sensors: they need to operate unattended for many years, they must maintain calibration over that period, and they must include systems that can identify sensor degradation. They must also be built to comply with much stricter guidelines which ensure that the sensor will survive the launch load and the harsh radiation that is present in space.

37.4 Available Platforms for Active and Passive Remote Sensing

Remote sensing includes measurements of electromagnetic (EM) radiation, which is the only signal received by satellite sensors. Aircraft measurements may apply both remote sensing and in-situ sampling techniques. Remote sensing is classified as either *passive*, where the natural radiation emitted or scattered by the atmosphere and the Earth's surface is measured, or *active*, where EM waves are emitted by the instrument and the subsequent scattered signal is evaluated. Passive sensors receive either solar EM radiation that has been scattered by atmospheric gases, aerosol particles, hydrometeors, and the Earth's surface, or terrestrial infrared and microwave radiation emitted by atmospheric and surface components. Sensors that actively emit EM radiation and measure the signal that comes back to a receiver

are called active remote sensing instruments (e.g., radar, which is based on microwave radiation, or lidar, which uses solar radiation). Both passive and active sensors evaluate signals in order to retrieve parameters such as air temperature profiles, wind and humidity fields, and aerosol, cloud, and precipitation distributions. Furthermore, the components of the solar and terrestrial radiative energy budget of the climate system are estimated from measurements taken by active and passive sensors installed on satellite and aircraft platforms. All of these applications of remote sensing observations require a detailed knowledge of radiative processes in the atmosphere and the radiative interactions between different components of the climate system.

37.4.1 Satellite Platforms

Table 37.2 provides an overview of the atmospheric and selected surface observation capabilities of the main Earth observation satellites. For more detailed information, the reader is referred to the Observing Systems Capability Analysis and Review Tool (OSCAR), which can be accessed at <https://www.wmo-sat.info/oscar/satellites>, Accessed 12 July 2021. The table only considers satellite platforms that are operated by major international agencies: NASA (see https://eospsa.gsfc.nasa.gov/files/mission_profile.pdf, Accessed 12 July 2021, for the NASA Earth Science Mission Profile) and NOAA from the United States of America (USA) as well as the European Organization for the Exploitation of Meteorological Satellites (EUMETSAT), jointly with the European Space Agency (ESA), from Europe. Today, most of the largest endeavors require close international collaboration. Information included in Table 37.2 includes the satellite constellations, launch years, instrumentation, measured parameters, and some links to further information.

The family of Sun-synchronous A-Train (Afternoon Train or Afternoon Constellation) satellites from NASA fly at an altitude of 705 km along the same orbit. They employ active (lidar, radar) and passive (imag-

ing and polarization spectrometers, limb sounders) remote sensing instruments. Although both CloudSat and CALIPSO are still part of the A-Train, these satellites were both recently (2018) dropped to the same lower orbit, and are now referred to as the *C-Train*. NASA maintains a series of satellites known as the Earth Observing System (EOS), including Terra, Aqua, Aura, and many more. NOAA operates geostationary satellites (GOES) and Sun-synchronous spacecraft such as Jason (which observes hurricanes) and JPSS (partly in collaboration with NASA and other contributors). Europe has a fleet of geostationary (Meteosat) and Sun-synchronous (EPS-MetOp, Sentinel) satellites. Other countries such as Japan, China, and India are also increasingly contributing to the collection of meteorological satellites observing the Earth.

37.4.2 Aircraft Platforms

Table 37.3 lists the main operators of high/mid-altitude aircraft that provide remote sensing observations of atmospheric and, to some extent, surface parameters. The table only considers major agencies and contains information on aircraft types, selected technical parameters, and major instrumentation. It also includes useful links to more detailed information on aircraft facilities.

37.5 Future Development

In January 2018, the Committee on the Decadal Survey for Earth Science and Applications from Space (ESAS) of the US National Academy of Sciences issued the 2017 Decadal Survey [37.16]. This survey also included plans for space-based observations of the Earth by US agencies for the next 10 years.

In Europe, EarthCARE is currently planned for launch in 2022. Its goal is to investigate the role of clouds and aerosol particles in reflecting solar radiation and absorbing/emitting terrestrial thermal infrared radiation. EarthCARE has a prime mission duration of two years. Four major measurement systems are planned: the Atmospheric Lidar (ATLID), Cloud Profiling Radar (CPR), Multispectral Imager (MSI), and Broad Band Radiometer (BBR). The ATLID provides vertical profiles of aerosols and thin clouds. It operates at a wavelength of 355 nm and has a high spectral resolution receiver and a depolarization channel. The CPR is a 94 GHz Doppler radar, while the MSI consists of thermal infrared and visible/near-infrared cameras.

ADM-Aeolus was launched on 22 August 2018. It is the first satellite mission to acquire wind profiles for the Earth on a global scale. The only instrument on this satellite is the Atmospheric Laser Doppler Instrument ALADIN, a lidar that measures the wind in the lowermost 30 km of the atmosphere. ADM-Aeolus is one of the ESA's Earth Explorer missions, which are intended to address key scientific challenges identified by the science community. Besides ADM-Aeolus and EarthCARE, other prominent European missions include: Gravity Field and Steady-State Ocean Circulation Explorer (GOCE), BIOMASS (which carries the first space-based P-band synthetic aperture radar), Soil Moisture and Ocean Salinity (SMOS, launched in 2009), CryoSat-2 (launched in 2010; this measures fluctuations in the thickness of ice on both land and sea), SWARM (launched in 2013; this surveys the geomagnetic field and its temporal evolution), and the Fluorescence Explorer (FLEX) mission (which maps vegetation fluorescence to quantify photosynthetic activity).

Table 37.2 List of operators, constellations, and information on the main satellites currently operated by the US and Europe, including launch years, major instrumentation onboard, measured parameters, and some links to spaceborne applications that perform atmospheric remote sensing, all links Accessed 12 July 2021

Manfred Wendisch

Physics and Earth Sciences
University of Leipzig
Leipzig, Germany
m.wendisch@uni-leipzig.de

Manfred Wendisch is a Professor at the University of Leipzig (Germany) and Director of the Leipzig Institute for Meteorology. He is involved in airborne field observations, studying the influence of clouds on the atmospheric radiative energy budget with a focus on cirrus and Arctic mixed-phase clouds, as well as on subtropical trade wind cumuli.

André Ehrlich

Leipzig Institute for Meteorology (LIM)
University of Leipzig
Leipzig, Germany
a.ehrlich@uni-leipzig.de

André Ehrlich is a Senior Scientist at the Leipzig Institute for Meteorology at the University of Leipzig in Germany. He received a PhD in Meteorology in 2009 from the Johannes Gutenberg University of Mainz, Germany. His research utilizes airborne remote-sensing techniques to characterize Arctic clouds in order to investigate their impact on the enhanced warming of the Arctic climate, also known as Arctic amplification.

Peter Pilewskie

Laboratory for Atmospheric and Space
Physics and Department of Atmospheric
and Oceanic Sciences
University of Colorado Boulder
Boulder, USA
peter.pilewskie@lasp.colorado.edu

Peter Pilewskie is a Professor at the University of Colorado Boulder's Department of Atmospheric and Oceanic Sciences and Laboratory for Atmospheric and Space Physics (LASP). He is Principal Investigator for the Total and Spectral Solar Irradiance Sensor and Lead Scientist at LASP for CLARREO Pathfinder. His research interests include quantifying the Earth's radiative energy budget, surface, airborne, and satellite remote sensing of clouds and aerosols, and atmospheric radiative transfer.

Airborne Lidar

38. Airborne Lidar

Martin Wirth 

Part D | 38.1

The lidar techniques used for ground-based measurements may all, in principle, be implemented on an airborne or spaceborne platform. This chapter describes the techniques and instruments that have been successfully applied on such a platform or are expected to be in operation in the near future. The theory part of the chapter extends the sections in Chaps. 24–27 on ground-based lidar systems with topics that are only relevant for a moving platform.

38.1	Measurement Principles and Parameters	1067	38.3.3	Relation to Meteorological Reference Frames	1078
38.1.1	Measurement Principles	1068	38.3.4	Inclusion of the Doppler Effect	1080

			References		1091

The lidar techniques described in Chaps. 24–27 may all, in principle, be used not only from the ground but also on an airborne or spaceborne platform. This allows a much larger measurement volume, up to a global scale, to be covered by spaceborne instruments. Applied on an airborne platform, targeted observations become possible, and an air mass can be easily tracked for process studies. Also, these carriers allow a downward-looking geometry, which has advantages such as lower signal dynamics or the possibility to use multiple absorption lines for trace gas retrieval. Furthermore, the blind range near the instrument is moved away from the often very interesting atmospheric ground layer. On the other hand,

the fast-moving platform only allows for low integration times, which lead to a low signal-to-noise ratio, thus limiting the performance of some techniques with very low return signals, such as Raman or fluorescence lidars. Most air- and spaceborne platforms are also limited in terms of electrical power, volume, and weight, but at the same time have to be isolated against vibrations and temperature and pressure gradients in the airborne case and against cosmic radiation in the spaceborne case. For spaceborne lidar systems, the very high velocity of about 7 km s^{-1} for a low Earth orbit forces one to consider aberration and Doppler effects, which can normally be neglected for ground-based or most airborne systems.

38.1 Measurement Principles and Parameters

Most, but not all, lidar techniques have been implemented on fast-moving platforms. The following subsections briefly describe the relevant measurement

principles and the corresponding atmospheric parameters. This section focuses on the benefits and problems associated with an airborne or spaceborne platform.

38.1.1 Measurement Principles

In principle, every lidar measurement that can be done by a stationary system is also possible from a moving platform. Chapters 24 to 27 introduce the basics of lidars for different applications. A more elaborate exposition may be found in the book edited by *Weikamp* [38.1]. The following paragraphs briefly describe the most common lidar types for which aircraft-based operation has been reported.

Simple Backscatter Lidar

Here only the atmospheric backscatter from molecules and aerosol and cloud particles is detected, possibly at several wavelengths and with the option of depolarization measurements. Its advantage is its simplicity and the possibility of building small, robust systems. The main purpose of such systems is to map the geometric distribution of aerosol and cloud layers. If depolarization channels are present, such a system allows for a rough discrimination of the type of particles, e.g., sea-salt aerosol (low depolarization) or mineral dust (high depolarization), or whether an ice cloud or a liquid-phase cloud is being probed. However, in general, due to ambiguities in the backscatter function, more detailed aerosol characterization is not possible. This would require additional extinction channels, as provided by much more complex high spectral resolution lidars (HSRLs) and Raman lidars.

High Spectral Resolution Lidar (HSRL)

This technique requires a single-mode laser source and a very narrow band filter in the receiver to separate the light scattered by molecules from that scattered by aerosol and cloud particles. This is made possible by the fact that the molecular constituents of the air are of much lower mass than the particles and hence their thermal speed is much higher ($v \approx 1/\sqrt{m}$). This higher velocity then leads to higher Doppler broadening of the backscattered light. The total spectrum of the light from a single-mode laser scattered back in the atmosphere is the sum of a broad molecular part and a narrow peak in the middle originating from scattering by aerosol and cloud particles. These two parts are separated with an optical filter of high spectral resolution (hence the name of the method). The molecular part is proportional to the density of air multiplied by the total atmospheric transmission. If the air density is known, e.g., from temperature and pressure data, the signal of the molecular channel of a HSRL system provides a direct method to measure the atmospheric transmission profile. By taking the logarithm and performing numerical differentiation, the extinction profile can be derived without making assumptions about the scattering function—

something not possible with a simple backscatter lidar. The main advantage for airborne use is the relatively low signal integration time that can be achieved when compared to Raman lidars, which provide a similar capability.

Raman Lidar

Raman lidars use the rotational and/or vibrational Raman effect of molecules in the air to derive several parameters. The total Raman signal is proportional to the density of the air multiplied by the atmospheric transmission. Therefore, it is possible to derive particle extinction profiles in the same manner as with the HSRL method. The requirements for the optical filter to separate the Raman scattering from the elastic scattering are even lower than for the HSRL method. The Raman spectrum consists of several lines whose relative intensities depend strongly on temperature. This can be used to retrieve the temperature profile. Up to now, temperature Raman measurements have only been reported for ground-based systems, but airborne applications are expected in the near future. The Raman scattering of H_2O molecules can be used to retrieve humidity profiles. However, the high versatility of the Raman lidar technique is counteracted by low scattering cross-sections, which lead to a signal that is about three orders of magnitude lower than that for a lidar based on elastic backscatter. On an airborne platform, this limits the range and resolution of such systems, so very few applications are reported in the literature (Sect. 38.4).

DIAL/IPDA

The differential absorption lidar (DIAL) principle uses the elastic backscatter for several emission wavelengths to derive trace gas concentrations. This requires a minimum of two laser pulses with wavelengths that show strongly contrasting absorption by the atmospheric trace gas under consideration. Further requirements are that the difference between the wavelengths is small enough to assume the same atmospheric backscatter and that possible interfering trace gases show much lower absorption for these wavelengths (strictly speaking, it is only required that other trace gases show the same absorption cross-sections, which can often be established by clever selection of the wavelength with low absorption—the so-called off-line). Under these assumptions, the derivative of the logarithm of the ratio of the backscatter signals for these two wavelengths with respect to the range only depends on the number concentration of the probed molecule, not on any other component of the atmosphere. All instrumental factors such as the laser pulse energy and the detector sensitivity cancel out, so no calibration is needed.

This makes the DIAL technique ideal for airborne applications, where the rapidly changing environmental conditions could render stable calibration of the system difficult. The integrated path differential absorption (IPDA) method is a simplified version of the DIAL where only the ground or cloud reflex is taken and the upper point of the partial column is replaced with an energy measurement within the instrument. It delivers only column values of the probed trace gas, but the very high hard target return as compared to atmospheric backscatter allows for relatively small systems or very high precision, as needed for CO₂ or CH₄ measurements. Compared to the Raman technique, the DIAL/IPDA is also applicable to trace gases with very low concentrations as long as they have high enough absorption cross-sections, and the averaging time to reach the same precision is much lower because the large elastic backscatter signal is used.

If the concentration of the absorbing gas is known, the DIAL technique can be used to derive the temperature and pressure. For example, [38.2] describes a technique for measuring the pressure profile, surface pressure, and cloud-top pressure height that utilizes the pressure-dependent absorption of trough regions in the wings of two molecular resonant absorption lines of oxygen near 760 nm. The temperature measurements sense the line center absorption of highly temperature-sensitive lines of oxygen. However, because of system complexity and difficulties in handling gradients in particle backscattering, temperature and pressure measurement by DIAL has not found widespread use.

Fluorescence Lidar

This technique uses the fluorescence that emerges from constituents of the air when they are excited by an appropriate laser light pulse to derive their concentrations or quantities such as temperature. There are two totally different applications where this technique is used. One is middle atmosphere research, where atomic metal layers are probed, e.g., the sodium layer (80–105 km). For excitation at the sodium D line, for example, the fluorescence cross-section is 13 orders of magnitude larger than that for Rayleigh scattering, which more than compensates for the low number of sodium atoms present in this layer. The fluorescence in this case is spectrally very narrow, but the spectral width is determined by the temperature. By scanning the fluorescence line, the temperature within the sodium layer can be retrieved. Other metals such as iron (Fe), potassium (K), and calcium (Ca) also form metal layers in the middle atmosphere and may be used in the same way. The other application of a fluorescence lidar is the characterization of aerosols in the troposphere. Organic aerosols in particular show characteristic fluorescence spectra that

may be used to discriminate them. The spectral bandwidth of the fluorescence is broad in this case, which generally makes daylight measurements impossible.

Doppler Wind Lidar

Light scattering by moving particles leads to a shift in the wavelength of the incident light—the so-called Doppler effect (Sect. 38.3.4 for details). This can be used to infer the velocity of the scatterers. For scattering from molecules or small aerosol particles, this is equivalent to the wind velocity. For larger particles, their sedimentation speed is superimposed. To implement a Doppler lidar, a single-mode laser with a very small bandwidth is necessary, as is a receiver system capable of discriminating very small wavelength shifts. For example, for a wind lidar operating at a wavelength of 2 μm, the shift is 1 MHz for a target velocity of 1 m s⁻¹ (expressed here in frequency units; this is 0.0133 pm in wavelength units). To resolve such tiny wavelength alterations, either interferometers (the Fabry–Pérot, Fizeau, and Mach–Zehnder types are commonly used) or a heterodyne technique is implemented. The latter works by superimposing a very stable continuous-wave laser source with a very close wavelength onto the backscattered light and measuring the frequency of the resulting intermodulation signal, which is in the high frequency (HF) range. The accuracy of the heterodyne method is essentially determined by the laser stability, and can be brought down to the mm s⁻¹ range. The downside of the heterodyne method is that only scattering by aerosol or cloud particles that are heavy enough not to show a broadening effect due to thermal motion can be used. In principle, the molecular scattering can also be detected by a heterodyne receiver, but with much higher noise and some as-yet unsolved systematic problems [38.3].

38.1.2 Measured Parameters

Table 38.1 lists the directly measured parameters for the most common airborne lidar types. References are given for systems with a high number of publications in the literature. Special methods that have been demonstrated but have not been applied more broadly, such as temperature and pressure measurements by DIAL, are not included.

Using auxiliary data, further data products may be derived from the primary ones given in Table 38.2.

Compared to ground-based lidars, airborne and spaceborne systems provide several advantages. The most prominent of these are described in the following.

The location of the measurement is freely selectable and optimally adaptable to the measurement problem at hand. There is no need to wait until the atmospheric

Table 38.1 Parameters that are directly measured by airborne lidar

Parameter	Symbol	Unit	Lidar technique	References
Attenuated backscatter coefficient	B	$\text{m}^{-1} \text{sr}^{-1}$	Elastic backscatter lidar	[38.4–9]
Backscatter coefficient	β	$\text{m}^{-1} \text{sr}^{-1}$	HSR (high spectral resolution) lidar, Raman lidar	[38.10–14]
Extinction coefficient	α	m^{-1}	HSR lidar, Raman lidar	[38.10–14]
Linear depolarization	δ		Depolarization lidar	[38.10, 11, 14]
H ₂ O molecular density	$\rho_{\text{H}_2\text{O}}$	m^{-3}	DIAL, Raman lidar	[38.12, 13, 15–20]
O ₃ molecular density	ρ_{O_3}	m^{-3}	DIAL	[38.21–24]
CO ₂ column density	χ_{CO_2}	m^{-2}	IPDA	[38.25–28]
CH ₄ column density	χ_{CH_4}	m^{-2}	IPDA, Raman lidar	[38.17, 28–30]
Wind velocity	v	m s^{-1}	Doppler lidar	[38.31–36]

Table 38.2 Parameters derived from airborne lidar measurements using auxiliary data

Parameter	Symbol	Unit	Primary parameter	Auxiliary data
H ₂ O specific humidity	q	kg kg^{-1}	H ₂ O molecular density	Air density profile
Relative humidity	RH		H ₂ O molecular density	Temperature profile
O ₃ mixing ratio	χ_{O_3}	mol mol^{-1}	O ₃ molecular density	Air density profile

situation of interest occurs at a research station. With a long-range aircraft, it is possible to reach remote locations that are otherwise not accessible given reasonable cost constraints, such as deserts, the open ocean, or the polar regions. Further, it is easily possible to scan larger areas within a short time. Depending on the orbit, a spaceborne lidar may even provide global coverage, but due to the essentially predetermined track, the measurement region is not flexibly selectable with respect to time. For a recurring orbit, which is the baseline for most missions, there are also locations on Earth that never get probed.

The freely selectable measurement location allows for coordinated measurements with satellites or other airplanes. This can be used to perform instrument validation by comparing instruments side-by-side under different measurement conditions, or the synergy with in-situ measurements on a lower-flying aircraft can be used to complement remote sensing measurements. (See [38.37] for a campaign description involving multiple coordinated aircraft.) Flight tracks that connect different ground stations can be chosen, and the airborne instrument can then be used as an intercalibration tool.

With a fast-moving platform, it is possible to perform so-called quasi-Lagrangian measurements, where the flight path is aligned with the motion of the atmosphere. Although, due to vertical wind shear, this is not always possible over large vertical intervals, it nevertheless provides the opportunity to study the evolution of air parcels—something not possible from a single station on ground, where a volume is only probed once. Measurements from ground lidar stations are often hindered by low clouds. With a high-flying aircraft, it is

always possible to perform measurements above clouds or through holes between clouds, thus greatly enhancing the atmospheric situations in which the lidar can be used.

In a downward-looking probing geometry, an airborne lidar has some advantages concerning the signal dynamics. The probed atmosphere gets denser with increasing range, partly compensating for the geometric signal decay (r^2 dependence) and the atmospheric transmission, which both cause the signal to decrease with range. From the ground, both effects work in the same direction. When compared, the downward-looking geometry has signal dynamics that are 1–2 orders of magnitude lower than those for the upward-looking geometry for a range of 10–15 km. For special applications such as an H₂O-DIAL, the advantage is even bigger. Since water vapor decreases by about four orders of magnitude between the ground and the tropopause, absorption measurements of upper layers cannot use strong absorption lines when the lidar is on the ground, since the transmission would be too low. In contrast, for a lidar on a high-flying platform, the water vapor profile allows the use of strong lines for the upper parts of the atmosphere and weak lines for the layers near the ground without incurring transmission problems.

For middle atmospheric research, a high-flying platform has several advantages, such as less atmospheric extinction, less stray-light from the sun, and a shorter distance to the target.

Besides the advantages listed above, there are of course also limitations.

The fast-moving platform only allows for short signal integration times. While ground-based lidars often

accumulate signals over minutes to hours, this would lead to horizontal averaging of 10–1000 km for the typical speed of a jet-engine research aircraft. Usable integration times for most tropospheric applications range up to only 10–20 s. For highly variable situations such as clouds, the integration time should be below 1 s. This puts strong constraints on the power-aperture product of the lidar and limits, for example, the application of a Raman or fluorescence lidar on an airplane. For a spaceborne system with a velocity of about 7 km s^{-1} , this situation is even worse.

Most smaller airplanes have a limited endurance of only 2–3 h. Together with the time needed to reach the target region and fly back afterwards, this limits the us-

able observation time to not much more than 1 h. This is often too short to study atmospheric processes that depend, for example, on the diurnal cycle, or to cover synoptic-scale phenomena.

The limited resources on an aircraft (Sect. 38.3.1) exclude some applications, depending on the aircraft's size and available power. For example, very few Raman lidars are flown on an airplane.

Last but not least, the operation of a research aircraft is expensive. This typically limits its deployment to dedicated field experiments. A long-term, regular monitoring application has not been reported so far, with the possible exception of pipeline monitoring with IPDA from a helicopter [38.29].

38.2 History

This section will give a short account of the history of airborne and spaceborne lidars. Readers interested in further details are referred to [38.38] for airborne and spaceborne lidars. A more recent history of spaceborne lidar can be found in [38.39].

The first ground-based lidar systems emerged during the mid-1960s (shortly after the invention of the laser), and the first attempts to operate such instruments on an airplane were carried out shortly after, in the late 1960s and early 1970s. These early systems were simple backscatter lidars for the detection of clear air turbulence and lower tropospheric aerosol. During the late 1970s, the first airborne upward-pointing lidar [38.40] and the first autonomous system on a high-altitude airplane [38.41] expanded the range of applications. Shortly after these relatively simple instruments, the first O_3 -DIAL [38.42] and the first H_2O -DIAL [38.43] were flown on NASA airplanes. In 1985, there was the first flight of an airborne lidar to measure pressure [38.44] using the DIAL technique. Around the same time, Doppler wind lidar instruments were implemented on aircraft [38.31, 32, 45]. These systems were only sideways-pointing and could not retrieve the full wind vector. The first conical scanning Doppler wind lidar that was able to get full wind information was implemented more than 10 years later [38.34]. Also in the 1980s, the first resonance fluorescence lidar for mesosphere research was flown on an airplane [38.46].

In the 1990s, a few new technologies were reported to have gone airborne for the first time. Existing technologies were made more robust and efficient (mainly due to advances in laser technology), and they found more widespread use [38.18, 20, 34, 47].

The next technological step in aerosol and cloud profiling occurred after the year 2000, with the introduction of more complex airborne backscatter lidars that had several wavelengths, depolarization channels,

and HSRL channels for extinction profiling [38.10, 11, 14]. With these systems, it became possible to discriminate aerosols of different origins without needing to make too many assumptions. This allowed airborne aerosol lidars to keep up with the capabilities of the growing ground-based Raman lidar networks. Raman lidars themselves are still very uncommon on airplanes, mainly because of their limited range, horizontal resolution, and daytime capability.

During the last few decades, growing interest in greenhouse gas monitoring has led to the development of airborne IPDAs for CO_2 and CH_4 monitoring [38.25–28, 30].

Many of the developments in the field of airborne lidars were achieved by national space agencies, with the ultimate goal being to make the technology ready for space. While several studies were conducted to prove the feasibility and usefulness of spaceborne lidar applications in the 1970s and 1980s, it took until 1994 for the first lidar in space, the *Lidar In-Space Technology Experiment* (LITE), to be launched as a short-term (10 day) experiment on a NASA Space Shuttle [38.48]. LITE was a quite sophisticated instrument, with three emission wavelengths, a powerful laser, and a 1 m diameter telescope.

The next three systems, which were placed into orbit during the years 1995–1997, were BAL-KAN-1 [38.49] on the Russian space station MIR, ALISSA (l'atmosphère par lidar sur salioût), [38.50] on the Priroda module docked onto MIR, and BALKAN-2 [38.51] on the Russian ALMAZ-1B satellite. These were much simpler and smaller systems that were mainly used to detect cloud tops and, in some cases, the boundary layer height.

The first long-duration spaceborne lidar was the *Geoscience Laser Altimeter System* (GLAS) on ICE-Sat [38.52]. Although primarily designed as an al-

timer to monitor ice-sheet topography, it featured channels for atmospheric measurements as a secondary goal [38.53]. GLAS used diode-pumped Nd:YAG lasers that were designed to provide the necessary lifetime for a multiyear mission with continuous operation. Unfortunately, however, the first laser failed after 37 days of operation. To fulfill its primary mission objective, the data collection strategy was changed to dedicated campaigns of ice shield mapping, with minimized laser operation. This allowed a 7 year record of polar ice height development to be established before the last of the three lasers ceased operation.

The first mission to be mainly dedicated to aerosol and cloud monitoring was *Cloud–Aerosol Lidar and Infrared Pathfinder Satellite Observation* (CALIPSO), a joint NASA and CNES mission launched in 2006. The lidar instrument on CALIPSO is called the *Cloud–Aerosol Lidar with Orthogonal Polarization* (CALIOP) [38.54]. Based on the experience gained from early laser failures on the GLAS mission, several countermeasures were taken for CALIOP. As a result, this system is still in operation after 12 years of continuous measurement in space. CALIOP is a simple backscatter lidar with 1064 and 532 nm channels. The 532 nm branch incorporates a depolarization channel for enhanced aerosol and cloud type discrimination.

38.3 Theory

This theory section only discusses points relevant to lidar applications where the instrument is mounted on a (fast) moving platform. In terms of physical measurement principles, there is no difference between a lidar operated on the ground and one operated on an airplane or satellite, so the general theory described in Chaps. 24–27 also applies to airborne/spaceborne applications. However, there are several constraints that impose strong limits on the possible realizations of such a system, the most important of which are described in Sect. 38.3.1.

Also, from a purely theoretical standpoint, there are two points that need special attention when the instrument is not stationary.

The first is the accurate determination of the geolocation of the measurement. The fast-moving platform, together with a variation in the pointing of the lidar (which may be caused by a rolling and pitching platform or induced deliberately by a scanning device), makes this much more involved than for a ground-based application. A short introduction containing some basic equations will be given here. For typical applications,

While the spaceborne lidars described up to now only had simple backscatter channels, it is planned that future systems will also incorporate extinction channels, like the more modern ground-based and airborne systems. In 2015, the *Cloud–Aerosol Transport System* (CATS) was installed on the International Space Station (ISS) as a technology demonstrator for such upcoming instruments [38.55]. CATS is a three-wavelength (1064, 532, and 355 nm) system with depolarization and extinction channels. Besides the large number of detection channels, it is also the first spaceborne lidar to use high repetition rate Nd:YVO₄ lasers (4–5 kHz). Since it was designed as a technology demonstrator with limited budget, not all operation modes are available at the same time. In October 2017, the mission ended after about two and a half years.

The latest step in spaceborne lidar happened in August 2018, when ESA (European Space Agency) launched the *Aeolus* mission. *Aeolus* is a single-instrument mission with the *Aladin* wind lidar onboard. *Aladin* implements a direct-detection Doppler wind lidar with one line of sight. Additionally, there will be aerosol and cloud products, but with a limited vertical resolution compared to dedicated aerosol-cloud missions such as CALIPSO.

More technical details regarding the spaceborne lidars mentioned here are given in Sect. 38.4.

It is not only necessary to know the exact geolocation of the measurement but also to relate it to model data in order to extract auxiliary data and for intercomparison and validation purposes. In general, this problem is not specific to a flying platform, but it is much more pressing than for a ground station, where a wealth of meteorological data is typically available from nearby measurements, whereas airborne or spaceborne data are often acquired over remote places.

The second point, which is much more pronounced for a moving platform, is the wavelength shift of the emitted laser light caused by the Doppler effect. From the ground, this effect can almost always be neglected or (in the case of a wind lidar) used for the retrieval, but no corrections for the movement of the platform are needed. The following subsection presents a form of the lidar equation where wavelength shifts are taken into account, and discusses the implications for trace gas measurements with a DIAL or IPDA, for a HSRL (with its narrow-band detection unit), and for wind lidars, based on the Doppler effect.

38.3.1 Technical Constraints for Airborne Lidar Instruments

The main differences when operating a lidar on a moving platform such as an airplane as compared to ground-based operation come from the various limitations, restrictions, and environmental conditions such a platform imposes. These may be the rapidly changing temperature and pressure, accelerations and vibrations, the limited space, electrical power or cooling, or the requirements from certification. These aspects all depend strongly on the type of aircraft, ranging from a helicopter to small propeller-driven machines, small business jets, and large airplanes such as NASA's DC-8. A further category is high-flying airplanes with only one or no pilot, such as the ER-2, M-55 Geophysics, or Global Hawk, for which the system has to run autonomously in a near-vacuum environment. In the following, the major constraints will be discussed, with a focus on small commercial passenger airplanes, as they are the aircraft most commonly used in atmospheric research. Because even this subclass of aircraft is highly diverse, only rough estimates for numbers or examples for a specific airplane will be given. This section should be regarded more as a checklist of things not to forget rather than a definite specification.

For spaceborne systems, other sets of restrictions apply due to their operation in vacuum, the extremely high vibrational load during launch, and cosmic radiation. Readers are referred to special literature on this topic, e.g., [38.39].

The Moving Platform

The roll angle reaches values of up to 30° during normal flight operation (Fig. 38.1a), which changes the range to altitude relation and hence the apparent optical thickness per range gate. This has to be corrected, when possible, or cut out during data processing. When longer signal averaging is required to achieve a good signal-to-noise ratio, the correction of curve flights shorter than the averaging interval can be very difficult or impossible. Therefore, it is advisable to optimize the flight planning for long straight legs. In addition to curve flights, the roll angle oscillates fast with an amplitude of about 1° , even during straight legs and quiet conditions. Besides, for Doppler and high-precision ranging lidars, this is a minor problem (the path length elongation is less than 2 m from an altitude of 10 km). For upward-pointing lidars, there is the possibility that the telescope is pointed towards the sun during turns, even when operated out of the tropics. Since this could damage the detector units, a protection device may be needed—one that blocks the light path in the receiver before it reaches any possibly sensitive component, and is triggered by a sun sensor.

The pitch angle is positive and around $2\text{--}4^\circ$ during level-flight conditions, but changes with speed and fuel loading. This means that the lidar is always looking forward (by ≈ 0.5 km from 10 km) as compared to its nominal pointing with respect to the aircraft fuselage. This has to be taken into account if correlated measurements with nadir-looking instruments are made, e.g., with radiometers.

Roll rates reach peak values of up to 6 deg s^{-1} and pitch rates reach up to 1 deg s^{-1} (Fig. 38.1b). This means that wind and ranging applications need high-rate attitude data for correction. There is also a possible problem for long-range/narrow field-of-view lidars, i.e., upper atmosphere applications. A change rate of 6 deg s^{-1} corresponds to an angle change of $62 \mu\text{rad}$ during the round trip time for a target at 60 km distance. If the receiver field of view is smaller than this $62 \mu\text{rad}$, there is the possibility that no signal from this range is detected at all.

The roll, pitch, and heading data from the inertial reference system of an aircraft has an accuracy of about 0.1° . For some systems, values that are more than ten times better can be reached by postprocessing the raw data. However, it should be noted that there is typically an offset between the zero position of the inertial reference system and the *zero* position of the lidar system, which is referenced to the aircraft floor. This offset has to be calibrated on the ground or determined in-flight though comparison with topographic targets [38.56].

The pressure altitude, which is usually given by the aircraft's data system, can differ from the geometric altitude above sea level by up to 1 km (Fig. 38.2). The alternative is to use data from a GNSS system such as global positioning system (GPS). The precision here is normally about 10 m peak-to-peak if enough satellites close to the local zenith are in view. Higher precisions are possible if additional correction data are used. The geometric altitude from GPS is sometimes referred to the reference ellipsoid of WGS84 and sometimes to the geoid. Care has to be taken to interpret the altitude data correctly. High-accuracy comparisons ($\Delta h < 10 \text{ m}$) with NWP-model data or other data given with pressure as the vertical coordinate should use the geopotential as an intermediate quantity. See Sect. 38.3.3 for a more detailed discussion of this point.

Since the target is rapidly changing at high platform speeds of 200 m s^{-1} or more, the clocks of different instruments on the same platform have to be synchronized if collocated synergistic retrievals are planned.

Non-laboratory Environment

An airplane is an environment with unstable pressure and temperature. Lidar components have to be specially de-

Fig. 38.1a,b Time series of the roll and pitch angles (a) and the rates of change in those angles (b) during a research flight of DLR's Falcon F-20 aircraft

Fig. 38.2 The pressure altitude from the aircraft's air data computer and the geodetic height from a GNSS receiver during a flight of the German research aircraft HALO from southern Germany to Kiruna in Sweden. Differences of up to 1 km are apparent

signed to cope with large spatial temperature gradients and relatively fast changes. For example, on DLR's research aircraft HALO, the air temperature in the middle of the cabin varies between 24 and 28 °C during a normal research flight, making it relatively stable when compared to the cabin air temperature on other airplanes. However, at the same time, the air temperature near the optical lidar window changes from 20 to -10 °C at rates

of about 1 °C min⁻¹. The coldest point in the aircraft is the ring mount of the optical window, which approaches -22 °C with an outer static air temperature of -65 °C. Because the window is the coldest spot in the cabin, there is a risk that water vapor will condense there on the inside. It is often necessary to purge with dry air to avoid this. Condensation from the outside is possible in strongly supersaturated regions, but because of the

large difference between the window temperature and the static air temperature due to the compression of the air caused by the motion of aircraft, this condensation not observed in practice for flights at a constant level. An exception is the special case of a fast descent of a still cold aircraft into warm and moist air.

The cabin pressure normally drops by more than 200 hPa during ascent, even in airplanes with a pressurized cabin. This can provide problems for pressure-tight but unstable housings of optical elements. Further, the associated refractive index change requires fast adaptive laser control for some applications and continuous recalibration of spectrometers and wavemeters, even if they are based on solid-state etalons. Special attention must also be given to the high-voltage circuits used in lasers to drive the Pockels cell or the flashlamps or used in the receiver as bias voltages for photomultipliers. Under reduced-pressure conditions, these devices can produce arcing if they are not specially designed. This is of course much more severe if the lidar is installed in an unpressurized section of the airplane.

Peak accelerations from bumps at the start of the flight can reach several times of the Earth's gravitational acceleration. On a jet aircraft, in-flight vibrations show a broad spectrum up to 2 kHz, with stronger excitation in the vertical direction at low frequencies. On propeller airplanes, the spectrum peaks more at the rotational frequency of the propeller and its harmonics. While such a vibrational environment does not provide problems for a simple backscatter lidar, more sophisticated setups that require single-mode operation of the laser or use very narrow band etalon-based filters in the receiver have to be specially isolated against vibrations or actively stabilized by a fast control loop.

Compared to a laboratory or container environment, many resources are quite limited on most research aircraft. Examples include space and weight. Lidar systems, especially the more powerful ones, are large and heavy. Even when they fit into a small research airplane, they often have to be assembled from smaller parts within the cabin and potentially readjusted afterwards. On most airplanes designed for commercial passenger transportation, the allowable floor load is rather limited. This means that the use of heavy optical tables is not possible and the mechanical structure of the lidar system has to be specially designed to have the required low weight as well as the stiffness necessary for stable optical alignment. Also, the balance constraints of the aircraft have to be met, so heavy items have to be kept close to the center of gravity—typically not a place where large openings for optical windows are located. Another resource that is limited is the electrical power, which often only reaches a few kW on a small aircraft. If commercial components are used to build the lidar

system, adaptation to the power nets used in aviation is necessary. Small airplanes use a 28 V DC based power unit and larger ones a 115 V/400 Hz AC version. However, an often more severe constraint than the available electrical power is the ability to get rid of the heat produced by a high-power lidar. The air conditioners of commercial passenger airplanes are not designed to remove all of the available power if it is dissipated into the cabin. A possible solution is to cool the laser directly against the outside using a heat exchanger mounted in an opening of the aircraft, e.g., a window.

An airplane is not a clean environment. The air conditioner typically does not have fine filtering, and the dust load in the cabin can be much larger than in, e.g., a container. This means that high-power laser optics have to be dust screened as much as possible in order to avoid damage to the optical coatings. If it is impossible to dust screen the light path, a workable solution is to expand the laser beam to a larger diameter in order to reduce the energy density and thus the risk of dust-induced damage to the optics.

38.3.2 Reference Frames

Obtaining the accurate geodetic coordinates of the scattering target for each laser pulse in an Earth-centered reference frame is crucial to successfully interfacing the measured quantity with other real-world or model data. As the airborne or spaceborne platform is moving relatively fast, and the probing direction may change, determining the location of the probed volume is not completely trivial. This is especially true for a satellite in orbit, where even small angles of a few degrees with respect to the nadir lead to a large horizontal offset—large enough that the *flat Earth approximation* does not hold any more and one has to deal with the ellipsoidal shape of the Earth in a more accurate way.

In this section, an outline of the fundamental reference frames and transformations involved is given. A more in-depth exposition can be found in, e.g., [38.57]. The reader should note that different conventions regarding reference-frame axis orientation are in use for different applications. For example, in aeronautics, the z axis is usually pointing downwards in the direction of the Earth's surface; in land vehicle applications, it is pointing upwards. This has to be taken into account when using transformations or relations from different sources. In this section, the conventions from aeronautics are used.

When determining an exact geolocation, four reference frames are involved:

BRF: the Body Reference Frame linked to the platform. Usually, for an airplane, the X_{BRF} axis is

Fig. 38.3 Illustration of the relative positions of the instantaneous ITRF, LO, and BRF reference frames as seen from an inertial reference frame, and of the angles and distances that are relevant for the derivation of the geodetic coordinates of the target in the ITRF reference frame. The flattening of the Earth’s reference ellipsoid and the platform altitude are greatly exaggerated for clarity. See the main text for definitions and more details

aligned with the long axis of the aircraft body, the Y_{BRF} axis is pointing to the right wing, and the Z_{BRF} axis is pointing downwards, such that a right-handed orthonormal reference frame is formed (refer to the red axes in Fig. 38.3).

LO: the LOcal reference frame, with its origin at the platforms’s center of mass P, Z_{LO} directed downwards perpendicular to the reference ellipsoid, Y_{LO} pointing east, and X_{LO} pointing (true) north (refer to the blue axes in Fig. 38.3).

ITRF: the International Terrestrial Reference Frame, which is rigidly linked to the Earth’s reference ellipsoid and thus corotates with the latter during its diurnal motion in space. It has its origin at the Earth’s center of mass, as defined by the International Earth Rotation Service (IERS) [38.58], and is virtually identical to the WGS84 reference frame down to a precision of 10 cm (refer to the black axes in Fig. 38.3).

GCRF: the Geocentric Celestial Reference Frame, which is the inertial reference frame with a fixed orientation with respect to extragalactic radio sources (mostly quasars). The GCRF is also defined by the IERS [38.58]. It has to be used as an intermediate reference frame when applying a physical law that is only valid in an inertial frame, i.e., in the absence of pseudo

forces such as the Coriolis force. (This reference frame is not shown in Fig. 38.3.)

Typically, the position of the platform is given with respect to the ITRF, e.g., based on data from a GNSS such as GPS, whereas the orientation of the platform is given with respect to the LO frame from an inertial reference system based on laser gyros or a star tracker for satellites. To calculate the georeferenced position of a target volume from these data, one has to calculate the position of the platform $(X_P, Y_P, Z_P)_{ITRF}$ and the pointing vector $(X_L, Y_L, Z_L)_{ITRF}$ of the lidar beam in Cartesian ITRF coordinates. If the effect of the atmosphere’s refractive index is neglected, the lidar range from the platform P to the target T, r_T , is the Euclidean distance between P and T, and therefore the target position is given by

$$\begin{pmatrix} X_T \\ Y_T \\ Z_T \end{pmatrix}_{ITRF} = \begin{pmatrix} X_P \\ Y_P \\ Z_P \end{pmatrix}_{ITRF} + \frac{r_T}{\sqrt{X_L^2 + Y_L^2 + Z_L^2}} \cdot \begin{pmatrix} X_L \\ Y_L \\ Z_L \end{pmatrix}_{ITRF} \quad (38.1)$$

See Fig. 38.4 for an illustration of the geometrical setup. Now, if $(X_L, Y_L, Z_L)_{BRF}$ is the direction vector (assumed to be known) of the laser beam with respect

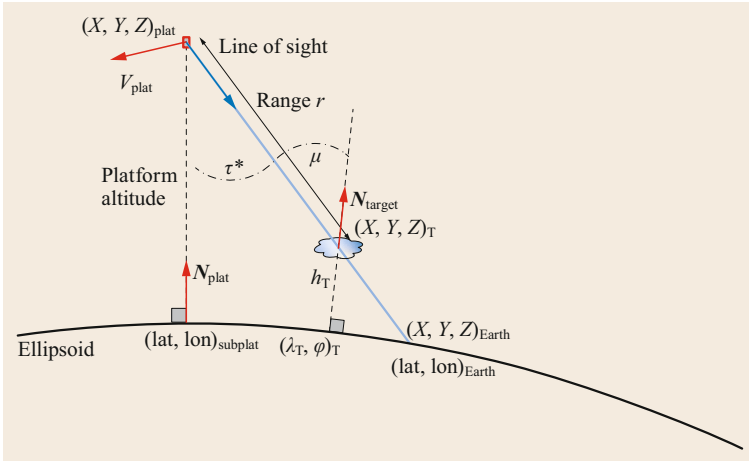

Fig. 38.4 Illustration of the platform position, velocity, and instrument line of sight. The geolocation of the target is computed using the range from the platform to $(X, Y, Z)_T$ as determined by the lidar. Normal vectors to the ellipsoid at the target and platform locations are also shown ($N_{\text{plat}}, N_{\text{target}}$)

to the instrument-fixed BRF system, and the orientation of the platform with respect to LO is given by the roll, pitch, and heading angles θ_{ro} , θ_{pi} , and θ_{he} , respectively, the laser pointing vector with respect to the LO system is given by

$$\begin{pmatrix} X_L \\ Y_L \\ Z_L \end{pmatrix}_{LO} = \begin{pmatrix} c_{pi}c_{he} & s_{ro}s_{pi}c_{he} - c_{ro}s_{he} & c_{ro}s_{pi}c_{he} + s_{ro}s_{he} \\ c_{pi}s_{he} & s_{ro}s_{pi}s_{he} + c_{ro}c_{he} & c_{ro}s_{pi}s_{he} - s_{ro}c_{he} \\ -s_{pi} & s_{ro}c_{pi} & c_{ro}c_{pi} \end{pmatrix} \cdot \begin{pmatrix} X_L \\ Y_L \\ Z_L \end{pmatrix}_{BRF}, \quad (38.2)$$

with the abbreviations

$$\begin{aligned} c_{ro} &\equiv \cos(\theta_{ro}) & s_{ro} &\equiv \sin(\theta_{ro}) \\ c_{pi} &\equiv \cos(\theta_{pi}) & s_{pi} &\equiv \sin(\theta_{pi}) \\ c_{he} &\equiv \cos(\theta_{he}) & s_{he} &\equiv \sin(\theta_{he}). \end{aligned}$$

Finally, to transform the direction vector from the LO system to the ITRF, the matrix

$$\begin{pmatrix} X_L \\ Y_L \\ Z_L \end{pmatrix}_{ITRF} = \begin{pmatrix} -\sin(\phi)\cos(\lambda) & -\sin(\lambda) & -\cos(\phi)\cos(\lambda) \\ -\sin(\phi)\sin(\lambda) & \cos(\lambda) & -\cos(\phi)\sin(\lambda) \\ \cos(\phi) & 0 & -\sin(\phi) \end{pmatrix} \cdot \begin{pmatrix} X_L \\ Y_L \\ Z_L \end{pmatrix}_{LO} \quad (38.3)$$

has to be applied, where λ is the geographical longitude and ϕ the geographical latitude of the point where the local LO frame is referenced to. Conventionally, the coordinates with respect to the ITRF are given as

the longitude, latitude, and altitude above the reference ellipsoid. The transformation from (elliptical) geodetic coordinates (λ, ϕ, h) to Cartesian coordinates is given by

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix}_{ITRF} = \begin{pmatrix} (R_N + h)\cos(\phi)\cos(\lambda) \\ (R_N + h)\cos(\phi)\sin(\lambda) \\ ((1 - e^2)R_N + h)\sin(\phi) \end{pmatrix}, \quad (38.4)$$

where $R_N = a/\sqrt{1 - e^2\sin^2(\phi)}$ is the radius of curvature of the prime vertical, $a = 6378137.0$ m is the semi-major Earth axis, and $e^2 = f(2 - f)$ (with $1/f = 298.257223563$) is the flattening of the Earth. The numerical values given here are taken from the definition of WGS84. There is no known simple closed form of the inverse relation that transforms the Cartesian coordinates to geodetic form, but there are numerous iterative solutions; see, for example, [38.59, 60].

In summary, the procedure for target geolocation is as follows. The coordinates of the platform are transferred into Cartesian form using (38.4). The attitude information from the platform (heading, roll, and pitch angles) is used to transform the lidar pointing vector from the BRF (where it is assumed to be known) to the LO via (38.2), and then to the ITRF by applying (38.3), where the geodetic coordinates of the platform also enter. Finally, (38.1) is used to derive the location of the target at range r_T in Cartesian ITRF coordinates. For further use, they have to be transformed back to geodetic form by a suitable inverse of (38.4).

For a low-flying aircraft, or if it is not necessary to know the geolocation to high precision, this procedure can be simplified by using the *flat Earth approximation*. If the lidar is pointing in the direction of the z axis of the BRF, the geolocation of the target can be determined

Fig. 38.5 Illustration of the model levels and their relationships to the ellipsoid, the geoid, the Earth’s topography, and the lidar geometry, where indices (i, j) refer to the horizontal grid coordinates and index k refers to the vertical coordinate. See the main text for more details

using the much simpler equations

$$\begin{aligned} \lambda_T &= \lambda_P + \frac{180^\circ r_T}{\pi R_E \cos(\phi_P)} (c_{ro} s_{pi} s_{he} - s_{ro} c_{he}) \\ \phi_T &= \phi_P + \frac{180^\circ r_T}{\pi R_E} (c_{ro} s_{pi} c_{he} + s_{ro} s_{he}) \\ h_T &= h_P - r_T c_{pi} c_{ro} \end{aligned} \quad (38.5)$$

where the same abbreviations for the sines and cosines of the attitude angles are used as in (38.2), and $R_E = 6371000.785\text{ m}$ is the mean radius of the Earth. For an upward-looking lidar, the sign before r_T in the third equation of (38.5) has to be reversed.

38.3.3 Relation to Meteorological Reference Frames

To make use of the data set acquired by an airborne or spaceborne lidar system, it is often necessary to relate the data to numerical weather models (NWM) or climate models. This may be the case when the data have to be assimilated into a model or used for validation purposes, or when the calculation of higher-level products from the lidar requires auxiliary data, e.g., the air density. The previous subsection described how to properly reference lidar data with respect to coordinates in the ITRF. Unfortunately, coordinate systems in NWM are typically not referenced to geodetic coordinates but rather to a coordinate space that is native to the equations describing the physical processes, thereby radically simplifying the formalism and increasing computational efficiency. Most significantly, the vertical discretization at each horizontal grid point is tied to predefined relationships between the pres-

ures at each atmospheric level. As long as the model remains self-consistent, the relationship between the *real-world* coordinates of an air parcel and the coordinates of this air parcel in the model is not of great interest to the NWM community. Furthermore, conventional (i.e., in-situ) observations that are assimilated by the models are already referenced to a model coordinate (e.g., surface weather station measurements or radiosonde profiles, both of which are referenced to the readings from a local pressure sensor), while nonconventional (i.e., remote-sensing-based) observations from passive instruments do not require a fine understanding of the *geometry of the atmosphere* (e.g., assimilation of top-of-the-atmosphere radiances). The assimilation of some relatively new types of altitude-resolved remotely sensed observations does, however, require a better understanding of the geometric relationship between model atmosphere and instrument. Besides lidar instruments, this is notably the case with GNSS meteorological data when making use of the radio occultation principle in a limb-sounding-like configuration. The following considerations show how to proceed, using the Integrated Forecasting System (IFS) of the European Centre for Medium-Range Weather Forecasts (ECMWF) as an example.

Figure 38.5 illustrates the geometry of the model’s idealized atmosphere. In order to account for the effects of the topography, the ECMWF’s model makes use of so-called *hybrid coordinates*, as outlined in [38.61]. The lower levels follow a simplified orographic model of the Earth, while the upper levels are defined by a constant pressure. They are defined dynamically at each horizontal grid point (λ_i, ϕ_j) by fixed relationships between the atmospheric pressures $p_{i,j,k\pm 1/2}$ at

their interfaces (so-called *half-levels*; light blue dots in Fig. 38.5) and the surface pressure $p_{Si,j}$ at the model orography, a model output. The pressure $p_{i,j,k}$ in the middle of the layers (so-called *full levels*; blue dots in Fig. 38.5) is then defined as the arithmetic mean value of $p_{i,j,k+1/2}$ and $p_{i,j,k-1/2}$. In addition to the pressure levels, the model parameters at any grid point that are typically needed for lidar data processing are the temperature and humidity profiles $T_{i,j,k}$ and $q_{i,j,k}$. Even if the humidity itself is not of direct interest, it is required to calculate the virtual potential temperature, which enters the equations for the geopotential given below. For some applications, the dry air mixing ratio is also needed, and hence the water vapor content has to be subtracted appropriately. For DIAL/IPDA applications, water vapor is often an interfering trace gas, and knowledge of its concentration is required to correct the optical thickness values in the retrieval of the species of main interest.

The problem at hand is twofold:

1. to horizontally and temporally interpolate the model profiles to the target location, and
2. to change the vertical variable from lidar range r to the natural vertical coordinate of the model and then interpolate the model variables to this vertical location, which generally lies in between model levels.

For objective (1.), the fact that NWMs widely make use of a spherical model of the Earth suggests an interpretation of the horizontal grid coordinates, from a strictly geometric viewpoint, as the *geocentric* longitude and *geocentric* latitude. However, as the orography of the model is taken from WGS84-referenced data sets [38.62], it is more consistent to interpret the model's latitude as the geodetic latitude ϕ , not the geocentric latitude, when a comparison to the real-world data is made. The question of how to interpolate the NWM profiles to the location of the target (i.e., how to obtain the parameters p_k , T_k , Φ_k , and q_k in Fig. 38.5) then remains. The simplest approach is to carry out a bilinear interpolation of all relevant model parameters using the target's four neighboring grid points at coordinates $(i+1, j+1)$, $(i+1, j-1)$, $(i-1, j+1)$, and $(i-1, j-1)$. This is done for two model outputs that bracket the time of the measurement, and then a linear interpolation in time is used to arrive at a model layer based data set at the time and location of the measurement.

For the second problem, the geopotential is used as an intermediate quantity to reference the model's vertical scale to the geometric altitude of the lidar target. For the reasons discussed above, the normal height h does not actually appear in the fundamental NWM equations as an internal variable nor as a model output.

From a NWM point of view, it is simpler to deal with the effect of the gravitational force through the associated potential energy, the geopotential Φ , defined as the potential energy of a unit mass of air in the Earth's gravity field relative to a reference surface. When combined with the ideal gas law for dry air, the geopotential-based hydrostatic equation takes the form

$$\frac{d\Phi}{dp} = -\frac{R_{\text{dry}}T_v(p)}{p}, \quad (38.6)$$

where R_{dry} is the gas constant for dry air and

$$T_v(p) \equiv T(p) \left(1 + \left(\frac{R_{\text{H}_2\text{O}}}{R_{\text{dry}}} - 1 \right) q(p) \right) \quad (38.7)$$

is the so-called virtual temperature, with $T(p)$ the temperature at pressure level p , $R_{\text{H}_2\text{O}}$ the gas constant for water vapor, and $q(p)$ the specific humidity at level p . The specific humidity is related to the dry air volume mixing ratio of water vapor $x_{\text{H}_2\text{O}}(p)$ through

$$x_{\text{H}_2\text{O}}(p) = \frac{m_{\text{dry-air}}q(p)}{m_{\text{H}_2\text{O}}(1-q(p))}. \quad (38.8)$$

Equation (38.6) is used in [38.61] in the discretized and integrated form

$$\Phi_{i,j,k+\frac{1}{2}} = \Phi_{Si,j} + \sum_{l=k+1}^{N_{\text{LEV}}} R_{\text{dry}}T_{v,i,j,l} \ln \left(\frac{p_{i,j,l+\frac{1}{2}}}{p_{i,j,l-\frac{1}{2}}} \right), \quad (38.9)$$

where N_{LEV} is the number of model levels and $\Phi_{Si,j}$ is the geopotential of the model surface layer (which remains constant over time), to calculate the half-level geopotentials. The geopotential at a full level is then given by

$$\begin{aligned} \Phi_{i,j,k} &= \Phi_{i,j,k+\frac{1}{2}} + R_{\text{dry}}T_{v,i,j,k} \\ &\times \left(1 - \frac{p_{i,j,k-\frac{1}{2}}}{p_{i,j,k+\frac{1}{2}} - p_{i,j,k-\frac{1}{2}}} \ln \left(\frac{p_{i,j,k+\frac{1}{2}}}{p_{i,j,k-\frac{1}{2}}} \right) \right). \end{aligned} \quad (38.10)$$

What remains is the calculation of the geopotential for each target altitude h . Φ is a function of the orthometric height H , i.e., the height above the geoid. Because of the ellipsoidal nature of the Earth, this relation is latitude dependent, and an established and accurate approximation is

$$\begin{aligned} \Phi(\phi, H_T) &= g(\phi)H_T \\ &\times \left(1 - \frac{H_T}{a} (1+f+m-2f \sin^2(\phi)) + \frac{H_T^2}{a^2} \right), \end{aligned} \quad (38.11)$$

where $m = \omega_0^2 a^2 b / (GM)$, a and b are the semi-major and semi-minor axes of the reference ellipsoid, $f = (a - b)/a$ is the ellipsoid flattening, G is Newton's gravitational constant, M is the mass of the Earth, and ω_0 is the Earth's angular velocity. Further, $g(\phi)$ is the magnitude of the normal gravity at the surface of the geoid as a function of geodetic latitude, as given by Somigliana's formula

$$g(\phi) = g_e \frac{1 + k \sin^2(\phi)}{\sqrt{1 - e^2 \sin^2(\phi)}}, \quad k = \frac{b g_p}{a g_e} - 1, \quad (38.12)$$

where g_e and g_p are the theoretical normal gravity values at the equator and the poles, respectively, and $e^2 = f(2 - f)$ is the reference ellipsoid's eccentricity. The orthometric height H is related to the geodetic height by

$$H = h - N(\lambda, \phi), \quad (38.13)$$

where $N(\lambda, \phi)$ is the so-called *geoid undulation*, i.e., the normal height of the geoid above the reference ellipsoid. A commonly used standard for $N(\lambda, \phi)$ is EGM96 [38.63], but there are various refinements from recent high-resolution gravimetric measurements.

The geopotential value of the target given by (38.11) is then transferred to the model world and, via a straightforward search, the level index k_T that satisfies

$$\Phi_{k_T + \frac{1}{2}} \leq \Phi(H_T) \leq \Phi_{k_T - \frac{1}{2}} \quad (38.14)$$

is determined. Finally, once more, a discretized form of (38.6) is used to calculate the target pressure p_T

$$p_T = p_{k_T - \frac{1}{2}} \exp\left(\frac{\Phi_{k_T - \frac{1}{2}} - \Phi(H_T)}{R_{\text{dry}} T_{v k}}\right). \quad (38.15)$$

For other model variables, which are defined at full levels, a similar procedure is used. Again, the full level Φ_k (given by (38.10)) that brackets $\Phi(H_T)$

$$\Phi_{k_T} \leq \Phi(H_T) \leq \Phi_{k_T - 1} \quad (38.16)$$

is found and then a linear interpolation is done; e.g., in the case of temperature,

$$T_T = \alpha T_k + (1 - \alpha) T_{k-1}, \quad \alpha \equiv \frac{\Phi_{k_T - 1} - \Phi(H_T)}{\Phi_{k_T - 1} - \Phi_{k_T}}. \quad (38.17)$$

For variables that tend to show a more linear vertical behavior, when pressure is used as the independent variable, the interpolation may also be done using the full pressure levels p_k .

38.3.4 Inclusion of the Doppler Effect

To discuss the effects of a Doppler shift caused by a rapidly moving platform, a form of the lidar equation that explicitly contains the spectra of the emitted and received light pulses is needed. The signal power from the backscattered laser radiation incident on the detector device of the receiver of the lidar system is described by the simple radiative transfer equation

$$P_D(t) = \int_0^\infty \left(\iint D(\nu_v) \tau_b(\nu_b, r) \frac{O(r)A}{r^2} \times \beta_L(\kappa_b(r) \nu_b, \kappa_f(r) \nu_f, r) \tau_f(\nu_f, r) \times S_L(\nu_f) d\nu_f d\nu_b \right) P_L(t - t_\pi(r)) dr, \quad (38.18)$$

for which the symbols are defined in Table 38.3.

Remarks

- The equation is written, from right to left, in the order of radiative transfer: first the laser spectrum is transformed by the forward transmission; it is then backscattered and possibly spectrally broadened; next, it is again transformed by the backward transmission; finally, it is spectrally filtered by the receiver. The geometrical factor A/r^2 is kept close to the backscatter coefficient because it defines the solid angle that the radiation is scattered into and thus logically belongs to β_L , although it is not frequency dependent and could be pulled out of the integral.
- The equation in the given form allows for inelastic scattering and laser pulses of arbitrary temporal and spectral shape. Simplifications for elastic scattering or short and/or spectrally narrow pulses lead to the usual lidar equation; see Chap. 25.
- This equation holds for all situations where multiple scattering can be neglected, i.e., outside of optically thick clouds. The strong forward scattering caused by large ice crystals in cirrus clouds does not lead to time stretching, and the transmission effects can be taken into account by a suitable modification of the transmission terms, so (38.18) is still applicable.
- The laser radiation is characterized by the frequency ν and not by the wavelength, which makes things simpler in the nonvacuum case and for the discussion of the Doppler effect. Alternatively, the vacuum wavenumber can be used, which is more common in molecular spectroscopy.
- In principle, due to the vectorial nature of the electromagnetic radiation field, the polarization of light

Table 38.3 Explanation of the symbols used in (38.18)

Symbol	Explanation
r	Distance from the lidar system to the scattering volume along the main propagation direction of the laser beam
t	Time coordinate at the receiver system
ν_f, ν_b	Frequency of the forward- or backward-propagating radiation, respectively, in the reference frame of the instrument
$P_D(t)$	Power of the light incident on the detector at time t
$\kappa_f(r), \kappa_b(r)$	Doppler-shift factors between the reference system of the instrument and the reference system of the scattering volume at distance r ; see definition below
$t_{\tau}(r)$	Time taken for the laser pulse to perform a round trip to the scattering volume at distance r and back. If refractive index effects are neglected, $t_{\tau}(r) = 2r/c_0$, where c_0 is the vacuum speed of light
$\tau_f(\nu, r)$	Transmission of the atmosphere from the transmitter to the point at distance r where the light is scattered back
$\tau_b(\nu, r)$	Transmission of the atmosphere from the point at distance r where the light was scattered back to the receiver
$\beta_L(\nu_b, \nu_f, r)$	Backscatter coefficient at range r averaged over the laser beam profile for incident light of frequency ν_f to a possibly shifted frequency ν_b
$S_L(\nu)$	Spectral density of the light source (normalized to $\int S_L(\nu)d\nu = 1$)
$P_L(t)$	Output power of the light source for time t (temporal pulse shape)
$D(\nu)$	Efficiency factor of the detection optics, including spectral filters
A	Effective area of the receiver (essentially given by the telescope aperture)
$O(r)$	Overlap function describing the deviation from a pure $1/r^2$ law

has to be taken into account. This can be achieved by expressing the terms of the lidar equation as Stokes vectors and transforming Mueller matrices. As polarization effects are not discussed in the following, this complication is avoided.

- The integration over frequency runs over the range where the laser emission spectrum is nonzero for ν_f (typically a few hundred MHz for a spectrally pure laser and up to several dozens of GHz if a broadband impurity is present) and over the range generated by the possibly nonelastic backscattering plus the laser bandwidth for ν_b .
- The spectral density $S_L(\nu)$ and the pulse shape $P_L(t)$ of the laser emission are not independent but linked. $P_L(t)$ is proportional to the low-frequency component of the absolute square of the electric field

strength, whereas $S_L(\nu)$ is the power spectrum of the electric field. For a chirp-free laser, they determine each other.

- If the integration over r is changed to integration over the round-trip time, it can be seen that the power incident on the detector is the convolution of the outgoing laser pulse shape with a function determined by atmospheric properties.

In the following, selected terms from the lidar equation are discussed in more detail.

Due to the Doppler effect, the transmission of the atmosphere as viewed from the reference system of the instrument depends on the velocity field of the atmosphere. A velocity component relative to the line-of-sight direction of the lidar system introduces a Doppler shift of the molecular absorption that has opposite signs for the two propagation directions. Since the absorption lines of typical trace gases of interest (e.g., H_2O , CO_2 , or CH_4) are very narrow in the infrared, the effect of Doppler shifting has to be incorporated into the lidar equation. The other reason to consider the Doppler effect is the total frequency shift seen at the receiver after a round trip. This becomes relevant if the receiver bandwidth is very small, as in HSR-lidar applications. In the case of Doppler wind lidars, this shift is also actively used to determine the mean velocity of the scattering volume.

In the reference frame where the lidar is at rest, the Doppler shift can be accounted for by introducing the Doppler factor

$$\kappa_f(r) = 1 - \frac{\mathbf{v}_T(r) \cdot \mathbf{e}_L}{c_0}, \quad (38.19)$$

which *shifts* the light frequency from the value seen at the lidar system to the value valid within the reference frame where the atmospheric scatterer or absorber is at rest. Here, $\mathbf{v}_T(r)$ denotes the velocity of the target air parcel at range r from the lidar, and \mathbf{e}_L is the unit vector pointing in the direction of laser beam emission. The speed of light in vacuum is denoted by c_0 . If, for example, the air parcel moves towards the lidar, the scalar product in (38.19) is negative because the two vectors point in opposite directions. Hence, $\kappa_f(r)$ is bigger than 1, which means a shift to a higher frequency—a blueshift. For applications to the Earth's atmosphere, the nonrelativistic approximation given here is sufficient. Also, the deviation of the speed of light from its vacuum value due to the refractive index of air can be safely neglected. On its way back, the light—which may be absorbed by a molecule—comes from the back, meaning that the direction \mathbf{e}_L has to be reversed. From

(38.19), it follows that

$$\kappa_b(r) = 1 + \frac{\mathbf{v}_T(r) \cdot \mathbf{e}_L}{c_0}. \quad (38.20)$$

These Doppler factors also enter the expression for the backscattering described by the coefficient $\beta_L(\kappa_b(r)v_b, \kappa_f(r)v_f, r)$. For elastic scattering, i.e., $\kappa_b(r)v_b = \kappa_f(r)v_f$, this gives a total frequency shift at the receiver of

$$\begin{aligned} \Delta\nu &\equiv \nu_b - \nu_f = \nu_f \left(\frac{\kappa_f(r)}{\kappa_b(r)} - 1 \right) \\ &\approx -2\nu_f \frac{\mathbf{v}_T(r) \cdot \mathbf{e}_L}{c_0} \\ &= -2\mathbf{v}_T(r) \cdot \frac{\mathbf{e}_L}{\lambda}, \end{aligned} \quad (38.21)$$

the well-known formula for a wind lidar. Note that this doubled shift in (38.21) is the shift seen by the detection unit on the platform, not the relevant one for the calculation of the absorption cross-section for DIAL/IPDA applications, as is explained in the following.

The transmissions from the lidar system to the point at distance r and back may be expressed as a product of a rest atmospheric transmission $\tau_A(r)$ that does not depend strongly on the light frequency ν and a part that comes from narrow absorption lines of trace gases. $\tau_A(r)$ may be caused by aerosol or cloud absorption and scattering or Rayleigh scattering of the air molecules. The induced forward and backward transmissions $\tau_f(\nu, r)$ and $\tau_b(\nu, r)$ then are given by

$$\begin{aligned} \tau_{f/b}(\nu, r) &= \tau_A(r) \prod_G \exp \left(- \int_0^r \rho_G(r') \sigma_G(\nu \kappa_{f/b}(r'), r') dr' \right) \\ &= \tau_A(r) \exp \left(- \sum_G \int_0^r \rho_G(r') \sigma_G(\nu \kappa_{f/b}(r'), r') dr' \right). \end{aligned} \quad (38.22)$$

Here, the index G runs over all trace gases with narrow line absorption features in the frequency region of interest. ρ_G denotes the volume density of the molecular species G and $\sigma_G(\nu, r)$ is the absorption cross-section for G . The cross-section depends on r since it is pressure and temperature sensitive in general. The Doppler factors shift the frequency of the laser to the value seen by a molecule at rest. For example, for a DIAL or IPDA operating at $\nu = 1.6 \mu\text{m}$, a relative line-of-sight wind velocity of 1 m s^{-1} leads to a Doppler shift

of 0.625 MHz between the emitted and absorbed frequencies (or 1.25 MHz for the round trip). Thus, under a slant viewing geometry of 2° , range-dependent shifts of up to 2 MHz may be encountered for an atmospheric wind shear of 100 m s^{-1} , which can typically be neglected for DIAL/IPDA applications.

For a wind lidar, this frequency shift is of course the interesting part that contains the information about the velocity of the air parcel. For this application, the effect is strongly enhanced by using a large off-nadir angle, e.g., 30° , in which case half of the horizontal velocity is in the line of sight, and a sensitivity of $3 \text{ MHz m}^{-1} \text{ s}$ is reached at a wavelength of 355 nm. For a wind lidar, only the frequency offset to the emitted light is measured, and absorption effects do not play any role.

There remains the non-range-dependent Doppler shift caused by the platform velocity in combination with the rotation of the Earth. This shift has to be calculated from the attitude and orbital velocity of the platform and incorporated into the calculation of the absorption cross-section used for the trace gas retrieval or subtracted as an offset in the case of a wind lidar.

As seen above, the velocity component relevant to the calculation of the Doppler shift at range r is the projection of the velocity of an air parcel with respect to the platform $\mathbf{v}_T(r)$ onto the line of sight direction \mathbf{e}_L . In an inertial frame such as the GCRF, the Doppler-shift-relevant velocity component, v_{Doppler} , is given by

$$\begin{aligned} v_{\text{Doppler}} &= ((\mathbf{v}_T - \mathbf{v}_L) \cdot \mathbf{e}_L) = (\mathbf{v}_T \cdot \mathbf{e}_L) - (\mathbf{v}_L \cdot \mathbf{e}_L) \\ &= v_{\text{Doppler,Target}} + v_{\text{Doppler,lidar}}, \end{aligned} \quad (38.23)$$

where it becomes evident that the Doppler shift includes a term associated with the Earth's rotation and air parcel movement, $v_{\text{Doppler,Target}}$, and a term associated with the platform's movement, $v_{\text{Doppler,lidar}}$.

For the part due to the Earth and wind, the worst case is obtained at Equator crossings, where the angle between the across-track plane and the velocity of the target point is smallest (thus maximizing the scalar product) while the magnitude of the nadir point's velocity is highest.

As can be seen from a short calculation, (38.23) still holds if all vectors are expressed with respect to the Earth-fixed and thus rotating ITRF. This is not completely trivial, since the ITRF is a rotating reference system, and hence velocity vectors do not transform simply with the corresponding rotation matrix; terms containing the Earth's angular velocity also appear in the equations. In the Earth-fixed system, \mathbf{v}_T is, by definition, the wind velocity, which can either be neglected in the DIAL/IPDA case (as outlined above) or is the

quantity of interest in the case of a wind lidar. The remaining part, which has to be used in the calculation of absorption cross-sections or subtracted in the wind lidar case, can be calculated from the platform velocity and the target pointing vector alone. Therefore, it is easiest to do the Doppler calculations in the ITRF, i.e.,

$$v_{\text{Doppler}} = v_{\text{wind}}^{\text{ITRF}} \cdot e_L^{\text{ITRF}} - v_L^{\text{ITRF}} \cdot e_L^{\text{ITRF}}. \quad (38.24)$$

DIAL/IPDA

As already noted in Sect. 38.3.4, the Doppler effect is—with the exception of CO₂ systems—mostly negligible for airborne DIALs. It only plays a relevant role for satellite-based systems, and even then, proper orbit and pointing angle selection helps to minimize the Doppler shift. The most stringent requirements come from CO₂ IPDA systems because of the high accuracy requirements for this trace gas and the lack of a suitable wavelength-shift-insensitive trough region in the absorption spectrum, such as that for CH₄; see [38.64]. For carbon dioxide, the Doppler shift caused by the wind will most likely have to be taken into account, as the frequency must be known to an accuracy of 100 kHz, and exact nadir pointing is not possible because it would generate other problems (with specular reflections, for example). For CO₂, even the aircraft case is demanding. During a typical research flight with the CHARM-F IPDA of DLR [38.28], the frequency shift of the carbon dioxide channel ranges from 3 to 9 MHz over all flight conditions, which would result in a retrieval error of 0.1%. Uncorrected, this is already about an order of magnitude too large, since the goal in terms of accuracy is 0.02% and the Doppler shift error is only one of several systematic error sources.

HSRL

High spectral resolution lidars use very narrow band filters in the receiver to separate the molecular backscatter from the scattering by aerosol and cloud particles. The effective transmissions of these filters for the laser wavelength and for the broadened spectrum of the molecular return signal have to be known for the retrieval. These transmissions depend on the central wavelength, which is in turn shifted by the Doppler effect. For example, for an iodine-cell-based HSRL operating at 532 nm [38.10], the emission frequency must be known to an accuracy of a few MHz. Using (38.21), one can see that at a typical aircraft speed of 200 m s⁻¹ and an off-nadir angle of 4° (which is often used to avoid specular reflection by ice cloud particles), the Doppler shift at the receiver is about 52 MHz. This value is too high to be neglected for precision mea-

surements and has to be corrected for in the retrieval. The exact value depends on the pitch and roll angles of the aircraft and on its speed relative to the air in the probed volume, which was assumed to be at rest in the example above. If a nonzero wind, possibly with shear, is present, there are additional uncertainties. For typical atmospheric wind speeds outside of high-level jets, the contribution from the wind can be neglected. The situation gets much worse in curves with high roll angles. If a precise HSRL retrieval during curve flight is required, this can only be done using additional wind information. This additional information can come from an external source or can be measured with the same lidar system through a second channel. The HSRL based on the Mach-Zehnder technology [38.14] provides the opportunity to simultaneously retrieve the wind along the line of sight without additions to the system, and hence a Doppler-shift-insensitive retrieval can be established.

For a spaceborne DIAL with a speed of about 7 km s⁻¹, the Doppler shifts due to the platform's motion are larger by a factor of 35 than those for a typical jet aircraft with a speed of 200 m s⁻¹. At a system level, this can partly be compensated for by pointing as nadir as possible. The small deviation from nadir usually required to avoid specular reflections should be chosen in such a way that the beam direction is perpendicular to the motion direction of the satellite. An active steering mechanism usually has to be implemented to maintain this condition over the whole orbit.

Wind

For a Doppler wind lidar, the frequency shift due to the movement of the target is the raw data quantity of interest. The part coming from the movement of the platform is an offset that has to be subtracted. Unfortunately, the speed of the platform is usually large compared to the accuracy required for wind measurement, which is well below 1 m s⁻¹. Especially for spaceborne Doppler lidars, the offset is several orders of magnitude larger than the part due to the wind. If only one wind component is of interest, it is possible to point the lidar in a direction perpendicular to the flight track, as done for ESA's Aeolus mission (Sect. 38.4.4), but this is not possible if the whole wind vector has to be measured. The velocity and attitude data for the platform are typically not known with high enough accuracy to simply calculate the offset from them. The solution is to use the Doppler shift of the ground, if available. In this way, correction parameters for the platform velocity data can also be established, which allows for a precise wind retrieval in cases where no ground return is available.

38.4 Devices and Systems

This section describes selected airborne and spaceborne lidar systems in more detail. To keep this section within reasonable bounds, only state-of-the-art systems that were or still are in regular use for atmospheric research as documented by peer-reviewed publications are considered.

38.4.1 Airborne Instruments for Aerosol and Cloud Parameters

For aerosol and cloud parameters, there are a number of mostly small systems with limited power and a limited number of channels. We will not list them here, but rather restrict the description to two more powerful systems with extinction channels based on the high-resolution lidar principle, as these systems set the standard upon which future developments will be based.

NASA HSRL

The National Aeronautics and Space Administration (NASA) Langley Research Center (LaRC) airborne High Spectral Resolution Lidar (HSRL) is a compact, nadir-viewing airborne HSRL developed for the accurate measurement of aerosol and cloud properties in the context of radiation- and chemistry-focused field missions and for validating the CALIOP on the CALIPSO satellite [38.11]. The system uses an injection-seeded Nd:YAG laser that is frequency doubled to provide pulse energies of 1.1 mJ at 1064 nm and 2.5 mJ at 532 nm at a repetition rate of 200 Hz. The laser is locked to a J_2 cell by a phase modulation technique. The receiving system uses a 40 cm diameter telescope with an adjustable field of view of 0.25–1.0 mrad. Photo multiplier tubes (PMTs) are used as detectors for the 532 nm channels and Si-APDs (avalanche photo diodes) are used for 1064 nm. The system provides depolarization channels for both wavelengths and a HSRL channel at 532 nm, which uses an iodine cell to suppress the particular backscatter. For each detection channel, the signal is split in the ratio 1 : 20 and fed to a low-signal and a high-signal detector unit to extend the dynamical range. This system was used in several field campaigns to establish a widely used aerosol classification database [38.65].

LNG

The French *lidar aerosols nouvelle génération* (LNG) is a HSRL based on a Mach–Zehnder interferometer [38.14]. A frequency-doubled and -tripled Nd:YAG laser with a 20 Hz repetition rate is used. The emitted pulse energies are 50 mJ at 1064 nm, 10 mJ at 532 nm, and 50 mJ at 355 nm. The pulsed laser is in-

jection seeded to provide stable single longitudinal mode operation with a line width of 70 MHz. The receiver uses a telescope 300 mm in diameter. The channels at 1064 and 532 nm are polarization insensitive, while there are parallel- and cross-polarized channels at 355 nm. The parallel-polarized channel is fiber coupled to a Mach–Zehnder interferometer (MZI). To establish the necessary stability, the MZI design is based on an arrangement of fused silica prisms and air gaps. Using the MZI technique to build a HSRL has several advantages as compared to a molecular absorption filter or an etalon-based system. For example, the laser does not have to be absolutely stabilized; it may drift slowly. Compared to etalons, the acceptance angle of the filter is much larger, and compared to molecular filters, the wavelength is freely selectable. The technique can also be used to infer the wind velocity, although the LNG layout yields lower accuracy than dedicated wind lidars. The downside is that the separation of molecular and particle backscatter is lower than for systems based on molecular filters, and the corresponding errors in extinction retrieval are higher.

38.4.2 Airborne Instruments for Trace Gas Measurements

This subsection covers the latest airborne DIAL instruments for water vapor and ozone and currently operational IPDA systems for greenhouse gas monitoring.

LASE

The latest operational version of NASA's airborne H₂O DIAL systems is the *Lidar Atmospheric Sensing Experiment* (LASE) [38.18, 19]. The transmitter is Ti:sapphire-laser based and emits double pulses with a separation of 300 μ s in the wavelength band 813–818 nm. The pulse-pair repetition frequency is 5 Hz and the pulse energy more than 100 mJ. The receiving telescope has an area of 0.1 m² and uses an APD with 80% quantum efficiency. The covered altitude range is the troposphere with the exception of the tropopause region and the lower stratosphere, where the optical thicknesses of even the strongest absorption lines in the region accessible to the system are too low. LASE has been used in a large number of field and validation campaigns and is thought to have an accuracy of about 5% in the upper troposphere, where accurate measurements are most difficult [38.66]. From a technological point of view, LASE is becoming outdated, so there are currently developments at NASA to replace it with a system using the latest laser and detector technology; see Sect. 38.9.

LEANDRE II

The airborne differential absorption lidar LEANDRE II (lidar pour l'étude des interactions aérosols nuages dynamique rayonnement et du cycle de l'eau) has been developed for tropospheric water vapor profiling by the French Centre National de la Recherche Scientifique (CNRS). The emitter uses a flash-lamp-pumped alexandrite laser, which operates in a double-pulse, dual-wavelength mode in the 727–736 nm spectral domain. Two 50 mJ successive on-line and off-line pulses with an output line width of less than 720 MHz and a spectral purity larger than 99.99% are emitted at a repetition rate of 20 Hz. The emitted wavelength is controlled in real time by a wavemeter with an absolute accuracy of 150 MHz. The receiver is a 30 cm aperture telescope with a 3.5 mrad field of view and a background-light filter bandwidth of 1 nm. A photomultiplier tube with a quantum efficiency of 4% serves as the detector. The precision of the instrument is better than 0.5 g kg^{-1} in the first 5 km of the atmosphere, it has a range resolution of 300 m, it integrates 100 shots, and it has an instrumental systematic error of less than 2% [38.20, 67].

WALES

The German Aerospace Center (DLR) developed a multiwavelength H_2O DIAL with additional channels for aerosol and cloud characterization [38.68] as an airborne demonstrator for a proposal to ESA regarding a spaceborne mission called WALES (water vapour lidar experiment in space) [38.69]. The WALES airborne demonstrator only uses technologies such as diode-pumped solid-state lasers and nonlinear conversion techniques that are suitable for an in-orbit deployment. It operates in the 935 nm region and is capable of emitting at four wavelengths at the same time for water vapor measurement. An optical parametric oscillator (OPO) is used to generate the pulses at 935 nm. Additionally, there are aerosol detection channels operating at wavelengths of 1064 nm and 532 nm, where the depolarization and aerosol extinction (only at 532 nm) in the atmosphere are measured. Output pulse energies are 45 mJ at 935 nm, 75 mJ at 532 nm, and 125 mJ at 1064 nm, with a total repetition rate of 200 Hz. Pulses at all wavelengths have a duration of about 8 ns and are single longitudinal mode, with a bandwidth below 150 MHz and a stability of better than 30 MHz for 935 nm and better than 1 MHz for 1064 nm and 532 nm. The receiver uses a telescope 48 cm in diameter and a field of view of 1.6 mrad. PMTs are used as detectors for the 532 nm channels and Si-APDs for 935 and 1064 nm channels. The raw data range resolution is 15 m. The temporal resolution is reduced to 5 Hz by the onboard averaging of signals. The system

Fig. 38.6 WALES: DLR's airborne demonstrator for a possible future spaceborne water-vapor DIAL system

is very compact for this power class, with a volume of only about 1 m^3 ; see Fig. 38.6. The uniqueness of this system is the possibility of measuring the whole tropospheric profile of water vapor (including the tropopause region and the lower stratosphere) simultaneously by combining the raw data profiles of four close wavelengths at 935 nm. The systematic error in the water vapor retrieval is estimated to be below 2.5% from multi-instrument comparisons [38.70].

TOPAZ

The National Oceanic and Atmospheric Administration (NOAA) developed an airborne DIAL for tropospheric ozone (tunable optical profiler for aerosol and ozone, [38.24]). The system is based on a tunable solid-state Ce:LiCAF laser which is able to generate short light pulses in the wavelength range 283–310 nm. This laser is pumped by a frequency-doubled Nd:YLF laser, which is, in turn, laser-diode pumped. The output energy ranges between 0.2 and 0.8 mJ, depending on the wavelength. The repetition rate is 1 kHz and the pulse length 100 ns. The laser is operated at three wavelengths that are generated sequentially. The third, intermediate, wavelength is used to reduce the retrieval error caused by aerosol. The tunability allows to adapt to different atmospheric conditions, and to reduce the cross-sensitivity to other trace gases such as SO_2 . The receiver uses a 0.5 m diameter telescope and photomultiplier tubes as detectors. To cover the large signal dynamics, a far-field and a near-field channel are implemented. The vertical resolution of O_3 profiles is 90 m, and the horizontal resolution is 600 m (10 s at a typical aircraft speed). The precision is about 5% close to the aircraft and increases to 12–30% at distances of 2.5 km and beyond. The accuracy is estimated to be better than 5% in most cases.

NASA CO₂ Sounder

To prepare for a proposed mission called ASCENDS (active sensing of CO₂ emissions over nights, days and seasons) that aimed to measure CO₂ from space with an active system, NASA developed several candidate airborne demonstrators. The most well developed is the so-called CO₂ Sounder [38.25]. This system has been upgraded over several years. Here we describe the version focused upon in the latest publication [38.71]. The CO₂ Sounder uses a pulsed, multiwavelength (i.e., more than two wavelengths) IPDA approach. In the 1570 nm absorption band of CO₂, a single line is scanned by typically 30 different wavelengths. The laser is operated at a 10 kHz pulse repetition rate and the wavelength is changed from shot to shot so that the line is scanned at about 300 Hz. A single laser pulse has an energy of up to 50 μJ at a pulse width of 1 μs. The laser is implemented as a continuous-wave (CW) master laser that is modulated into pulses 1 μs in duration and amplified in erbium-doped fiber amplifiers. A 20 cm diameter telescope is used as the receiver, and the field of view is 500 μrad. In the latest version, the detector is a HgCdTe APD with a quantum efficiency of 70% and an internal gain of 300. The line scanning approach has several advantages with respect to the detection and elimination of spectroscopic or instrumental effects that depend on the wavelength. The downside is the relatively high laser power needed compared to a two-wavelength system with an optimally selected optical depth. The measurement precision for a 1 s averaging interval is about 0.7 ppm over desert (high reflectivity at 1.6 μm) and 2.5 ppm over snow (low reflectivity) from a flight altitude of 8 km. Comparisons with an in-situ sensor made during vertical profiling with the aircraft led to an estimation of less than 1 ppm for the systematic error.

CHARM-F

CHARM-F is a combined CO₂ and CH₄ IPDA instrument developed by the German Aerospace Center DLR [38.28]. It uses short-duration (20 ns), high-energy (10 mJ) laser pulse pairs at a repetition rate of 50 Hz. To illuminate nearly the same target, the temporal separation within one pair is 500 μs. The laser wavelength is about 1572 nm for CO₂ and 1646 nm for CH₄. To generate these wavelengths, Nd:YAG-laser-pumped OPO are used. They are injection seeded to ensure a spectral width below 50 MHz at a jitter of about 2 MHz root mean square (RMS). The transmitter divergence and receiver field of view are set to 3 mrad to ensure an illuminated ground spot of about 30 m at a typical aircraft altitude. This is favorable since the relative difference in illuminated surface area between the on-line and off-line pulses within one pulse pair gets lower as the spot size increases. For each trace

gas, the receiver has two channels. One uses a 200 mm telescope with a quadrant PIN diode. This allows active monitoring of the overlap of the transmitted beam with the receiver field of view. The other channel uses an InGaAs-APD similar to those intended for future space missions. These devices have a much lower diameter, which forces the use of a much smaller telescope (60 mm) at the prescribed field of view (F-number limited). The APDs have higher sensitivity but may be subject to nonlinearities, so the presence of two detectors enables cross-checking for such effects. The measurement precision is about 1 ppm for CO₂ and 7 ppb for CH₄, both for 10 s of averaging time. Comparisons with in-situ profiles acquired during aircraft dives point to an accuracy of better than 1.5 ppm for CO₂ and 15 ppb for CH₄.

38.4.3 Airborne Instruments for Wind

There are two detection principles for Doppler lidar: direct and heterodyne (Sect. 38.1). Both types are represented in the following list.

A2D

The Aladin Airborne Demonstrator (A2D) [38.72] is a direct-detection Doppler wind lidar developed by the German Aerospace Center (DLR) to very closely resemble the Aladin instrument on ESA's Aeolus mission (Sect. 38.4.4). It uses a very similar frequency-tripled Nd:YAG laser and an engineering model of the receiver of the spaceborne system. Like the spaceborne instrument, it is only capable of measuring one line of sight, so the main purpose of this system is to produce test data and evaluate the processing chain for the space mission. However, since an aircraft is much more free to choose its flight track than a satellite, dedicated atmospheric problems can also be investigated with this lidar, even though it has just one line of sight [38.36].

HRDL

The High Resolution Doppler Lidar (HRDL) is a heterodyne detection system developed by The National Oceanic and Atmospheric Administration (NOAA) [38.35]. It uses a Tm:Lu YAG laser emitting at a wavelength of 2 μm. The pulse length is 200 ns at a repetition rate of 200 Hz and a typical pulse energy of 1.5 mJ. The pulsed laser is injection seeded by a Tm:Lu YAG CW reference laser. The combined transmit/receive telescope has a diameter of 0.2 m. An InGaAs-PIN diode with a quantum efficiency of 60% that is operated at room temperature is used as the detector. By mixing the return pulse with a frequency-shifted (by 100 MHz) part of the light from the ref-

erence laser, a beat note is generated that is digitized after down-mixing to the baseband. The down-mixing is done to avoid high sampling rates and large raw data rates. The velocity measurement range is $\pm 25 \text{ m s}^{-1}$. The velocity precision is close to the theoretical limit for such a system and below 0.1 m s^{-1} for most atmospheric conditions. Systematic errors are estimated to be on the order of 0.01 m s^{-1} .

38.4.4 Spaceborne Instruments

This section on spaceborne systems is limited to lidars that were or still are in orbit. Future developments are briefly described in Sect. 38.9.

LITE

On 9/9/1994, the first lidar in space, LITE, was launched as a 10 day experiment on the NASA Space Shuttle *Discovery* [38.48]. The LITE used a Nd:YAG laser to generate three emission wavelengths: 1064, 532, and 355 nm. The laser was flash-lamp pumped and operated at a repetition rate of 10 Hz. For redundancy, a second laser of the same type was also integrated. The pulse energies were approximately 445 mJ at 1064 nm, 557 mJ at 532 nm, and 162 mJ at 355 nm. The receiver had a telescope diameter of 1 m, which—together with the quite high single pulse energies and the low orbit of 259 km—led to an overall sensitivity that has not been achieved again since. The receiver field of view could be switched between 1.1 mrad, 3.5 mrad, and an annular field stop for multiple scattering measurements. This feature was also unique and allowed the effect of multiple scattering on the retrieval to be estimated. In terms of detectors, photomultipliers (PMTs) were used for the 532 and 355 nm channels and an avalanche photodiode was used for the 1064 nm channel. The analog signals were digitized with a 12 bit A/D converter running at 10 MHz, resulting in a range binning of 15 m. The real range resolution was about 35 m, limited by the bandwidth of the analog electronics. The overlap between transmitter and receiver could be adjusted by a two-axis gimbaled turning prism to steer the direction of the outgoing beam. Part of the return signal at 532 nm was monitored by a microchannel plate quadrant detector, and the resulting signals were used to set up closed-loop beam stabilization.

Although LITE was a simple backscatter lidar without depolarization and extinction channels, it clearly showed the value of globally available two-dimensional curtains of backscatter data to address problems such as desert dust transport, biomass burning, pollution outflows from megacities, and the monitoring of stratospheric aerosol.

GLAS

The first spaceborne lidar on its own satellite was NASA's GLAS on ICESat [38.52]. Although primarily designed as an altimeter to monitor ice-sheet topography, it also featured channels for atmospheric measurements [38.53]. GLAS used three diode-pumped Nd:YAG lasers in a redundant configuration designed to provide the necessary lifetime for a multiyear mission with continuous operation. The laser generated two emission wavelengths, 1064 and 532 nm, at a repetition rate of 40 Hz. The pulse energies were approximately 75 mJ at 1064 nm and 35 mJ at 532 nm. The receiver had a telescope diameter of 1 m. The receiver channel at 1064 nm was optimized for altimeter applications, had a field of view of $500 \mu\text{rad}$, and used two redundant Si-APDs with a bandwidth of approximately 160 MHz. The signals were digitized with a 1 GHz sample rate, corresponding to a 15 cm range resolution. For the atmospheric signals, the 1064 nm channel was simultaneously filtered and digitized at a 2 MHz sample rate or a range resolution of 75 m. For the 532 nm channel, an array of eight APDs operated in Geiger mode was used to implement a photon-counting detection unit. The range gates for the counting were set to 75 m, just as for the infrared channel. For the suppression of stray light from the sun, the 532 nm channel contained a two-stage optical filter with a 0.37 nm bandwidth prefilter and a 30 pm Fabry–Pérot etalon as the second stage. The field of view was limited to $170 \mu\text{rad}$ for further sunlight reduction.

Unfortunately, the first laser failed after 37 days of operation. An analysis by an anomaly review board found an error source common to all three lasers onboard, so it was decided that continuous operation should be abandoned and that the data collection strategy should be changed to three 33 day campaigns per year dedicated to ice shield mapping. In this way, a 7 year record of polar ice height development was established before the last of the three lasers ceased operation.

Due to the limited operation times, the impact of GLAS on atmospheric studies was not as expected. Nevertheless, the mission was able to collect a large data set of aerosol height structure, cloud top heights and layering, and cloud optical depths down to very low values of 0.02.

CALIOP

The GLAS system described in the previous paragraph did not implement a depolarization channel, so the ability to discriminate different aerosol types was very limited. This changed with the launch of the joint NASA and CNES mission called *Cloud–Aerosol Lidar and Infrared Pathfinder Satellite Observation* (CALIPSO). The lidar instrument on CALIPSO is

called the CALIOP [38.54]. CALIOP, like all previous spaceborne lidars, uses Nd:YAG lasers to generate the two emission wavelengths, 1064 and 532 nm. The repetition rate is 20.16 Hz and the pulse energy is approximately 110 mJ at each emitted wavelength. Operation of the laser is continuous, and two lasers in a redundant configuration are onboard. The receiver has a telescope diameter of 1 m and a field of view of 130 μ rad. The optical filters for background light suppression have a bandwidth of 35 pm for the 532 nm channel and 400 pm for 1064 nm. CALIOP implements a linear depolarization channel at 532 nm. Photomultiplier tubes (PMTs) were chosen for the 532 nm channel detectors, and an avalanche photodiode (APD) for the 1064 nm channel. All operate in analog detection mode and are digitized at a rate of 10 MHz, resulting in a raw data range binning of 15 m. For each channel, two 14-bit analog digital converters are stacked in a low- and high-sensitivity configuration so that the dynamical range spans about 4×10^6 . The raw data resolution for downlinking is reduced by temporal and vertical averaging, depending on the altitude region covered. For example, the highest resolution is available for the altitude region between -0.5 and 8.2 km, with an along-range gridding of 30 m for the 532 nm channel and 60 m for 1064 nm, and no coaddition of shots. For higher layers, several shots and more range bins are added; see [38.73] for details.

The standard data products from CALIOP are attenuated (i.e., not extinction corrected) backscatter for 1064 nm and for the parallel and perpendicularly polarized channel at 532 nm; cloud geometry, such as top and bottom altitudes, and optical depth and phase (ice or water); aerosol layer geometry, optical depth, and aerosol type; profiles of backscatter coefficients and extinction for clouds and aerosol; and finally a feature mask for cloud phase and aerosol type. It should be emphasized that CALIOP does not have a channel to directly measure the extinction (HSRL or Raman), so the attenuation-corrected products and the extinction profiles depend on assumptions about the scattering properties of the aerosol or cloud under investigation. In the case of vertically isolated layers, the transmission is estimated by comparing the signals above and below the layer. Where this is not possible, prescribed values for the lidar ratio are assumed; see [38.54] for details. So, while the data set of CALIOP is quite complete for a cloud and aerosol lidar, there is some basic uncertainty for uncommon scenes where the type classification fails.

Besides standard backscatter lidar products, CALIPSO enables more indirect retrievals, such as sea surface wind inferred from the sea surface roughness [38.74]. CALIPSO is part of the A-Train, a con-

stellation of satellites for Earth observation that fly in the same orbit with close temporal spacing. The original A-Train consisted of the satellites Aqua, CloudSat, CALIPSO, PARASOL (polarization & anisotropy of reflectance for atmospheric sciences coupled with observations from a lidar), and Aura, all flying with a separation of less than 15 minutes. The temporal separation between CALIPSO and CloudSat with its cloud radar is only 15 s. This near-collocation enables synergistic retrievals using data from several instruments [38.75].

CATS

Simple backscatter lidars show deficiencies in the discrimination of different aerosol types. For ground-based systems, this has been overcome by using Raman or HSRL lidars, which provide additional extinction channels, so the logical step would be to use one of these methods from space. In 2015, the CATS was installed on the ISS as a technology demonstrator for such upcoming instruments [38.55]. CATS had two Nd:YVO₄ lasers. The first laser generated pulses of about 1 mJ at 1064 and 532 nm at a repetition rate of 5 kHz. The second laser produced three wavelengths (1064, 532, and 355 nm) with an output of 2 mJ at a repetition rate of 4 kHz. This second laser was injection seeded to produce single longitudinal mode radiation, as necessary for a HSRL. The receiver had a telescope 60 cm in diameter with a field of view of 110 μ rad. The photon-counting detectors were fiber coupled to the telescope. The mission ended in October 2017, after about two and a half years [38.55, 76].

Aeolus

On August 22, 2018, ESA launched the Aeolus satellite. Aeolus is a single-instrument mission with the Aladin wind lidar on board. Aladin implements a direct-detection Doppler wind lidar with one line of sight [38.77]. It uses two frequency-tripled Nd:YAG lasers in a redundant configuration that produce pulses of 120 mJ at a wavelength of 355 nm and with a repetition rate of 50 Hz. The lasers are injection seeded to run at a stable single longitudinal mode. The receive/transmit telescope is a SiC structure 1.5 m in diameter with a field of view of only 19 μ rad.

To simplify the instrument concept, only one component of the wind vector is sensed. This line of sight (LOS) direction is perpendicular to the satellite velocity in order to nullify the contribution of the satellite ground speed to the Doppler frequency shift. Additionally, yaw steering of the complete satellite is applied to compensate for the Earth's rotation. Only the projection of the wind vector to the LOS is obtained, for which an off-nadir angle of 35° was chosen.

The optical receiver consists of two spectrometers: a Rayleigh spectrometer measures the Doppler frequency shift from molecular backscatter and a Mie spectrometer measures the Doppler frequency shift from aerosol and cloud particles backscatter. Separation of the molecular and aerosol backscatter requires significantly different spectral bandwidths of the two signals—the broad bandwidth signal from the molecular scattering in the atmosphere and the narrow bandwidth from aerosol scattering. Rayleigh–Brillouin scattering on molecules causes a broad bandwidth signal with a FWHM of 1.6 pm due to the thermal motions of the molecules. The aerosol scattering has a bandwidth that is a factor of almost 80 lower: 0.021 pm (or 50 MHz at 355 nm). A double-edge technique is used for the molecular backscattered signal and a fringe

imaging technique for the aerosol return. The imaging detector needed for the Mie spectrometer is realized by a charge-coupled device (CCD). The CCD allows the accumulation of backscattered signal from a number of laser pulse returns directly on the CCD itself, a novel concept for lidar instruments. The minimum vertical resolution of the Aladin instrument is limited by the CCD detector to 250 m, and only a limited number (24) of atmospheric altitude ranges can be acquired. The number of laser pulses accumulated directly on the detector is typically set to 20–35. Further averaging of 600–700 laser pulses (12–14 s) is needed to reach the random error requirement of 1 or 2 m s⁻¹.

Additionally, there will be aerosol and cloud products, but with a limited vertical resolution as compared to dedicated aerosol-cloud missions such as CALIPSO.

38.5 Specifications

The most prominent error source for lidar systems is photon noise. Because of this, the resolution and precision of a lidar system depend on each other and are determined by size of the instrument, which is roughly described by the power-aperture product, i.e., the product of the emitted mean laser power and the effective area of the receiving telescope. For a prescribed precision, a certain number of photons have to be collected. Here, the power-aperture product determines the total number of photons received from a certain range interval for one laser pulse. The nec-

essary photon count can be reached if the single pulse performance is not sufficient by adjusting the range interval (i.e., the vertical resolution) and coadding the signals from several laser pulses. From the list of systems discussed in Sect. 38.4, it can be seen that, for example, the range resolution covers the interval from below 1 m to more than 1 km, depending on the system layout and technology. Therefore, it is not possible to give simple specification tables for certain types of lidars. Details about individual systems can be found in Sect. 38.4.

38.6 Quality Control

The procedures for quality control do not differ for an airborne/spaceborne lidar when compared to

a ground-based system, so all the measures described in Chaps. 24–27 also apply here.

38.7 Maintenance

The necessary maintenance procedures for an airborne lidar differ quite significantly between systems, as they depend on system complexity and size, the technology used, the quality standards applied during the development and manufacturing process, etc. Some research-grade systems need maintenance actions after every flight, while spaceborne systems are designed to have minimal maintenance needs. It is therefore not possible to give standard check intervals here, even if the same basic technology is implemented.

However, for airborne systems, all maintenance actions must be laid down during aircraft certification. For the certification of a lidar system on an airplane, it has to be shown that, among other things, the system is electrically safe and has no electromagnetic interference (EMI) with other systems, that it is mechanically stable enough to withstand crash load conditions (typical values are 9g forward, 6g downward, and 3g sideways for several seconds), that it is made of nonflammable material, and that the risks posed by other potentially dan-

gerous components (such as those from water systems, gases under pressure, toxic/radioactive substances, hot components, etc.) are under control. This all means that it is not possible to use standard laboratory components without modification. Typically, special housings have to be designed, and the cables and hoses have to be replaced with those conforming to aviation standards. It can also be difficult for pulsed lasers to meet the EMI requirements without additional screening and line filtering.

It has to be shown that the laser system is eye-safe for the crew, for people on the ground, and for other airplanes. This often places strong limits on the pulse

energy and/or the minimum divergence of the transmitter. For Europe, the European Aviation Safety Agency (EASA) has published guidelines on how a laser that is operated on an aircraft can be certified [38.78].

After the lidar system has been certified, maintenance actions are only possible according to the procedures described in the maintenance manual, which is part of the certification documentation. In particular, this means that parts may only be replaced by those of the exact same type. Thus, gradual upgrading of the lidar, as often practiced for ground-based research systems, is not possible. Every alteration requires a recertification.

38.8 Applications

Airborne lidars have been applied to various topics in atmospheric research. The first applications of backscatter lidar systems were dedicated to the monitoring and analysis of the origin and transport of aerosol and pollution in the troposphere [38.5, 6, 8, 79, 80]. More complex systems with several wavelengths and depolarization and extinction capabilities are used to retrieve the optical properties of aerosol, which are then used to classify the aerosol type and possible mixtures [38.9, 65, 81, 82].

Although lidar cannot penetrate most tropospheric clouds, it is successfully applied in research into optically thin clouds, e.g., cirrus [38.83, 84]. Even if it is not possible to penetrate the cloud, the downward looking geometry allows the detection of the cloud top height [38.85], which can then be used in combination with passive remote sensing.

In boundary layer research, airborne lidar is used to map the geometric structure of the layer, especially the top of the layer, using aerosol as a tracer [38.7, 86, 87]. Using a combination of water vapor and wind lidars, it is even possible to determine latent heat flux profiles in the boundary layer [38.88].

Understanding water vapor transport in the upper troposphere lower stratosphere (UTLS) leading to stratosphere/troposphere exchange is crucial to under-

standing and modeling the radiation budget of the atmosphere. Airborne water vapor measurements are used to study the large-scale isentropic mixing processes that dominate the transport of humidity into the lowermost stratosphere at higher latitudes [38.37, 89].

The possibility of collecting long-range two-dimensional cross-sections of the atmospheric humidity and wind field by airborne DIAL makes it an ideal tool to validate numerical weather models [38.90]. In a further step, such data can be assimilated into the model to increase the forecast skill [38.91–95].

From early on, airborne lidar has been used to investigate stratospheric aerosol [38.40, 96, 97], clouds [38.4, 98–100], and ozone [38.21], especially in connection with the winter time polar vortex. The remote locations of these phenomena often make them only accessible from airborne platforms.

Airborne lidar is even used to provide insight into the physics of the mesosphere, where the propagation of gravity waves and their momentum deposition are the main targets [38.46, 101].

For climate research, the monitoring of greenhouse gases by airborne IPDA instruments has become a valuable tool to investigate the emissions from point and distributed sources in recent years [38.28, 30].

38.9 Future Developments

For airborne lidar, advances in laser technology will allow more compact and robust systems to be built. In this way, the capabilities of current large, research-grade systems will become the standard for future airborne lidars. The higher average laser powers that are possible for Raman lidars will allow them to be used for more airborne applications than currently possible.

Over the years, there have been several proposals for new spaceborne lidar missions, such as DIAL or Raman systems to measure water vapor or ozone. However, currently only two lidar projects are advanced enough to have mission status: EarthCARE and Merlin, which is described briefly below.

To continue and extend the dataset on aerosol and clouds gathered by NASA's Calipso and Cloudsat missions, ESA is developing a satellite mission called EarthCARE that implements an advanced lidar and a radar on the same platform [38.102]. The EarthCARE lidar will have an extinction channel based on the high spectral resolution principle, and the cloud radar will have a Doppler capability giving information on convective motions as well as ice and rain fall speeds.

The other space project under development that uses the lidar technique is the French–German methane monitoring mission Merlin [38.103]. This will use the IPDA principle to measure column-integrated values of CH₄, which will then be used for the inverse modeling of surface sources and sinks of this, the second most important greenhouse gas. Due to the low bias of Merlin data, the error budget for methane emissions is expected to be considerably smaller than currently possible with passive remote sensing data [38.104].

Martin Wirth

Institut für Physik der Atmosphäre
Deutsches Zentrum für Luft- und
Raumfahrt e. V. (DLR)
Weßling, Germany
martin.wirth@dlr.de

Martin Wirth received his PhD in Physics in 1996 from the LMU in Munich. He is currently a research scientist at the Lidar Department at the German Aerospace Centre (DLR) in Weßling, where he has developed several airborne lidar systems for measuring aerosols and atmospheric trace gases (e.g., ozone and water vapor). He is also a member of the Science Advisory Group for MERLIN, the French-German methane lidar space mission.

Airborne Radar

39. Airborne Radar

Martin Hagen , Julien Delanoë , Scott Ellis, Florian Ewald , Jeffrey French , Samuel Haimov , Gerald Heysmsfield , Andrew L. Pazmany 

Ground-based radar systems have been used to observe clouds and precipitation since the 1940s. While weather radars that use centimeter waves can observe precipitation several hundred kilometers away, radars that are dedicated to cloud observations use millimeter waves and have limited ranges of just a few tens of kilometers. Airborne radars have the advantages that they can perform measurements close to the region of interest and they provide radar information on regions that ground-based radars cannot access. There is no such thing as a standard airborne radar system; all systems are tailored for use on specific research aircraft, although some of them are designed to be modular so that they can be mounted on various aircraft. Airborne radar systems use frequencies ranging from those in the X band to those in the W band. Radars that use shorter wavelengths are preferred due to spatial restrictions on antenna size in aircraft, but C-band systems are also being considered for installation in large aircraft. Besides reflectivity (the backscatter signal), the radial motions of scattering particles can be measured and used to retrieve atmospheric motion. In addition, several airborne radars are able to measure dual-polarization backscatter signals that can be employed to identify different types of hydrometeors.

Clouds and precipitation play an important role in atmospheric science. While detailed studies of microphysical properties such as particle concentration, shape, phase, and density can only be achieved through airborne or ground-based in-situ observations, the three-dimensional structures of cloud and precipitation systems can only be accessed by radar and, to some extent, lidar observations. The measurements ranges of ground-based radar systems are limited, meaning that phenomena of interest (e.g., hurricanes) are not within range. In contrast, airborne radars have the advantage that they can provide targeted radar measurements in regions—such as over oceans—that cannot be probed by ground-based radars.

A number of research aircraft can be equipped with additional remote-sensing instruments or in-situ cloud probes. It is difficult to achieve the optimal combina-

tion of in-situ cloud probes [39.1] and remote-sensing observations if the probes are mounted on the same aircraft because measurements of the same location in the cloud cannot be performed by both systems at the same time. Remote-sensing instruments such as microwave radiometers (Chap. 41) and lidars (Chap. 38) provide additional information about clouds and precipitation and can be used for synergistic retrievals of microphysical parameters.

This chapter does not discuss the weather radar systems used by commercial and private aircraft to avoid severe weather, even though these systems have occasionally been used for meteorological research. Such systems are poorly suited to providing quantitative measurements, as they are intended for the detection and localization of regions in the atmosphere (such as thunderstorms) that are not suitable for aircraft.

39.1 Measurement Parameters and Principles

The measurement parameters and principles of meteorological radars are described in much more detail in Chaps. 30 and 32 of this Handbook and in other textbooks such as [39.2, 3]. Further details on airborne measurement systems can be found in the book by *Wendisch and Brenguier* on airborne measurements [39.4]; Chap. 9 of that book describes airborne radar and lidar systems in detail [39.5]. Radar techniques are described in depth in [39.6].

39.1.1 Measurement Principles

Radar, an acronym for *radio detection and ranging*, is the technique of detecting a target using the electromagnetic waves reflected from that target. Meteorological

radar systems also use these reflected waves to quantify the target. Typically, a radar system transmits a short electromagnetic pulse towards the target, and the range of the target is evaluated by measuring the transit time of the radar pulse. Provided the direction in which the narrow beam was emitted by the radio antenna is known, the direction of the target can also be estimated (Fig. 39.1).

The power of the backscattered signal depends on the size and number of the targets (i.e., cloud and precipitation particles) within the measurement volume. A number of radar pulses are typically averaged to get a more stable signal from the randomly distributed targets within the measurement volume. If the radar is coherent (which can be achieved through various techniques), it is possible to estimate the Doppler shift of the backscattered signal. This allows the motion of the particles relative to the radar beam to be estimated. The design of the antenna and its components determine the polarization plane of the transmitted and received pulses. Different techniques allow the target to be measured using different polarizations of the electromagnetic wave. Since the backscattered signal of a target can differ for different polarized waves, target classification is possible.

39.1.2 Measured Parameters

A number of radar parameters are measured by airborne radars. Typical measured parameters are summarized in Table 39.1, and are described in more detail in the following sections.

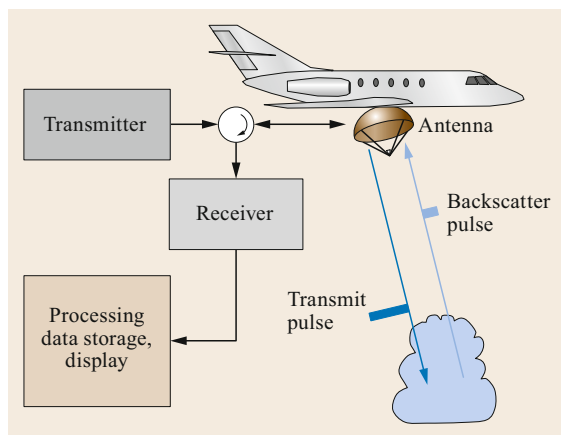

Fig. 39.1 Measurement principle of radar

Table 39.1 Parameters measured by airborne radars (note that some radar systems cannot measure all of the parameters shown)

Parameter	Description	Unit	Symbol
Reflectivity	Backscatter signal	$\text{mm}^6 \text{m}^{-3}$	z
	Logarithm of the backscatter signal	dBz	Z
Doppler velocity	Radial velocity of particles	m s^{-1}	V or v_r
Spectral width	Width of the Doppler spectrum	m s^{-1}	W or σ_v
Linear depolarization ratio	Ratio of the copolar and crosspolar backscatter signals	dB	LDR

Radar Reflectivity Factor

Radar reflectivity is a synonym for the magnitude of the reflected radar pulse. The relationship between the received signal P_r and the scattering cross-section σ of the target is given by the radar equation for volume targets,

$$P_r = \frac{P_t g^2 \lambda^2}{64 \pi^3 r^4} \frac{\pi r^2 \theta_0^2 h}{8} \frac{1}{2 \ln(2)} \sum_{i=1}^n \sigma_i, \quad (39.1)$$

where P_t is the transmitted power, g is the antenna gain, λ is the wavelength, θ_0 is the beamwidth, h is the pulse length, r is the distance to the targets, and σ_i is the scattering cross-section of the targets within the measurement volume. It is assumed that the measurement volume is uniformly filled with scattering targets. The first term of the equation is the radar equation for a single-point target, the second gives the measurement volume, and the third term accounts for the fact that only part of the transmitted power is within the measurement volume bounded by the half-power beamwidth θ_0 .

For particles that are large compared to the wavelength (diameter $D > 10\lambda$), the scattering cross-section σ of the target is given by its geometric cross-section. For particles that are much smaller than the wavelength ($D < 1/10\lambda$), the scattering cross-section can be approximated by Rayleigh scattering, i.e.,

$$\sigma = \frac{\pi^5}{\lambda^4} |K|^2 D^6, \quad (39.2)$$

where $K = (m^2 - 1)/(m^2 + 2)$ represents the complex refractive index m of the scattering particle ($|K|^2 \approx 0.93$ for water and $|K|^2 \approx 0.2$ for ice). Note that the value of $|K|^2$ for water is dependent on the temperature and frequency. Assuming that the targets are water particles that are much smaller than the wavelength, the radar reflectivity factor z is defined as the sum of D^6 for all particles within the unit volume V ,

$$z = \frac{1}{V} \sum_{i=1}^n D_i^6. \quad (39.3)$$

The unit of z is $\text{mm}^6 \text{m}^{-3}$. It is common in radar meteorology to express the reflectivity factor as a logarithmic ratio with respect to the reflectivity factor ($z = 1 \text{ mm}^6 \text{m}^{-3}$) of a single water sphere with a diameter of 1 mm per unit volume,

$$Z = 10 \log_{10} \left(\frac{z}{1 \text{ mm}^6 \text{m}^{-3}} \right). \quad (39.4)$$

The unit of the logarithmic quantity Z is dBz (decibel z). Informally, but also in a large number of publications, the term *reflectivity* is used instead of reflectivity factor. This should not be confused with the wavelength-dependent reflectivity η , defined as the sum of the scattering cross-sections (39.7), which must account for Mie scattering in the case of a cloud radar.

Doppler Velocity and Spectral Width

If there is relative motion with velocity v between the radar and the target, a frequency shift of the reflected wave is observed by the radar. This frequency shift is given by

$$f_D = \pm \frac{2v}{\lambda}, \quad (39.5)$$

as the Doppler effect occurs twice: once on the way to the target and once on the way back to the radar.

Even though a radar cannot measure the frequency shift directly (it actually measures phase differences between subsequent pulses), the term *Doppler velocity* or radial velocity is widely used in radar meteorology, whereas scientists working on lidar systems prefer the term *line-of-sight component* (or *velocity*). Only motion towards or away from the radar (the radial or line-of-sight component) can be detected based on the Doppler effect. If the target moves perpendicular to the radar beam, no Doppler effect is visible.

The standard deviation of the phase measurements is termed the spectral width since it describes the width of the Doppler velocity spectrum. The spectral width is a measure of the turbulence within the measurement volume or—in the case of a radar viewing vertically—a measure of the diversity in the fall speeds of different particle types and sizes.

Fig. 39.2 Example of a measured Doppler spectrum (blue line). The gray area indicates the noise level, the green area above the noise level is the signal-to-noise power, the red line is the mean Doppler velocity, and the line with black arrows indicates the spectral width

Doppler Spectrum

Besides using the technique described above, the phase measurements can be transferred by a Fourier transform into the frequency domain. Frequency is equivalent to Doppler velocity in this case; see (39.5). The Doppler spectrum gives the backscatter power or reflectivity for each Doppler velocity bin. Figure 39.2 shows an example of a Doppler spectrum from a vertically pointing ground-based cloud radar. The green area is the signal-to-noise ratio (SNR) after the noise has been subtracted. Noise levels can be estimated using the Hildebrand and

Sekhon algorithm [39.7]. The reflectivity can be estimated from the SNR using the radar equation. The mean Doppler velocity is the first moment of the spectrum, which is indicated by the red vertical line in Fig. 39.2. The horizontal line with arrows indicates the estimated spectral width (the second moment of the spectrum).

Linear Depolarization Ratio

The linear depolarization ratio (LDR) describes how much of the energy of the transmitted polarized wave is scattered back in the orthogonal crosspolar scattering plane (Sect. 39.3.6). It is given by

$$\text{LDR} = 10 \log \left(\frac{z_{\text{cx}}}{z_{\text{co}}} \right), \quad (39.6)$$

where z_{cx} is the reflectivity factor (in $\text{mm}^6 \text{m}^{-3}$) for the crosspolar backscatter signal when a signal with copolar polarization z_{co} is transmitted. The unit of the LDR is dB. Depolarization is caused by irregularly shaped particles that are canted or that tumble or rotate heavily while falling. These are often particles that are coated in water, such as melting snowflakes, wet graupel, or hail. The LDR is about -35 dB for weak rain, -25 dB for graupel, and -15 dB or higher for melting hail, meaning that the LDR can be used to identify hydrometeors. The LDR is also a good indicator of ground clutter returns. The lower limit of the LDR is given by technical constraints such as the isolation between the two receiver channels and the purity of the antenna shape and feed horn.

39.2 History

In the late 1960s and early 1970s, several groups discussed the need for aircraft equipped with weather radar systems as well as the technical feasibility of installing such systems on aircraft. An airborne radar investigation of Hurricane Debbie was performed in 1969 [39.8], and the installation of meteorological Doppler radars on aircraft was proposed in [39.9]. Although the main aim of these systems was to probe the motion of particles at vertical incidence, it was also proposed that they could be used to measure the horizontal wind field of a storm. At that time, radars used long wavelengths (3 or 10 cm) to study precipitation processes. During the Battan Memorial and 40th Anniversary Radar Meteorology Conference in 1987, airborne cloud radars were proposed and discussed by several groups [39.10, 11]. These discussions led to the development of the Wyoming Cloud Radar and ELDORA.

39.2.1 The Wyoming Cloud Radar (WCR)

The WCR was developed as a collaboration between the University of Wyoming (UW) Department of Atmospheric Science and the University of Massachusetts Microwave Remote Sensing Laboratory (MIRSL). Development work commenced in 1989. After some ground-based tests at the UW Elk Mountain Observatory, the MIRSL W-band radar was mounted on the University of Wyoming King Air Research aircraft (UWKA) in October 1992, leading to the first cloud measurements performed with airborne radar [39.12, 13]. By June 1995, the first version of the WCR was built by Quadrant Engineering (now ProSensing Inc.) and installed on the UWKA. It was a fully polarimetric radar with Doppler capabilities that utilized a single dual-polarization antenna oriented horizon-

Fig. 39.3a,b Illustration of the ELDORA sampling strategy and geometry. The fore and aft beams swept out conical helices (a). These helices provided two separate viewing angles for locations within the echo as the aircraft flew by, illustrated in (b)

tally and laterally with respect to the aircraft track or that vertically profiled the atmosphere above the aircraft. The WCR was first deployed in the Small Cumulus Microphysics Study (SCMS) in 1995 [39.14, 15]. Since then, the WCR has undergone several major upgrades and now has the capabilities described in Sect. 39.4. The WCR has participated in numerous field campaigns that have studied marine clouds and precipitation, ice clouds, cumulus clouds, convection initiations, and many more phenomena, allowing the collection of unique high-resolution cloud microphysics and cloud dynamics data.

39.2.2 ELDORA

The Electra Doppler Radar (ELDORA) was an X-band, dual-beam, airborne research radar that was operated by the National Center for Atmospheric Research (NCAR) Atmospheric Technology Division (ATD, now EOL) as a National Science Foundation Lower Atmospheric Observing Facility. ELDORA made groundbreaking observations of high-societal-impact weather, including severe thunderstorms, tornadoes, and hurricanes [39.16]. The radar was mounted on the tail of an aircraft. One of its two beams pointed about 16° forward of vertical; the other pointed about 16° aft (Fig. 39.3a). The two beams were produced by two flat-plate, slotted-waveguide antennas that were mounted back-to-back. These antennas were then rotated along the longitudinal axis of the aircraft to sweep out two conical helices. This configuration permitted two viewing angles of the same location within the echo of interest as the aircraft passed by (Fig. 39.3b), enabling two-dimensional (2-D) and three-dimensional (3-D) wind retrievals (Sect. 39.3.5). The antennas were scanned very quickly (about 24 revolutions per minute, RPM)

in order to sample the atmosphere with the required resolution. Such rapid scanning, however, necessitated the use of advanced waveforms to acquire a sufficient number of independent samples to achieve the required Doppler velocity accuracy ($< 1 \text{ m s}^{-1}$). The approach taken for ELDORA was a four-element stepped chirp, with each element distinguished by discrete shifts in transmit frequency. This enabled the received signals to be processed individually by separate radar receivers, increasing the number of independent samples and thus improving the sampling statistics of the radar measurements.

The ELDORA research radar was designed based on input from the user community via workshops, town halls, and surveys. The development was a joint effort between NCAR and France's Centre de Recherches en Physique de l'Environnement Terrestre et Planétaire (CRPE). The radar was first deployed in Toga Core in 1993 on the NCAR Electra aircraft [39.17]. After the Electra was retired in 2000, the radar was moved to the NRL P-3. ELDORA supported nine major field campaigns between 1993 and 2008, resulting in more than 145 publications.

39.2.3 NASA High-Altitude Radars (EDOP, CRS, HIWRAP, EXRAD)

NASA has conducted radar measurements from high-altitude (18–20 km) aircraft since the early 1990s to address various scientific questions and to provide simulators for satellite missions such as CloudSat and Global Precipitation Measurement (GPM). Several radars that operate at different frequencies with both fixed-nadir and scanning beams have been developed. The primary aircraft used have been the ER-2, WB-57, and the Global Hawk Unmanned Aerial System, all of which

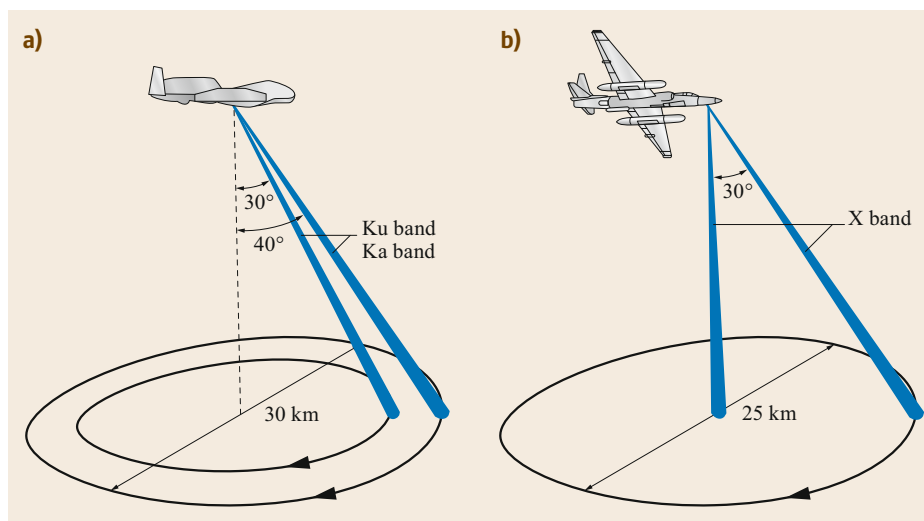

Fig. 39.4a,b
Illustration of
(a) the HIWRAP
and (b) EXRAD
conical sampling
strategies

are capable of altitudes of > 18 km. These aircraft have flight durations of 8, 6, and 26 h, respectively.

The X-band ER-2 Doppler Radar (EDOP, 9.6 GHz) was developed to study severe deep convection, but its emphasis rapidly shifted to tropical precipitation after the launch of the Tropical Rainfall Measuring Mission (TRMM) satellite [39.18]. EDOP has two fixed beams, one at nadir and the other 30° forward of nadir, to provide data on horizontal (along-track) and vertical winds below the aircraft. The first EDOP flights occurred in 1993, and subsequent flights until 2007 were field experiments with a particular focus on tropical convection and hurricanes [39.19].

Development on the W-band (94 GHz) Cloud Radar System (CRS) for cloud measurements was initiated in 1991. CRS first flew in 2001 [39.20, 21]. In combination with X-band measurements from EDOP, CRS provides information on snow and rain properties from dual-frequency retrievals [39.22, 23].

The High-Altitude Imaging Wind and Rain Airborne Profiler (HIWRAP) is a conical-scanning, dual-beam (30° and 40° off-nadir), Ku- and Ka-band (≈ 13.5

and 35.5 GHz) radar that was developed for long-duration, high-altitude operation on the NASA Global Hawk unmanned aircraft [39.24]. HIWRAP provides wind measurements within hurricane precipitation regions as well as ocean surface winds from ocean scatterometry. The scan geometry is shown in Fig. 39.4. The conical scans provide Doppler velocities from both the Ku and Ka bands at two incidence angles and from multiple azimuth angles (forward- and backward-looking as the aircraft flies over the region), from which the three components of the wind are retrieved [39.25].

The ER-2 X-Band Radar (EXRAD) is a new scanning and nadir-pointing radar that is intended to replace the EDOP system. EXRAD has a single conical/cross-track scanning beam and a dedicated nadir beam to provide the versatility needed to study all types of deep precipitation systems. The X-band conical scanning beam provides similar information to HIWRAP at the Ku band, but with less attenuation from hydrometeors. The nadir beam provides high-resolution measurements of vertical hydrometeor motions similar to those provided by the retired EDOP radar.

39.3 Theory

The basic principle of radar and the theory behind it are described in Sect. 39.1.2 and Chaps. 30 and 32 of this Handbook as well as in other relevant textbooks listed above. For completeness, some points that are relevant to airborne systems will be discussed in the following sections.

39.3.1 Radar Principle

Meteorological radars are typically pulsed systems that transmit a short (on the order of $0.1\text{--}2\ \mu\text{s}$) electromagnetic pulse using a high-power (kW to MW) transmitter such as a magnetron or klystron or a less power-

Table 39.2 Frequency bands used for airborne meteorological radars

Band	Frequency (GHz)	Wavelength (cm)	Antenna diameter for a 0.6° beam (m)	Remarks
C	5.2–5.7	5.2–5.7	6.4	Sect. 39.9.1
X	9.3–9.5	3.1–3.2	3.6	
Ku	13.6–13.8	2.2	2.6	Also used by meteorological satellites such as TRMM, GPM, CloudSat, and EarthCARE
Ka	35.2–35.5	0.8	1.0	
W	94–95	0.3	0.4	

ful (10–100 W) solid-state transmitter. Short pulses allow for high spatial resolution along the range; on the other hand, a short pulse contains less power than a long one. Since meteorological scatterers are distributed randomly, the backscatter signal is stochastic, so it is necessary to average over a number of independent pulses to achieve stable and representative measurements. A relevant factor in this context is the pulse repetition frequency (PRF). A high PRF enables frequent measurements and short observation times, which are important considering that airborne systems fly at high speeds. A high PRF is also necessary for a high Nyquist velocity and for high spectral resolution of the Doppler velocity. On the other hand, the PRF is limited by the duty cycle of the transmitter and the maximum range of unambiguous radar measurements. The duty cycle is the proportion of the time that the transmitter can transmit within a given time interval, and is typically on the order of 1 : 100 to 1 : 1000 for tube transmitters and up to 1 : 10 for solid-state transmitters. A PRF of 5000 Hz limits the unambiguous range to 30 km.

A few radar systems use frequency-modulated continuous wave (FMCW) technology. In such systems, the transmit frequency is modulated by several MHz in a sawtoothed manner. This is advantageous because it only requires low power. However, some complexity arises from the unambiguous frequency shift due to the Doppler velocity and ranging. Hard targets such as ground echoes for airborne systems are spread over several range bins for a FMCW radar.

While the depth of the measurement volume of a pulsed radar is given by the pulse duration, the width of the measurement volume is given by the beamwidth or the half-power width of the antenna. The beamwidth is defined as the angular difference between the half-power (–3 dB) points on the main lobe. For a radar, the beamwidth is on the order of 0.2°–3°. A narrow beam (pencil beam) gives high spatial resolution but requires large antennas. A beamwidth of 0.6° gives a spatial resolution of 50 m at a range of 5 km, or 100 m at 10 km. See later sections for a discussion of the influence of wavelength on the beamwidth and constraints on airborne systems. For example, a W-band ($\lambda \approx 0.3$ cm) cloud radar with a 50 cm antenna has a beamwidth of about 0.5°. Side lobes are not generally relevant,

although they must be considered for airborne radars when the side lobe for a tilted beam hits the ground before the main lobe. In this case, the measurements from the main lobe will be contaminated by side-lobe echoes. Multiple scattering effects (see below) are relevant for a wide beam. Due to the large measurement volume of a wide beam, the measurement range should be limited to close to the aircraft.

39.3.2 Wavelength Selection

Various frequency bands are assigned for use by meteorological radars. Table 39.2 gives some characteristics of the bands used for airborne radars. For further detailed discussion of millimeter (mm) waves, see also Chap. 32. The utilization of bands with higher frequencies, such as the G band (≈ 200 GHz), to observe small ice particles is also under discussion [39.26]. Constraints due to antenna size and installation on an aircraft are discussed in Sect. 39.5. Table 39.3 gives pros and cons of the different wavelengths.

Backscatter and Attenuation

Centimeter waves are used to observe precipitation particles, while mm waves are used to observe cloud particles. The backscatter signal (39.1) or reflectivity

$$\eta = \frac{\pi^5}{\lambda^4} |K|^2 \sum_{\text{Vol}} \sigma_i^6 \quad (39.7)$$

is inversely proportional to the wavelength. This indicates that less transmit power is needed to receive a signal above the noise floor for short wavelengths, so mm waves are more suitable for the observation of small cloud droplets and ice crystals. On the other hand, shorter wavelengths suffer from greater attenuation by precipitation and the atmosphere (oxygen and water vapor).

The scattering cross-section depends on the ratio of the wavelength to particle size. If the particles are small compared to the wavelength, the Rayleigh approximation $\sigma \approx D^6$ can be assumed. If the particle size is similar to the wavelength, Mie resonance makes a significant contribution to the backscatter signal. Mie computations for water spheres are shown in Fig. 39.5. Especially for the Ka and W bands, strong Mie effects are visible with rain, complicating the process of esti-

Table 39.3 Some pros and cons of different radar wavelengths

Frequency band, frequency, wavelength	Pros	Cons

mating the rain rate or other microphysical properties from the reflectivity. For shorter wavelengths, the particle shape should also be considered in simulations, necessitating more complex algorithms.

Multiple Scattering

One effect that is often discussed in the context of spaceborne cloud radars is multiple scattering [39.28, 29]. This can be neglected for precipitation radars with centimeter (cm) wavelengths (S band to X band) and a narrow beam. The effects are even considered to be

small for the Ka band (e.g., the GPM satellite). In the Rayleigh scattering regime, lateral scattering will occur. If a narrow beam is used, it is quite unlikely that the laterally scattered signal will reach the radar via multiple scattering. For larger particles or short wavelengths, Mie forward scattering dominates, so the scattered signal will stay within the beam and will therefore be received by the radar. This effect is mainly visible for lidar systems. For radar systems, multiple scattering at mm waves occurs mainly in regions with strong attenuation. Strong forward scattering reduces

the visible effects of attenuation, such that the attenuation appears to be relatively low. The presence of irregularly shaped ice particles can enhance multiple scattering. In general, multiple scattering is expected for spaceborne systems with large footprints, but it is generally negligible for airborne systems with narrow beamwidths [39.29]. Data from airborne radars emitting in the W- to Ku-band region have recently shown that multiple scattering can be a serious problem in deep convective hailstorms [39.30]. It was found that the LDR (if available) can be used to identify regions with multiple scattering [39.29].

Multiple Wavelengths

The different scattering and attenuation behaviors observed for different particle sizes and shapes at different radar frequencies can be utilized in multiple-wavelength systems. This is common for atmospheric radiation measurement (ARM) sites [39.31], but also for spaceborne applications such as the GPM satellite [39.32, 33]. GPM uses a combination of the Ku and Ka bands to improve rain rate estimation. As will be shown in Sect. 39.4.5, airborne combinations are also available. A number of coordinated flights of the HAMP (HALO Microwave Package; Ka band; Sect. 39.4.4) and RASTA (Radar System Airborne; W band; Sect. 39.4.3) radar systems have been performed to investigate the potential of the Ka and W bands. The HIWRAP system uses the Ku and Ka bands, similar to the GPM satellite. HIWRAP has been combined with CRS and EXRAD (Sect. 39.4.5) to provide four frequencies: X, Ku, Ka, and W [39.30].

The power received depends on the wavelength of the radar system due to the backscatter properties of the particles (Rayleigh or Mie scattering) and the two-way attenuation between the radar and the target. For Rayleigh scattering, the backscatter is proportional to D^6 , whereas the attenuation is proportional to D^3 . This property can be used to improve rain rate estimation, as exemplified by the GPM dual-frequency precipitation radar (DPR) system [39.32], for which attenuation due to rain is present at the Ka band but negligible at the Ku band. Because of their complex shapes and densities, retrievals of the microphysical properties of ice particles are based on a number of assumptions. A number of algorithms that use the scattering properties of ice particles at different frequencies to probe their microphysical properties have been proposed [39.34, 35].

39.3.3 Technology

The significant advances made in radar technology in recent years are driving the development of airborne research radars that are smaller, lighter, more power

efficient, and possess enhanced performance. Two advances that have recently had a profound impact on airborne radars are the improved signal processing capabilities facilitated by field-programmable gate arrays (FPGAs) and solid-state power amplifiers (SSPAs). FPGAs and their implementations continue to improve, and they have come to the forefront of radar signal processing. They are well suited to airborne radar processing and enable the use of advanced signal processing algorithms employing complex pulse waveforms. Airborne radar transmitters that use tube-based transmitters such as magnetrons, extended-interaction klystrons (EIKs), and traveling-wave tubes (TWTs) can be problematic on an aircraft as they use high-voltage modulators and only permit low duty cycles (typically up to 5–10%). These modulators are heavy and fairly large in size, require significant input power, and run at very high voltages, which could lead to arcing for some airborne installations. Nevertheless, non-SSPA radars have been used successfully in a number of flight campaigns. On the other hand, SSPAs are well suited to airborne systems. They do not use high voltages, they are small, lightweight, and reliable, and they allow a duty cycle of 100%. While SSPAs have lower output powers than tube systems, they generally make use of their high duty cycle to achieve pulse compression such that the average transmit power of a SSPA-based radar is roughly comparable to that of a high-power radar. Several airborne radars use FPGA and SSPA technologies at frequencies in the Ku- to W-band region [39.24, 36, 37]. SSPA technology continues to improve in terms of both transmit power and power efficiency. The drawback of using pulse compression is that range side lobes are produced, which can bias radar returns around high reflectivity gradients, such as near the surface or within strong convective storms. Range side lobe contamination requires special attention and can be minimized in most cases. In addition, the ability to run a SSPA at a high duty cycle allows new techniques to be explored (Sect. 39.9.2).

39.3.4 Airborne Doppler Measurement

Airborne Doppler radars measure the reflectivity-weighted radial (i.e., along the radar beam direction) Doppler velocity using the same principle as weather Doppler radars on the ground. The main difference is that the radar is installed on a moving platform with a velocity vector that is not necessarily orthogonal to the radar beam-pointing vector (Fig. 39.6). This means that a component of the aircraft motion may be present (in fact, it almost always is present) in airborne radar Doppler measurements.

An airborne Doppler measurement for a given radar resolution volume along the beam can be expressed

Fig. 39.6 Coordinate system relative to the aircraft, and the attitude angles (roll ϕ and pitch θ)

as the scalar product $v_r = \mathbf{b} \cdot (\mathbf{V}_s + \mathbf{V}_p)$, where $\mathbf{b} = (b_x, b_y, b_z)$ is the unit vector of the radar beam-pointing vector

$$|\mathbf{b}| = \sqrt{b_x^2 + b_y^2 + b_z^2} = 1,$$

\mathbf{V}_s is the mean three-dimensional 3-D velocity vector of the scatterers within the radar resolution volume, and $\mathbf{V}_p = (V_{px}, V_{py}, V_{pz})$ is the 3-D velocity vector of the aircraft at the radar antenna. v_r is the reflectivity-weighted mean velocity along the radar beam and relative to the aircraft. All vectors are referenced in their native aircraft coordinate system [39.38]. To retrieve the mean radial velocity of the scatterers in the resolution volume, i.e., $v_s = \mathbf{b} \cdot \mathbf{V}_s$, the aircraft motion contribution $\mathbf{b} \cdot \mathbf{V}_p$ must be removed. Only then can airborne radar Doppler measurements be used to estimate atmospheric winds and/or to study the motions of the scatterers in the atmosphere. Removal of the contribution due to aircraft motion requires the precise determination of the radar beam-pointing vector (Sect. 39.6.2) and the aircraft velocity vector.

A further effect of the moving platform is the broadening of the Doppler spectrum caused by the finite beamwidth of the radar [39.9, 39]. For an antenna pattern with a half-power beamwidth θ_0 in radians, the broadening of the Doppler spectrum can be estimated as $\sigma \approx 0.3V_x\theta_0$, where σ is the spectral width that describes the broadening of the spectrum and V_x is the motion of the platform perpendicular to the beam-pointing vector. In this context, the spectral width represents the uncertainty in the Doppler velocity. For the HALO cloud radar (Sect. 39.4.4) with a beamwidth of 0.6° on an aircraft flying at a typical speed of 210 m s^{-1} , σ is on the order of 0.7 m s^{-1} . The results of simulations are shown in Fig. 39.7. Note that the Mie notch ($v \approx 9.4 \text{ m s}^{-1}$) arising from raindrops 4.4 mm in diameter is smoothed over and cannot be used to estimate the vertical air motion [39.40].

Fig. 39.7 Simulated Doppler spectra for a monodisperse distribution of particles with no fall speed, and raindrop size distributions for a Ka-band radar with a beamwidth of 0.6°

39.3.5 Multi-Doppler Principle

In the multi-Doppler technique, multiple radial Doppler velocities of a volume of atmospheric scatterers are measured at a given location and time from different aspect angles. If three accurate and orthogonal velocity measurements can be made simultaneously, the 3-D mean velocity vector of the scatterers in the resolution volume can be determined in the desired reference frame (e.g., the ground coordinate or storm/cloud-relative coordinate system). In practice, such idealized 3-D measurements cannot be achieved. Constrained multi-Doppler measurements can be performed with an airborne radar from several noncollinear directions by taking advantage of the motion of the aircraft and scanning or fixed-pointing antennas.

The ability to retrieve the 2-D or 3-D velocity field using multi-Doppler measurements has important applications, such as the estimation of 3-D winds, hydrometeor trajectories, hydrometeor fall velocities, cloud kinematics/dynamics, and turbulence [39.42–47].

Fig. 39.8 Dual-Doppler concept: a given scatterer volume is illuminated by two beams separated by a short time interval. V_1 and V_2 are the mean Doppler radial velocities, ϑ_{π} is the cross-plane component (i.e., the unmeasured component of the velocity normal to the plane of the beams), and v_{xp} is the retrieved scatterer velocity in the plane of the beams (after [39.41] © 2006 IEEE)

Depending on the radar antenna configuration employed, multi-Doppler measurements can be acquired in several ways. For a radar with a single non-scanning (fixed) antenna or an antenna scanning normal to the aircraft flight track, various flight patterns that allow the same atmospheric phenomenon to be illuminated from different directions are used (e.g., an L pattern). This approach was used in the early days of airborne weather Doppler radar (e.g., the National Oceanic and Atmospheric Administration (NOAA) P-3 tail radar [39.48, 49]). This leads to large time lags between illuminations of the same atmospheric volume, and is therefore the least accurate approach. Radars that use scanning dual antennas (e.g., ELDORA [39.17]) or fixed multi-antennas (e.g., WCR [39.41, 50] and RASTA [39.51]) collect multi-Doppler data from several antennas that illuminate nearly the same volume but with a slight time lag between them while the aircraft is flying straight and level legs. The time lag is range dependent. For example, if the aircraft speed is 100 m s^{-1} and almost nadir-pointing and a 30° slant-pointing illumination of targets is performed, the time delay is 1.2 and 17.3 s for target ranges of 0.2 and 3 km, respectively.

The most typical application of multi-Doppler measurements is the dual-Doppler technique, which involves measuring radial Doppler velocities from two or more different angles that are usually separated by between 25° and 45° and aligned in a plane (Fig. 39.8).

These measurements then are used to determine the two orthogonal velocity components in the plane of the measurements, thus providing estimates of 2-D hydrometeor motion and the wind (Fig. 39.8). Dual-Doppler measurements can only resolve the 2-D velocity field. In order to determine the 3-D velocity field, additional information in the third dimension is needed. Multiantenna configurations (scanning or fixed) that provide multi-Doppler data in the vertical and horizontal directions can improve the retrieval of the 3-D dynamics [39.42, 51].

All multi-Doppler retrieval techniques involve some uncertainties. For instance, the mean 3-D velocity vector of the hydrometeors in the resolution volume must be stationary longer than the time lag or an error will occur. The magnitude of this error depends on the time lag, the scale of the observations, and the scale of the observed phenomenon, and is difficult to estimate. The uncertainties due to errors in the beam-pointing direction (Sect. 39.6.2), the mismatch between the volumes illuminated by the different beams, errors in the advection scheme, a low signal-to-noise ratio (SNR), and differences in attenuation all affect the accuracy of the retrieval. Note that this is not a complete list of all possible uncertainties. In addition, there are errors specific to the retrieval technique that must be taken into account [39.41]. It is also implicitly assumed that any folding in the Doppler measurements is resolved be-

Fig. 39.9a,b Technical realizations of a dual-polarization radar (TX = transmitter, RX = receiver; *blue* and *red* waves indicate horizontal and vertical polarization, respectively): (a) measurement of copolar and crosspolar signals; (b) measurements at two orthogonal polarization planes using two transmitters or a power splitter

fore a multi-Doppler synthesis of the velocity field is applied. Notwithstanding all possible errors, airborne multi-Doppler retrieval techniques can provide good results with reasonable overall uncertainty [39.41, 42, 50].

39.3.6 Dual Polarization

Most meteorological radars use linearly polarized waves; in other words, the electric field vector and the (orthogonal) magnetic field vector (\mathbf{E} and \mathbf{H} , respectively) remain in the transmitted plane (Chap. 30) [39.3]. The orientation of the polarization is defined by the orientation of \mathbf{E} . The signal received with the same polarization as the transmitted wave is the copolar signal, whereas the signal received by the orthogonal polarization is the crosspolar signal. Different technical realizations are in use (Fig. 39.9). If the crosspolar signal LDR is of interest, one transmitter and two receivers are necessary. More complex realizations are possible for measurements of differential reflectivity and differential phases. The power from a single transmitter can

be split into the two polarization planes (STAR mode: simultaneous transmit and receive); two independent transmitters with similar frequencies can be used; or the power from one transmitter can be fed alternately into the two polarization planes (AHV mode: alternating H and V transmit). The latter mode allows the full backscatter matrix to be measured, whereas the STAR mode measures the principal diagonal only.

Good isolation (> 25 dB) of the crosspolar from the copolar signal is necessary to measure the crosspolar signal. Depolarization is caused by aspherical particles, which present irregular falling behavior. These are irregularly shaped ice particles or any melting ice particles. Cloud droplets and raindrops do not cause depolarization. The LDR values observed with rain are an indicator of the channel isolation. Depolarization cannot be measured using the STAR mode, and depolarization causes crosstalk between the two polarizations. Due to the preferred orientation of falling particles, differential reflectivity or differential phase measurements are preferred in a horizontal or slanting beam orientation.

39.4 Devices and Systems

A wide selection of current (as of the year 2018) systems are described in this section. Note that these are research systems that undergo regular modifications and upgrades.

39.4.1 W-Band Wyoming Cloud Radar (WCR)

The Wyoming Cloud Radar (WCR) is a 95 GHz pulsed Doppler radar. It is designed for installation inside an aircraft cabin and is mount-ready for the University of Wyoming King Air (UWKA) and NCAR/NSF C-130 research aircraft. The transmitter is a klystron-based extended-interaction amplifier (EIA) from CPI that delivers a peak power of up to 1.8 kW and a maximum duty cycle of 3%. The transceiver front end can accommodate up to five antennas. The current configuration used for the UWKA and C130 utilizes two single-polarization antennas and one dual-polarization

antenna (Fig. 39.10a). The two down antennas are aligned in a near-vertical plane for dual-Doppler data acquisition below the aircraft [39.41]. The third antenna points laterally on the starboard side of the UWKA and near to the zenith on the NCAR/NSF C-130. On the UWKA, there is also an external reflector for redirecting the side-pointing beam to near the zenith. Another configuration with four antennas can be used for the UWKA; this employs an additional lateral forward (beam WCR 3 in Fig. 39.10b) pointing antenna for dual-Doppler measurement in a horizontal plane (Fig. 39.10b). The transceiver includes two receiver channels that provide full polarimetric measurement capabilities. The receiver back end utilizes a 16-bit dual-channel digital receiver, and the data system is capable of recording the signal in-phase and quadrature (I&Q) components as well as processing, displaying, and recording the received power, pulse-pair products, and full Doppler spectra in real-time. WCR data are

integrated with the new Ka-Band Precipitation Radar (Sect. 39.4.6), the UWKA's other remote sensors, and its extensive suite of in-situ probes [39.52].

39.4.2 W-Band HIAPER (HCR)

The National Center for Atmospheric Research (NCAR) operates a 95 GHz pulsed, dual-polarization, Doppler research radar on its High-Performance Instrumented Airborne Platform for Environmental Research (HIAPER) Gulfstream V (GV) aircraft [39.53]. The HIAPER Cloud Radar (HCR) operates from an underwing pod, as shown in Fig. 39.11, and uses a single standard instrument rack in the cabin of the GV. The transmitter is an extended-interaction klystron amplifier (EIKA) which, together with the modulator, can

operate at maximum duty cycle of 5%. The lens antenna illuminates the rotating reflector (Fig. 39.11), resulting in a 3 dB beamwidth of 0.68° that is transmitted perpendicular to the longitudinal axis of the pod. The beam can be scanned in the cross-track plane or operated at a constant pointing angle (staring mode) such as the nadir or zenith. In staring mode, the beam is stabilized with respect to changes in platform orientation that occur during flight. This stabilization is accomplished by adjusting the reflector pointing at a rate of 10 Hz using the position measurements of the dedicated inertial navigation system (INS)/Global Positioning System (GPS) unit mounted at the front of the pod. The stabilization keeps the pointing angle within about 0.1° of the requested angle, mitigating errors at vertical incidence from horizontal winds. The HCR data system is capable of recording the full suite of dual-polarization moment data as well as the raw I&Q time series data. The HCR is commonly deployed in conjunction with a high spectral resolution lidar (HSRL) [39.54] that detects aerosols, ice crystals, and cloud droplets, and can determine regions of supercooled liquid water. HCR and HSRL measurements are often complementary and can be used together to characterize clouds, precipitation, and aerosols in much greater detail than is possible with a single instrument (Sect. 39.8.5).

39.4.3 W-Band RASTA

The French research aircraft fleet operated by SAFIRE (Service des Avions Français Instrumentés pour la Recherche en Environnement) can be equipped with a multibeam 95 GHz Doppler radar, RASTA [39.55, 56]. This system was developed by LATMOS (Laboratoire Atmosphères, Milieux, Observations Spatiales), and is flown on the SAFIRE Falcon 20 and ATR 42. It is combined with a HSRL in order to retrieve cloud microphysical properties.

RASTA measures the Doppler velocity and reflectivity at 95 GHz along a radial defined by the pointing direction of the antenna. The RASTA radar includes three downward-looking and three upward-looking beams (nadir, 28° off-nadir and opposite to the direction of travel, 20° off-nadir and perpendicular to the direction of travel, zenith, 25° off-zenith and in the direction of travel, and 20° off-zenith and perpendicular to the direction of travel; see Fig. 39.12). The antennas are installed in the cabin of the aircraft, and the radar beams are directed through bottom and top windows. This unique configuration permits the retrieval of the three-dimensional wind beneath the aircraft by combining the independent Doppler radial velocities from the multibeam antenna system (Sect. 39.3.5). Raw data are

recorded for each beam, allowing radar moments and Doppler spectra to be reprocessed.

Since 2000, RASTA has been flown in a number of campaigns for various scientific missions. An example of a wind field retrieved by RASTA is shown in Sect. 39.8.5.

39.4.4 Ka-Band HALO (HAMP)

The German research aircraft HALO (High Altitude and Long Range Research Aircraft; [39.57])—a modified Gulfstream G550—can be equipped with an ac-

tive and passive microwave package, HAMP [39.58]. HAMP consists of a high-power (30 kW) Ka-band cloud radar (a MIRA35 radar manufactured by METEK GmbH) that is tailored for aircraft integration and five microwave radiometers that operate between 22 and 183 GHz. Together with HAMP, a high spectral resolution lidar for water vapor (WALES; see Chap. 38) is also flown. The radar and radiometers were jointly provided and integrated by the Max Planck Institute for Meteorology, the Meteorological Institute of the University of Hamburg, and the DLR Institute of Atmospheric Physics.

Fig. 39.13 Images showing the installation of the cloud radar antenna, including the clutter fence, lidar window, and microwave radiometers, in the HALO research aircraft belly pod (photos © M. Hagen)

The radar electronics are installed within the aircraft cabin and the radar antenna is mounted beneath the fuselage in the external belly pod (Fig. 39.13). The Cassegrain antenna has a diameter of 1 m, resulting in a beamwidth of 0.6° , and has a clutter fence to minimize lateral scatter and reflections within the belly pod. The antenna is fixed at the fuselage but not to the direction of motion of the aircraft, meaning that the pitch and roll angles of the aircraft must be considered when evaluating the Doppler velocity. During signal processing, Doppler spectra are recorded for both the co- and crosspolar polarizations, and the average reflectivity, Doppler velocity, spectral width, and LDR are available in real time. A recent upgrade of the radar has made in-flight recording of raw I&Q data possible, which can be used for off-line signal processing. A detailed calibration of the radar and a comparison with other radar systems are reported in [39.59].

So far, HAMP has spent about 300 h in the air during four campaigns focusing on the Atlantic trade wind region (out of Barbados) and the North Atlantic (out of Iceland) in 2013, 2014, and 2016 (the Next-Generation Aircraft Remote Sensing for Validation (NARVAL) and North Atlantic Waveguide and Downstream Impact Experiment (NAWDEX)) campaigns [39.60, 61]. Some results are shown in Sect. 39.8.2.

39.4.5 HIWRAP (Ku, Ka), CRS (W), EXRAD (X)

The High-Altitude Radar (HAR) Group at the Goddard Space Flight Center developed the EDOP, CRS, EXRAD, and HIWRAP radars using a variety of commercial and custom parts. These radars require special thermal and high-altitude design considerations since they use high-voltage transmitters and numerous heat-producing components. In addition, these high-altitude radars must be compact and lightweight due to the limited space available on an aircraft, they require turn-key operation, and (more recently) they must allow remote operation and data transmission to the ground using high-speed satellite data links. HIWRAP (Fig. 39.14) is the most advanced of the HAR radars, as it was designed for the NASA Global Hawk, a developmental version of the US Air Force version of the unmanned plane. It has also been flown on NASA's WB-57 high-altitude aircraft with a similar conical scan configuration, and with a fixed nadir beam on the ER-2 aircraft. The HIWRAP hardware uses solid-state transmitters (≈ 40 W at the Ka band and ≈ 90 W at the Ku band) along with pulse compression to improve sensitivity. It employs a FPGA-based processor and a unique transmit waveform with a sequence of 2, 20, and $2\mu\text{s}$ pulses (for returns near the surface and in the blind zone near the aircraft)—where each pulse has a slightly different frequency for

Fig. 39.14a–d Images showing the (a) EDOP in ER-2 nose, (b) EXRAD in ER-2, (c) HIWRAP, and (d) CRS radars (photos © G.M. Heymsfield)

improved isolation—to mitigate range sidelobe contamination associated with pulse compression, which is particularly problematic near the surface for down-looking radars [39.24, 62]. HIWRAP operates with dual PRFs (≈ 4000 and 5000 Hz) to mitigate Doppler aliasing. Calibration is performed using an internal calibration loop on a pulse-to-pulse basis. This accurately accounts for variations in radar stability associated with large environmental temperature changes from the surface to the flight altitude and the fact that SSPA outputs can vary by 1–2 dB due to these temperature changes. Calibration is performed using both the internal calibration loop and the ocean surface, similar to the approaches used by precipitation satellites and airborne radars [39.21, 63]. The weight of HIWRAP on the Global Hawk is ≈ 160 kg due to its heavy scanner mechanism; its weight is only ≈ 100 kg when it is installed on the ER-2.

The current CRS (version 2.0) and the version that is under development (version 3.0) incorporate many of the advances in solid-state transmitter and pulse compression technology used in HIWRAP. It has a single nadir beam and Doppler and polarimetric (LDR) capabilities. CRS version 1.0 [39.21] used an EIK-based transmitter, but it was upgraded in 2014 to utilize a 30 W SSPA-based transmitter and pulse compression, yielding comparable performance to the EIK-based transmitter used in version 1.0 while allowing the size and weight of the system to be reduced by $\approx 50\%$. This version of CRS (2.0) used a custom reflectarray antenna that was a subscale prototype of a dual-wavelength spaceborne radar with W-band nadir and Ka-band electronic scanning [39.64]. However, only the W-band antenna is currently used. CRS version 3.0 will be a complete repackaging of version 2.0 with increased

transmit power (50 W) for better sensitivity, improved calibration (similar to HIWRAP’s calibration loop), and a further size reduction due to the use of a newer FPGA-based compact digital processor. The total weight of CRS version 3.0 will be less than ≈ 70 kg.

EDOP is a conventional Doppler radar that uses a 25 kW TWT-based transmitter [39.18]. It has been replaced with EXRAD (Fig. 39.14), which has two slotted-waveguide antennas with beamwidths of $\approx 3^\circ$, one of which is conically scanned at $\approx 24^\circ \text{ s}^{-1}$ and at an incidence of 30° , while the other performs fixed nadir pointing. It uses a 10 kW TWT-based transmitter that alternates between the two beams, has dual PRFs (≈ 4000 and 5000 Hz) and a pulse width of $2 \mu\text{s}$, and oversamples at 4 MHz . EXRAD has flown in both the ER-2 and the Global Hawk with similar hardware; its weight is ≈ 90 kg.

39.4.6 Ka-Band Precipitation Radar (KPR)

The weight that can be carried by an aircraft and the space and electrical power available on it are always limited. Advances in microwave technology (Sect. 39.3.3), especially in mm-wave range solid-state transmitters, have made it possible to develop compact, lightweight, low-power, but sensitive cloud and precipitation radars [39.37]. ProSensing Inc., in collaboration with the University of Wyoming (UW), developed the Doppler Ka-Band Precipitation Radar (KPR), which is operated from a standard Particle Measuring Systems (PMS) canister [39.36, 65]. Key components of this radar system include an arbitrary transmit pulse waveform generator, a 10 W solid-state power amplifier, and a pair of 14 cm diameter flat-plate slotted-waveguide array antennas for interleaved profiling above and below the aircraft. The KPR is installed on the right wing tip of the UW King Air research aircraft (Fig. 39.15). The specifications of the KPR are listed in Table 39.4. The radio frequency (RF) components and the front end of the receiver are installed in a pod-mounted insert. The total weight of the insert and the canister is less than 20 kg. The power consumption of the unit is about 130 W. A small form-factor computer located in the aircraft cabin houses a 16-bit dual-channel digital receiver and executes radar control, data acquisition, and real-time display software. A miniature GPS-aided inertial measurement unit can be installed in the KPR head cone for more accurate Doppler measurements. The transmitted waveform consists of a linear frequency-modulated long pulse segment followed by an offset-frequency short RF pulse. Pulse compression is used to enhance the sensitivity of the radar to cloud and precipitation at far ranges (the typical maximum range is about 10 km), and the short pulse can be used

to measure precipitation closer to the aircraft (at ranges of 100 m to about 1 km). An additional improvement in sensitivity is achieved by utilizing a high pulse repetition frequency (PRF) of up to 20 kHz, which provides a large number of pulses to average during a typical dwell time of 200 ms. The radar reflectivity factor can

be estimated directly from the received power or from the lag-1 and lag-3 coherent power for optimal detection [39.36].

Sample measurements of reflectivity and Doppler velocity are shown in Fig. 39.16. Note that Doppler velocity has not been corrected for aircraft motion.

39.5 Specifications

It is not possible to provide general specifications for airborne cloud and precipitation radar systems. These radar systems are tailored by the various research groups involved to the aircraft available. The systems presented above as well as other systems listed in [39.4] show great diversity in terms of aircraft integration, technical properties, and signal processing. Table 39.4 provides a summary of the technical properties of the radar systems described in Sect. 39.4.

Various radar configurations are used, depending on the size and type of the aircraft employed as well as

the scientific missions that the radar is anticipated to be utilized for. The space available for the antenna is the most important influence on the selection of the radar wavelength and beamwidth. Wavelength selection is discussed in Sect. 39.3.2. A wide beamwidth and thus a small antenna can be used when the clouds of interest occur close to the aircraft and the aircraft is flying relatively slowly. If the aircraft is flying quickly at high altitude, a narrow beam is needed to achieve high spatial resolution.

39.6 Calibration and Quality Control

In principle, the calibration and quality control of airborne radar systems are similar to those of ground-based radars. However, direct calibration using fixed targets is often not possible. While the sun can be used

as an external reference for the pointing direction of a ground-based radar, a different approach is needed for an airborne system.

39.6.1 Radar Calibration

The power or reflectivity of a cloud radar system is typically calibrated using a budget approach. In this, the gain or loss of system components like transmitter, receiver, waveguides, antenna, and radome are characterized in the laboratory first. All gains and losses are subsequently combined into an overall radar calibration. Furthermore, variable system parameters need to be continuously logged for subsequent drift correction. In addition, an external calibration source should be used to check for systematic errors in this budget approach (e.g., [39.59]).

For ground-based radars equipped with a scanning antenna, trihedral corner reflectors or calibration spheres are established calibration methods for the radar reflectivity [39.66]. In contrast, the radiometric calibration of airborne cloud radar instruments remains a difficult task. Comparing fixed, nadir-pointing cloud radars on aircraft with external calibration sources is almost impossible.

One of the remaining external references is the well-defined ocean surface backscatter [39.21, 63, 67]. For this technique, roll maneuvers of the aircraft are used to measure the normalized radar cross-section (NRCS) of the ocean surface at different incidence angles. Measurements and simulations have shown that the NRCS becomes very stable and almost independent of the wind speed and wind direction for an incidence angle of 10° from the nadir [39.68, 69]. Various airborne cloud radar instruments such as the Ku/Ka-band cloud radar APR-2 [39.69], the W-band cloud radar RASTA [39.70], and the HAMP MIRA35 [39.59] have been successfully calibrated using this technique.

Further calibration verification can be carried out during campaigns when two or more airborne radars observe the same cloud systems. Another possibility is to fly beneath the track of a satellite that carries a cloud radar [39.59].

Note that the Doppler velocity does not need to be calibrated.

39.6.2 Pointing Direction Calibration

For any weather radar, ground or mobile, it is important to precisely determine the direction of the radiation. At a minimum, this allows the returned echo to be correctly assigned to a given frame of reference. For airborne radars, as discussed in Sect. 39.3.4, the direction of the radiation must be known before the contribution of the aircraft's motion to the measured Doppler velocity can be removed. Moreover, a change in the beam-pointing direction affects the magnitudes of the contributions of the vertical and horizontal components of the 3-D

velocity vector of the weather echo (winds and hydrometeor fall velocity) to the radial Doppler measurement. Therefore, accurate knowledge of the radar beam pointing direction is crucial to correctly interpreting the measured Doppler velocity.

Any aircraft frequently changes its attitude during flight. Even under the best meteorological conditions (flying straight and level in clear air with no winds and turbulence), there are small changes in the roll, pitch, and yaw of the aircraft. Aircraft are not perfectly rigid bodies and are prone to mechanical vibrations and airframe distortions. This can affect the mounting and the beam pointing of the radar antenna. It also means that there is always a level of uncertainty in the direction of the beam—at least a small fraction of a degree. A beam-pointing error of 0.1° in the direction of the velocity vector of an aircraft flying at 100 m s^{-1} will affect the Doppler measurement by about 0.2 m s^{-1} . For a vertically pointing airborne radar that measures vertical velocities, a deviation of the beam-pointing vector from vertical will also add a contribution from the horizontal wind [39.71]. Using a stabilized radar platform to maintain a fixed pointing direction helps to counter variations in the attitude of the aircraft, but cannot completely eliminate small deviations. Airborne scanning radars that mechanically or electronically steer the beam have additional beam-pointing uncertainty due to the limited accuracy of scanning angle measurements.

To estimate a beam-pointing vector of an airborne radar in flight in the ground coordinate system at the sampling rate of the radar data, the following measurements must be performed at a rate equal to or higher than the radar data rate:

- Aircraft ground velocity vector
- Aircraft attitude, attitude rate, and position
- Antenna beam-pointing vector.

The first two sets of required measurements are provided by an inertial reference system (IRS), also known as an inertial measurement unit (IMU), which is either used by the aircraft for navigation (an INS) or is specifically dedicated to the radar. The third required measurement is a beam-pointing calibration. All of the measurement components have uncertainties associated with them. Data from global navigation satellite systems (GNSSs) are used to reduce errors in the aircraft position, velocity, and attitude measurements from the IRS. Even modern high-accuracy hybrid IMU/GNSS devices that employ sophisticated Kalman filters suffer from drifts in accuracy during a flight, particularly for yaw. This is due to the fact that the heading measurement is only well measured during lateral accelerations (i.e., turns); it is poorly constrained for straight and

level flight. These yaw errors can also impact pitch and roll. It is therefore recommended that the aircraft should perform turns periodically during flight to constrain the heading measurements and minimize errors due to drift. Detailed information about IRSs and GNSSs can be found in [39.4, Sect. 2.3].

There are techniques that can correct the Doppler data for the aircraft motion contribution and are applicable to scanning radars (ELDORA and the NOAA P-3 tail radar). Variational and optimization procedures that utilize Doppler measurements of the Earth's surface are used to minimize the errors in the antenna-pointing and navigational data [39.72–75]. However, beam-pointing calibration is not performed in advance for these techniques since they are developed to correct errors in the antenna scanning position and the navigational data collected during research flights.

A different approach is to first calibrate the antenna-pointing beam vector at a fixed position by flying prescribed aircraft maneuvers while collecting surface Doppler data. An airborne Doppler return from the Earth's surface is equal to the component of the aircraft velocity vector into the radar beam assuming that the target within the radar resolution volume has zero velocity (see Fig. 39.8; $v_r = \mathbf{b} \cdot (\mathbf{V}_s + \mathbf{V}_p)$ where $\mathbf{V}_s = \mathbf{0}$). Thus, if the aircraft's velocity and attitude at the radar antenna are known, one can solve for the unknown beam-pointing vector \mathbf{b} . A nonlinear least-squares method can be used to minimize the residual velocity of the ground. The result of this procedure is the fixed-position beam-pointing vector in the aircraft coordinate system. Given the presence of random errors in the IMU/GNSS and radar Doppler data, the solution for the beam vector is a probability distribution with a mean value and a standard deviation that represents the uncertainty in the pointing direction [39.38].

The calibrated fixed mean beam-pointing vector and the aircraft's navigational data from a research flight are used to determine the radar data beam-pointing vectors in ground coordinates and correct the Doppler measurements for this flight.

With the advent of inexpensive and highly accurate IMU/GNSS devices, this approach does not typically require corrections for the IMU/GNSS data during a research flight, and is simpler. It can be used for airborne radars with scanning antennas (e.g., the HCR) for which the offset of the scanning beam from its calibrated fixed position is measured and the offset error is small.

This approach to calibration and Doppler correction was used for the WCR on UWKA and the HCR on NCAR/NSF GV aircraft. The results for the WCR on UWKA indicated that there was a root mean square error in the antenna beam-pointing vector of less than

0.03° and a residual error in the corrected Doppler measurements of less than 0.1 m s^{-1} [39.38]. The results for the HCR [39.53] were similarly encouraging. The HCR has a dedicated IMU/GNSS unit with a reported pitch error of 0.06° . Using a calibration based on the method described in [39.38], the antenna pointing bias was found to be smaller than 0.05° . It is important to have well-calibrated pointing angles during radar operation because the HCR employs beam stabilization in the nadir and zenith staring modes in order to reduce the errors in the measured vertical motion from the horizontal wind. The stabilization is accomplished by moving the beam in response to the changes in aircraft attitude reported by the IMU/GNSS, and any pointing bias will cause Doppler measurement errors. A final correction is applied to the nadir-pointing data from the HCR that utilizes the stationary surface echo as a reference [39.76]. This surface-reference correction was shown to result in Doppler velocity errors of less than 0.05 m s^{-1} for data collected during the Nor'easter research flight [39.77].

39.6.3 Quality Control

Quality control for radar systems involves regular calibration of the system and monitoring system performance during measurements or inspecting system-generated log files.

As described above, power measurements can be calibrated either on the ground or when airborne. Some systems are difficult to calibrate on the ground due to technical constraints. Airborne calibration of reflectivity often requires dedicated maneuvers that must be planned in advance during campaigns. In addition to power calibration, it is also important to verify the pointing direction of the radar beam, especially after modifying the mounting of the antenna or the IMU. The pointing direction needs to be verified during special maneuvers or during regular measurement flights. It should always be possible to correct the Doppler velocity of the surface to zero; if it is not, the estimation of the attitude of the aircraft—and thus the radar antenna—is erroneous.

During the flight, or at least before the next flight, all radar parameters (reflectivity, dual-polarization parameters, Doppler velocity) should be inspected for plausibility and related to other observations such as visual impression, satellite images, and lidar or radiometer data.

More quality control can be applied during postprocessing or data evaluation. This includes estimating the noise level or identifying multiple peaks in the Doppler spectrum.

39.7 Maintenance

Unlike radars that are operated continuously (Chap. 30), fixed maintenance intervals are not applicable to airborne radar systems. Due to the high costs of airborne campaigns, it is advisable to perform technical maintenance according to the instructions of the manufacturers of the radar system before each campaign. It will also be necessary to perform calibration, especially if the radar system is removed from the aircraft between campaigns.

39.8 Applications

To demonstrate the potential of airborne radars and their applications, some examples from recent campaigns are discussed in this section.

39.8.1 Cumulus Cloud Observations

The WCR (Sect. 39.4.1) has been used extensively to investigate the microphysical and kinematic structure (and the interplay between these two) within cumulus and cumulus congestus cloud systems. Aspects studied include the development of drizzle within shallow, warm cumulus [39.78], the initial development of ice through primary and secondary mechanisms in marine and continental environments [39.79–81], the detailed kinematic structure of developing cumulus [39.82] (including compelling evidence for toroidal circulations [39.83–85]), and the pulsating nature of cumulus growth with successive thermals, which can act to precondition the environment and promote further convective growth [39.84, 86, 87].

The data shown in Fig. 39.17 demonstrate the powerful synergy between airborne in-situ measurements and high-resolution reflectivity and velocity radar observations in a vertical curtain directly above and below aircraft flight level. In this example (taken from [39.79]), cloud tops are at -8°C , the top of the so-called Hallett–Mossop zone. Slightly elevated LDRs measured by the WCR directly beneath the aircraft (black boxes in Fig. 39.17b) indicate regions of mixed hydrometeor populations, suggesting the presence of graupel. Indeed, observations from particle imaging probes reveal some small ($D \approx 500\ \mu\text{m}$), lightly rimed graupel at the center of the core updraft. The presence of strong downward Doppler velocities in the same region (Fig. 39.17c) suggests the presence of even larger graupel particles that are falling from higher in the cloud through a region with a strong updraft and significant cloud liquid water, while near-zero Doppler velocities indicate a region where graupel particles

are balanced within the updraft. These conditions are expected to be highly conducive to ice production through rime splintering [39.88], and likely account for the high ice concentrations found in relatively warm cumuli.

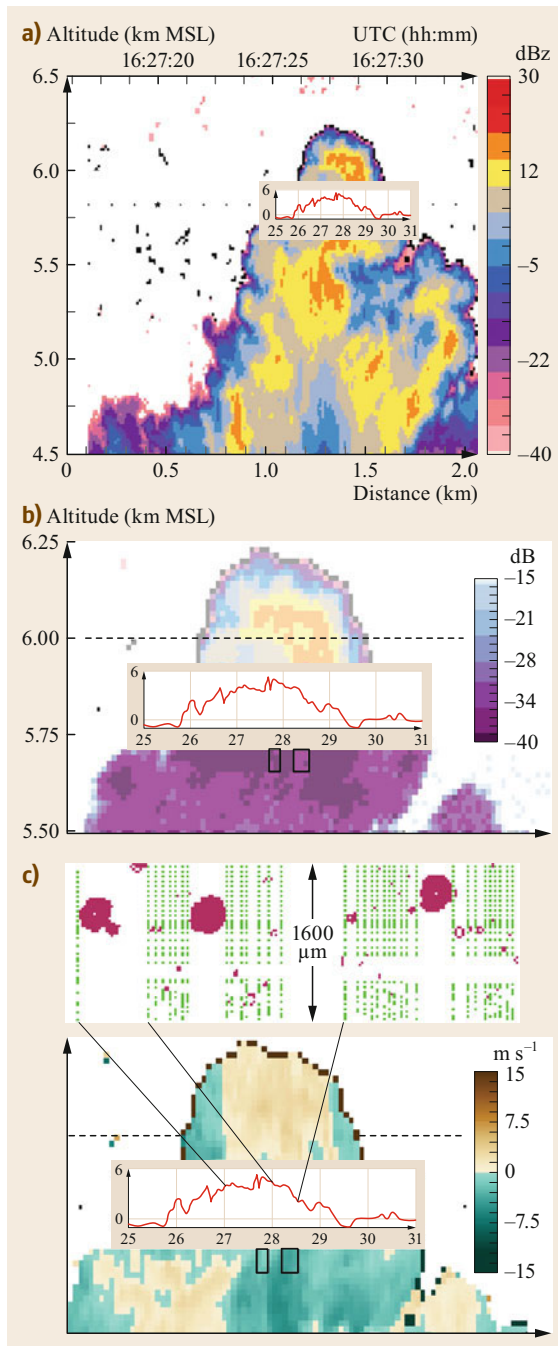

In cases such as that described above, interpretations of the detailed in-situ microphysical measurements from the aircraft are aided by high-resolution radar measurements that provide the context of the cloud. Likewise, interpretations of the radar observations rely on measurements from the aircraft to (in this instance) deconvolve the particle fall velocity from the vertical air motion.

In cases such as that described above, interpretations of the detailed in-situ microphysical measurements from the aircraft are aided by high-resolution radar measurements that provide the context of the cloud. Likewise, interpretations of the radar observations rely on measurements from the aircraft to (in this instance) deconvolve the particle fall velocity from the vertical air motion.

39.8.2 Observations of Synoptic-Scale Frontal Systems

During the NARVAL North campaign in January 2014 [39.60, 89] and the NAWDEX campaign in September and October 2016 [39.61], a number of synoptic-scale frontal cloud and precipitation systems were investigated over the North Atlantic. The HALO aircraft equipped with the HAMP payload (Sect. 39.4.4) was based at Keflavik Airport in Iceland.

Figure 39.18 shows the flight track and the radar observations for a mature extratropical cyclone on 12 January 2014. The occlusion and cold front of the cyclone produced a spiraling convective cloud and precipitation band with partly deep convection. During the 6 h 38 min flight, the band was crossed several times. The flight was performed at FL 270 ($\approx 7900\ \text{m}$ above sea level (ASL)) in order to obtain permission to release dropsondes. The radar operation was started about 40 min after take-off, and the radar was switched off about 15 min prior to landing. The precipitation area of the occlusion was crossed after take-off and before landing. Also, the southern turns were within the spiraling band with deep convection. At about 11:00 UTC, the center of the cyclone was crossed, and low post-

frontal showers were observed at about 13:30 UTC. The aircraft flew through the cirrus clouds of the cold front during the eastern turn at about 14:00 UTC.

Though this was a relatively short flight (other flights lasted for up to 9 h), the long range of HALO facilitates detailed studies of synoptic-scale cloud and precipitation systems. Since the radar is flown together

with the microwave radiometers and the water-vapor lidar, additional information on water vapor, ice, and the liquid water path is available. Dropsondes also provide thermodynamic background information.

Dropsondes also provide thermodynamic background information. **Fig. 39.17a–c** Observations of a cumulus tower that was penetrated near the cloud top at 5.75 km above mean sea level (MSL) ($\approx -6^\circ\text{C}$) during the ICE-T experiment. **(a)** Radar reflectivity from the WCR above and below the aircraft flight level. **(b)** Radar reflectivity above and LDR below the aircraft flight level, and vertical particle velocity above and below. 39.8.3 Deep Convection

The NASA ER-2 with EXRAD (Sect. 39.4.5) flew over intense hailstorms during the Integrated Precipitation and Hydrology Experiment (IPHEX) during 2014. EXRAD provided unique conical scan and nadir-pointing measurements from a group of deep convective storms that propagated across North Carolina into South Carolina and produced up to 5 cm of hail. Measurements from EXRAD's nadir beam, HIWRAP, and CRS are presented in [39.30] and attest to the large ice hydrometeors present in these storms. Figure 39.19 shows horizontal winds derived from EXRAD's conical scan beam during one aircraft pass, obtained using the approach presented in [39.25]. The images show a high-reflectivity (> 60 dBZ) core at the 6 km level, strong low-level inflow from the south-southeast at the 1 km level, and strong divergent outflow above the 6 km level. These images are typical of the swath provided by the conical scan, which was ≈ 25 km wide at the surface and 12.5 km wide at an altitude of 10 km. The conical scan provided reasonably accurate horizontal winds over the swath, but vertical winds were less reliable away from the nadir. When the nadir Doppler velocities (essentially reflectivity-weighted vertical hydrometeor motions) were combined with modest estimates for the hail fall speed, vertical air velocities were estimated to exceed $30\text{--}40$ m s $^{-1}$ in the convective core at the north-west end of this line.

39.8.4 Stratocumulus Observations

Their long ranges and endurance make airborne research platforms with integrated remote and in-situ measurements a critical tool for studying large, remote cloud systems over the world's oceans, including stratocumulus. These cloud systems are important to re-

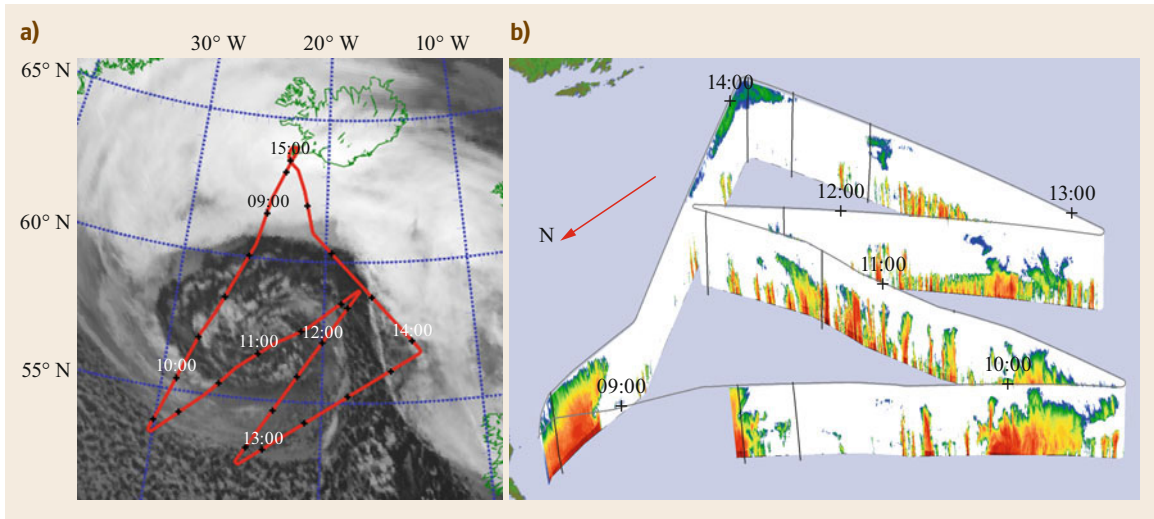

Fig. 39.18a,b Extratropical cyclone on 12 January 2014. **(a)** HALO flight pattern overlaid on a SEVIRI infrared (10.8 μm) satellite image. **(b)** Observations (reflectivity) from a downward-looking cloud radar; vertical black lines indicate the paths of dropsondes (image courtesy of M. Wirth, DLR)

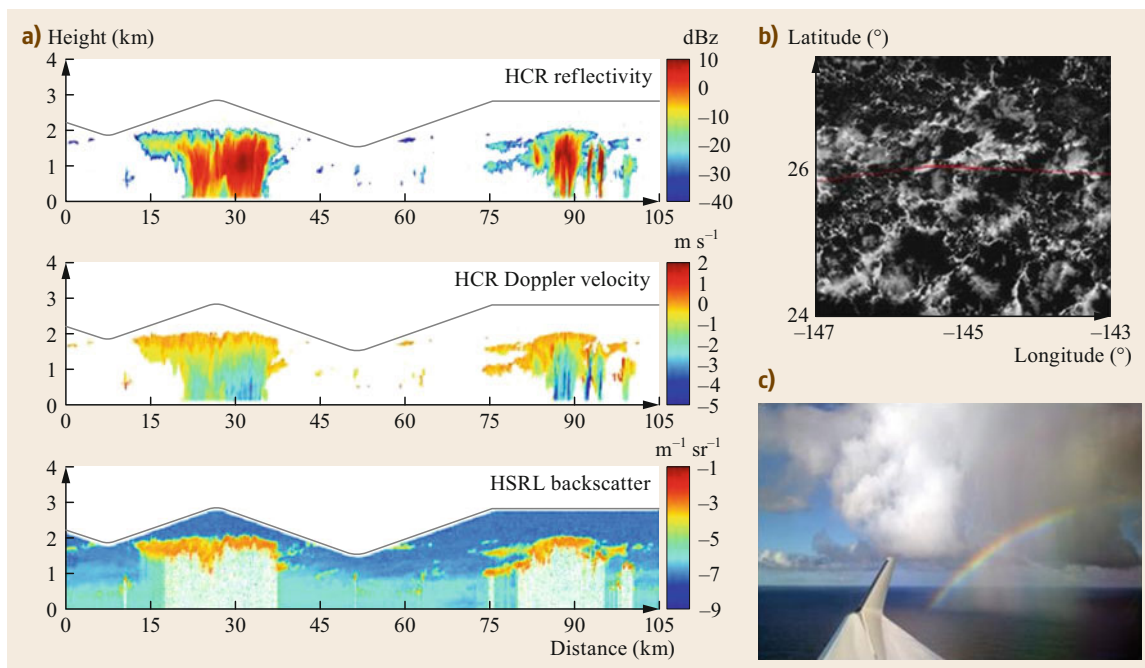

Fig. 39.20a–c Radar and lidar observations from the CSET study. **(a)** HCR and HSRL returns from mesoscale cloud and precipitation complexes observed on 19 July 2015 at 19:10–19:20 UTC. **(b)** A GOES high-definition visible image showing the location of the aircraft near the time of the sampling. **(c)** A photo of drizzle falling from the cumulus and a rainbow that was taken during a 500 ft leg at 18:02 UTC (after [39.90] © 2018 American Meteorological Society (AMS))

gional weather and climate as well as the global climate system, but are often poorly represented by numerical weather and climate models [39.90–94]. Airborne radars are an important component of the measurements that can be used to study these complicated cloud systems.

The NCAR HIAPER Cloud Radar, used in combination with the HSRL and onboard in-situ probes, has been an important tool for studying the microphysics, aerosol interactions, and evolution of large-scale oceanic stratocumulus cloud systems. The Cloud System Evolution in the Trades study (CSET) [39.90], which took place in the summer of 2015, investigated the evolution of boundary-layer aerosol, cloud, and precipitation as well as the thermodynamic structure of stratocumulus clouds in the Pacific Ocean. The associated missions consisted of two legs: a flight from Sacramento (California) to Kona (Hawaii) and the return flight. The outbound flights were planned using the Global Forecast System forecast trajectories to ensure that the return flight could sample the evolution of the same cloud population in a Lagrangian fashion two days later. Each leg included segments above, below, and within the clouds, and the radar and lidar were operated at nadir or were zenith-pointing.

Figure 39.20 shows the synergy of the radar and lidar observations. The radar measures the structures throughout the cloud and precipitation, while the lidar is highly sensitive to the clouds and aerosols but the signal is quickly completely attenuated by liquid clouds. However, as reported in [39.91] (and following [39.95]), the HCR and HSRL were used in combination to retrieve the liquid water content and effective droplet radii in the optically thin veil clouds in the zone of transition from stratocumulus to cumulus during CSET. They found that the veil clouds had few relatively large droplets, making their albedo highly sensitive to changes in concentration.

39.8.5 Wind Field Retrieval in Stratiform Precipitation

The RASTA cloud radar [39.56] is capable of retrieving the 3-D wind field. The three components of the wind field in a vertical plane below and above the aircraft are retrieved using the six-antenna configuration by combining independent measurements of the projected wind on radar radials. This is achieved by using a variational approach [39.96] and a Doppler velocity forward model to iteratively adjust the estimated wind field and

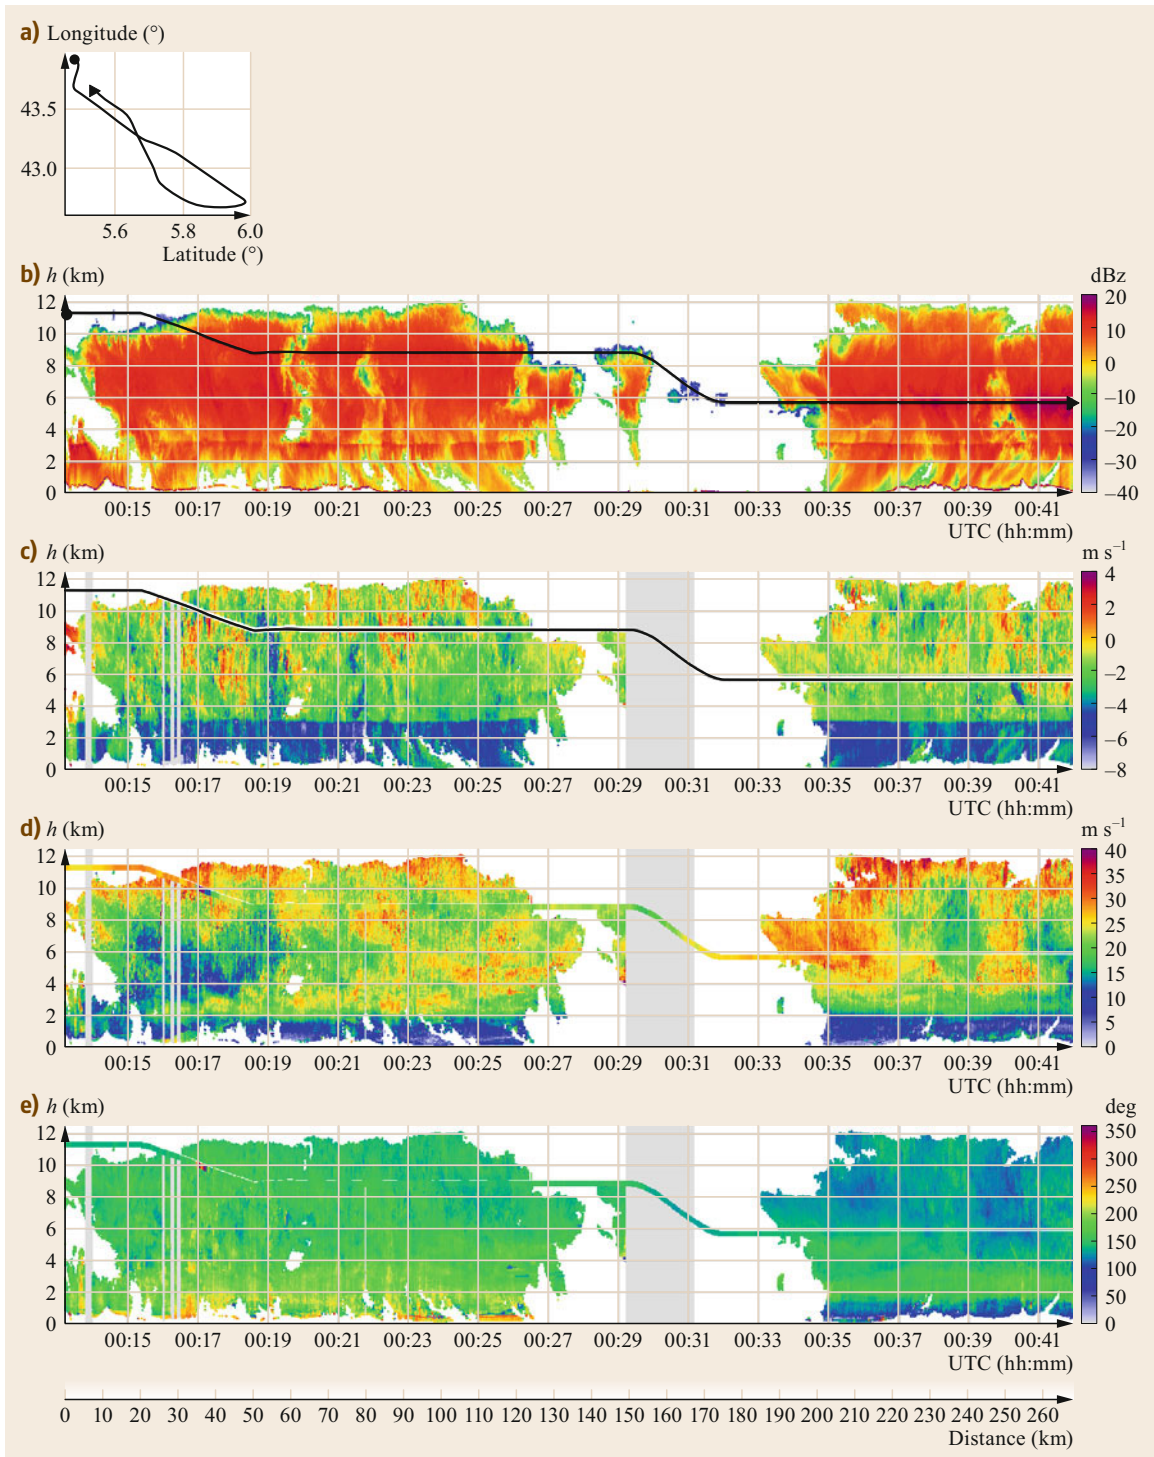

Fig. 39.21a–e Example of airborne multi-Doppler cloud radar retrieval (RASTA) based on a combination of data from three antennas looking down and three antennas looking up during the HYMEX campaign on 21 October 2012 (see the main text for more details): **(a)** The aircraft track, **(b)** nadir and zenith reflectivities, **(c)** retrieved vertical velocity, **(d)** horizontal wind speed, and **(e)** wind direction

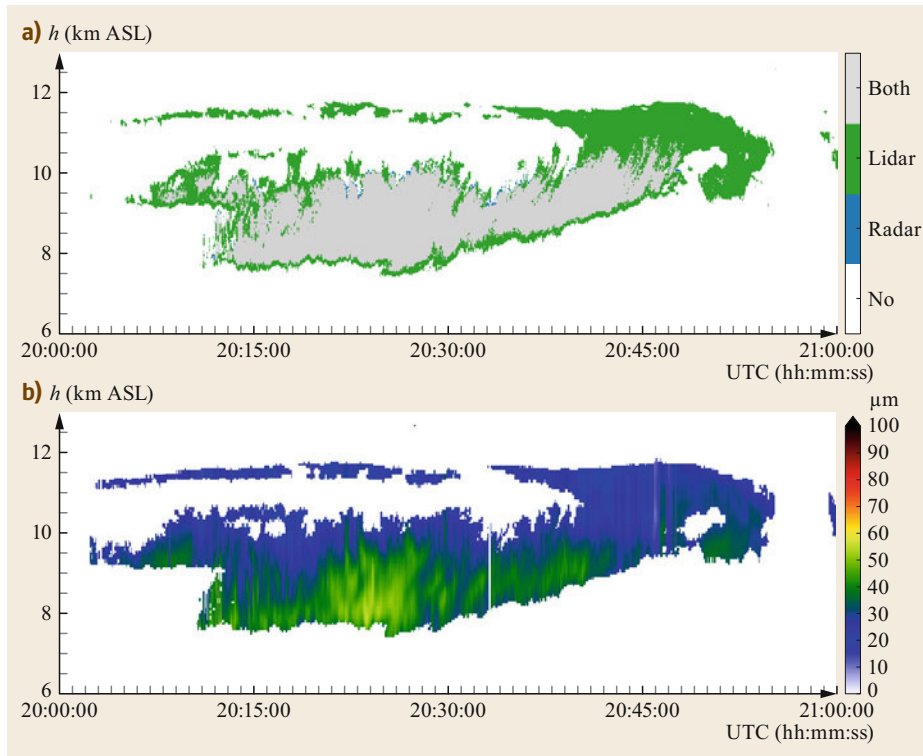

Fig. 39.22a,b

particle fall velocities to the measured Doppler velocities. The six antenna measurements are assimilated to retrieve the vertical velocity (the sum of the terminal fall velocity of the hydrometeors and the vertical air motion) and the along- and cross-track wind speeds, based on precise knowledge of the attitude of the aircraft and the pointing angles. Along- and cross-track wind velocities can be converted into meridional and zonal winds or the horizontal wind speed and direction.

Figure 39.21 shows the wind retrievals derived from measurements collected during the Hydrological Cycle in the Mediterranean Experiment (HyMeX) field campaign [39.51] on 21 October 2012 above the Marseille region in France (the aircraft track is presented in Fig. 39.21a). Nadir and zenith reflectivities are presented in Fig. 39.21b. The blind zone (240 m) was assigned interpolated values of the reflectivity between the upward and downward domains. The retrieved vertical velocity (a combination of the terminal fall velocity of the hydrometeors and the vertical air motion V_z) and the horizontal wind speed and direction are presented in Fig. 39.21c–e respectively. The sharp gradient observed in the vertical velocity is due to the conversion from ice crystals to rain drops, thus highlighting the melting layer. Clear-sky data are excluded and appear white in the panels. Areas where the retrieval cannot be used or where the algorithm does not converge and therefore

leads to unrealistic winds are shown in gray. For instance, the vertical component of the wind cannot be retrieved above and below the aircraft when the aircraft is turning to the right and the left, respectively. The in-situ horizontal wind speed and direction measured by the aircraft at flight level are plotted over the path of the aircraft. This example shows that the retrievals above and below the aircraft are in good agreement.

39.8.6 Synergetic Retrieval of Cloud Microphysics Using Radar and Lidar

Lidar and cloud radar instruments are sensitive to different ice crystal sizes. In order to retrieve profiles of ice cloud microphysics by remote sensing, it is necessary to combine cloud radar and lidar measurements. Since the radar wavelength used is normally larger than the ice crystals, interactions with radar signals can be described by Rayleigh scattering. In contrast, the interaction of ice crystals with laser light that has a much shorter wavelength is described by Mie scattering. This leads to complementary sensitivities: the radar is sensitive to the larger ice crystals in optically thicker regions whereas the lidar provides information on the optically thinner regions found at the top of an ice cloud. These complementary sensitivities are illustrated by the instrument mask shown in Fig. 39.22a for a cirrus cloud

measured by the HALO research aircraft on 16 December 2013 during the NARVAL South campaign [39.89]. Here, the gray-colored cloud region shows the overlap of the radar and lidar measurements, while the green-colored cloud region is solely contributed by the lidar.

When radar and lidar instruments are flown on the same platform, their complementary sensitivities can be exploited to retrieve profiles of ice cloud microphysics.

An optimal estimate approach such as VarCloud [39.97] can be used to combine both sets of measurements. This algorithm starts with assumed climatological profiles of ice cloud microphysics and iteratively tries to converge forward-simulated instrument signals with the actual measured signals. Figure 39.22b shows that the synergistically retrieved ice crystal sizes decrease with height.

39.9 Future Developments

Besides the radar systems mentioned in Sect. 39.4, there are a number of developments that are currently under investigation. Two examples are discussed below.

39.9.1 C130 C-Band Phased Array Radar

At the NCAR Earth Observing Laboratory, a collaborative effort to design and build a new airborne research radar that takes advantage of modern phased-array radar technology is underway. The proposed system consists of four removable active electronically scanned array (AESA) antennas with Doppler and dual-polarimetric capabilities that are operated in the C band from the NCAR C-130 aircraft (Fig. 39.23). The planned 3 dB beamwidth of the four radars is $< 2^\circ$, and their along-track resolution will be approximately 130 m. The peak transmit power will be about 12 kW and the pulse width will range from 0.5 to 40 μ s, resulting in a minimum detectable signal of around -15 dBz at a range of 10 km, depending on the specific operating parameters.

Several airborne research radar strengths could be realized with the airborne phased array radar (APAR) design. C-band radars generally require larger antennas than traditional airborne radars that use shorter

wavelengths. However, the size and robust flight characteristics of the C-130 enable the use of larger antennas, making the C band a feasible choice. Attenuation at the C band is substantially less than that at the X band and shorter wavelengths. For example, attenuation from liquid drops that satisfy the Rayleigh scattering approximation is greater at the X, Ka, and W bands than at the C band by factors of about 3.9, 46.7, and 272.2, respectively. Thus, the C band is highly advantageous for observing the heavy precipitation associated with tropical storms, severe convection, and mesoscale convective complexes, among other phenomena. The electronic beam steering of the proposed APAR antennas enables flexible scanning that can be optimized for the particular phenomena observed and sampling strategies employed. Each of the four panels depicted in Fig. 39.23 will be able to scan fore and aft beams at various elevation angles, enabling dual-Doppler wind estimates (Sect. 39.3.5). Surveillance scanning is also enabled by APAR, which, combined with the nose-cone radar, provides near-complete coverage around the aircraft. The combination of C-band dual-polarimetric scanning with dual-Doppler scanning will provide simultaneous precipitation microphysics and kinematic

Fig. 39.23 APAR scanning geometry and configuration on the NCAR C-130 aircraft. Courtesy of NCAR/EOL

measurements when airborne. This promises to be a powerful tool for studying precipitation and storms in remote regions.

39.9.2 Quadratic Phase Coding with Solid-State Weather Radars

Over the past decade, advances in solid-state technology have led to the development of a new generation of high duty cycle amplifiers (SSPAs) with peak powers that are still less than, but average powers that are comparable to, those of many vacuum tubes. The challenge to radar engineers has been how to utilize this higher duty cycle capacity to match the sensitivity of conventional radars that employ transmitters with similar average powers, lower duty cycles, but much higher peak powers.

The typical method of increasing the operating duty cycle of a radar is to implement some form of pulse compression. FMCW radars can operate at 100% duty and achieve very fine range resolution at all ranges, but they usually require two antennas, which significantly increases the size and complexity of the system. Also, at mm wavelengths, it is difficult to keep narrow beam-width antennas reliably aligned. Another method that is commonly used to increase the operating duty cycle is to transmit a long, frequency-modulated pulse compression waveform. However, the duty cycle of the pulse

compression waveform is typically 5–20%, and it is operated well below the average power capacity of most SSPA-based transmitters, meaning that it is much less sensitive.

One potential technique for dramatically boosting the duty cycles of single-antenna weather radars is quadratic phase coding (QPC) [39.98]. The QPC technique uses the Chu sequence to separate (but not spread) the ambiguous return signals in the spectral domain, so the radar PRF can be on the order of 1000 times higher than is used with conventional radar systems. This high PRF has several advantages, the most significant being that the duty cycle can approach 50%, yielding a sensitivity comparable to that of a continuous-wave radar at all ranges but without the need for two antennas.

ProSensing Inc. developed the QPC technique in 2016–2017 [39.98], and has demonstrated QPC-mode operation at PRFs of up to 3.1 MHz using X-, Ka-, and W-band radar systems running at duty cycles of approximately 45%. When compared to a conventional pulsed radar operating at the same maximum target range, the QPC-coded radar will exhibit much higher sensitivity, with the improvement equal to the ratio of the PRF of the QPC radar to the PRF of the conventional radar. Initial tests indicated a ≈ 20 dB improvement in sensitivity for a QPC-mode radar operating at a PRF of 3.1 MHz as compared to a conventional short-pulse radar operating at a PRF of 10 kHz.

39.10 Further Reading

A thorough introduction to airborne measurements in general is given by:

- Wendisch, M. and Brenquier, J.-L., 2013: *Airborne Measurements for Environmental Research: Methods and Instruments*, Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim, Germany, 655 pp

Of particular interest is Chap. 9 of that book, on lidar and radar measurements:

- J. Pelon, G. Vali, G. Ancellet, G. Ehret, P.H. Flamant, S. Haimov, G. Heymsfield, D. Leon, J.B. Mead, A.L. Pazmany, A. Protat, Z. Wang, M. Wolde: Lidar and radar observations. In: *Airborne Measurements for Environmental Research: Methods and Instruments*, ed. by M. Wendisch, J.-L. Brenguier (Wiley-VCH, Weinheim 2013), Chap. 9, pp. 457–526

Further details on meteorological radars can be found in Chaps. 30 and 32 of this Handbook and in textbooks such as:

Martin Hagen

Institut für Physik der Atmosphäre
Deutsches Zentrum für Luft- und
Raumfahrt e. V. (DLR)
Weßling, Germany
martin.hagen@dlr.de

Dr. Martin Hagen, leader of the Radar Team at the DLR Institute of Atmospheric Physics, has over 25 years of experience in the operation and development of the polarimetric C-band Doppler radar POLDIRAD. His focus is on the development of radar methods that use dual-polarization and Doppler techniques to analyze mesoscale phenomena. He is involved in radar training for meteorological services and teaching at universities at national and European levels.

Julien Delanoë

LATMOS/IPSL, UVSQ Université Paris-Saclay,
Sorbonne Université, CNRS
Guyancourt, France
julien.delanoë@latmos.ipsl.fr

Julien Delanoë is an associate professor in LATMOS (Laboratoire Atmosphères, Milieux, Observations Spatiales) at the University of Versailles Saint-Quentin—Paris Saclay. He received his PhD in remote sensing in 2005. The main focus of his research is cloud and light precipitation mechanisms and observational strategies for studying them. He develops cloud radars and elaborates methodologies for combining radar and lidar.

Scott Ellis

Research Applications Laboratory
National Center for Atmospheric Research
Boulder, USA
sellis@ucar.edu

Scott Ellis is a Project Scientist in the Research Applications Laboratory (National Center for Atmospheric Research, Boulder, CO, USA). He received his PhD in 2010, and his research interests focus on radar data quality and retrievals of physical quantities from airborne and ground-based radar data. Dr. Ellis has participated in over 20 major field campaigns in various roles ranging from science support to principal investigator.

Florian Ewald

Institut für Physik der Atmosphäre
Deutsches Zentrum für Luft- und
Raumfahrt e. V. (DLR)
Weßling, Germany
florian.ewald@dlr.de

Florian Ewald received his PhD in 2016 from Ludwig Maximilian University (LMU) in Munich for his research on cloud remote sensing using passive cloud side measurements. He is currently working as a postdoc at the Institute of Atmospheric Physics of the German Aerospace Center (DLR). His research focuses on the synergistic use of active and passive techniques for the remote sensing of cloud microphysics.

Jeffrey French

Department of Atmospheric Science
University of Wyoming
Laramie, USA
jfrench@uwyo.edu

Jeffrey French is a Professor of Atmospheric Science at the University of Wyoming, USA. He is also Facility Manager for the Wyoming King Air Research Aircraft, a National Science Foundation-funded Lower Atmospheric Observing Facility. He received his PhD in Atmospheric Science from the University of Wyoming in 1998. Dr. French's expertise is in airborne measurements of clouds and precipitation.

Samuel Haimov

Atmospheric Science Department
University of Wyoming
Laramie, USA
haimov@uwyo.edu

Samuel Haimov is Senior Research Scientist at the Atmospheric Science Department, University of Wyoming, USA. He received his PhD in electrical systems engineering in 1982 from Sofia Technical University, Bulgaria. He is a senior member of the IEEE. Dr Haimov's expertise is in signal processing and radars. His current interest is the remote sensing of the atmosphere using millimeter-wave radars.

Gerald Heymsfield

Mesoscale Atmospheric Processes
Laboratory
Goddard Space Flight Center
Greenbelt, USA
gerald.heymsfield@nasa.gov

Gerald Heymsfield is a Senior Research Scientist in the Mesoscale Atmospheric Processes Laboratory at the NASA Goddard Space Flight Center. He has a PhD in meteorology from the University of Oklahoma. He leads the High Altitude Radar Group at Goddard, which has developed several airborne Doppler radar systems and performs scientific studies with their data. His scientific interests include deep convection, hurricanes, and winter storms.

Andrew L. Pazmany

ProSensing Inc.
Amherst, USA
pazmany@prosensing.com

Andrew L. Pazmany is a Senior Engineer and Managing Partner at ProSensing Inc. He received a BS, a MS, and a PhD in electrical and computer engineering from the University of Massachusetts Amherst in 1982, 1986, and 1993, respectively. After graduation, he stayed at UMass as a Research Professor until 2005. His research interests are signal processing and designing and developing novel remote sensing instruments.

Airborne Solar

40. Airborne Solar Radiation Sensors

K. Sebastian Schmidt , Manfred Wendisch , Bruce Kindel 

This chapter gives an overview of airborne radiometry, specifically solar spectral and broadband radiation (irradiance, radiance, actinic flux) measurements and their use for quantifying the radiative effects of atmospheric constituents (clouds, aerosols, gases), photochemistry, and surface properties. Crucially, airborne radiometers establish a link between the properties of atmospheric constituents as retrieved from remote sensing and their radiative impact on weather and climate. The chapter addresses important advances in instrumentation, motivated by challenging problems in radiation science and examines remaining challenges and expected developments.

40.10	Further Readings	1146
	References	1147

Airborne measurements of solar radiation complement ground-based monitoring (Chap. 12) and spaceborne remote sensing of atmospheric constituents (clouds, aerosols, gases) by providing information on atmospheric radiative energetics and photochemistry that is not directly accessible from orbit or from surface stations. Neither irradiance (F , also known as flux density, Table 40.1) nor actinic flux density (F_{act} , also known as mean intensity or mean radiance) can be measured remotely because they are defined via the angular integration of the radiance field at a given point in the atmosphere ([40.1]; Sect. 40.3). A sensor measuring irradiance weights incoming radiance by the cosine of the incidence angle; actinic flux density sensors weight in-

coming radiance isotropically. The distinct advantage of airborne radiometers is that they acquire simultaneous measurements of upward (nadir-viewing) and downward (zenith-viewing) radiative energy flux densities at any level in the troposphere and the lower stratosphere (depending on the aircraft), providing validation for radiative quantities derived from remote-sensing data directly quantifying radiative effects (e.g., absorption and heating rate) of atmospheric constituents. After discussing measurement principles and parameters, theory, and history, this chapter describes the current instrumentation, as well as applications of aircraft solar radiation measurements.

Table 40.1 Radiometric quantities for airborne solar radiation sensors

Name	Symbol	Unit	Relation	Notes
Flux	Φ	W	$\frac{dE}{dt}$	Radiated power (energy/time)
Solid angle	Ω	sr	$d\Omega = \sin(\vartheta)d\vartheta d\varphi$ ϑ : polar angle; φ : azimuth angle	In spherical coordinates
Radiance	L	$\text{W m}^{-2} \text{sr}^{-1}$	$\frac{d\Phi}{dA_{\perp}d\Omega}$	Area \perp beam direction
Downward irradiance	F^{\downarrow}	W m^{-2}	$\int_0^{2\pi} \int_0^{\pi/2} L(\vartheta, \varphi) \cos(\vartheta) d\Omega$	Integration over upper hemisphere
Upward irradiance	F^{\uparrow}	W m^{-2}	$\int_0^{2\pi} \int_{\pi/2}^{\pi} L(\vartheta, \varphi) \cos(\vartheta) d\Omega$	Integration over lower hemisphere
Actinic flux density	F_{act}	W m^{-2}	$\int_0^{2\pi} \int_0^{\pi} L(\vartheta, \varphi) d\Omega$	Also known as mean radiance
Net irradiance	F_{net}	W m^{-2}	$F^{\downarrow} - F^{\uparrow}$	
Albedo	α	–	$\frac{F^{\uparrow}}{F^{\downarrow}}$	

40.1 Measurement Principles and Parameters

Because the measurement parameters and principles for airborne solar radiation sensors are similar to those used on the ground, the reader is referred to Chap. 12 for a detailed description of ground-based instruments. Table 40.1 defines only those quantities that are relevant

to this chapter. For simplicity, only broadband quantities are listed. In this chapter, their spectral equivalent is denoted by a λ subscript (e.g., F_{λ}^{\uparrow} , with units of $\text{W m}^{-2} \text{nm}^{-1}$).

40.2 History

Aircraft solar irradiance measurements began in the 1920s, with pyranometers that had been adapted for airborne use in an ad hoc fashion. Although not specifically designed for flight, they allowed direct observations of parameters driving radiative energetics of atmospheric layers and provided a tool to survey surface albedo (1929 in Germany [40.2]; 1948 in the USA [40.3]—Fig. 40.1; 1951 in the USSR [40.4]; and 1961 in the UK [40.5]). The first flux divergence (absorption) measurements were made in the 1940s and 1950s, with blimps [40.6], tethered balloons [40.7], and stacked aircraft [40.5, 8]. These early studies suggested that the atmosphere might absorb considerably more solar radiation than theoretical estimates, and they proposed absorbing aerosol particles as the likely cause [40.9]. This problem—never fully resolved—motivated a series of new instruments and dedicated

aircraft campaigns. While substantial progress has been made, questions remain.

As in most fields, progress in understanding has required new observational strategies. During the 1969 Barbados Oceanographic and Meteorological Experiment (BOMEX), for example, National Aeronautics and Space Administration's (NASA) CV990 aircraft was instrumented with two pairs of nadir and zenith-viewing pyranometers, of which one was equipped with commercial long-pass filters that had been previously explored for surface observations [40.10]. By separating partial-band (wavelengths less than $0.7 \mu\text{m}$) from broadband solar irradiances in this way, the aerosol signal (largest in the visible range) could be observationally isolated from that of water vapor, which absorbs almost exclusively in the wavelength range greater than $0.7 \mu\text{m}$ [40.11]. Follow-on research, such

Fig. 40.1 Early aircraft irradiance measurement (after [40.3] with permission of the American Meteorological Society)

as the 1972 Global Atmospheric Aerosol and Radiation Study (GAARS [40.12]) used more elaborate filter combinations alongside in-situ aerosol instrumentation and airborne sun photometers for multispectral aerosol optical thickness (AOT) retrievals, which had advanced considerably by the 1970s.

The first solar irradiance spectrometers, developed in the late 1960s for the Soviet Aerosol and Radiation Research Program, capitalized on photomultiplier tubes as detectors. Spectra were acquired in as little as 10 s using motor-controlled dispersion devices in three wavelength ranges simultaneously [40.13]. Spectral absorption measurements during the 1970 Complete Atmospheric Energetics Experiment (CAENEX), conducted with an IL-18 research aircraft in the Karakum desert, revealed the spectral dependence of dust optical thickness and enabled the rigorous separation of gas and particulate contributions to atmospheric absorption in the solar range [40.7].

With the adaptation of pyroelectric detectors for airborne radiation science, broadband and partial-band radiometers with a faster response time relative to traditional thermopiles entered the field [40.14]. This type of device is ideally suited for aircraft measurements because it also mitigates thermal drift and feedback. However, it requires an optical chopper—a moving part that introduces some complexity. The original radiometer was designed to measure upward and downward irradiance with the same sensor by periodically inverting the assembly, thus minimizing the calibration error when deriving net irradiance and subsequently absorption from flux divergence [40.14]. This is important because the absorption is small relative to the quantities from which it is derived (Sect. 40.3, (40.5)).

For fast-response multispectral measurements, silicon photodiodes, combined with narrow-band filters, were used in the *total direct and diffuse radiometer* (TDDR). It measured global (total) and diffuse solar irradiance at several discrete spectral bands (≈ 10 nm full-width half maximum, FWHM) by rotating a shadow band over the detector surface, thereby blocking the direct beam of the Sun periodically for a diffuse sample [40.15]. From the direct irradiance (difference of global and diffuse), the AOT was derived at seven wavelengths ranging from 0.50–1.75 μm , similarly to methods later applied to the surface-based multifilter rotating shadowband radiometer (MFRSR, [40.16]). While not providing the same accuracy as sunphotometers, which determine the direct solar beam attenuation by pointing at the Sun, the TDDR did not require a Sun tracker.

Broadband, partial-band, and multispectral radiometers were combined to make up an instrument package that was specifically optimized for aircraft [40.17]. This package was deployed in aircraft campaigns throughout the 1980s and 1990s [40.15, 18, 19]. During that time, clouds had come into renewed focus as atmospheric absorbers because clear-sky absorption caused by aerosol particles and gases was understood, at least in principle. However, observations beginning with the first flux divergence experiments [40.6] continued to suggest absorption by clouds that exceeded theoretical estimates. Hypothesized explanations for this discrepancy (e.g., absorption by aerosols, unknown gases, or large cloud drops) called for spectrally resolved observations to test them [40.20]. Surprisingly, the first flux divergence flights with a combination of broad-band and partial-band radiometers [40.21, 22] suggested that clouds absorb in the visible (where water does not absorb). To investigate the issue of apparent (also called enhanced or anomalous) cloud absorption, several campaigns were conducted. They largely confirmed the model-measurement discrepancy with a range of instruments, but ruled out absorption by aerosol particles [40.23].

By the end of the 1990s, commercially available compact grating spectrometers with silicon (Si) and indium–gallium–arsenide (InGaAs) linear detector arrays (Sect. 40.4) began to replace multispectral instruments such as TDDR and photomultiplier scanning spectrometers, offering contiguous spectral measurements at fast sampling frequencies (1 Hz) and high signal-to-noise ratio. In photochemical applications, actinic flux density measurements with spectrometers enabled the simultaneous photolysis rate derivation of multiple reactions with varying spectral dependencies of the molecular absorption cross sections and quantum

efficiencies (Sect. 40.3, (40.8)), replacing dedicated filter radiometers for individual reactions that had been common before. Previous to the advent of filter or spectrometer systems for measuring actinic flux, photochemical reactions themselves were used, so-called *actinometers*. These date back to the nineteenth century. The new generation of instruments, first flown around the year 2000 [40.23–28], is still used today.

Subsequent field campaigns gave insights into spectral aerosol particle optical properties and radiative effects throughout various regions of the world (review by [40.29]), informing the NASA A-Train era aerosol satellite retrieval algorithms. These measurements explained apparent cloud absorption as a sampling artefact under inhomogeneous cloud conditions due to net horizontal radiation transport [40.30], and parameterized its spectral dependence [40.31] (Sect. 40.8).

About the same time (early 2000s), actively controlled leveling platforms were introduced [40.24] to counteract aircraft attitude changes in flight. They increased the measurement accuracy and data yield, enabling measurements during vertical aircraft maneuvers

(e.g., spirals) for radiation science [40.32]. Flying actively leveled irradiance spectrometers and actinic flux density spectrometers in tandem gave insights into the enhancement of photochemistry reaction rates in the presence of aerosol particles and clouds (especially near the cloud top: [40.28]).

When paired with airborne imagers, leveled irradiance spectrometers (also called albedometers) proved useful in deriving surface-leaving upwelling radiance from flight level measurements (atmospheric correction) even under partially cloudy conditions [40.33], enabling the remote sensing of ecosystems with frequent cloud cover. They are also increasingly successful in isolating fairly small radiative perturbations in complex scenes with large background variations, for example, aerosol radiative effects above clouds [40.34] or cloud radiative effects over bright snow and ice [40.35, 36]. Recent new instrument developments, such as the Sunshine Pyranometer (SPN-1: [40.37], Sect. 40.4) for simultaneous diffuse and global irradiance measurements will augment existing capabilities and pave the way toward miniaturization and deployment of solar radiation sensors on autonomous airborne vehicles.

40.3 Theory

Airborne radiometers acquire simultaneous measurements of upward (nadir-viewing) and downward (zenith-viewing) radiative energy flux densities within the altitude range of the aircraft at nearly any vertical resolution, providing validation for radiation quantities derived from remote sensing and directly quantifying radiative effects of an atmospheric constituent. An overview of the primary quantities and derived parameters is given in Table 40.1. The flight level albedo

$$\alpha = \frac{F^\uparrow}{F^\downarrow} \quad (40.1)$$

is frequently used to infer surface albedo through atmospheric correction [40.24, 33, 38, 39]. The instantaneous radiative forcing (radiative effect, RE) is defined as the change of the net irradiance

$$F_{\text{net}} = F^\downarrow - F^\uparrow \quad (40.2)$$

in the presence of an atmospheric constituent

$$\text{RE} = F_{\text{net}}^{\text{with constituent}} - F_{\text{net}}^{\text{without constituent}} \quad (40.3)$$

The net irradiance, which quantifies the radiative energy flux density into the atmospheric column below the flight altitude, is directly accessible to airborne

measurements, serving as a starting point for studying radiative effects as a function of scene conditions, such as surface albedo, aerosol or cloud properties, and water vapor concentration.

The absorbed radiative flux per volume (units of W m^{-3}) can be derived from vertical profile flight patterns or collocated flight legs at the top z_{top} and base z_{base} of an atmospheric layer through flux divergence as

$$\frac{d\Phi}{dV} = -\nabla F = -\left(\frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial y} + \frac{\partial F_z}{\partial z}\right), \quad (40.4)$$

if the vertical term $\nabla F_V = \partial F_z / \partial z$, measured as the vertical gradient of net irradiances

$$\nabla F_V \approx \frac{\Delta F_V}{\Delta z} = \frac{F_{\text{net}}^{\text{top}} - F_{\text{net}}^{\text{base}}}{z_{\text{top}} - z_{\text{base}}}, \quad (40.5)$$

is much larger than the combined horizontal terms $\partial F_x / \partial x + \partial F_y / \partial y$ (i.e., $\nabla F_H \ll \nabla F_V$), a condition that is often not met for horizontally inhomogeneous scenes (see Sect. 40.5 and [40.34]). In this case, $\Delta F_V \approx F_{\text{abs}}$ is the absorbed irradiance of the layer, with a corresponding instantaneous heating rate [40.40]

$$\frac{\Delta T}{\Delta t} = \frac{1}{\rho c_p} \frac{\Delta F_V}{\Delta z} = -\frac{g}{c_p} \frac{\Delta F_V}{\Delta p}, \quad (40.6)$$

where the Δp is the pressure differential corresponding to Δz (g , c_p , and ρ are the gravitational acceleration, constant pressure specific heat capacity and density of air). If both absorption and actinic flux density are measured, the layer absorption coefficient k_{abs} (m^{-1}) can be obtained from

$$F_{\text{abs}} = k_{\text{abs}} F_{\text{act}} \Delta z, \quad (40.7)$$

establishing a connection between actinic flux density and absorbed irradiance [40.41]. The primary use of actinic flux density measurements is the determination of photo-dissociation rates (also called photolysis frequencies or simply j -values) as

$$J \left(\text{AB} \xrightarrow{h\nu} \text{A} + \text{B} \right) = \int_0^{\infty} \sigma_{\text{AB}}(\lambda, T, p) \Phi_{\text{AB} \rightarrow \text{A} + \text{B}}(\lambda, T, p) \frac{F_{\text{act}}(\lambda)}{hc/\lambda} d\lambda, \quad (40.8)$$

where

$$\frac{F_{\text{act}}(\lambda)}{hc/\lambda} = \frac{F_{\text{act}}(\lambda)}{h\nu} \quad (40.9)$$

is the photon flux density at a given wavelength or frequency ν (h : Planck constant; c : speed of light). Most reactions with relevance for air quality studies are driven by ultraviolet (UV) and visible radiation, with a distinct wavelength dependence of the absorption cross section σ_{AB} of molecule AB and the reaction's quantum efficiency $\Phi_{\text{AB} \rightarrow \text{A} + \text{B}}$ (both known

from laboratory spectroscopy). In order to determine the photodissociation rates of multiple molecular species, measurements of actinic flux density are now performed with spectrometers. The measurement is challenging due to low signal levels in the ultraviolet wavelength range.

Irradiance measurements are also increasingly performed spectrally because this facilitates the partitioning of observables such as heating rates into contributions from atmospheric constituents. For instance, strong water vapor absorption occurs in distinct bands in the near-infrared spectral range, whereas aerosol absorption decreases smoothly with wavelength, enabling the direct spectral decomposition with few assumptions. At the same time, discrepancies between directly measured and model-derived irradiances can be attributed to errors arising from:

1. Inaccurate model input (cloud, aerosol particles, gas, or surface properties as obtained from remote sensing)
2. Three-dimensional (3-D) radiative transfer effects not captured by most models
3. Measurement artefacts [40.42–44].

In some cases, spectral irradiance measurements are used for remote sensing, for example to determine aerosol-intensive optical properties [40.34, 45]. Despite their versatility for a range of applications as described in Sect. 40.8, spectral instruments cannot replace their broadband counterparts because they usually do not encompass the whole solar wavelength range and tend to be less accurate than broadband radiometers when integrated over wavelength.

40.4 Devices and Subsystems

Airborne radiation measurements impose unique demands on instrument design and function that are not encountered with ground-based operations. They experience an extreme and rapidly varying temperature, pressure, and moisture environment, along with vibrations mostly during takeoff and landing of the aircraft that adversely affects instrument stability, functioning, and signal-to-noise ratio. These circumstances limit the types of instruments that can be deployed on a flying platform. For example, standard sun-tracking shades (Chap. 12) for separating diffuse and global (total) irradiance are impractical, given the aerodynamic drag on externally moving parts and the varying solar geometry. The rapidly changing radiation fields for spatially variable scene types (e.g., broken clouds and hetero-

geneously vegetated surfaces) must be sampled at high frequency, which requires detectors with a fast response time and low inertia or hysteresis.

In atmospheric applications, irradiance is defined with respect to a horizontally aligned surface. Therefore, an irradiance sensor needs to be actively leveled, or correction procedures need to be applied—one of the major difficulties unique to aircraft radiation observations. For sensors that are fix-mounted to the aircraft fuselage, significant measurement errors (especially in downward irradiance measurements) arise under turbulent conditions and changes in aircraft attitude (turns, spirals, etc.) [40.24, 32].

These aircraft-specific errors exceed common sources of uncertainty for ground-based operations,

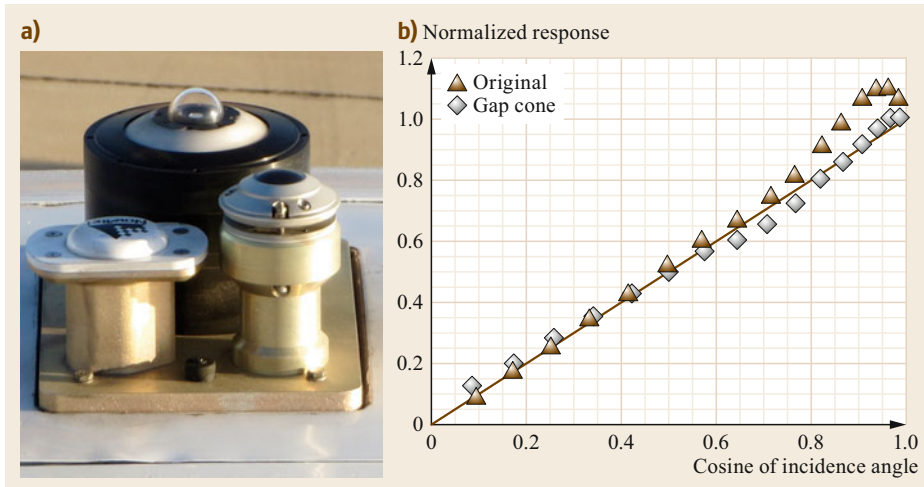

Fig. 40.2 (a) Solar spectral irradiance light collector mounted on a leveling platform (*back*), along with antenna for leveling platform subsystem; pyrometer for thermal irradiance (*front, right*). (b) Angular response of a typical light collector (integrating sphere), normalized by normal incident irradiance, before and after improvements (after [40.46] with permission of B.C. Kindel)

and generally cannot be corrected adequately after the flight. Therefore, it has become common to mount sensors on active leveling platforms, greatly increasing data return and accuracy. Despite such improvements, accurate airborne observations are far more challenging to make than at the surface. Accuracy and precision depend on the specific instrument constellation on the host platform, but often the error budget is dominated by terms that do not factor into fixed installations on the ground. Recent campaigns with radiation science goals have transitioned to redundant or mutually complementary instruments to reduce uncertainty—an approach that has long been standard practice for surface observations.

Here, we only cover non-imaging devices (irradiance and actinic flux density radiometers and spectrometers) that are commonly flown on aircraft, keeping general sensor descriptions at a minimum (details in Chap. 12). Sun photometers are described in Chap. 29.

Figure 40.2a shows a typical irradiance radiometer installation mounted on top of a research aircraft. The pedestal on the right carries a broadband radiometer (in this case, for thermal irradiance) that is fix-mounted to the interface plate and combines the aperture, sensor, and electronics in a single, compact enclosure. Analogue or digitized signals are transmitted by a signal harness to a data logger in the body of the aircraft. For measuring spectrally resolved radiation, the required dispersive devices (usually monolithic grating spectrometers) need to be connected to a light collector, often an integrating sphere, that appropriately weights the incident radiance (Table 40.1) and transmits suffi-

cient signal to the sensors. In most cases, such systems are distributed; the light collector is mounted externally on the aircraft fuselage, the detector (spectrometer) and data acquisition assembly are housed inside the cabin. The light is transmitted from the light collector to the spectrometer with fiber optics. For pressurized aircraft, the optical cable and any signal or power harnesses connecting to externally mounted components have to pass through a pressure seal.

The light collector contained in the black cylinder in Fig. 40.2a (*back*) is mounted on a leveling platform. In this case, the light collector is an integrating sphere. Other subdevices are described below (see Table 40.3 for a summary). The platform includes a GPS (GNSS) antenna (*front, left*) connected to an inertial navigation system (INS) mounted on the underside of the interface plate. Several such systems with various form factors exist [40.24, 32]. Common elements include the INS for accurate determination of the attitude angles of the aircraft (pitch and roll), and a dual-axis tip/tilt stage. No single design works for all aircraft, which have different space, weight, and environmental limitations (altitude range, vibrations, etc.). Leveling platforms are important ancillary systems on aircraft because they actively stabilize light collectors or compact radiometers and keep them horizontally aligned during pitch and roll changes. They are especially useful for radiometers with nonideal angular response (see below). Also, they prevent radiation from the lower hemisphere (for instance, in the presence of clouds) to affect downward irradiance measurements (and vice versa). Design considerations are response time, an-

Table 40.2 Airborne solar radiation sensors—advantages and drawbacks

Sensors	Advantages	Drawbacks
Thermopile pyranometer	Simple, off-the-shelf design; no moving parts	Slow/temperature-induced biases
Pyroelectric radiometers	Fast response time; no thermal inertia issues	Moving parts; not commercially available
Spectrometers	Fast response time; no thermal inertia; allows remote sensing and attribution of radiative effects	Straylight; detector nonlinearities; requires separate light collector; does not cover full solar spectrum

gular range, and system latency. A dedicated INS, mounted in close proximity to the light collector can be costly and impractical because of space requirements. Alternatively, aircraft INS can be used if their signal can be transmitted with a low latency. Since the mechanical components are externally mounted, the enclosure needs to be weatherized. Water vapor condensation often occurs after rapid altitude changes, especially after cold-soaking of metal parts, requiring a desiccant or purge gas mechanism.

Figure 40.2b shows the angular response of an integrating sphere used for spectral solar irradiance radiometers [40.46] with respect to the cosine of the incidence angle ϑ (1: overhead, 0: horizontal radiance). An almost ideal response (a straight line) is typically only achieved by broadband radiometers with a flat receptor area (Chap. 12). Even those do not have an ideal response as the incidence angle exceeds 70° . It is difficult to correct the measured irradiance for a nonideal angular response because it requires knowledge of the radiance distribution. Therefore, the diffuse and direct irradiance are typically corrected separately [40.32], which requires a few assumptions (e.g., isotropy of the diffuse component). Without a leveling platform, it becomes very difficult if not impossible to apply a correction after the fact, especially when clouds are present.

Spectral radiometers require either transmissive diffusers (such as Delrin[®] or flashed opal [40.47]) or integrating spheres made of highly reflective Spectralon[®] or Fluorilon-99W[®] with a circular aperture (Fig. 40.2, [40.46]). Which system is used for a specific application depends on the predominant incidence angles for an aircraft campaign and on the wavelength range of the radiometer. For example, integrating spheres have an almost spectrally flat transmittance over a wide wavelength range, but their optical throughput is low, and they exhibit a *hotspot* close to normal incidence. It can be minimized with modification of the internal baffle guided by optical component modeling [40.46], but the response at steep incidence angles has not been made completely linear with respect to the cosine of the incidence angle (Fig. 40.2b). Transmissive diffusers, on the other hand, usually have a better response at near-normal incidence, but dete-

riorate for shallow incidence angles. Specially shaped surfaces are in use to improve the shallow incidence angle response. While transmissive diffusers have a larger optical throughput than integrating spheres, most materials have spectrally variable scattering (diffusing) or absorbing properties, limiting their use to certain wavelength regions. For instance, flashed opal acts as a good diffuser, but only works up to $1\ \mu\text{m}$. Delrin works for longer wavelengths, but exhibits absorption in some wavelength regions, resulting in large deviations from an ideal cosine response. Whatever the diffusing element, the throughput and cosine response needs to be carefully characterized, as does the fiber optics cable that transmits the light to the spectrometer subsystem. In some cases, the throughput depends on the bending radius. Thus, once installed and calibrated, the cables should be fixed in place.

Table 40.2 lists the advantages and drawbacks of broadband and spectral sensors that have been commonly used. For aircraft operations with rapidly changing signals, the slow response time of thermopiles is not ideal, especially when flying sensors with a large mass and, therefore, a large thermal inertia. Pyroelectric radiometers [40.14] have a response that is adequate for aircraft operations, but they require a moving part (chopper). Both of these radiometers have a near-ideal angular response up to 70° incidence angle—superior to those of spectrometers with their imperfect light collectors as described previously.

Spectrometers are more complicated in their design than broadband radiometers. They may suffer from straylight and detector nonlinearities, as well as temperature-dependent dark currents. Typical systems are described by [40.24, 25]. They consist of commercially available single-enclosure units with optical fiber pigtailed that are coupled with the optical fibers from the externally mounted light collector through optomechanical shutters. The shutters enable periodic measurements of the dark signal. After the dispersion of the light by a diffraction grating, the spectrum is measured by a linear photodetector array. Order sorting filters are included, typically placed directly above the detector array, if the wavelength range spans more than one octave. The detector signal is preamplified, digitized, and

Table 40.3 Subsystems and ancillary components

Component	Comment
Irradiance transmissive diffuser	Diffusive properties are wavelength dependent
Irradiance integrating sphere	Flat spectral response over wide range; nonideal response at near-zenith incidence
Actinic flux density diffuser	Provide isotropic angular response (frosted quartz)
Radiance baffle system	Narrow field-of-view aperture with lenses and baffles
Domes and optical filters	Provide protection from the elements and limit radiation to fractional or narrow bands
Fiber optic cables (optical shutters)	Transmit (block) radiation from light collector to spectrometer; sensitive to bending radius
Shadow mask (SPN)	Used in conjunction with thermopiles or spectrometers to separate global/diffuse radiation
Leveling platforms	Actively stabilize light collectors with tip/tilt stages
Inertial navigational system	Provides aircraft pitch and roll to leveling platform

recorded (typically at 1 Hz, with an integration time ranging from 50–500 ms). To cover most of the solar wavelength range, two off-the-shelf spectrometers with overlapping subranges are used: spectrometers with silicon detector arrays from the UV to the near-infrared (about 1 μm), and spectrometers with InGaAs detector arrays from about 1–2 μm . Identical spectrometer pairs are used for zenith and nadir light collectors. For the InGaAs spectrometers, the temperature of the detector array needs to be stabilized, and the spectrometer enclosure and preamplifier should also be kept at a constant temperature.

The recently commercialized sunshine pyranometer (SPN-1) [40.37] provides broadband global and diffuse downwelling irradiances. This is accomplished by an array of seven detectors under a shadow mask, which is designed such that at least one detector is shaded and measures the diffuse radiation, whereas the unshaded detectors measure the global irradiance component. The detectors are miniature diffuser-covered thermopiles with low thermal inertia; their angular response is similar to that of pyranometers. Their stated measurement accuracy is somewhat lower than that of traditional pyranometers (Table 40.4). A new spectral prototype instrument based on the same shadow mask design measures spectrally resolved global and diffuse irradiance from 350–1000 nm. It was recently tested on an aircraft field campaign and will enable new remote sensing applications once it is commercially available.

Ideally, a combination of solar irradiance radiometers should be flown as *canonical payload*:

1. Pyranometers (high accuracy, full spectral coverage of the solar range, and near-ideal angular response up to 70°)
2. Spectrometers (spectrally resolved irradiance for physical interpretation of signals and no thermal inertia)
3. Diffuse/global radiometers (correction of angular response; new remote sensing opportunities).

These three instruments can be used synergistically to ensure high-fidelity spectral irradiance measurements even in difficult environments such as the Arctic [40.36], with extremely low sun angles (zenith angles up to 85° are feasible).

Table 40.3 summarizes the components that go along with the radiometers themselves. In addition to the two types of irradiance light collectors, there are diffusers for collecting isotropically weighted radiance (actinic flux) with a series of elongated frosted quartz domes. Because the hemispheres are measured separately, the instrument horizon (field-of-view cutoff at 90°) for the two subsystems needs to be defined carefully to minimize artifacts due to reflections from the aircraft and to avoid signal contamination from the opposing hemisphere. This is done with a black artificial horizon under the diffuser. Otherwise, the design of the actinic flux radiometer systems (fiber optic cables linking light collectors to spectrometers) is similar to irradiance instruments [40.28]. The grating spectrometers that are now commonly used are prone to straylight contamination, especially in the UV-B range, more so than the older scanning double-monochromator systems [40.48]. However, scanning systems use moving parts and require more time to complete a scan than fixed-grating spectrometers with a photodiode array or CCD (charge-coupled device). Therefore, they are rarely used operationally today. Filter radiometers, once the mainstay instrument, are no longer widely used either [40.49].

40.5 Specifications

The radiometric accuracy and instrument precision of commonly used radiometers is provided in Table 40.4. The overall accuracy of broadband irradiance is higher

than that of spectral radiometers, mainly because of the better angular response of broadband radiometers. The error sources include: radiometric uncertainty, imper-

Table 40.4 Specifications of precision and accuracy for solar range aircraft radiometers

Quantity	Accuracy/Precision	Notes
Downward spectral solar irradiance	7%/1% of dynamic range	With leveling platform
Upward spectral solar irradiance	3–5%/1% of dynamic range	Varies with wavelength
Broadband solar irradiance	2–5%/1–3%	Excludes attitude correction
Global/diffuse BB irradiance	8%/1–3% of dynamic range	SPN-1
Actinic flux density	3–5%	UV-B: stray light cont.
Spectral radiance	7%/1% of dynamic range	Calibration limited

fect angular response, aircraft attitude stabilization (or postflight correction), straylight contamination, calibration drift, and thermal effects. Additional specifications are wavelength range (330–4000 nm for pyranometers, depending on quartz dome transmittance cutoff; 400–2700 nm for SPN-1, 350–2150 nm for spectral irradiance, > 295 nm for spectral actinic flux density), spectral sampling (4–8 nm for spectral irradiance, 1–2 nm for spectral actinic flux density) and spectral response (Sect. 40.6). For a broadband sensor, the spectral response should be constant (flat) across the full wavelength range; a spectral sensor's response varies with wavelength and is determined through the radiometric calibration (Sect. 40.6).

For radiance light collectors, the field-of-view needs to be specified (typically 1–4°); for irradiance and actinic flux density, obstructions by the aircraft (e.g., tail,

propellers, protruding antennae, or landing gear) need to be assessed on a case-by-case basis (by calculating the fractional solid angle they occupy). In some cases, reflections by the aircraft can lead to a high-bias in the measurements. This is usually quantified empirically for a given installation; occasionally, wingtip-by-wingtip comparisons of different aircraft help quantify such effects.

Finally, the instrument line shape or *slit function* determines the wavelength resolution of a spectrometer (8–12 nm FWHM for commonly used systems). The wavelength uncertainty is usually about 0.5–1 nm. Wavelength registration is determined in the laboratory (Sect. 40.6) and can be verified in the field with low-pressure line sources. Mercury, for example, provides a good assortment of isolated emission lines in the visible and near-infrared.

40.6 Calibration and Quality Control

Calibration procedures for airborne radiometers (described in detail by [40.47]) include the characterization of their radiometric, angular, and wavelength response (Sects. 40.6.1–40.6.3). Any uncertainties propagate into the final product, requiring careful error assessment (Sect. 40.6.4).

40.6.1 Radiometric Calibration

There are various different methods for establishing the radiometric response of airborne solar radiometers. One method is to reference the radiometer to a primary or secondary standard that is traceable to the World Radiation Reference (WRR, Davos, Switzerland), the National Institute of Standards and Technology (NIST, USA), or to other national standards. Broadband radiometers are run side by side with such standards to transfer the calibration under a wide range of insolation conditions from a calibration source. During this transfer, it is important to calibrate the instrument across the full dynamic range expected during flight to ensure the linearity of the response. Also, since the spectral composition during measurements may deviate from that

during calibration, the spectral response should be flat. A research-grade instrument's data sheet should provide this information, but it needs to also be measured in the laboratory—for example with a monochromator [40.50]. More details on the radiometric calibration of broadband radiometers can be found in Chap. 12.

An alternate calibration source for broadband radiometers is a cavity pyrheliometer, which serves as an absolute standard for direct irradiance. To transfer the calibration from such an instrument, the diffuse radiation needs to be subtracted from the global irradiance (it is obtained by periodically obstructing the direct beam). Global/diffuse radiometers (SPN-1) can also be calibrated by the Langley method, where the Sun serves as the calibration source. This is only possible when flying extended legs at high altitude, during which the solar zenith angle and thus the airmass factor $m = 1/\cos(\vartheta)$ change significantly.

Spectral radiometers are calibrated with incandescent calibration lamps that are also traceable to a standard (NIST or otherwise). They come with a data sheet that provides the spectral irradiance at a distance of 50 cm, at a specified current. Since these primary stan-

dards degrade with burn time due to changes to the filament and optical elements, it is advisable to keep their usage at a minimum. This is done by transferring their calibration to secondary lamps. Installed in portable field calibrators, the secondary standards can be taken to field campaigns for on-site calibration of radiometers and be recalibrated after a field campaign in the laboratory. Radiance calibrations are done in a similar fashion. In this case, a Spectralon[®] panel with known reflectance is placed at 50 cm from the primary standard, and the radiance light collector is pointed at its center on the optical axis. The nonlinearity of a system can be characterized by either varying the integration time constant of the spectrometers or by varying the distance to the calibration source. The latter method requires an absolute reference measurement (either broadband or at a single wavelength) alongside the spectrometer light collector. For integrating spheres, the effective receiving plane does not necessarily coincide with the location of the aperture, but is slightly inside the sphere. This slight offset (about 1/10 of the diameter of the integrating sphere) can be determined by recording the instrument counts for a varying distance to the light source while also recording the signal from a reference radiometer. For the absolute calibration, the 50 cm distance from the light source needs to be measured against the effective receiving plane.

40.6.2 Angular Calibration

The angular calibration is done by illuminating the light collector by a collimated light source at normal incidence (for reference), and then rotating it about its receiving plane. Noncollimated light sources, such as the radiometric calibration lamps (point sources), may lead to an incorrect characterization of the instrument's angular response. Care needs to be taken to rotate the light collector about the accurate location of the receiving plane (aperture). This is straightforward for pyranometers with a physical surface but challenging for an integrating sphere or transmissive diffusers, where the location of the effective receiving plane may depend on the angle of incidence. However, collimated light minimizes these biases. Outdoor tests under clear-sky conditions [40.37] are only effective if the direct and diffuse irradiance can be separated. The angular response needs to be assessed spectrally, since the properties of the transmissive or reflective material may change. Temperatures should be held close to the operating conditions if possible; overheating of the optical elements in the characterization process may change their response.

The *azimuthal* response of a sensor or light collector is usually fairly constant for a given polar incidence

angle. However, at shallow incidence, it may vary due to imperfections of the sensor surface. For integrating spheres, any internal impurities of the reflector material that are asymmetric will lead to azimuthal asymmetry, even at steeper incidence angles. The calibration in the laboratory can be accomplished with rotating tables.

40.6.3 Wavelength Calibration

The spectrometer wavelength registration is typically provided by the manufacturer. However, wavelength shifts sometimes occur, even for fixed-grating devices, and may require recalibration at least once before a field campaign. This is accomplished with line sources with gas lamps (Ar, Hg, Ne, Kr) and with lasers. Tabulated line positions are compared with their reported location in the literature [40.51], and the wavelength coefficients for the spectrometer channels are adjusted with this information. At the same time, the apparent line width in the measurement provides information on the instrument spectral resolution (slit function). At least once per lifetime of a spectrometer, the slit function should be measured with a monochromator, with representative samples across the full wavelength range. Straylight and order-sorting errors are best diagnosed with measurements of laser light because monochromators output higher-order light that may be mistaken for spectrometer artifacts. The wavelength calibration is the first step in the calibration of a spectrometer system (followed by radiometric/nonlinearity and angular calibration).

40.6.4 Field Data Processing and Error Assessment

Calculating irradiance from the raw data first requires bias corrections for any thermal offsets (pyranometers) or subtraction of dark counts (spectrometers). Next, the instrument raw counts are divided by the spectral response function (obtained from the radiometric calibration). For a nonlinear instrument response, this step may also entail a correction based on laboratory measurements as described in Sect. 40.6.1. The resulting irradiance is often archived as field data, based on the most recent radiometric field calibration. The aircraft attitude and angular correction is usually performed after a campaign, at which point diffuse and direct irradiance undergo separate correction steps before they are recombined. If no global-diffuse radiometer is available, radiative transfer calculations are used to separate the global irradiance into diffuse and direct components. Specific correction steps are described by [40.32]. For low-elevation Sun angles, it is especially difficult to correct for changing attitude angles

in the absence of a leveling platform. It is essential to measure the angular offset between the aircraft INS and the horizon of the fix-mounted sensor or light collector at least once during the mission. With a leveling platform, only the angular correction for the light collector is required. After completing all processing steps, the measurements are compared with radiative transfer calculations. This step facilitates data quality and error assessment. Uncertainties may arise from all system components and processing steps, and they may depend on the specific aircraft configuration, temperature environment, and Sun-sensor geometry. Quick in-field data quality control helps to identify instrument issues and

the optimization of instrument settings, such as integration time, acquisition frequency, and temperature set points. For example, some instruments have dual gain (or integration time) settings, which are alternated to adequately capture low and high signal levels and require adjustment early in the mission to maximize the signal-to-noise ratio. As noted above, mutually complementary and partially redundant measurements (broadband, spectral, and global/diffuse radiometers) lead to high-fidelity results. Unlike in operational ground-based observations, standards for processing joint data sets systematically have yet to be established by the airborne community.

40.7 Maintenance

Routine tasks during field operations include regular radiometric calibrations, angular offset measurements between the INS and the horizon of the instruments, and cleaning of external optical components (domes) with alcohol or water (especially after flying through dust or soot aerosol plumes). For spectrometers, optical fibers need to be monitored; partially broken fiber strands can lead to errors that are difficult to correct after the fact (even with regular radiometric field cal-

ibrations). Any moving parts (optical shutters, leveling platform actuators) need to be inspected. Those system components that may be exposed to the elements need to be checked for water or ice intrusion, and heaters in these areas need to be monitored during flight. Integrating spheres are either operated under vacuum or with a purge line to keep water vapor and condensation out. This requires checking the vacuum with a pump or adjusting the purge air with a flow meter.

40.8 Applications

Current applications of airborne solar radiometry focus on atmospheric energetics (absorption, heating rates), remote sensing of atmospheric constituents, and surface characterization (albedo, atmospheric correction), with a growing emphasis on the connection between remote sensing and radiation measurements. This linkage is necessary when considering complex atmospheric and surface scenes with inhomogeneous clouds, variable surface properties, or aerosols co-occurring with clouds.

40.8.1 Energetics and Remote Sensing

Many field campaigns now include airborne remote sensing instrumentation. These observations provide 3-D radiative transfer calculations with the necessary input to put radiation measurements into context. Figure 40.3 illustrates this approach for the 2007 TC⁴ (Tropical Composition, Cloud and Climate Coupling) campaign [40.52], where two research aircraft (ER-2 and DC-8) flew collocated legs above, below, and within cloud fields to sample their microphysical and radiative properties. In this case, 3-D irradiance fields were calculated from the cloud products generated by

an imager aboard the ER-2 (swath width: about 20 km; length of the leg: 200 km), embedded in the larger context of geostationary imagery, and validated with the spectral irradiance measurements on both aircraft. The visible-range vertical flux divergence ∇F_V from the net flux difference between the ER-2 and DC-8 spectral radiometers compares fairly well with the 3-D calculations. Since clouds do not significantly absorb solar radiation in the visible, the observed positive (negative) areas of ∇F_V are entirely due to net horizontal loss (gain) of radiation. This kind of transport is not always tied to the cloud optical thickness distribution as the plot suggests. Rather, photon *donor* and *recipient* regions (red and blue in Fig. 40.3a) exchange radiation over a range of scales that are distinct from the cloud structure (Fig. 40.3b). When measured with broadband radiometers, ∇F_V in the visible (related to net horizontal photon transport) cannot be distinguished from true absorption in the near-infrared spectral range. In this case, apparent and true absorption have similar magnitudes at many points along the flight track with a net loss of visible radiation into the surrounding areas. Unless these are equally sampled over adequate scales, the net export from the cloud field of inter-

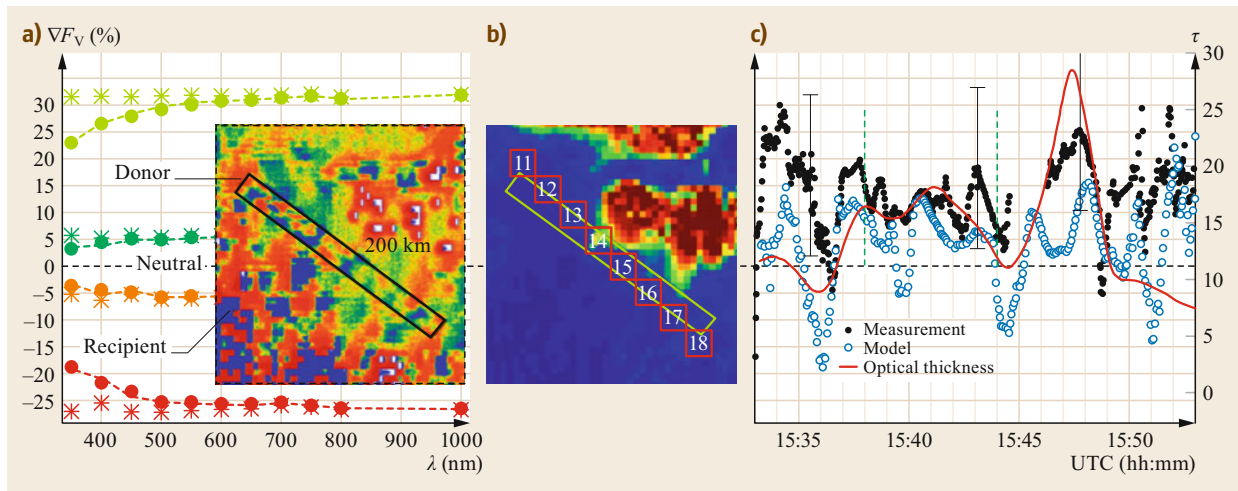

Fig. 40.3a–c Radiation measurements and cloud passive imagery of an inhomogeneous cloud scene observed during the 2007 Tropical Composition, Cloud and Climate Coupling (TC⁴) campaign in Central America. The images in (b) and (a) show the optical thickness τ and net horizontal photon transport, obtained from geostationary and airborne imagery (200 km \times 20 km domain along the flight track of two collocated aircraft) through 3-D radiative transfer calculations (after [40.31]). (a) Vertical flux divergence ∇F_V spectra for representative points in the domain (full symbols/stars: calculations with/without molecular scattering). (c) Point-by-point 500 nm observations along the flight track along with the calculations and the optical thickness τ within the field-of-view of the radiometers (after [40.30]). (a,b) (after [40.31] © Author Creative Commons license 3.0) and (c) (after [40.28] with permission of the American Geophysical Union)

est is insufficiently compensated by recipient regions. This is interpreted as cloud absorption in broadband measurements, explaining the longstanding problem of enhanced absorption [40.30].

Separate measurements in the visible subrange provide information on the contribution of horizontal flux to the overall observed vertical flux divergence [40.21]. The correct way of using this information for mitigating the apparent absorption bias is the conditional sampling of net irradiance pairs along collocated legs above and below a layer of interest [40.43, 53]. This is done by selecting those points where ∇F_V in the visible is close to zero and averaging their broadband ∇F_V . If spectral observations are made, another method is to use the spectral slope of the mid-visible ∇F_V , which is proportional to its magnitude [40.31]. Neither of these filtering methods work in the presence of aerosol particles, which commonly do absorb in the visible, with a distinct spectral dependence. In this case, spiral measurements are more appropriate than collocated legs (Figs. 40.5b and 40.6; Sect. 40.8.2). For pure cloud layers, accurate sampling allows the direct spectral partitioning of absorption by contributions from clouds, water vapor, and other atmospheric constituents of the layer. In many cases, cloud absorption accounts for a fraction of the total layer absorption. For a marine stratus layer case, [40.43] attributed 25% to liquid water, 59% to water vapor, and the rest to enhanced

absorption due to multiple scattering (increased photon path length) of various gases in clouds.

Absorption and other radiation parameters can also be obtained *indirectly* by using irradiance measurements at various flight levels to validate imagery-based 3-D radiative transfer calculations and then deriving the parameters of interest from the calculations. This method is particularly useful for single-aircraft campaigns, where radiation fields above and below a layer are sampled sequentially. Because the cloud field changes on time scales smaller than the sampling time, its radiative properties are best obtained from the measurement-constrained model output—provided that imagery is available to drive the model. This does not work if the imagery-derived cloud properties are themselves biased by 3-D effects. In this case, calculated and measured irradiances will be inconsistent. For example, the optical thickness of broken clouds tends to be underestimated by passive imagery retrievals, translating in an underestimation of a cloud's absorption and an overestimation of its transmission [40.31].

40.8.2 Combination of Cloud/Aerosol Microphysics and Radiation

When imagery is unavailable, the link between cloud microphysics (sampled by in-situ instruments) and macroscopic distribution to the associated radiation

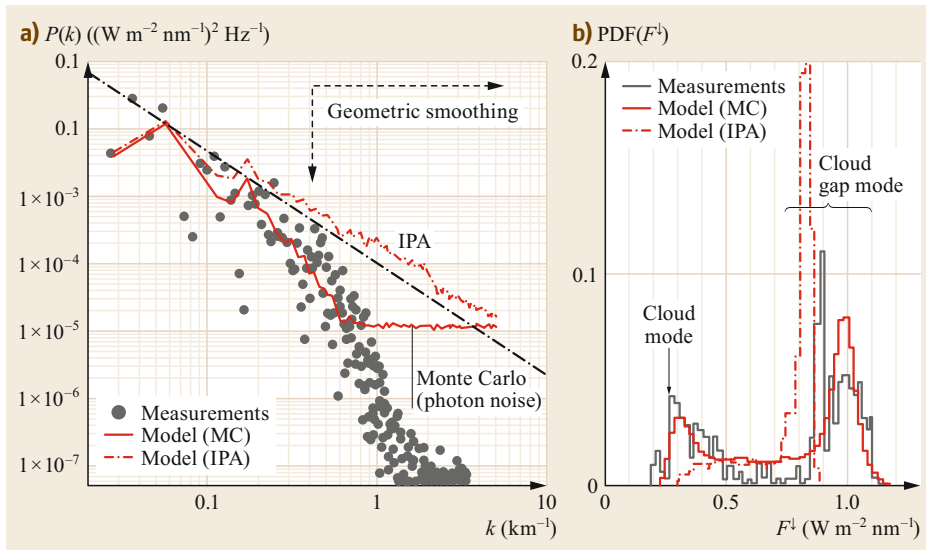

Fig. 40.4a,b Downward irradiance measurements and calculations below a broken cloud field (500 nm wavelength (after [40.54])). **(a)** Power spectrum $P(k)$ (calculations with horizontal photon transport (MC: Monte Carlo 3-D radiative transfer model) and without (IPA: independent column approximation)). The $k^{-5/3}$ scaling law of the underlying liquid water field is included (dash-dotted line). **(b)** Histogram with two primary modes: 0.3 and $1.0 \text{ W m}^{-2} \text{ nm}^{-1}$ under clouds and cloud gaps. The *left* (cloud) mode is only reproduced when horizontal photon transport is enabled in the 3-D radiative transfer model (MC) (after [40.54] with permission of the Royal Meteorological Society (Great Britain))

fields can be achieved through cloud simulators [40.55]. These generate synthetic 3-D distributions of parameters, such as liquid water content from measured mean profiles, and two-point statistics, such as power spectra. While not placing individual clouds accurately, the statistical properties of a cloud field are sufficiently well reproduced to match measured radiation fields when feeding the synthetic cloud fields into a 3-D radiative transfer model [40.54]. Figure 40.4b shows the downward irradiance below a broken cloud field. Two modes can be distinguished, one corresponding to gaps between clouds (direct and diffuse irradiance), the other to the irradiance transmitted through clouds. If the modes are as well separated as in this example, the area under the left mode can be interpreted as *radiative* cloud fraction. *Radiative closure* in this case can be understood as the consistency between the cloud micro- and macrophysics-driven 3-D calculations and the observations—individually for the two modes. In the traditional sense, radiative closure between measured and calculated cloud transmittance, reflectance, and absorptance is achieved if the radiative cloud fraction and therefore the domain average (from cloud and gap mode) irradiance fields are consistent between observations and calculations. This is harder to achieve, and a mode-by-mode assessment is often preferable.

Beyond closure itself, the power spectrum (Fig. 40.4a) is a metric for characterizing horizon-

tal structure. It relates cloud microphysical scaling laws (the $k^{-5/3}$ Kolmogorov eddy dissipation) to the associated radiation fields. Irradiances mirror the microphysical scaling down to a characteristic scale, below which radiative smoothing decreases the spatial variability of the radiation fields relative to the microphysical structure.

A persistent challenge for airborne radiation science is the isolation of aerosol radiative effects in the presence of clouds. Figure 40.5a illustrates a strategy using measurements on horizontal legs below scattered clouds embedded in an aerosol layer. Here, the locations of the two modes discussed in the previous figure are plotted as a function of wavelength, along with calculations (in this case, based on large-eddy simulations) with and without considering aerosols [40.56]. The direct aerosol radiative effect (DARE) in the presence of clouds can simply be derived from the measurement-constrained modeled net irradiance fields in the presence and absence of the aerosol layer. Figure 40.5a shows that the aerosol perturbation for the downward irradiance (the difference between closed and open symbols) decreases with the wavelength, as expected. The aerosol radiative effect in the presence of clouds is not necessarily the same as in the absence of clouds. Consequently, quantifying DARE as a function of the cloud context is one of the ongoing themes in radiation science.

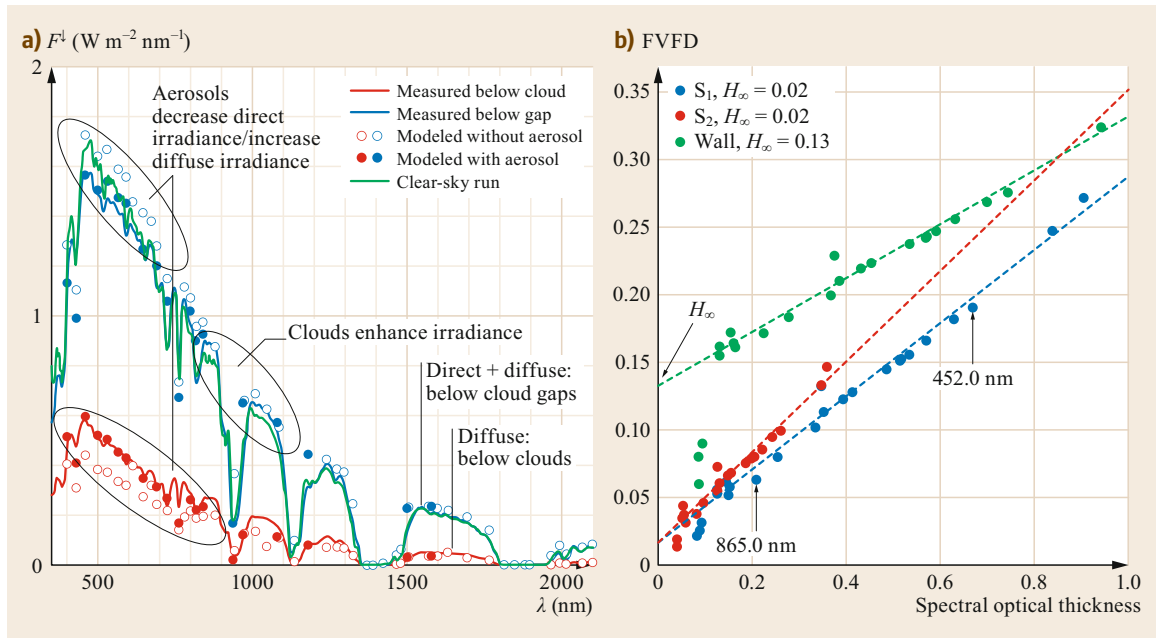

Fig. 40.5 (a) Measured and modeled downward irradiance below a scattered cloud field embedded in an aerosol layer, sampled separately under clouds and cloud gaps. The model results show that the addition of the aerosol decreases the global (direct and diffuse) irradiance in cloud gaps and increases the diffuse irradiance under clouds (after [40.56] with permission of the American Geophysical Union). (b) FVFD, vertical flux divergence normalized by incident irradiance (fractional) plotted as a function of spectral optical thickness. In the limit of large wavelengths (zero aerosol optical thickness, AOT), this reveals the contribution of horizontal flux divergence. The example shows the vertical flux divergence obtained for an aerosol layer above clouds from two (vertical) spirals (S_1 and S_2) and collocated (horizontal) legs (so-called wall). For the spirals, horizontal flux has a negligible impact on the absorption measurements (2%, in contrast to 13% from wall measurements) (after [40.34] © Author Creative Commons license 3.0)

The absorption and heating rate of an aerosol layer above various surfaces (including cloud fields) is best obtained from vertical profiles through the layer, ideally in so-called square spiral patterns with four short level legs per full circle, provided that a leveling platform is available enabling this sampling pattern. These spirals have the advantage of minimizing the variability in the underlying scene while maintaining a constant descent rate of, e.g., 1000 ft min^{-1} . More importantly, they provide a large number of irradiance measurements that can be regressed against altitude or the AOT (obtained from other measurements) as vertical coordinates. The change of net irradiance throughout the layer (i.e., the layer absorption) is obtained from the slope of the linear fit and incorporates multiple samples from the full profile, rather than the two samples above and below the aerosol layer as available from stacked legs. In addition to providing more robust absorption estimates than stacked legs, spiral profiles are also less prone to sampling biases associated with net horizontal photon transport. Its contribution to the measured vertical flux divergence ∇F_V , and thus the bias

in the derived absorption, can be determined by plotting $\nabla F_{V,\lambda}$ against the spectral optical thickness of the aerosol layer, as done in Fig. 40.5b for a NASA field campaign in the Southeast Atlantic that targeted aerosols above low-level clouds (ORACLES: Observations of Aerosols above Clouds and Their Interactions).

In the limit of large wavelengths, and therefore negligible aerosol absorption, one can interpret H_{∞} as a metric for net horizontal photon transport, as the intercept (AOT $\rightarrow 0$). A reasonable measurement of the true absorption and heating rate can be expected if $\nabla F_V \gg H_{\infty}$. In this case, the two spirals meet this condition much better than the wall measurements, even for wavelengths into the near-infrared where AOT becomes small [40.34].

Figure 40.6 shows the measured irradiance profile from such a spiral (Fig. 40.6a) along with the heating rate profile (Fig. 40.6b). In principle, the total heating rate can be directly obtained from profile measurements of broadband solar irradiance (as shown for clouds in [40.40] using ramp descents and ascents) if the scene is homogeneous. With spectral measurements, one can

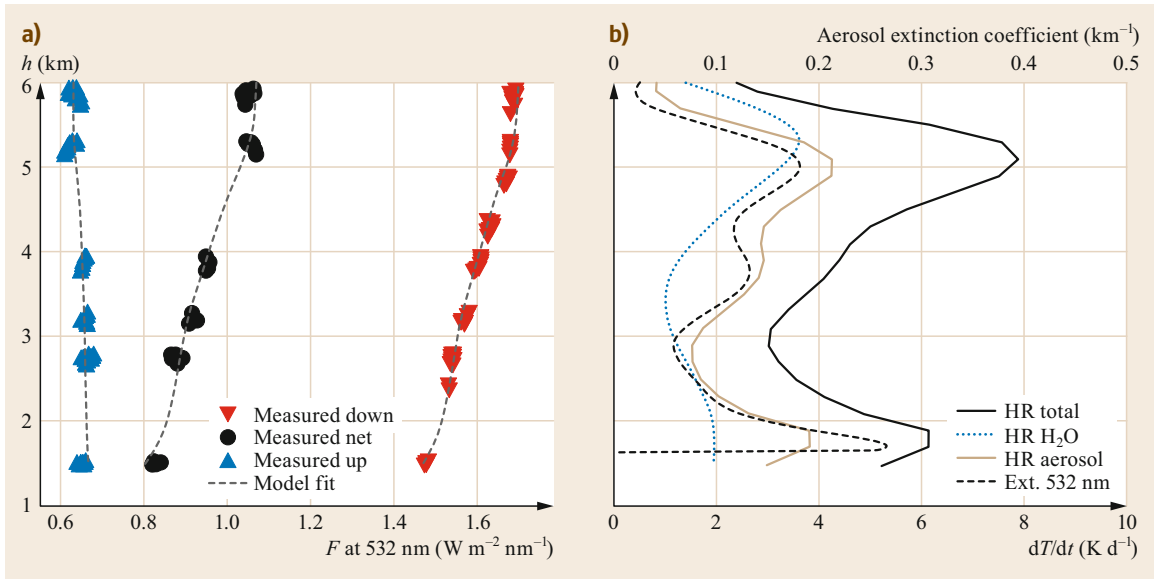

Fig. 40.6 (a) Spiral profile measurements (532 nm wavelength) through aerosol layer above clouds, along with radiative transfer calculations based on AOT and retrieved intensive aerosol optical properties (single-scattering albedo, asymmetry parameter) as dashed lines (model fit). (b) Heating rate dT/dt profile (total and for aerosol and water vapor). The aerosol extinction coefficient profile is also shown

also segregate by absorbers, as shown in Fig. 40.6b, and derive the aerosol single-scattering albedo (SSA) and scattering asymmetry parameter (ASY) by varying them in a radiative transfer model until the calculations match the observed profiles [40.34, 57, 58].

The resulting spectra of aerosol SSA and ASY are shown in Fig. 40.7a, up to a wavelength where H_∞ becomes too large relative to the true absorption (black line Fig. 40.7a) for a meaningful retrieval [40.34]. AOT and absorption are both smooth functions of wavelength; the local maxima are due to atmospheric gases (mainly oxygen in the plotted wavelength range). From AOT, SSA, and ASY, DARE at any level can easily be calculated for any scene albedo. For ORACLES, the top-of-layer DARE switches from negative (cooling) to positive (warming) at 0.25 ± 0.05 , the so-called critical albedo. Similar studies have been made for various aerosol and surface types (for example, dust in the Sahara [40.59]). The systematic study by [40.29], summarizing results from multiple aircraft campaigns, emphasizes that aerosol single-scattering albedo in conjunction with scene albedo largely determines whether a layer has an overall warming or cooling top-of-atmosphere effect.

40.8.3 Surface Characteristics

Figure 40.7b shows a collection of surface albedo spectra for various scene types. Because of its importance

for aerosol and cloud radiative effects, aircraft surface albedo measurements are routinely acquired. They are used to validate surface albedo derived indirectly from spaceborne imagers via the bidirectional reflectance distribution function (BRDF, e.g., [40.60]). For dark surfaces (e.g., water), the atmospheric correction of radiances from spaceborne imagery leads to substantial errors in the derived surface-leaving radiance. To avoid atmospheric correction errors, airborne surface albedo legs should be conducted at a low altitude [40.24, 39, 58]. When flown under clouds, aircraft can acquire so-called white-sky (diffuse) albedo, which may differ from blue-sky (global) albedo [40.33]. Figure 40.7b illustrates the diversity of surface types from multiple aircraft campaigns: ASTAR (Arctic Study of Tropospheric Aerosol and Radiation, 2000: [40.61]), SAMUM (Saharan Mineral Dust Experiment, 2006: [40.62]), MELTEX (Impact of Melt Ponds on Energy and Momentum Fluxes between Atmosphere and Sea Ice, 2008: [40.63]), and ARISE (Arctic Radiation IceBridge Sea and Ice Experiment, 2014: [40.36, 64]). It shows, for example, that vegetation is dark in the visible and becomes bright in the very near infrared; the opposite is true for ice and snow. Characterizing spatially and temporally variable surfaces, such as sea ice and snow in the Arctic, is difficult for both spaceborne and airborne observations, yet important for filling gaps in our understanding of the surface radiation budget. Recent campaigns in the region have led to innovative approaches to simultaneously re-

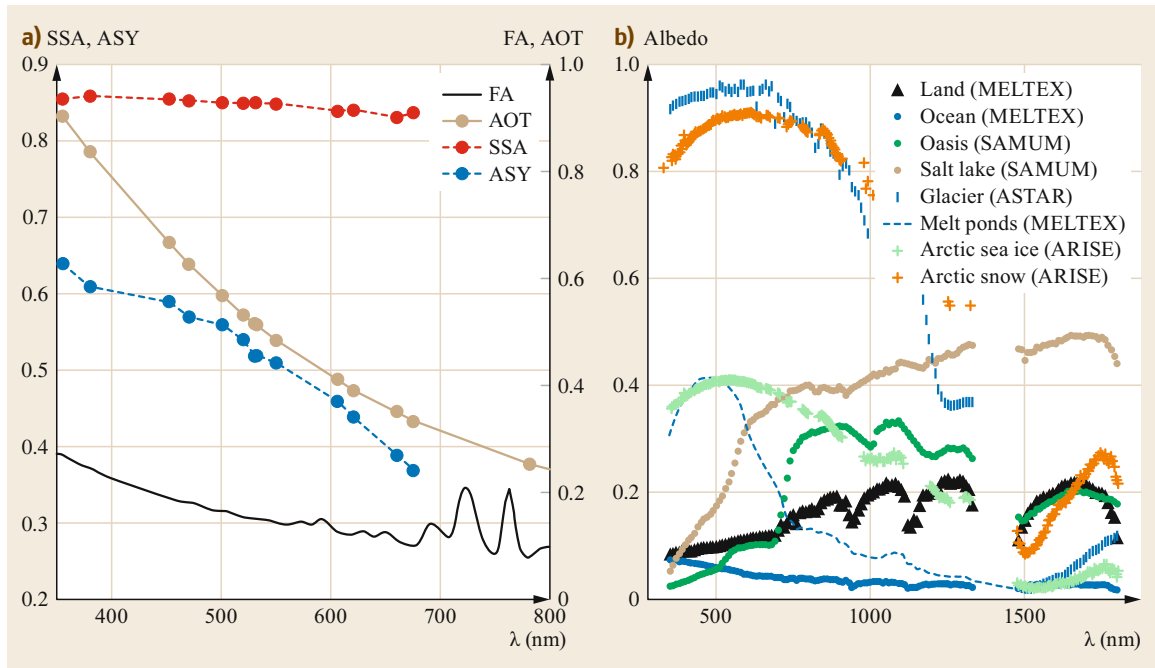

Fig. 40.7 (a) Spectral AOT and absorption normalized by the incident irradiance (fractional absorption, FA) and retrieved SSA and ASY; (b) various different surface albedo spectra from multiple field campaigns

trieve cloud and surface properties [40.35] and to validate imagery-derived cloud radiative effects over snow and ice [40.36]. Such developments and validation ac-

tivities ultimately improve spaceborne observations and therefore our understanding of the radiation budget of the globe.

40.9 Future Developments

Currently, a *canonical* radiometer payload is emerging that maximizes accuracy and information content with spectrally resolved radiation measurements on heritage aircraft. Meanwhile, the future necessitates standalone sensors on small platforms. This calls for innovative instrumentation and calibration techniques to achieve an acceptable level of accuracy. Recently, miniaturized subsystems have become available (e.g., spectrometers,

mini-INS systems), and they may soon fly on remotely piloted aircraft and on autonomous platforms taking observations in regions inaccessible to traditional aircraft. For example, routine surface observations in the high Arctic may be achieved by dropping disposable sondes from a helicopter or aircraft that collect and transmit surface data for part of a season, filling one of the remaining gaps in the global radiation observation system.

40.10 Further Readings

A thorough review of ground-based radiometers is provided by F.J. Vignola et al.: *Solar and Infrared Radiation Measurements, Energy and the Environment* (CRC, Boca Raton 2012). Aircraft radiometers and calibration techniques are described by M. Wendisch et al.: *Atmospheric radiation measurements*. In: *Airborne Measurements for Environmental Research – Methods and*

Instruments, ed. by M. Wendisch and J.-L. Brenguier (Wiley-VCH Weinheim, 2013), while K.S. Schmidt, P. Pilewskie: *Airborne measurements of spectral short-wave radiation*. In: *Cloud and Aerosol Remote Sensing and Energy Budget Studies*, Light Scattering Reviews, Vol. 6, ed. by A. Kokhanovsky (Springer, 2011) show cases applications.

Acknowledgments. We thank Anthony Bucholtz (Naval Postgraduate School, Monterey, CA, USA) and Sam Hall (National Center for Atmospheric Research, Boulder, CO, USA) for their valuable contributions to

this chapter. The first author was supported by NASA grant NNX14AP72G. Irradiance data collection for NASA ARISE [40.36, 64] and ORACLES [40.34] was supported through NNX12AC11G and NNX15AF62G.

K. Sebastian Schmidt

Laboratory for Atmospheric and Space Physics
University of Colorado at Boulder
Boulder, USA
sebastian.schmidt@lasp.colorado.edu

Sebastian Schmidt is an Associate Professor at the Department of Atmospheric and Oceanic Sciences and at the Laboratory for Atmospheric and Space Physics at the University of Colorado in Boulder. He received his PhD in 2005 from the University of Leipzig, Germany. His research focuses on atmospheric remote sensing and energy budget studies using aircraft, ground-based, and spaceborne observations. He is a member of the International Radiation Commission.

Manfred Wendisch

Physics and Earth Sciences
University of Leipzig
Leipzig, Germany
m.wendisch@uni-leipzig.de

Manfred Wendisch is a Professor at the University of Leipzig (Germany) and Director of the Leipzig Institute for Meteorology. He is involved in airborne field observations, studying the influence of clouds on the atmospheric radiative energy budget with a focus on cirrus and Arctic mixed-phase clouds, as well as on subtropical trade wind cumuli.

Bruce Kindel

Laboratory for Atmospheric and Space Physics
University of Colorado at Boulder
Boulder, USA
bruce.kindel@lasp.colorado.edu

Bruce Kindel is a research scientist at the Laboratory for Atmospheric and Space Physics (LASP) at the University of Colorado, Boulder. He received his PhD in Atmospheric and Oceanic Sciences from the University of Colorado, Boulder in 2010. His research focuses on remote sensing of the Earth's atmosphere and surface from satellite, aircraft, and surface instrumentation, with an emphasis on hyperspectral measurements.

41. Spaceborne Microwave Radiometry

Susanne Crewell , Catherine Prigent , Mario Mech 

Since several decades, microwave radiometers have been an essential component of the satellite observation system, enabling the retrieval of a multitude of parameters. Conical scanning imagers are mainly dedicated to deriving characteristics of the Earth's surface, e.g., soil moisture, sea-surface temperature, salinity, and sea ice. For this purpose, they make use of channels at low frequencies where the atmosphere is relatively transparent. By exploiting the differential absorption along pressure-broadened rotational lines, coarse resolution vertical profiles of water vapor and temperature can be derived from microwave sounders observing along the wings of atmospheric absorption lines. Furthermore, clouds and precipitation produce distinct spectral signatures in the microwave region, which can be best used over ocean surfaces that have a lower surface emissivity than land. Due to the rather long wavelengths, the spatial resolution of microwave satellite instruments is relatively poor, of the order of 10 km or more. By deploying microwave radiometers onboard aircrafts, much finer resolution can be achieved, which allows dedicated process studies. Microwave instruments flown on several polar orbiting satellites are an essential ingredient into today's numerical weather prediction, and their measurements are assimilated directly as radiances by several meteorological services worldwide. With measurements having been available for more than three decades, microwave observations are starting to play an important role

in monitoring and understanding the effects of climate change, such as the melting of the polar ice caps. With the upcoming new generation of satellites, the frequency range of the measurements is expanded into the submillimeter range to better capture ice clouds.

This chapter deals with spaceborne and airborne microwave radiometers operating in the spectral range between 1 and 300 GHz, which are utilized in a variety of environmental and engineering applications, including weather forecasting and climate monitoring. Using microwave radiation provides complementary information to the visible and infrared spectral range (Chap. 42). Compared to visible and infrared observa-

tions, passive microwaves are less affected by clouds and can, to some extent, provide *all-weather* surface and atmospheric information. The general design of microwave radiometers is similar to that of ground-based radiometers (Chap. 29), however, the antenna design and scanning concept become highly important for reaching global coverage with reasonable spatial and temporal resolutions.

41.1 Measurement Principles and Parameters

The microwave spectral range offers some distinct advantages for remote sensing of geophysical parameters. First, the high transmittance of the atmosphere ($> 80\%$ below 40 GHz) provides possibilities for the observation of surface properties for downlooking geometry, i.e., from space and aircraft. Second, the fact that wavelengths are relatively large compared to atmospheric particles allows scattering processes to be neglected for most applications, simplifying the retrieval and allowing observations under nearly all weather situations. The semitransparency of clouds and precipitation also allows us to determine information on atmospheric hydrometeors.

Today, various microwave instruments are flown on polar orbiting instruments and provide key information for data assimilation in numerical weather prediction (NWP) centers [41.1]. Microwave radiometers on research aircraft have served as prototypes for upcoming satellite missions and also within calibration and validation (CAL/VAL) activities. Compared to satellite missions, they allow finer scale observations than satellites in remote areas, such as the tropical trade wind region [41.2].

41.1.1 Measured Parameters

Microwave radiometers (MWR) are passive remote sensing instruments that measure the natural thermal emission by atmospheric components and from the ground. Typically, microwave radiation is measured in several spectral channels and is provided as the brightness temperature (BT), i.e., the temperature a blackbody producing the same radiance would have according to Planck's law (Table 41.1). Note that this is the typical nomenclature of the satellite community, while the ground-based community typically uses TB as an acronym for brightness temperatures (Chap. 29). The reflection of microwave radiation at the surface, as well as scattering by hydrometeors in the atmosphere, can lead to polarization and serves as an additional information source. The MWRs are polarization sensitive, and BT are often measured in vertical and horizontal polarizations. To observe the wind vector over the ocean even the full Stokes vector is used [41.3].

For NWP, BT are directly assimilated at most operational centers by using forward operators, including the description of radiative transfer. By applying retrieval algorithms to sets of different spectral regions, a variety of atmospheric and surface variables can be derived (Table 41.2).

Table 41.1 Measured parameters of microwave radiometers

Parameter	Description	Unit	Symbol
Brightness temperature	Radiances detected by microwave receivers in a limited frequency interval (bandwidth) and a certain polarization state are calibrated to the Planck equivalent brightness temperatures	K	BT

Table 41.2 Parameters retrieved from measurements of brightness temperatures in different frequency channels

Parameter	Description	Unit	Symbol
Temperature profile	Vertically resolved atmospheric temperature	K	T
Precipitable water vapor	Column integrated amount of water vapor	kg m^{-2}	PWV
Humidity profile	Vertically resolved water vapor mixing ratio	kg kg^{-1}	q
Liquid water path	Column integrated amount of liquid water	kg m^{-2}	LWP
Precipitation	Precipitation rate at the surface	mm h^{-1}	R
Ice water path	Column integrated amount of frozen hydrometeors	kg m^{-2}	IWP
Snowfall rate	Liquid equivalent of frozen precipitation rate	mm h^{-1}	S
Ocean wind speed	Wind speed at the ocean surface	m s^{-1}	OWS
Soil moisture	Volumetric soil moisture	%	SM
Land surface temperature	Skin temperature of the land surface	K	LST
Sea surface temperature	Skin temperature of the sea	K	SST
Sea surface salinity	Percentage of salt in sea water at the sea surface	PSU	SSS
Sea ice concentration	Area covered with sea ice relative to the total area	%	SIC
Sea ice type	Classification of sea ice into first-year and multiyear ice		
Snow water equivalent	Equivalent height of melted snowpack	mm	SWE
Stratospheric trace gases	Vertically resolved concentrations of different gases such as ozone, ClO, BrO, HCl, HNO ₃	ppm	

Fig. 41.1 Atmospheric transparency at sea level (solid line) and at 5 km elevation (dotted-dashed line) in the microwave spectrum for the clear-sky standard atmosphere showing the absorption features related to water vapor (grey) and oxygen (brown)

41.1.2 Principles of Measurements

All natural objects emit thermal radiation in the microwave spectral region. The transparency of the atmosphere is rather high at low microwave frequencies and generally decreases with increasing frequency (Fig. 41.1). The emissivity ε of the surface strongly depends on the surface roughness and dielectric properties of the material, varying roughly between 0.3 for ocean surfaces to 1 over vegetated land surfaces (Fig. 41.2). When the emissivity is known and the atmosphere is highly transparent, i.e., at low frequencies (< 20 GHz), the thermal radiation received at the satellite is closely proportional to the surface brightness temperature, and sea and land surface temperatures (SST and LST) can be derived. Sea-surface emissivity depends on surface roughness, temperature, and salinity. As the land emis-

sivity depends on the water content, especially at low frequencies, the soil moisture content can be derived. The strong contrast between the emissivity of sea water and sea ice allows us to distinguish open ocean from sea ice. The emissivity of snow and ice strongly depends on their morphologies allowing us to retrieve more details on the age and thickness of sea ice (Table 41.2).

Several atmospheric gases exhibit rotational transitions (Fig. 41.1), which allows us to derive information about their abundance and vertical structure. Examples of such absorption features are the oxygen absorption complex (caused by magnetic dipole transitions) around 60 GHz, which is used to derive temperature profiles or the water vapor absorption line at 183.31 GHz (dipole rotational transition). Other significant absorption lines are found at 118.75 GHz (oxygen absorption) and at 22.235 GHz (water vapor absorption). The 183.31 GHz line is much stronger than the 22.235 GHz one and is used for spaceborne moisture profiling [41.7] as the strong atmospheric absorption masks the surface. Weak absorption features of trace gases like ozone, nitrous dioxide, or chlorine monoxide are also used for profiling of these species. To derive their stratospheric profiles, limb sounding is employed and spectrally resolved measurements around the center of the pressure broadened absorption lines are performed (Chap. 28 Spectrometry).

In addition to the distinct absorption features of molecular transition lines, there are also nonresonant contributions by hydrometeors (liquid drops and frozen particles). Liquid water emission increases with frequency. Hence, measurements at window channels dominated by liquid water emission (typically 37 GHz), together with those close to the water absorption line (22.235 GHz), are used to observe the vertically in-

Fig. 41.2 Microwave emissivity ε for vertical polarization (unless otherwise stated) between 10 and 100 GHz at 53° incidence angle for different surface types derived from FASTEM calculations for ocean [41.4] and emissivity atlas TESSEM² for the continental surfaces (after [41.5, 6])

Table 41.3 The most important microwave instruments, their acronyms, satellite platforms, and operation time periods

Acronym	Instrument	Primary Usage	Platform	Time frame
AMSR AMSR-E AMSR-2	Advanced Microwave Scanning Radiometer	Sea ice and snow, SST, precipitation, PWV, LWP	ADEOS-2, EOS-AQUA, GC-COM-W, GOSAT-3	Since 2002
AMSU-A	Advanced Microwave Sounding Unit – A	Temperature profiling, PWV, LWP	Since NOAA-15, AQUA, MetOp	Since 1998
AMSU-B	Advanced Microwave Sounding Unit – B	Specific humidity profile	NOAA-15 to NOAA-17	1998–2004
ATMS	Advanced Technology Microwave Sounder	Precipitation, sea ice, wind speed, PWV, LWP, water vapor and temperature profiles	NOAA NPP	Since 2011
GMI	Global Precipitation Mission (GPM) Microwave Imager	Precipitation, PWV, LWP	GPM Core Satellite	Since 2014
MHS	Microwave Humidity Sounder	Specific humidity profile	Since NOAA-18, MetOp	Since 2005
MLS	Microwave Limb Sounder	Ozone, chlorine monoxide, nitric acid	UARS, EOS-AURA	1991–2018
SMOS	Soil Moisture and Ocean Salinity	Soil moisture, sea surface salinity	SMOS	Since 2009
SMAP	Soil Moisture Active–Passive	Soil moisture	SMAP	Since 2015
SSM/I	Special Sensor Microwave/Imager	Precipitation, sea ice, wind speed, PWV, LWP	Since DMSP-F08 until DMSP-F15	Since 1987
SSMIS	Special Sensor Microwave Imager/Sounder	Precipitation, sea ice, wind speed, PWV, LWP, temperature, water vapor and temperature profiles	Since DMSP-F16	Since 2003
TMI	Tropical Rainfall Measuring Mission (TRMM) Microwave Imager	Precipitation	TRMM	1997–2015
WindSat	WindSat	Sea surface wind vector	Coriolis	Since 2003

Table 41.4 Principles of microwave remote sensing for different applications and most important satellite instruments

Applications	Measurements		Instrument
	Principle	Frequencies used (GHz)	
Temperature profile	Sounding along oxygen absorption complex	50–60	AMSU-A, ATMS
Precipitable water vapor	Emission above radiatively cold ocean with correction for liquid water	19/24 & 31/36	SSM/I, AMSR, GMI
Humidity profile	Sounding along water vapor line	183	AMSU-B, MHS, ATMS
Liquid water path	Emission in window channels corrected for water vapor	31/36/90 & 24	SSM/I, AMSR, GMI
Precipitation	Emission algorithms over ocean and	19, 22, 36	SSM/I, AMSR, GMI
	scattering algorithms over land	90, 150	
Ice water path and snowfall rate	Scattering signature	90, 150, 183	AMSU, MHS, GMI
Wind speed	Surface roughness, polarization signal at the ocean surface	10, 19, 36	SSM/I, AMSR, GMI, WindSat
Soil moisture	Surface emission	1.4	SMOS, SMAP
Land surface temperature	Surface emission	19, 36	SSM/I, AMSR, GMI
Sea surface temperature	Surface emission	6	AMSR
Ocean (or sea) salinity	Surface emission	1.4	SMOS, SMAP
Sea ice concentration	Surface emission	6, 10, 19, 36, 90	SSM/I, AMSR, GMI
Sea ice type	Surface emission	6, 10, 19, 36, 90	SSM/I, AMSR, GMI
Snow water equivalent	Surface emission	19, 36, 90	SSM/I, AMSR, GMI

tegrated liquid water path (LWP) and simultaneously the precipitable water vapor (PWV) over ocean surfaces. The so-called *water vapor continuum* increases strongly with frequency with a nearly opaque atmo-

sphere in the far-infrared part of the electromagnetic spectrum.

Large rain drops, as well as large frozen hydrometeors (snow, graupel, hail), also scatter microwave

radiation, especially at higher frequencies (> 90 GHz). [41.8] first suggested a scattering index to identify and subsequently derive precipitation also above land surfaces. Furthermore, the scattering signal is exploited in integrated retrieval algorithms to obtain the snowfall rate [41.9].

Several satellite missions employ microwave instruments to measure land surface and atmospheric parameters for different applications. The World Meteorological Organization (WMO) keeps an inventory of the different satellite instruments on their webpage <https://www.wmo-sat.info/oscar/instruments#>, Accessed 15 July 2021. Information on the most important ones is

provided in Table 41.3 and the measurement principles for the different applications are given in Table 41.4. Here, the focus is on routine measurements performed from polar orbiting satellites operated by the European Organization for the Exploitation of Meteorological Satellites (EUMETSAT), the Defense Meteorological Satellite Program (DMSP), the Japan Aerospace Exploration Agency (JAXA), and the National Oceanic and Atmospheric Administration (NOAA). Furthermore, Earth Observation System (EOS) satellites (AQUA, AURA, TERRA) by the National Aeronautics and Space Administration (NASA) dedicated to Earth Observations are included.

41.2 History

Microwave radiometry was developed in the field of astronomy and extraterrestrial applications. In 1962, the Mariner-2 mission to Venus was launched by NASA and included a two-channel radiometer at 16 and 22 GHz to investigate water vapor and temperature. In 1972, the first systematic microwave observations of the Earth, between 22 and 58 GHz were made aboard the NASA operated Nimbus 5 missions in polar low Earth orbit. These microwave data produced for the first time temperature profiles in the presence of clouds and provided the vapor and liquid water contents of the Earth's atmosphere over the ocean [41.10]. Within the Nimbus series, radiometers advanced further, and in 1978 the nine-channel scanning multichannel microwave radiometer (SMMR, [41.11]) was launched into space. This demonstrated the considerable potential of passive microwave measurements for meteorology and their complementarity with visible and infrared observations.

These Nimbus satellite missions were mainly dedicated to research and paved the way for low-orbit operational meteorological satellites as we know them today. Starting in 1979, low-orbit meteorological satellites managed by NOAA were equipped with microwave sounders. The MSU radiometer (Microwave Sounding Unit) was first placed in orbit aboard the TIROS-N satellite at the end of 1978. The MSU radiometers (nine in total) included four channels between 50 and 60 GHz to provide measurements of atmospheric temperature down to the lower troposphere, with a ground spatial resolution of about 250 km.

With the operational deployment of the SSM/I instrument, a follow-up of SMMR, on the DMSP satellite series in 1987, global precipitation observations over ocean became possible. Their data built the backbone of global precipitation records in the satellite era [41.12].

For the tropics, TRMM provided a milestone, as for the first time, microwave passive (from radiometers) and active (from radar) observations were combined to improve the accuracy of precipitation estimates. Geostationary satellites allow temporal resolutions of the order of 15 min. However, these satellites are still not equipped with passive microwave instruments, as large antenna systems would be required even for moderate spatial resolution (Sect. 41.4). The temporal repeatability of microwave measurements is, therefore, limited by the number and temporal spacing of low-orbiting satellites within a constellation, such as GPM, currently providing observations at the same location every 3 h.

In the 1980s, thanks to advances in microwave radiometer technology, more accurate observations at higher frequencies were possible, up to 200 GHz. This opened the possibility of analyzing the water vapor profile in the atmosphere by measurements in the 183 GHz water vapor line. In 1998, the Advanced Microwave Sounding Unit (AMSU) instrument was launched onboard of NOAA-15, the first satellite of the NOAA fifth generation/Polar Operational Environmental Satellites, which was specifically designed for temperature profiling but also for providing information on water vapor and hydrometeors. Launched on nine satellites in total, the AMSU instrument provides core information for numerical weather prediction.

With the detection of the Antarctic ozone hole in 1995, the need to monitor stratospheric trace gases became apparent. MLS onboard the Upper Atmospheric Research Satellite (UARS) launched in 1991 for the first time provided global observations of species involved in the catalytic cycle of ozone depletion, e.g., chlorine monoxide, and nitric acid. The follow-up mission on the Earth Observation System (EOS) Aura satellite expanded spaceborne microwave mea-

measurements into the submillimeter range to observe the hydroxyl radical (OH) at 2.5 THz.

For the next generation of Meteorological Operation satellites (MetOp-SG, for the Second Generation, after 2020), Europe decided to strengthen the passive microwave observations, with the addition of two instruments, the Microwave Imager (MWI) and the Ice

Cloud Imager (ICI), in addition to the temperature and humidity sounder (Microwave Sounder (MWS)). With the ICI instrument, observations up to 664 GHz will be made for the first time for operational meteorology. These measurements will have a high sensitivity to ice in the clouds and will allow an estimate of the ice water content, a variable that is currently poorly known.

41.3 Theory

The basics of microwave radiative transfer in the atmosphere are described in the literature [41.13–15], as well as in Chap. 29. While ground-based microwave radiometers observe the atmospheric contribution against the cold cosmic background ($T_{\text{cos}} = 2.7$ K), the Earth's surface emission becomes the background for the airborne and satellite perspective. For simplicity, we assume an atmosphere with constant vertical properties that has the optical depth τ_{atm} and the blackbody brightness temperature BT_{atm} . The simplified monospectral radiative transfer equation then consists of four different contributions to the brightness temperature at the satellite

$$BT = BT_{\text{atm}} + \varepsilon BT_{\text{surf}} e^{-\tau_{\text{atm}}} + (1 - \varepsilon) BT_{\text{atm}} e^{-\tau_{\text{atm}}} + (1 - \varepsilon) BT_{\text{cos}} e^{-2\tau_{\text{atm}}}. \quad (41.1)$$

In addition to the direct atmospheric BT (first term), the satellite senses the emission of the surface according to the emissivity ε times blackbody brightness temperature of the surface (second term) attenuated by the atmosphere. The third term describes how downwelling atmospheric radiation is reflected by the surface and attenuated by the atmosphere on its path to the satellite. The fourth term becomes important only for rather low-opacity conditions and for reflective surfaces, in which case the cosmic background signal is reflected and attenuated twice by the atmosphere. For sounding channels with high opacity, only the first term is important, while for land surface missions, frequencies with low τ_{atm} are chosen to avoid atmospheric contributions such that the second term dominates. Knowing the surface properties and the vertical profiles of thermodynamical variables and all absorbing gases, synthetic satellite measurements of BT can be calculated using radiative transfer models.

Equation (41.1) describes the simplified case of a nonscattering atmosphere. However, in the presence of large hydrometeors and especially frozen hydrometeors, scattering cannot be neglected. Thus, scattering must be considered, and the effects from all directions need to be included. Furthermore, in order to treat po-

larization effects from the surface or hydrometeors, the Stokes formalism needs to be used. The atmospheric radiative transfer simulator (ARTS; [41.16]) is an example of a complex community model that can treat these effects, as well as different geometries. For many applications, a fast model is necessary. In Europe, the radiative transfer for ATOVS (RTTOV) [41.17] is frequently used to calculate synthetic satellite measurements from NWP or climate model output (Sect. 41.8.1).

41.3.1 Surface Emissivity

In principle, the Fresnel equations that describe the reflection and transmission of light at an interface can be used to calculate the frequency dependent emissivity ε_v of a flat water surface for any incidence angle and orthogonal polarization with the water permittivity calculated as a function of temperature and salinity. However, over the oceans, the effects of near surface winds on surface roughness and foam production, as well as the appearance of larger-scale waves and swell influence emissivity. Efficient models have been set up to estimate the emissivity as a function of surface wind speed and direction, sea-surface temperature, and salinity. These models are based on a two-scale approach combining the small-scale effect of ripples and those of large-scale waves that can be treated as an ensemble of facets, for which the Fresnel reflection applies. Estimating the surface coverage of foam and its emissivity is difficult, and several models exist. The dielectric properties of sea water depend upon its temperature and salinity. Salt is a good conductor and contributes to the imaginary part of the dielectric constant for low frequencies. Above 20 GHz, the effect of salinity becomes negligible. Double Debye models have been developed to fit observations [41.18]. The Fast Microwave Emissivity Model (FASTEM) [41.4] is adopted in RTTOV and in the Community Radiative Transfer Model (CRTM). Herein, a two-scale model is parameterized, which is optimized for the frequencies up to 200 GHz that are currently observed. Recently, the Tool to Estimate Sea

Surface Emissivity from Microwave to Submillimeter waves (TESSEM²; [41.19]) became available to handle frequencies above 200 GHz.

Over continental surfaces, the physical modeling of the microwave emissivity is very challenging. First, the interaction of electromagnetic waves with the surface components is very difficult to model, and different schemes have to be developed, depending on the surface types. Second, the land surface emissivity is sensitive to a large number of parameters (e.g., soil moisture, topography, as well as the presence and physical properties of vegetation or snow) and shows a broad spatial and temporal variability. Specific emissivity models have been developed for different surface types, taking into account more or less complex processes. A major obstacle is the limited availability and/or reliability of model inputs (such as soil moisture, snow grain size, vegetation water content). Given the difficulty to model the emissivities of land surfaces and sea ice, they have also been derived directly from satellite observations. The satellite measurements have been exploited to analyze spectral, angular, and polarization dependence of satellite-derived emissivities. The Tool to Estimate the Land Surface Emissivity from the Microwaves to the Millimeter Waves (TELSEM²; [41.5, 6]) provides a parameterization of the emissivity for all observing conditions and for all continental surfaces, given the surface location and month of the year, for frequencies from 6 to 700 GHz.

41.3.2 Atmospheric Gases

In the microwave spectral range, absorption by atmospheric gases can be separated into contributions by resonant transitions (by gases like H₂O, O₂, O₃) and nonresonant absorption. The latter is commonly known as continuum absorption and is less well understood, as the relative contributions of bimolecular absorption and far-wing effects are unclear [41.20]. To describe the absorption coefficient α leading to atmospheric opacity in (41.1), frequently used absorption models describing both resonant and continuum absorption are the one by [41.21] or the Microwave Propagation Model (MPM) by [41.22]. These models only include the major effects of oxygen, nitrogen, and water vapor, while trace gases important for atmospheric chemistry, e.g., O₃, N₂O, or ClO, are not considered. For these gases, whose main absorption features occur above 100 GHz, line catalogues like the high-resolution transmission molecular absorption database (HITRAN; [41.23]) are available. The improvement of absorption models is an ongoing process and is pursued by performing laboratory measurements and radiative closure studies using field measurements. A thorough review on microwave

spectroscopy relevant for the remote sensing of water vapor can be found in [41.24].

The strong absorption features of oxygen and water vapor, around 60 and 183 GHz, respectively (Fig. 41.1), are frequently used by satellite instruments to profile temperature and water vapor, respectively. Within these bands, the atmosphere becomes opaque, and due to the low transmission of the atmosphere, all terms in (41.1), except the first one, can be neglected. However, the temperature of the atmosphere is not constant with altitude, and instead of a simplified BT_{atm} , we need to consider the thermal emission in each height z , depending on its temperature and absorption coefficient, which is subject to attenuation along its path to the satellite. This leads to the definition of the temperature weighting function W_T , which relates the brightness temperature at a frequency ν at the satellite to the atmospheric temperature profile

$$BT_\nu \approx \int_0^\infty W_{T,\nu}(z)T(z)dz, \quad (41.2)$$

with

$$W_{T,\nu}(z) = \alpha_\nu(z)e^{-\int_z^{\text{TOA}} \alpha_\nu(z')dz'}. \quad (41.3)$$

The weighting function at a given frequency describes the contribution of each height to the total signal; W_T is equal to the change in transmission with height [41.25]. As shown in Fig. 41.3, frequency channels in the center of the absorption feature, e.g., 57 GHz, have a strong contribution from the upper atmosphere. In fact, the absorption is so high that emission by lower layers is completely absorbed by higher layers. Therefore, a clear maximum in the weighting function at a certain height is observed. This height constantly moves to lower altitudes the more transparent the atmosphere becomes, i.e., the further the frequency moves away from the center of the absorption feature. For very transparent frequencies, e.g., 31.4 GHz, the maximum contribution stems from the surface.

The broad vertical range of the weighting functions illustrates that temperature profiles can only be retrieved with coarse vertical resolution. Furthermore, the relation between BTs measured at a set of microwave frequencies and the temperature profile is ambiguous. Therefore, retrieval algorithms do not perform a direct matrix inversion but rather stabilize the solution by introducing prior knowledge on the structure of the atmosphere. The simplest algorithms make use of a database of synthetic BTs calculated from a set of typical atmospheric states, for example from radio soundings or NWP output. Statistical algorithms based on linear regressions or neuronal networks are then trained with

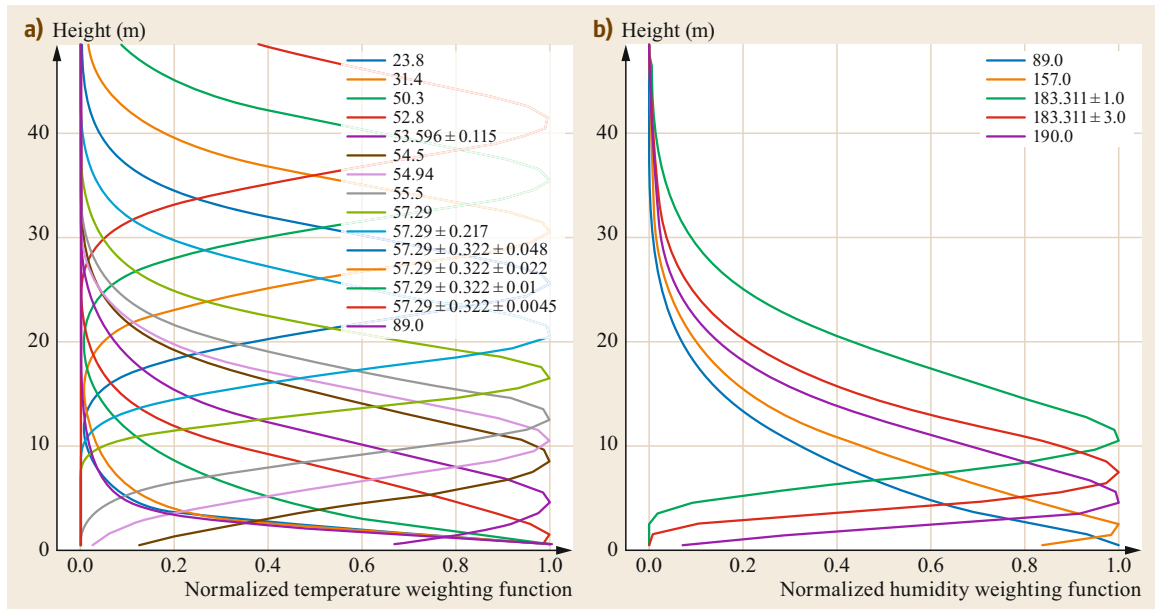

Fig. 41.3a,b Normalized weighting functions for the different frequency channels used by AMSU-A (a) and MHS (b)

the data set. More physically based algorithms employ Bayesian methods for the retrieval.

41.3.3 Atmospheric Hydrometeors

Atmospheric hydrometeors, e.g., cloud droplets, rain drops, ice particles, and graupel, show a large variety in terms of size, shape, density, etc., which determines how they interact with radiation. Cloud droplets with a size of about $10 \mu\text{m}$ are small compared to microwave wavelengths, and, therefore, no significant scattering occurs. Their mass absorption coefficient can be calculated using the Rayleigh approximation, and it increases with frequency. It depends on the dielectric permittivity that is accurately known for temperatures above zero degree Celsius but it is more uncertain for supercooled liquids [41.26].

In general, absorption and scattering of spherical particles can be calculated using Mie theory. With larger rain drops, the shape deviates more and more from a sphere as they become flattened. Therefore, more complex methods to calculate the single-scattering properties are needed. The T-matrix method [41.27] can handle homogeneous, rotationally symmetric, nonspherical particles in fixed and random orientations,

which is suitable to describe absorption and scattering by rain drops. With the axis ratio parameterized as a function of particle size, polarization effects due to the nonspherical shape can be described.

For frozen hydrometeors, particle absorption is mostly negligible compared to scattering, but the situation becomes more complex due to the enormous variety of individual particles in terms of size, shape, density, and orientation. Still, the T-matrix method is frequently employed in the assumption that the single-scattering properties of a spheroid to some extent approximate the ensemble-averaged properties of more realistically shaped particles. For a more accurate description of the single-scattering properties of complex ice particles, the discrete dipole approximation (DDA; [41.28]) can be used. However, besides it being computationally expensive, the problem lies in the realistic description of the size and composition of the particles. To overcome the high computational demand, databases have been generated that contain the single-scattering properties for common shapes and frequencies [41.29–31]. These databases still do not cover the full frequency range, especially for the higher frequencies, as well as more complex particles, such as the ones found in the melting layer.

41.4 Devices and Systems

Microwave radiometers onboard satellites have a similar design to those operated from the ground (Chap. 29). The major difference is in the antenna system, as narrow beams are needed to achieve useful resolution at the Earth's surface. Narrow beams are obtained through large apertures, and therefore the antenna system often becomes the driver in the design of the satellite payload. Currently, microwave radiometers are only employed in low-Earth orbits with typical flight altitudes of about 800 km above the Earth's surface. For example, the EUMETSAT MetOp series is in Sun-synchronous orbit at 827 km passing the Equator at 09:30 LT on its descending branch. With an orbital period of 101 min, about 14 orbits per day are performed. To obtain a broad swath and good global coverage, cross track or conical antenna scanning is exploited. In the following, more details for the three geometries used by microwave instruments are given, together with their advantages and disadvantages (Table 41.5).

41.4.1 Microwave Imagers

The passive microwave imagers are equipped with a conical scanning mechanism that makes it possible to observe with a constant incidence angle, over a set of selected frequencies. Figure 41.4 schematically depicts the scanning configuration of a conically scanning imager like SSM/I or AMSR. For example, AMSR-2, a large-frequency range imager launched in 2012, has an antenna main reflector with a 2 m-diameter and a fixed off-nadir angle of $\theta = 46.5^\circ$ providing an incidence angle of 55° at the surface. It rotates at 40 rounds per minutes to provide successive fields of view (FOV) over a 1450 km swath. AMSR-2 observes at seven frequencies (6.9, 7.3, 10.65, 18.7, 23.8, 36.5, and 89 GHz) in both orthogonal polarizations. The FOV, defined as the intercept between the half-power beam width and the Earth's surface, has an elliptical shape and is largest (35×62 km) at 6 GHz. With a constant antenna size, it is smallest (3×5 km) at 89 GHz, i.e., the shortest wavelength. The receivers are regularly calibrated using hot

and cold references. The cold reference is provided by the deep space, whereas the hot loads are blackbodies at a controlled temperature.

Sun-synchronous passive microwave polar imagers provide a quasi-full coverage of the globe each day, with ≈ 14 orbits. Figure 41.5 presents the descending orbits for half a day from SSMIS on the DMSP-F17 satellite, on 11 November, 2007, for two frequencies (19 and 91 GHz) and both vertical and horizontal polarizations. One can immediately note the difference in atmospheric absorption at these two frequencies: the surface structures appear very clearly at 19 GHz, whereas 91 GHz is clearly more sensitive to the atmospheric features, such as water vapor, cloud, and rain. The polarization difference at 19 GHz is rather large over the ocean and depends upon the wind-induced surface roughness; this effect is exploited to estimate the wind speed of the ocean. Over the poles, the large variability of the surface emissivity at these frequencies is analyzed to extract the ice cover, which can be seen especially well in the Southern Hemisphere.

Fig. 41.4 Conical scanning configuration. The color shading illustrates the different FOV sizes at different frequencies, i.e., darker areas indicate higher frequencies

Table 41.5 Advantages and disadvantages of different viewing geometries

Devices	Advantages	Disadvantages
Conical scanning by microwave imagers	<ul style="list-style-type: none"> • Always the same geometry with respect to the surface, and as a consequence, possibility to build an image • Possibility to measure the different polarizations 	<ul style="list-style-type: none"> • Large incidence angle (around 53°) that provides lower spatial resolution than close to nadir views • Calibration issues
Cross track scanning by microwave sounders	<ul style="list-style-type: none"> • Good spatial resolution close to nadir 	<ul style="list-style-type: none"> • Varying observing conditions (incidence angle, polarization) that makes retrieval more complicated
Limb sounders	<ul style="list-style-type: none"> • Good vertical resolution • No impact of the Earth's surface background 	<ul style="list-style-type: none"> • Poor horizontal spatial resolution

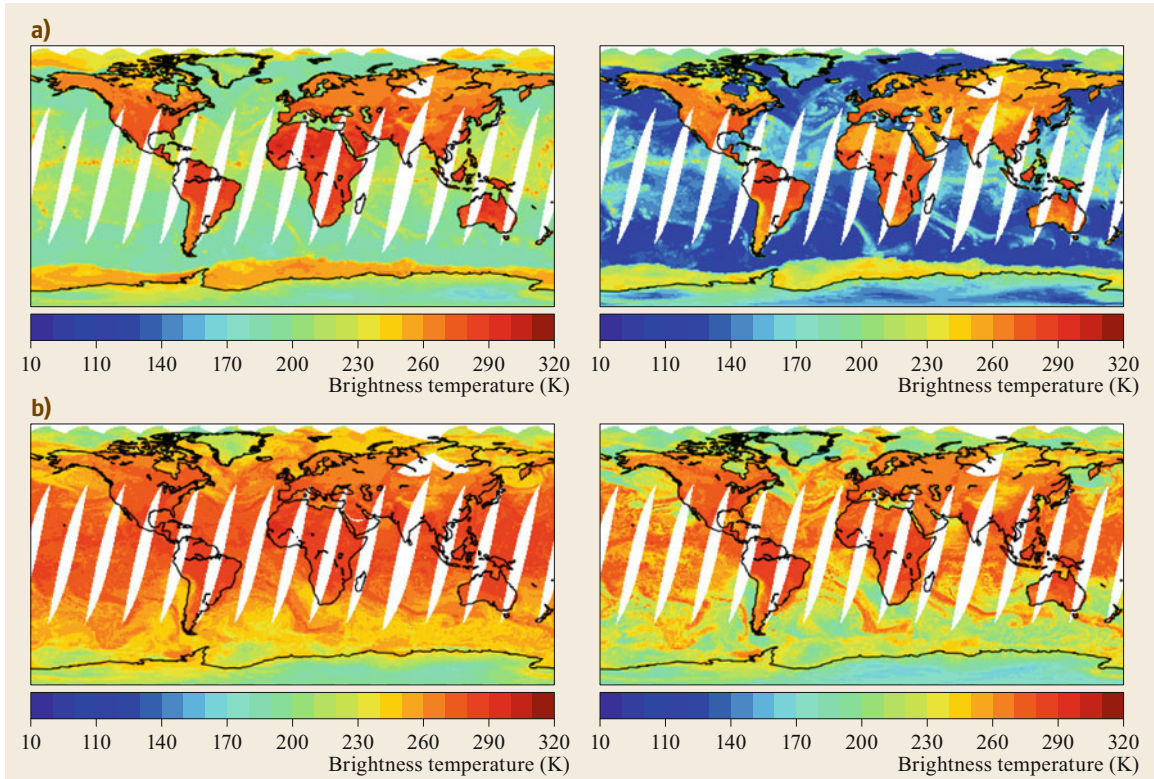

Fig. 41.5a,b Examples of passive microwave images over half a day on 11 November, 2007, from SSMIS (F17) descending orbits, at 19 GHz (a) and 91 GHz (b) for both vertical (*left*) and horizontal (*right*) polarizations

41.4.2 Nadir Sounders

Because nadir sounders like AMSU aim at vertical profiling, the fixed incidence angle at the surface is not necessary and cross-track scanning is employed. AMSU is a cross-track step-scan instrument and executes one complete revolution every 8 s period. The AMSU-A antenna systems have a nominal beamwidth of 3.3° covering a 48 km-diameter FOV at nadir. In each cross-track scan (see Fig. 41.6 for illustration), 30 Earth FOVs within an angular range of $\Phi = \pm 48.3^\circ$ from nadir are performed, as well as one cold calibration towards deep space and one view of the warm blackbody. With 837 km nominal orbital altitude, the swath width is 2074 km. The FOV size increases towards the outermost scan positions of the Earth views. AMSU-A has been mainly designed for temperature profiling with 12 frequency channels along the 60 GHz oxygen absorption complex. Additional channels are located along the weak water vapor line at 23.8 GHz and in two windows,

at 31.4 and 89 GHz, providing information on water vapor and clouds.

AMSU-B and its successor MHS are self-calibrating, cross-track scanning, five-channel microwave, full-power radiometers, operating in the 89 to 190 GHz region dedicated to water vapor profiling. AMSU-A and AMSU-B (or MHS) share the same antenna. Therefore, due its shorter wavelengths AMSU-B/MHS channels have a narrower beamwidth (1.1°), yielding a 15 km

Fig. 41.6 A cross-track scanning configuration. The *color shading* illustrates the different pixel sizes at different frequencies ▶

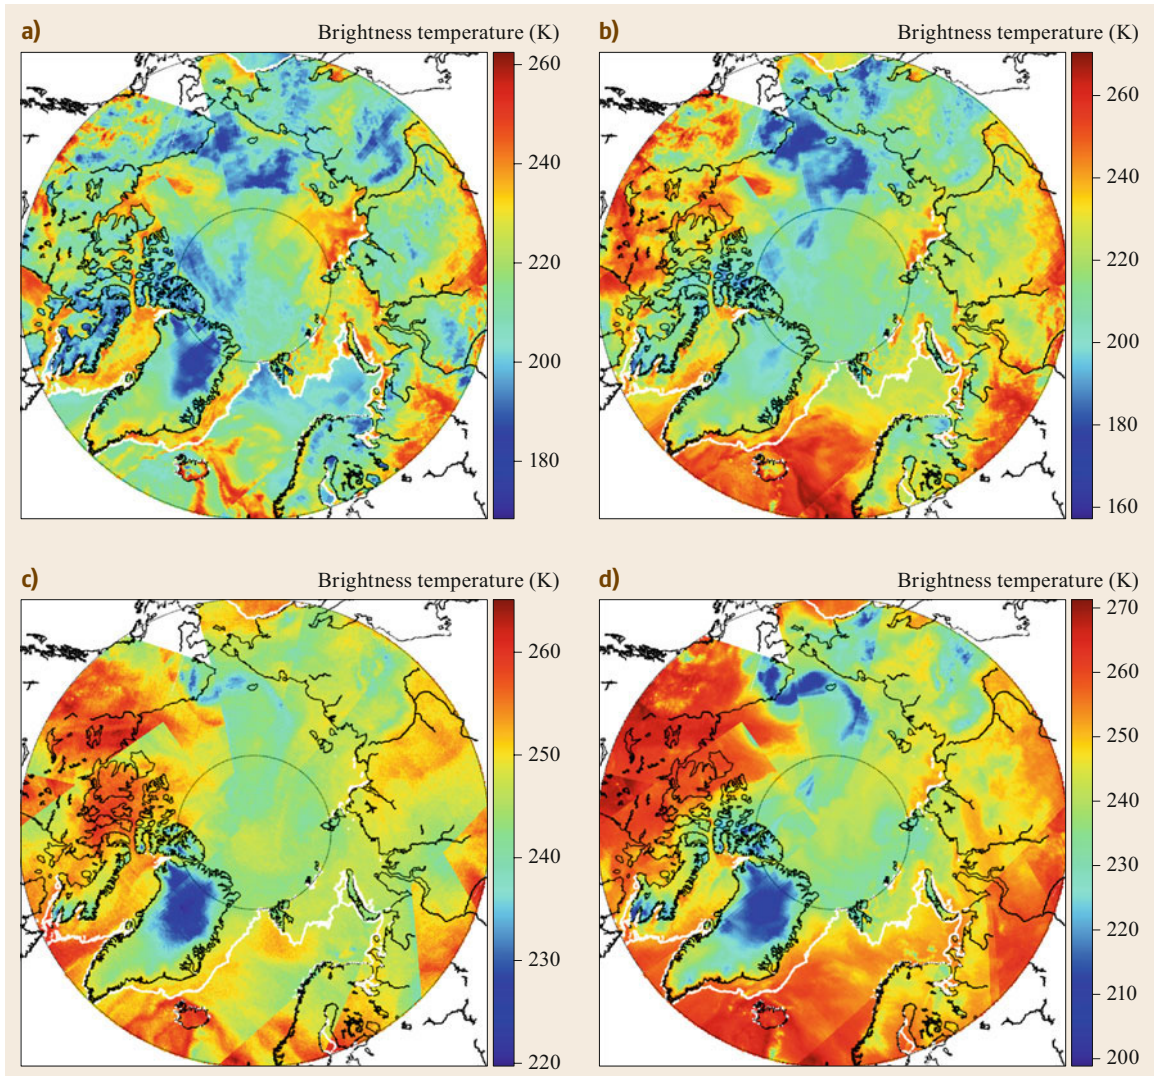

Fig. 41.7a–d Example of the brightness temperatures at 89 (a), 150 (b), (183.31 ± 7) GHz (c), and (183.31 ± 3) GHz (d) for the whole Arctic domain (coverage north of 60°) measured by all AMSU-B/MHS instruments in orbit on the first 6 h (00:00–06:00 UTC) of an individual day (31 March, 2011). The *white contours* mark the area with sea-ice concentration $> 15\%$

resolution at nadir. The instrument is able to scan through 90 Earth views once every 2.667 s.

Polar orbiting satellites have best coverage at high latitudes. Figure 41.7 shows that already within 6 h the whole Arctic is well covered. The example of the brightness temperatures measured by all AMSU instruments in orbit on March 31, 2011 illustrates the strong influence of surface characteristics at the relatively transparent frequency of 89 GHz. Especially the sea-ice margin can be detected well, due to its higher emissivity compared to the open ocean, which is why these measurements are used

to derive sea-ice concentration. At the higher frequency of (183.31 ± 3) GHz surface effects become less apparent, and the higher temporal variability of atmospheric compared to surface features can be seen in the stronger changes between different orbits.

41.4.3 Limb Sounders

Limb sounders avoid the influence of the surface by viewing the Earth's atmosphere along a path that has its closest point to the Earth in the so-called tan-

gent point (Fig. 41.8). By scanning measurements, the

Fig. 41.8 Limb sounding geometry

tangent height can be varied to achieve profile information. This observation technique allows a good vertical resolution, however, at the cost of a relatively large horizontal resolution. The method is therefore best suited for stratospheric and mesospheric measurements with tangent heights typically between 10 and 50 km that can give profile information with about 3 km vertical resolutions. MLS, first launched on UARS in Septem-

41.5 Specifications

Depending on the characteristics of the individual satellite instruments and their observing geometry, the uncertainty in the retrieved parameters is variable. Ta-

ber 1991 and later with spectrally enhanced capabilities on the Aura satellite, has provided vital information for the understanding of stratospheric ozone chemistry and the interaction of atmospheric composition and climate [41.32]. Several atmospheric chemical species (e.g., ClO, BrO, HCl, HNO₃, HO₂, H₂O, N₂O, O₃, OH, and volcanic SO₂) were measured from spectrally highly resolved measurements around absorption lines between 118 GHz and 2.5 THz. Measurements at low tangent heights were used to measure cloud ice to investigate pollution in the upper troposphere.

The joint Swedish, Canadian, Finnish, and French Odin satellite was launched in February 2001 with the submillimeter radiometer (SMR) on board. SMR performed measurements at 486–504 and 541–581 GHz, and one fixed band at 118.75 GHz with spectral resolutions from 150 kHz to 1 MHz [41.33]. The mission served both the astronomical and the atmospheric communities. It provided information on stratospheric ozone, nitric acid, and water vapor, as well as measurements of the upper tropospheric cloud ice.

ble 41.6 gives a rough estimate of these uncertainties and describes the limitations of the products.

Table 41.6 Specification of microwave satellite measurement methods for different parameters

Method	Uncertainty	Limitations
Temperature profile	1–2 K	Coarse vertical resolution
Precipitable water vapor path	1–2 mm	Over ocean surfaces only
Humidity profile	15% RH	Coarse vertical resolution Not possible under low humidity conditions No information on lower atmosphere under moist conditions.
Liquid water path	25 g m ⁻²	Over ocean surfaces only Difficult to distinguish cloud and rain water
Precipitation	20%	Strongly depending on intensity and aggregation time period or region
Ice water path	20%	Not sensitive to very low amounts Depends on the assumptions of particle habit
Ocean wind speed	1 m s ⁻¹	Good sensitivity at rather high wind speeds, less sensitivity at low wind speed Limited sensitivity to wind direction (as compared to the scatterometer)
Soil moisture	< 0.04 m ³ m ⁻³	Rather low spatial resolution (40 km at best), especially when using low microwave frequencies at 1.4 GHz
Land surface temperature	> 2 K	Low spatial resolution and precision as compared to infrared (IR) estimates, but <i>all-weather</i> capability
Sea surface temperature	< 0.5 K	Low spatial resolution and precision as compared to IR estimates, but <i>all-weather</i> capability
Sea surface salinity	< 0.3 PSU (weekly product)	Low spatial resolution due to the necessary use of the 1.4 GHz observations
Sea-ice concentration	15%	Compromise between high spatial resolution (using frequencies > 30 GHz) and high precision (using lower frequencies)
Snow-water equivalent	20% (monthly means)	Significant retrieval errors for individual measurements due to the large variety in snow morphology

41.6 Quality Control

Space agencies employ various quality checks to ensure high accuracy of observed brightness temperatures. In the last years, the degradation of microwave satellite observations due to radio frequency interference (RFI) is becoming more problematic as modern telecommunication systems exploit higher microwave frequencies more and more as they enable higher data rates. The radio regulations at the International Telecommunication Union (ITU) define the frequency bands that are primarily allocated for the passive Earth Exploration Satellite Service (EESS). The intensity of natural microwave radiation from terrestrial and atmospheric sources is generally much lower compared to the intensity from man-made emitters on the ground, on aircraft, or spaceborne systems. Therefore, even an emission outside an allocated band can potentially affect the measurements, as the receiver passband might not completely suppress the external signal. Furthermore, not all satellite frequencies are protected, e.g., 36 GHz, the protected bandwidths are small, and commercial interests threaten even existing protected bands.

The situation is worst at low microwave frequencies due to the high occurrence of RFI sources and the large satellite footprints, which enhance the likelihood for disturbances. SMOS and SMAP (Table 41.3), operating in the passive L band at 1.4 GHz to measure soil moisture and sea salinity, have been particularly severely affected by RFI over continental areas [41.34]. To reduce the effects of RFI, the elimination of illegal sources is attempted, and algorithms to minimize the interference, for example by pulse, frequency or spectrogram blanking have been developed. However, all these techniques reduce observation time. For future missions, RFI resistant receivers are planned for channels that are especially exposed to RFI.

Satellite measurements are mostly used for near-realtime use. However, with the record of conical microwave imagers now covering more than 30 years, climate monitoring is gaining increasing importance. For this purpose, the brightness temperature data from different satellites need to be harmonized, quality controlled, and corrected for different issues to create fundamental climate data records (FCDR). This in-

cludes corrections for cross-track biases, view angle and geolocation errors, emissive reflector issues, solar and lunar intrusions into the warm load, antenna pattern spillover effects, and intercalibration of the instruments. Recently, Berg [41.35] published a > 30 year FCDR using data from a total of 14 research and operational conical-scanning microwave imagers. The data by the SSM/I and SSMIS instruments are available at <http://rain.atmos.colostate.edu/FCDR/>, Accessed 15 July 2021. An interim climate data record is updated in near realtime, and updates to the FCDR are done once a year. With the advent of the GPM, also NASA developed a Level 1C FCDR dataset, available at <https://pmm.nasa.gov/data-access/downloads/gpm>, Accessed 15 July 2021, which has been extended back in time to the SSM/I on board DMSP F08 in July 1987. The imager observations have recently been carefully intercalibrated at the Climate Satellite Application Facility (Climate SAF) under EUMETSAT support and are provided to the community with a quality compatible with climate applications (https://wui.cmsaf.eu/safira/action/viewDoiDetails?acronym=FCDR_MWI_V002, Accessed 15 July 2021).

For nadir sounders, AMSU-A, AMSU-B, and MHS have been in operation since 1998, starting with the launch of NOAA-15 (Table 41.3). In order to arrive at a consistent FCDR, the thorough treatment of cross-scan asymmetry of AMSU-A window channels is of high importance. Ferraro [41.36] utilized a brightness temperature CDR for these satellites to create a dataset called the *Hydrological Bundle* which consists of thematic CDRs (TCDRs) for precipitable water, cloud liquid water, sea-ice concentration, land surface temperature, land surface emissivity for 23, 31, and 50 GHz, rain rate, snow cover, ice-water path, and snow-water equivalent.

Since 2011, ATMS has been combining the capacity of AMSU-A and B in a single compact instrument on board the Suomi National Polar-Orbiting Partnership (NPP) program, with performances superior to AMSU. Based on pitch manoeuvre, a physical model has been developed to correct the scan bias that is often an issue with cross-track scanners [41.37].

41.7 Maintenance

Before launch, satellite instruments are thoroughly tested to check whether they fulfill the requirements, and preliminary calibrated parameters are derived. Past launch a systematic calibration and validation

(CAL/VAL) phase takes place to check the instrumental performances with real orbit data before official data are released. The cold space with the well-known cosmic background serves as the most reliable reference target

and can be used to check whether the radiometric temperature sensitivity (noise equivalent differential temperature, NEDT), i.e., the minimum change in a scene radiometric temperature that can be detected, agrees with prelaunch values. Several checks like systematic differences between ascending and descending overpasses, the spectral dependence of different channels over well-defined surfaces like the ocean, or the variation of long-

term brightness temperature means across track are studied [41.38] for the CAL/VAL assessment of MetOp AMSU instrument. During the lifetime of the satellite instrument, long-term trends in NEDT and housekeeping parameters are continuously monitored to track the instrument performance and system stability. Any maintenance, e.g., the orbit adjustment, is performed by space agencies and depends on the individual mission.

41.8 Application

Microwave satellite measurements are used for a manifold of applications. Here, we only provide a few examples with respect to numerical weather prediction and climate monitoring.

41.8.1 Numerical Weather Prediction (NWP)

Both conical imagers (Sect. 41.4.1) and nadir sounders (Sect. 41.4.2) have become essential ingredients for NWP worldwide. Measurements made by microwave temperature and humidity probes are used in global and regional scale weather forecast models within the *assimilation* process [41.39]. At first, retrieval products from microwave measurements, e.g., temperature profiles, were assimilated. *Gerard and Saunders* [41.40] first used a 1-D variational retrieval for total columnar water vapor from SSM/I measurements at the European Center for Medium-Range Weather Forecasts (ECMWF) forecast model. In a second step, the retrievals were then assimilated using the operational, 4-D variational (4DVar) analysis at ECMWF.

In order to directly assimilate microwave measurements into an NWP model, a fast-forward model is needed to calculate the measurements from the NWP model output. As shown in Fig. 41.9, by using the prognostic temperature, moisture, hydrometeor, and further information from model output, synthetic brightness temperatures can be calculated. Herein it is important that similar assumptions to those in the NWP model are made in the radiative transfer (RT), e.g., the size and shape of hydrometeor particles. However, in order to be computationally efficient fast models are needed, which, for example, employ simplified approaches to scattering. To improve the NWP model using the difference between the synthetic and the real measurements, most assimilation schemes need an adjoint version of the fast RT model. An example for this is the RT-TOV model [41.17], which is used by many operational weather centers.

Together with other satellite measurements and in addition to classical synoptic data, microwave measure-

ments describe the atmospheric column with more precision and allow an improvement of the meteorological forecast. In fact, observations from microwave temperature sounders like AMSU-A are those contributing the most to the improvement of weather prediction, among all the observations assimilated [41.41]. This important impact comes not only from the high information content of each microwave observation, but also from the fact that more data are assimilated, since they are less contaminated by clouds than other satellite observations. This is despite the low intrinsic data volume provided by AMSU compared to high spectral resolution infrared sounders, such as the Atmospheric Infrared Sounder (AIRS) or the Infrared Atmospheric Sounding Interferometer (IASI) (Fig. 41.10).

41.8.2 Earth System and Climate Monitoring

The fact that microwave satellite observations of sufficient quality have now been available for three decades offers the opportunity to build climatological records and to investigate trends of different variables. Most frequently, retrievals from conical imagers, e.g., SSM/I, are used as they provide homogeneous records since 1987. However, for atmospheric parameters they are limited to open water surfaces.

In a warmer climate, it is expected that with constant relative humidity the water vapor increases, and due to its strong greenhouse gas effect, the water vapor feedback amplifies warming. Recently, *Mears* [41.43] combined measurements from 11 satellites and found an increase of about 1.5% in precipitable water vapor per decade over the global ice-free oceans for the time period from 1988 to 2017. In absolute numbers, the trend is highest in the deep tropics (20° S–20° N) with 0.63 kg m⁻² per decade.

Passive microwave observations from conical imagers are also playing a key role in the quantification of the decline of the Arctic sea-ice cover over the last decades. The methodology to estimate the ice cover is based on the large difference in emissivity between the

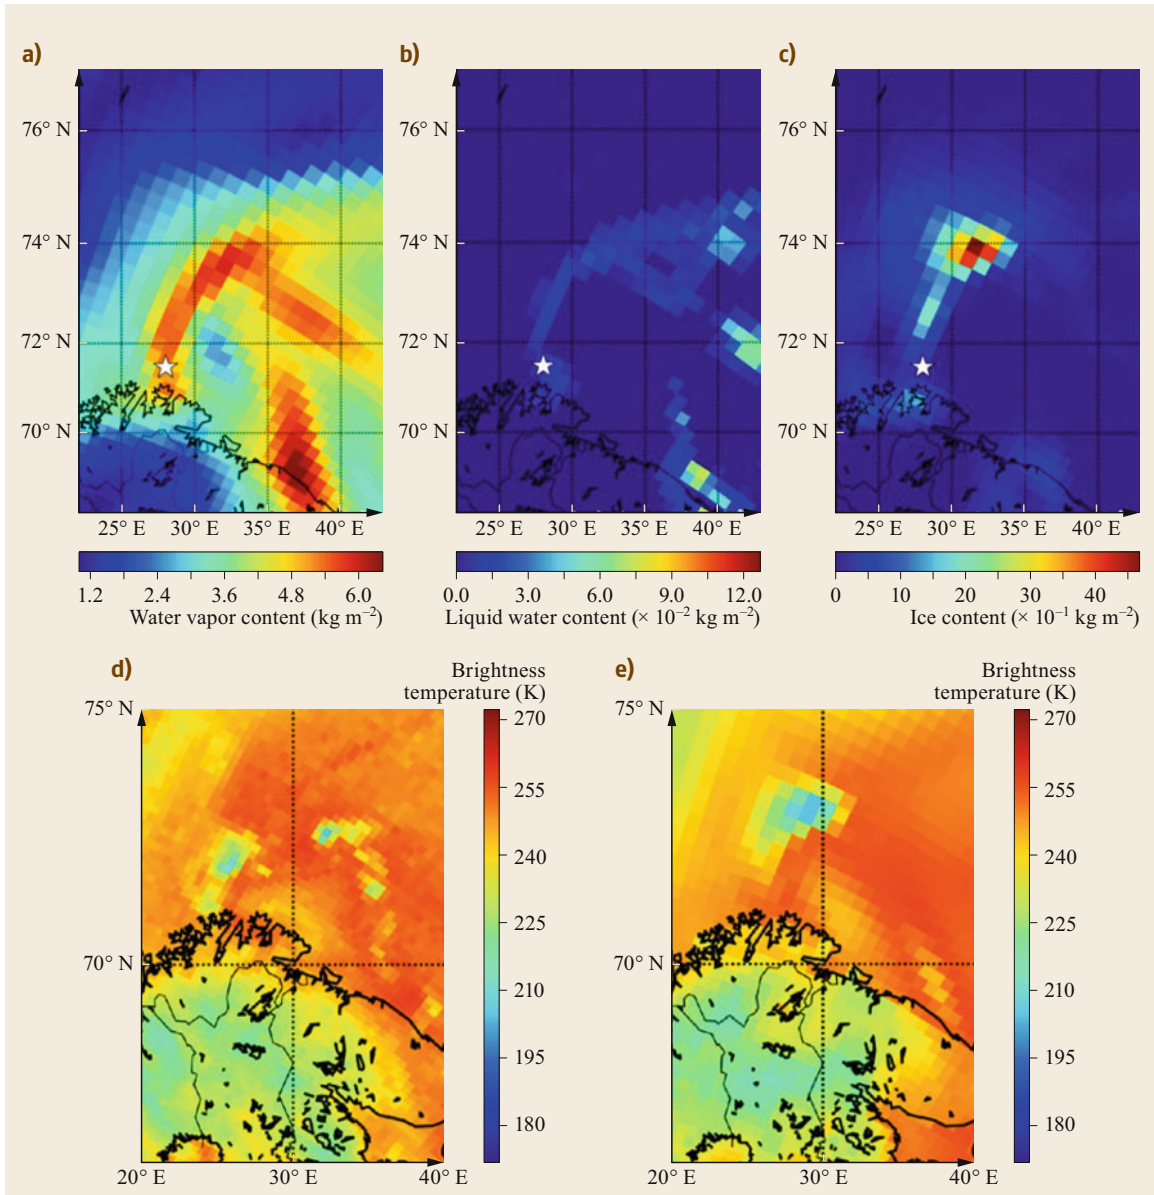

Fig. 41.9 (a) Vertically integrated water vapor; (b) sum of cloud and rain liquid water content, (c) sum of cloud ice, graupel, and snow, all from the Arctic System Reanalysis (ASR); the *star* marks the center of the polar low in (a–c); (183.31 ± 7) GHz BT observed by AMSU-B (d) and simulated BT based on ASR (e)

open ocean and the ice, from 6 and 90 GHz. The higher the frequency, the better the spatial resolution but at the expense of the uncertainty in the ice cover. A continuous series of consistent passive microwave observations from SMMR, SSM/I, and SSMIS have been available since 1978 to provide sea-ice cover over the poles. Fig-

ure 41.11 shows the monthly anomalies in ice area in the Northern Hemisphere, from 1978 to 2016, as estimated from different algorithms [41.44]. Regardless of the retrieval methodology, a similar significant decline in the ice cover is observed, giving rise to a strong confidence in these passive microwave estimates.

Fig. 41.10 The contribution of different data sources, satellite and in-situ, to the ECMWF assimilation system. The error reduction for each type of data is indicated: the more the number is negative, the more the data contribute to the reduction of error (after [41.42] with permission from Wiley and Sons)

Fig. 41.11 Monthly anomaly in the sea-ice area in the Northern Hemisphere, as estimated from different algorithms from a series of passive microwave instruments (SMMR, SSM/I, SSMIS) (after [41.44] with permission from Wiley and Sons)

41.9 Future Developments

Microwave measurements are sensitive to a wide range of atmospheric and surface parameters. Contrary to infrared observations that are blocked by clouds, passive microwave observations at low frequencies can, for example, provide estimates of SST in all weather conditions except rain. The merging of the infrared and passive microwave SST estimates are today used for operational purposes not only for SST but also for precipitation.

The potential of miniaturized satellites to provide more flexible and higher resolved observations is currently investigated within different projects. The Time-Resolved Observations of Precipitation structure and storm Intensity with a Constellation of Smallsats (TROPICS) mission [41.45] is scheduled for launch in 2022 by NASA. It will combine six CubeSats, each equipped with radiometers between 90 and 205 GHz to provide a median refresh rate better than 60 min in the tropics to observe thermodynamics and precipitation structure over the entire storm lifecycle. In the framework of the Temporal Experiment for Storms and Tropical Systems – Demonstration [41.46] six CubeSats were deployed from the International Space Station in July 2018 observing at 5 millimeter-wave frequencies from 89 to 182 GHz. In order to reduce the sensitivity to RFI the CubeRRT (CubeSat Radiometer Radio Frequency Interference Technology Validation)

mission [41.47] investigates on-board realtime RFI processing.

The next generation of European operational meteorological satellites planned after 2020 (Metop-SG) will be equipped with two passive microwave instruments MWI and ICI, in addition to MWS sounder for temperature and humidity. With the ICI instrument, observations above 200 GHz will be made for the first time for operational meteorology. These measurements will have a high sensitivity to ice in the clouds and will allow an estimate of the ice content in the clouds, a variable that is currently poorly known. Currently, an aircraft demonstrator has been developed and installed on a British aircraft, and the community is analyzing these new observations, between 183 and 700 GHz.

In addition, a conical scanning radiometer between 1.4 and 37 GHz and a large antenna (ca. 7 m) are under study in Europe, for high-resolution *all-weather* observations of the polar regions, within the Copernicus program: the Copernicus Imaging Microwave Radiometer (CIMR) [41.48]. With no guarantee of successors to AMSR2, SMOS, and SMAP, the CIMR mission will provide continuity in the observations of low-frequency microwave measurements with much improved radiometric and/or spatial characteristics for all-weather observations of key surface parameters over all surface types.

Susanne Crewell

Institute for Geophysics and Meteorology
University of Cologne
Köln, Germany
susanne.crewell@uni-koeln.de

Susanne Crewell is a Professor for Meteorology at the University of Cologne (Germany). She received her PhD at the University of Bremen in 1993. She has been active in the field of microwave remote sensing, including instrument development for more than two decades, covering ground-based, airborne, and satellite measurements for different applications emphasizing a better understanding of atmospheric water cycle processes.

Catherine Prigent

LERMA
CNRS, Observatoire de Paris
Paris, France
catherine.prigent@obspm.fr

Catherine Prigent is a researcher at the Centre National de la Recherche Scientifique (CNRS, Paris). She received a PhD in Physics from Paris University (1988) and worked at the NASA/Goddard Institute for Space Studies (1995–2000). Her research covers satellite microwave remote sensing of the Earth, for both surface and atmosphere characterization, for global applications. She is involved in the preparation of several satellite instruments with ESA, EUMETSAT, and CNES.

Mario Mech

Institute for Geophysics and Meteorology
University of Cologne
Köln, Germany
mario.mech@uni-koeln.de

Mario Mech is Senior Research Scientist of Meteorology at the Institute for Geophysics and Meteorology at the University of Cologne in Germany. He received his PhD in Meteorology in 2008 from the University of Cologne. His research focus is airborne remote sensing of clouds and precipitation and the simulation of active and passive radiative transfer in cloudy atmospheres for the microwave wavelength region.

Imaging Tech

42. Imaging Techniques

Jan Cermak , Isabel F. Trigo , Julia Fuchs 

This chapter introduces techniques for characterizing the properties of the Earth's surface and atmosphere using satellite sensors. The utilization of passive imagers to measure visible and infrared radiation is at the focus of this chapter.

Earth observation satellites are among the most important means of gathering information about our planet, as they can be used to monitor the various physical, chemical, and biological states and processes that drive the climate and influence the environment. Imaging techniques are methods of creating two-dimensional spatial representations of geophysical parameters, i.e., *images*.

In this chapter, we discuss imaging techniques used by passive-sensor satellite systems that observe the visible (solar) and infrared (terrestrial) ranges of the electromagnetic spectrum. These techniques can be used to characterize either the Earth's surface or its atmosphere. Both of these aims are considered in detail in this chapter.

42.1 Measurement Principles and Parameters

In a classical satellite imaging approach, a sensor mounted on an Earth observation (EO) satellite measures radiation from a target. This radiation reaches the sensor from a variety of directions and angles. The measurements are then mapped onto a data array in a very similar way to the sensor of a digital camera. If the sensor performs *passive* imaging, the radiation from the target was originally generated by a natural source (in contrast to *active* imaging, where the radiation from the target was originally produced by an artificial source on the satellite platform). Thus, passive sensor systems observe radiation that originated from the Sun (visible radiation) or the Earth's surface (infrared radiation). The measurements obtained by these sensors are used to evaluate surface and atmospheric parameters such

as the surface temperature, vegetation and snow cover, cloud properties, aerosol optical depth, and radiation fluxes [42.1]. Satellite imagers provide measurements of large areas, ranging up to the global scale. Depending on the imaging width (swath width) of the sensor and the orbit of the satellite, sampling can be performed at temporal frequencies that complement in-situ observations [42.2]. Geophysical parameters can be extracted from top-of-atmosphere radiances measured by a satellite-based sensor by exploiting the interaction between electromagnetic radiation and the atmosphere and/or the surface via absorption, scattering, emission (thermal or not), or refraction, as further discussed in Sect. 42.3.

A wide range of parameters pertaining to atmospheric or surface properties are retrieved from satellite

Table 42.1 Parameters associated with the Earth's surface (a nonexhaustive list)

Parameter	Description	Unit	Symbol
Land or sea surface temperature	The radiometric temperature of the land or sea surface, corresponding to an aggregated value within the sensor's field of view.	K	LST and SST
Albedo	The ratio of the radiation flux reflected by the surface in all directions to the incoming solar irradiance.	–	AL
Vegetation indices	Combination of radiances measured in two or more channels in the visible and near-infrared that is utilized to identify vegetated areas and the spatiotemporal variability of these areas. This chapter considers the normalized difference vegetation index (NDVI) and the enhanced vegetation index (EVI).	–	NDVI and EVI
Leaf area index	One-half of the total leaf area per unit ground area, accounting for the leaf surface present in a vertical column normalized to its cross-sectional area.	$\text{m}^2 \text{m}^{-2}$	LAI
Fraction of the photosynthetically active radiation absorbed	Fraction of the solar energy incident on the surface that is absorbed by vegetation for photosynthesis.	–	FAPAR
Snow cover/fraction	At the pixel level, this usually corresponds to a yes/no classification for presence of snow. The corresponding aggregation allows the snow cover to be estimated at a lower spatial resolution.	%	SC
Fire radiative power	The total rate at which identified fires are emitting thermal radiation, integrated over all wavelengths and directions.	W m^{-2}	FRP

Table 42.2 Atmospheric parameters (a nonexhaustive list)

Parameter	Description	Unit	Symbol
Shortwave incoming surface radiation	The flux density of solar radiation reaching the Earth's surface	W m^{-2}	SIS
Aerosol optical depth/thickness	Integral of the radiation extinction due to atmospheric aerosols along the satellite sensor's line of sight	–	AOD/AOT
Fractional cloud cover	Fraction of a given satellite pixel covered by cloud	–	CF
Cloud type	Categorization of the clouds detected into common types	–	CT
Cloud optical depth/thickness	Integral of the radiation extinction caused by a cloud along the satellite sensor's line of sight	–	COD/COT
Cloud droplet effective radius	Area-weighted radius of cloud droplets (usually near the cloud top)	μm	DER (also: r_e , a_e)
Cloud liquid water path	Column-integrated liquid water mass per area	g m^{-2}	LWP
Cloud top height	Altitude of the cloud top with respect to a reference level (typically sea level or terrain elevation)	m	CTH

imaging data. This chapter provides an overview of the parameters that are most commonly evaluated through remote sensing, as well as the underlying algorithms employed to derive the values of the surface and atmospheric variables detailed in Tables 42.1 and 42.2. This set of variables cover the satellite products most

commonly applied for climate and environmental monitoring or numerical weather prediction (NWP) model assessment and improvement.

While the abbreviations and symbols used for parameters vary in the scientific literature, those employed in this chapter are widely used.

42.2 History

The history of using spaceborne sensors to retrieve parameters pertaining to the Earth's surface is closely linked to the history of extracting information about the atmosphere using satellites. Many of the sensors that have been used on satellites are identical, and the various methods that have been applied to retrieve useful

images of the Earth's surface and the atmosphere from satellite-based sensors are also related—some surface retrievals require the removal (and thus knowledge) of atmospheric conditions, and some atmospheric retrievals require information on the radiative properties of the surface (such as the *background signal*).

42.2.1 Surface Parameters

The Advanced Very High Resolution Radiometer (AVHRR), which was originally launched into space on TIROS-N in October 1978, is arguably the oldest sensor design still in use by the remote-sensing community. Originally designed as a 4-channel radiometer, it evolved into a 5-channel instrument (AVHRR/2) that was carried by many of the National Oceanic and Atmospheric Administration (NOAA) family of satellites (NOAA-7 to NOAA-14, with launch dates between 1981 and 1994), and later into a 6-channel instrument (AVHRR/3) that was fitted to NOAA-15 (1998) and subsequent NOAA satellites as well the MetOp satellites (Meteorological Operational Satellite; first launched in 2006) operated by the EUMETSAT. This radiometer was designed to allow multispectral analysis of the Earth in the visible to thermal infrared domain as a means to infer cloud cover, surface temperatures, and surface reflectances, which could in turn be used to probe the surface vegetation. The AVHRRs have been, and continue to be, an important source of continuous measurements of our planet at the global scale.

Many algorithms for deriving surface temperatures based on data from AVHRR/2 and later sensors have been proposed since the 1970s and early 1980s. Surface temperature estimation relies on measurements of top-of-atmosphere radiances (converted to brightness temperatures) by channels sensitive to the radiation emitted from the surface; these radiances are then corrected for atmospheric absorption and emission and surface emissivity. Sea surface temperatures (SSTs) have been derived from clear-sky AVHRR observations using the split-window theory (atmospheric absorption can be partially accounted for by analyzing the differences between measurements from split-window channels) and assuming that sea and water surfaces have emissivities that are equal or very close to 1 [42.3–8]. Similar methodologies have also been applied to derive SSTs using other instruments, including the Along Track Scanning Radiometer (ATSR-1 and ATSR-2 on the satellites ERS-1 and ERS-2, respectively)—later replaced by the Advanced Along Track Scanning Radiometer (AATSR) launched on the Envisat satellite [42.9]—and the Moderate Resolution Imaging Spectroradiometer (MODIS).

Strategies to estimate land surface temperatures (LSTs) from satellites have often utilized the split window approach first developed for SST measurements, except that infrared measurements within the thermal window channels provided by the sensors referred to above are analyzed instead [42.10–12]. However, the uncertainty in the surface emissivity and the spatial and temporal variabilities are significantly higher when

attempting to estimate LSTs rather than SSTs. The pronounced diurnal cycle of the LST favors the use of top-of-atmosphere observations acquired by geostationary platforms instead of (or as well as) those obtained by the abovementioned sensors, all of which are installed on polar orbiters. Sensors onboard geostationary satellites, such as the Meteosat Visible and Infrared Imager (MVIRI) on the Meteosat First Generation (first launched in 1977), the Spinning Enhanced Visible and Infrared Imager SEVIRI on the Meteosat Second Generation (launched in 2002), and the imager onboard the North American GOES series (Geostationary Operational Environmental Satellite), have the advantage of providing a higher observation frequency (from 30 to 10 min full disk) at the cost of lower spatial resolution when compared to optical instruments in lower orbits.

It has long been acknowledged that the green vegetation cover can be estimated by comparing the surface reflectance in the visible (red, e.g., AVHRR channel 1) with that in the near-infrared (e.g., AVHRR channel 2). For instance, the normalized difference vegetation index (NDVI), which has been used since the 1970s to monitor vegetation cover [42.13, 14], is estimated as the normalized difference between the reflectances in the red and near-infrared, i.e.,

$$\text{NDVI} = \frac{\text{NIR} - R}{\text{NIR} + R}, \quad (42.1)$$

where NIR is the reflectance in the near-infrared band and R is the reflectance in the red band, and normalized by the sum of both. The NDVI was traditionally estimated using top-of-atmosphere reflectances; however, to compensate for perturbing factors such as the different reflectance attenuations of the channels due to variations in aerosol optical depth and water vapor content, and to reduce the impact of the directional effects atmospheric correction is performed.

Combining various surface reflectance measurements in the visible and near-infrared domains allows the surface bidirectional reflectance distribution function (BRDF), and therefore the surface albedo [42.15, 16], to be estimated. Analyzing the BRDF signatures of surface vegetation within the main biomes allows vegetation variables such as the leaf area index (LAI) and the fraction of absorbed photosynthetically active radiation (FAPAR) to be inferred [42.17–20].

A critical aspect of the retrieval processes for all surface variables that are derived from visible and infrared observations is cloud screening [42.21]. Clouds partially or completely mask the window channels within this domain of the electromagnetic spectrum, often severely hampering attempts to measure the radiation reflected or emitted by the surface.

Table 42.3 Milestones in satellite imaging [42.22–24]

Platform	Launch	Milestone in parameter retrieval
Rocket flight	1929	First meteorological instruments on a rocket
Rocket flights	Late 1940s	Cloud formation photographed by cloud cameras
Explorer 6 and 7	1959	First successful use of a meteorological instrument on an orbiting satellite First coarse maps of solar and infrared radiation obtained using an imaging system and a Suomi-type radiometer
TIROS-1 to -10 (Television Infrared Operational Satellite)	1960–1965	TIROS-1: First satellite completely dedicated to satellite meteorology First integrated view of the Earth and its weather systems using radiometers TIROS-9 and -10: First polar-orbiting meteorological satellites
Nimbus 1–7	1964–1978	First use of spaceborne microwave radiometers, atmospheric sounders, ozone mappers, and infrared radiometers First quantitative use of satellite data in numerical weather prediction First spaceborne ultraviolet instrument to measure ozone Paved the way for the Landsat program
ESSA-1 to -9 (Environmental Science Service Administration)	1966–1969	First operational meteorological satellite Advanced vidicon camera systems and Suomi-type radiometers
ATS-1 to -3 (Applications Technology System)	1966–1967	First rapid imaging of the Earth and clouds First of six spacecraft that were used to test the feasibility of placing a satellite into geosynchronous orbit (GSO) First high-quality images of cloud cover and continuous observation of global weather patterns ATS 3: First color images of the Earth
SMS-1 and -2 (Synchronous Meteorological Satellite)	1974–1975	Specifically tasked with atmospheric observations
GOES	Since 1975	Series of US geostationary weather satellites
Himawari	Since 1977	Series of Japanese geostationary weather satellites
Meteosat	Since 1977	Series of European geostationary weather satellites
NOAA ITOS (Improved TIROS Operational System) TIROS-N/NOAA program (TIROS Next-generation)	1978–1981	High-resolution imaging (AVHRR) Improved observations and expanded operational capabilities Climate data record
POLDER (Polarization and Directionality of the Earth's Reflectances)	1996–2013	First remote-sensing instrument designed for aerosol measurements and surface anisotropy
A-Train	2006	Combination of active and passive instruments dedicated to aerosol–cloud interactions
MetOp	Since 2006	European polar-orbiting weather satellite system Improved accuracy of temperature, humidity, and wind measurements

42.2.2 Atmospheric Quantities

The development of satellite-based sensors for atmospheric measurements has resulted in significant progress in weather and climate prediction.

Remote sensing of atmospheric quantities dates back to the first rocket flights performed in 1946, as the rockets were equipped with cloud cameras (Table 42.3). However, a short rocket flight is not a suitable platform for weather observations [42.22]. After its launch in 1960, TIROS-1, the first successful weather satellite, provided the first complete pictures of clouds and synoptic weather systems from space using television cameras and infrared sensors. The series of satellites known as the TIROS Operational System (TOS) became operational in 1966. It was superseded by a new

series of spaceborne scanning radiometers in the 1970s, including the AVHRR series, which have contributed an important data record (Sect. 42.2.1). The Nimbus series, launched a few years after TIROS-1, was a testbed for atmospheric remote-sensing systems and facilitated various Earth system applications such as observations of the ozone hole and storm forecasting [42.23].

The first retrievals of cloud optical thickness and effective particle radius were achieved by performing visible and infrared measurements using airborne and spaceborne instruments [42.25, 26]. Methods that are employed to derive cloud optical depth and effective particle radius are typically based on their relationships to the nonabsorbing band of the visible spectrum and the absorption band of water in the near-infrared, respectively [42.27]. Retrieval methods and satellite instrumen-

tation are continually being refined and upgraded in order to improve the precision, the temporal resolution, and the spatial resolution of atmospheric observations [42.28].

42.3 Theory

In this section, we introduce the theory behind the algorithms applied in satellite-based imaging. These algorithms utilize spectral information provided by the various types of satellite-based sensors used for surface and atmospheric imaging. An overview of common applications of particular wavelength regions is given in Table 42.4. The channel characteristics of two passive imaging sensors are shown as examples in Tables 42.5 and 42.6.

42.3.1 Surface Parameters

We now examine the main concepts behind the estimation of surface variables, focusing on the medium- to low-resolution sensors that are typically installed on meteorological satellites. Although microwave instru-

Table 42.4 Typical wavelength regions probed by passive imaging sensors, and the atmospheric or surface parameters or properties that can be derived from measurements of those regions

Wavelength region (μm)	Parameters
0.5–0.8	Land surface properties, e.g., albedo, vegetation Aerosol optical thickness Cloud optical thickness (atmospheric window)
1.6	Snow, cloud phase
2.1	Cloud droplet size
3.9	Cloud droplet size
6–7	Water vapor
9–12	Temperature of the surface and atmospheric features (atmospheric window)

Table 42.5 Sensor example 1: channels of the Advanced Very High Resolution Radiometer 3 (AVHRR/3)

Channel	Wavelength (μm)	Resolution at nadir (km)
1	0.58–0.68	1.09
2	0.725–1.00	1.09
3A	1.58–1.64	1.09
3B	3.55–3.93	1.09
4	10.30–11.30	1.09
5	11.50–12.50	1.09

A brief summary of the milestones in the history of satellite imaging by spaceborne sensors is provided in Table 42.3.

ments have also been used to infer surface temperatures and vegetation properties, here we consider the measurements most commonly used to evaluate the parameters identified in Table 42.1, which are confined to the optical domain.

Visible and Shortwave Observations

One of the first applications of spaceborne remote-sensing observations was to estimate the NDVI in order to monitor vegetated areas. The simplicity of this index, which relies on the fact that healthy plants absorb photosynthetically active radiation (PAR) and reflect near-infrared (NIR) radiation, has facilitated the creation of a long NDVI time series that started in the late 1970s and is still being added to today. While plants use PAR for photosynthesis, they would overheat if they absorbed longer wavelengths. NDVI, the normalized difference between the reflectances in the NIR and the visible (VIS) or red channels, is high for green healthy vegetation and low for surfaces that are good reflectors of both wavelengths (e.g., dry vegetation, bare ground, clouds, snow). As noted earlier, although the NDVI was initially derived from top-of-atmosphere reflectances, it is now commonly obtained from top-of-canopy (i.e., atmospherically corrected) reflectances instead. However, NDVI estimates can be sensitive to the viewing angle and illumination geometry of the observations [42.29], so satellite NDVI products are often presented as composites (8-day, 10-day, or monthly).

Table 42.6 Sensor example 2: channels of the Spinning Enhanced Visible and Infrared Imager (SEVIRI)

Channel	Wavelength (μm)	Resolution at nadir (km)
1	0.56–0.71	3
2	0.74–0.88	3
3	1.50–1.78	3
4	3.48–4.36	3
5	5.35–7.15	3
6	6.85–7.85	3
7	8.30–9.1	3
8	9.38–9.94	3
9	9.80–11.80	3
10	11.00–13.00	3
11	12.40–14.40	3
12	≈ 0.4 –1.1 (broadband)	1

The NDVI presents saturation problems for densely vegetated areas, as it does not accurately reflect changes in green biomass across regions with dense vegetation [42.30, 31]. Other indices have therefore been proposed to overcome this and other limitations of the NDVI. One of the most common is the enhanced vegetation index (EVI), which uses the reflectance in the blue band (e.g., available with MODIS) as well as a canopy background adjustment term that enhances its sensitivity to green vegetation [42.32].

As widely demonstrated by the many indices that have been created to monitor vegetation (and also soil) properties based on relatively simple relations between the reflectances of channels within the shortwave domain (visible to near-infrared), detailed knowledge of the surface reflection properties for any combination of illumination and viewing angles within this domain (i.e., knowledge of the surface BRDF) is highly beneficial when attempting to retrieve more complex vegetation properties, including the LAI and FAPAR. Furthermore, the BRDF is intrinsically linked to the surface albedo, which in turn crucially influences the radiation balance and hence the energy balance at the surface.

To estimate the surface BRDF, it is usually necessary to accumulate a sufficient number of satellite observations of the same surface scene from different viewing angles (as provided by MODIS, MISR (Multi-angle Imaging SpectroRadiometer), or AVHRR instruments on polar orbiters) and/or different sun zenith angles (as provided by MVIRI, SEVIRI, ABI (Advanced Baseline Imager), or AHI (Advanced Himavari Imager) sensors on geosynchronous platforms). The most popular procedures [42.33, 34] assume that the BRDF can be modeled as a sum of weighted kernels, each associated with a basic aspect of surface reflection (e.g., an isotropic component, volumetric scattering, and a geometric shadow-driven component) [42.16].

The kernel weights may be estimated by fitting the clear-sky top-of-canopy (i.e., atmospherically corrected) reflectances for bands within the solar domain, although the approach was also successfully transposed to the thermal infrared (TIR) domain [42.35]. Hemispherical integration of the BRDF provides the spectral (or channel) albedo; empirical (often linear) regression of this spectral albedo yields a broadband value for the whole shortwave region (e.g., 0.3–3 μm). The albedo can be defined for a given solar illumination or the integral of the solar illumination during a day. If the BRDF is known, the directional hemispherical reflectance (black-sky albedo) can be generated for any solar zenith angle of interest, as can the bihemispherical reflectance (white-sky albedo). Both are operationally derived from measurements provided by instruments on polar orbiters after accumulating observations over

periods ranging from about 1 week to 1 month [42.33, 36–38]. Given the higher temporal frequency of geostationary observations, albedo values can be estimated from Meteosat or GOES series as often as daily [42.34, 39].

LAI and FAPAR are more tangible vegetation variables than vegetation indices. The former can, for instance, be incorporated into land surface schemes within NWP or climate models. Several authors have proposed that the specific spectral and directional reflectance signatures of vegetation should be explored so that the BRDF can be used to derive those vegetation variables [42.17, 20].

42.3.2 Atmospheric Quantities

In order to retrieve atmospheric properties from passive sensor measurements in the visible and infrared spectral ranges, it is necessary to interpret the signal received at the satellite appropriately. This signal is either a terrestrial signal that has been modified by one transition through the atmosphere, or a signal of solar origin that has been modified by two atmospheric transitions and a reflection at the Earth's surface. In both cases, two unknowns need to be disentangled: the radiative properties of the Earth's surface and atmospheric features [42.1]. Since the focus is on the retrieval of the latter, reliable information on the former is required before attempting almost any atmospheric retrieval. Some relevant surface retrievals were covered in the previous section. This section addresses the second set of problems: deriving information on the presence and properties of atmospheric features.

In general, passive retrieval algorithms for the properties of atmospheric features such as aerosols and clouds use the transmission, emission, and scattering of electromagnetic radiation [42.28].

Aerosol optical depth (AOD), the integral of the extinction due to aerosols along the atmospheric path, varies with the wavelength of the radiation measured. It is thus usually reported for a particular wavelength. In general, the contribution of the AOD to the signal received at the satellite sensor decreases with wavelength, whereas the contribution of the Earth's surface increases. Therefore, short wavelengths are particularly useful for retrieving the AOD, as are dark, relatively homogeneous surfaces in the background such as the oceans and large continental water bodies. Upon discarding cloudy pixels from further analysis, a radiative transfer scheme is applied to retrieve the AOD. Most of the time, this involves assuming that an idealized aerosol is present and making assumptions about the shape and size distributions. Other aerosol parameters such as the Ångström coefficient, fine-mode fraction,

aerosol indices, and single-scattering albedo are also retrieved in some cases, but these are either less robust or more specific in terms of their scientific context [42.40].

The solar radiation received at the Earth's surface is a direct function of the solar signal and the modification of this signal by the atmosphere. A commonly used technique, Heliosat [42.41], makes use of this insight. The clear-sky solar signal is derived from radiative transfer calculations, and the solar radiation that actually reaches the Earth's surface is estimated by scaling the clear-sky solar signal by the relative cloudiness in a given location. This relative cloudiness is expressed as a *cloud index*, which is computed for each pixel by comparing the observed reflectivity at that pixel to the minimum and maximum observed reflectivities for the same location.

Cloud presence and cloud properties are derived in a number of ways, and the following discussion only touches on the main principles. Visible measurements play a central role for many of the parameters considered here, but such measurements are, of course, only available during the daytime.

Cloud presence and fraction are commonly detected in either a single channel (especially in older systems and for continuity purposes) or a combination of channels. As clouds tend to be cooler than the Earth's surface, they can often be identified in the thermal infrared. Low clouds and cold surfaces (e.g., fog over snow) are not, however, suited to this approach. The same type of situation can be problematic when using visible-range information. Introducing additional channels, e.g., the mid-infrared $\approx 1.6\ \mu\text{m}$, as well as in the thermal IR $\approx 9\ \mu\text{m}$, leads to increased accuracy in delineating clouds. The cloud fraction is often defined as either the fraction of an area of several pixels

that is covered by cloud or a fraction of an individual pixel based on scaling radiative signals in a predefined range [42.42, 43].

Cloud-type determination utilizes spectral and textural features [42.43, 44]. Clouds are typically classified by altitude, opacity, and cloud family (i.e., stratiform, cumuliform, or cirrus). Classifications are usually based on predefined thresholds.

Cloud optical thickness and droplet effective radius are commonly derived in a dual-channel approach based on the knowledge that visible-range reflectivity increases with cloud optical thickness whereas the mid-infrared signal is determined by droplet effective radius [42.43, 45]. Both signals are modeled using a radiative transfer code and then inverted. The droplet effective radius reflects the conditions near the cloud top, with smaller wavelengths (e.g., $1.6\ \mu\text{m}$) representing greater penetration depth into the cloud than larger wavelengths (e.g., $3.9\ \mu\text{m}$). The liquid-water path is usually computed as the product of COT and DER scaled by a constant [42.27, 43]. This approach involves assuming that there is an adiabatic or slightly subadiabatic increase in cloud liquid-water content with altitude, and different values have been used in different studies [42.46].

Finally, cloud top height can be obtained by either comparing an atmospherically and emissivity-corrected cloud-top temperature to a (standard) atmospheric profile or using a split-window approach. In the latter, one channel is at a wavelength that is strongly absorbed by a gas with a well-known atmospheric distribution (e.g., oxygen) while the other is at a nearby wavelength unaffected by this absorption. The difference in signal between the channels can be interpreted as the length of the atmospheric path above a cloud and thus the cloud top height.

42.4 Devices and Systems

This section highlights the fundamental differences between existing satellite systems and discusses selected product suites that are available to users.

42.4.1 Satellite Systems and Orbits

Most satellite systems that are used to image parameters associated with the Earth's surface or the atmosphere allow for both types of retrievals, and are therefore treated jointly here (Chap. 34).

As mentioned above, this chapter focuses on passive-sensor satellite systems that generally probe the visible and infrared ranges of the electromagnetic spectrum. Since a comprehensive analysis of the at-

mosphere and how it is changing is of great interest in many applications, wide-area coverage—up to the global scale—is desirable. At the same time, monitoring patterns and changes to the climate requires repeated measurements obtained at intervals determined by the specifics of the desired application or study. In general, the main choice to be made when selecting an adequate system for the scientific problem at hand is between satellite platforms on polar orbits and geostationary platforms. The former orbit the Earth at altitudes of a few hundred kilometers and provide observations at spatial resolutions of between a few tens of meters and a few kilometers. The swath (the area covered on both sides of a satellite's nadir) of a polar orbiter ranges up

Fig. 42.1 The MetOp-C satellite is the newest of the first generation of Europe’s EUMETSAT Polar System series (following Metop-A and -B) that orbit at 817 km (© ESA)

to a few hundred kilometers (e.g., for MODIS [42.45]). The main disadvantage of a polar orbiter is its low repeat rate—it only images a given location at specific times of the day, and therefore takes a number of orbits (which often corresponds to days) to completely observe the entire Earth (Fig. 42.1). Geostationary satellite systems, on the other hand, are placed at an altitude of around 36 000 km above the Earth and at a fixed longitude along the equator. At this location, they can monitor wide areas at spatial resolutions of between 500 m and a few kilometers. Given the constant position and very high altitude of a geostationary satellite relative to the Earth’s surface, the sensors on such a platform can provide coverage of a very wide, approximately circular area (the *full disk*) at a high repeat rate. Depending on the sensor characteristics, full-disk scans can be achieved every 5 min (e.g., GOES [42.47]), while selected smaller areas can be imaged at 30 s intervals (Fig. 42.2).

Fig. 42.2 The Meteosat Second Generation satellites monitor weather systems over Europe and Africa (© ESA: D. Ducros)

A summary of the main advantages and disadvantages of various observation systems is given in Table 42.7.

42.4.2 Product Suites and Comparisons

A large number of algorithms for retrieving geophysical parameters have been developed for numerous satellite sensors. Many of the associated products are generated operationally and distributed freely or commercially by government, private, and academic institutions around the world. In the following, two examples of coordinated efforts to produce, compare, and distribute information derived from satellite imagers are introduced.

Table 42.7 Advantages and disadvantages of various observation systems

Observation systems	Advantages	Disadvantages
Imagers on geostationary platforms, e.g., – SEVIRI/MSG – ABI/GOES-R – AHI/Himawari	Temporal resolution ranging from 5 to 15 min. Variables with strong diurnal cycles (surface temperature, solar radiation) or those that change rapidly (cloud cover) to be monitored	Coarse spatial resolution Limited vertical information
Imagers on polar orbiters, e.g., – AVHRR/3/MetOp – MODIS/Aqua, Terra – MSI/Sentinel-2 – SLSTR/Sentinel-3 – VIIRS/Suomi NPP – OLI/Landsat-8 – MISR/Terra	Near-global coverage of various meteorological, cloud, and aerosol properties is provided Moderate to high spatial resolution	Coarse temporal resolution Limited vertical information

MSI: Multispectral Instrument; NPP: National Polar-orbiting Partnership; OLI: Operational Land Imager; SLSTR: Sea and Land Surface Temperature Radiometer; VIIRS: Visible Infrared Imaging Radiometer Suite

Moderate Resolution Imaging Spectroradiometer (MODIS) Product Suite

The Moderate Resolution Imaging Spectroradiometer (MODIS) is installed on the Terra satellite (in orbit since 2000) as well as on the Aqua satellite (launched in 2002). A range of operational products have been developed by scientists at various institutions that comprise the MODIS Science Team. The data produced are jointly distributed via the National Aeronautics and Space Administration (NASA, atmospheric products) and the United States Geological Survey (USGS, Earth's surface products).

Network of Satellite Application Facilities (SAFs)

The European Organization for the Exploitation of Meteorological Satellites (EUMETSAT) operates a network of Satellite Application Facilities (SAFs) that develop, maintain, and in some cases distribute products based on mostly European satellite systems. Most SAF contributors are European national meteorological and hydrological services, although some are academic and private institutions. The Land Surface Analysis SAF (LSA SAF) and the Ocean and Sea Ice SAF (OSI SAF) provide and distribute a number of products relating to Earth's surface parameters. The Climate Monitoring SAF (CM SAF) and the support to Nowcasting and Very Short Range Forecasting SAF (NWC SAF) produce and distribute products and software for atmospheric properties.

42.5 Specifications

Accuracy targets are usually defined before developing a satellite product and evaluations are performed afterwards. Since the potentials and requirements of sensor systems vary markedly, the targeted and obtained accuracies also vary substantially. Providing general-

ized estimates of the accuracy would not, therefore, be very meaningful. Instead, Table 42.8 lists the reference measurements that are usually taken to assess the quality of the satellite-derived parameters considered here.

Table 42.8 Specifications for different measurement methods

Parameter	Reference measurement	Details
LST	In-situ radiometers (broadband or thermal infrared)	e.g., ARM (Atmospheric Radiation Measurements) sites [42.48] (Chap. 63), LSA-SAF validation sites [42.49]
Albedo	Two pyranometers measuring downward & upward radiation in-situ	e.g., NETWORK of FLUX measurement sites (FLUXNET), LSA-SAF validation sites [42.49]
Vegetation index (VI)	Characterization of VI sensitivity to actual vegetation conditions; assessment of long-term stability	Reference sites, e.g., FLUXNET, Chap. 64, Aerosol RObotic NETWORK (AERONET, Chap. 63), Enviro-Net (Chap. 64)
LAI	In-situ foliage sampling	Integrated Carbon Observation System (ICOS network)
FAPAR	(direct radiation measurement)	ICOS network
SC	Ground-based station observations	Networks of national hydrological and meteorological services
FRP	Ground-based event observations	
SIS	Pyranometers	Baseline Surface Radiation Network (BSRN, see Chap. 63) [42.50]
AOD	Sun photometers	Most belong to the global AERONET and MPL networks [42.51] (Chap. 63)
CF	Human observers, ground-based, airborne, and spaceborne lidar and radar observations	Observation networks of ground-based stations, e.g., SYNOP (surface SYNOptic observation) [42.43]; validation campaigns, e.g., Atlantic Stratocumulus Transition Experiment (ASTEX) [42.52], Arctic High-Spectral Resolution Lidar (AHSRL), Cloud Physics Lidar (CPL), and Geoscience Laser Altimeter System (GLAS) [42.53]
CT	Human observers, ground-based and space-based lidar and radar observations	
COT	Ground-based and space-based lidar and radar observations	Observation networks of ground-based stations, e.g., SYNOP [42.43] (Chap. 63); validation campaigns, e.g., ASTEX [42.52]
DER	In-situ droplet probes, spectrometer, particulate volume monitor	Validation campaigns, e.g., ASTEX [42.52]
LWP	Microwave radiometers, spectrometer, particulate volume monitor	e.g., CloudNET observations [42.54]
CTH	Spaceborne lidar and radar observations	e.g., CloudSat and Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) [42.43]

42.6 Quality Control

To ensure consistency, and to aid further product development, systematic comparisons of existing products are organized by various organizations. A notable international example of such efforts is the Climate Change Initiative (CCI) of the European Space Agency (ESA). The CCI examines the present-day ability to derive selected essential climate variables (ECVs) from satellite data by systematically evaluating existing products

(e.g., LST, aerosol, and cloud products). This quality control process adheres to norms such as the Q4ECV, which is employed as a reference to appraise the quality of C3S products. The World Meteorological Organization (WMO) also supports initiatives through the Global Climate Observing System (GCOS), which establishes specifications and provides directions for future initiatives relating to long-term ECV data series.

42.7 Maintenance

The satellite products and algorithms presented here are constantly being developed and improved, and adjustments are made when new platforms become available. Satellite sensors are often calibrated in space by comparing their data with synchronous observations from other

sensors (intersatellite calibration), measuring an object (blackbody) onboard the satellite, or pointing the sensor at a background object with well-established properties (e.g., open space or the Moon). For more on this topic, please refer to the chapter on remote-sensing platforms.

42.8 Applications

The amount of information obtained from satellite-based imaging is immense, so applications of satellite products span a wide range of fields. These include:

- *Environmental monitoring.* Near-real-time evaluation of imaging observations provides a sound basis for monitoring changes in parameters that are relevant to society and ecology (e.g., air quality, vegetation health, and weather systems).
- *Climate change monitoring.* By examining long homogenized time series, it is possible to gain insights into how components of the global climate system develop over time as a basis for studying climate change.
- *Evaluation of climate and weather models.* To assess their applicability, numerical models of climate and weather need to be evaluated against independent observations. With its spatial component, satellite imaging is a crucial and commonly used source of such measurements.
- *Earth system analysis.* Satellite imaging datasets facilitate systematic studies of components of the Earth–atmosphere system. Such studies frequently use statistical methods ranging from bivariate correlation analysis to machine learning.
- *Communicating science.* Finally, satellite imaging produces spatial datasets, which can easily be presented as maps, which are useful tools for communicating scientific insights.

42.9 Future Developments

Future satellite missions will take advantage of advances in satellite detector technology, optical sensor properties, and electronics. Continuous monitoring of essential climate and environmental variables, the op-

erational use of research instruments, and the implementation of low-cost missions will be core activities. A few planned satellite missions are listed in Table 42.9.

Table 42.9 Planned satellite missions and primary instruments

Future mission	Mission description	Primary instrument(s)
CLARREO (Climate Absolute Radiance and Refractivity Observatory)	Solar and Earth radiation characteristics for understanding climate forcing	Broadband radiometer Absolute spectrally resolved interferometer
GPSRO (Operational GPS Radio Occultation)	High-accuracy, all-weather temperature, water vapor, and electron density profiles for weather, climate, and space weather	GPS receiver
XOVWM (Extended Ocean Vector Winds Mission)	Sea surface wind vectors for weather and ocean ecosystems	Backscatter radar
SMAP (Soil Moisture Active–Passive)	Soil moisture and freeze–thaw for weather and water cycle processes	L-band radar, L-band radiometer
ICESat-II (Ice, Cloud, and Land Elevation Satellite II)	Ice sheet height changes for climate change diagnosis	Laser altimeter
DESDynI (Deformation, Ecosystem Structure, and Dynamics of Ice)	Surface and ice sheet deformation for understanding natural hazards and climate; vegetation structure for ecosystem health	L-band InSAR Laser altimeter
HypIRI (Hyperspectral Infrared Imager)	Land surface composition for agriculture and mineral characterization; vegetation types for ecosystem health	Hyperspectral spectrometer
ASCENDS (Active Sensing of CO ₂ Emissions over Nights, Days, and Seasons)	Day/night, all-latitude, all-season CO ₂ column integrals for climate emissions	Multifrequency laser
SWOT (Surface Water and Ocean Topography)	Ocean, lake, and river water levels for ocean and inland water dynamics	K _a - or K _u -band radar K _u -band altimeter Microwave radiometer
GEO-CAPE (Geostationary Coastal and Air Pollution Events)	Atmospheric gas columns for air quality forecasts; ocean color for coastal ecosystem health and climate emissions	High-spatial-resolution hyperspectral spectrometer Low-spatial-resolution imaging spectrometer IR correlation radiometer
ACE (Aerosol–Cloud–Ecosystem)	Aerosol and cloud profiles for climate and water cycle; ocean color for open ocean biogeochemistry	Backscatter lidar Multiangle polarimeter Doppler radar
LIST (Lidar Surface Topography)	Land surface topography for landslide hazards and water runoff	Laser altimeter
PATH (Precipitation and All-Weather Temperature and Humidity)	High-frequency, all-weather temperature and humidity soundings for weather forecasting and sea surface temperature	Microwave array spectrometer
GRACE-II (Gravity Recovery and Climate Experiment II)	High-temporal-resolution gravity fields for tracking large-scale water movement	Microwave or laser ranging system
SCLP (Snow and Cold Land Processes)	Snow accumulation to monitor freshwater availability	K _u - and X-band radars K- and K _a -band radiometers
GACM (Global Atmospheric Composition Mission)	Ozone and related gases for intercontinental air quality and stratospheric ozone layer prediction	UV spectrometer IR spectrometer Microwave limb sounder
3D-Winds (Three-Dimensional Tropospheric Winds)	Tropospheric winds for weather forecasting and pollution transport	Doppler lidar
MTG (Meteosat Third Generation)	Next generation of geostationary satellites; continuous observation in the visible and IR spectrum with improved spatial, temporal, and radiometric resolutions	Flexible combined and lightning imagers Infrared and ultraviolet sounders
EUMETSAT Polar System—Second Generation (EPS-SG)	Climate monitoring and nowcasting	Infrared and microwave imagers and sounders
Copernicus Satellites (Europe’s Copernicus program: Sentinel-4 to -6)	Measurements of atmospheric composition and global sea-level (Sentinel 6)	Instruments of the MTG and EPS-SG programs, Radar altimeter
EarthCare (the ESA’s cloud, aerosol and radiation mission)	Across-track information on clouds and aerosols	Atmospheric lidar, cloud profiling radar, multispectral imager, broadband radiometer
FLEX (Fluorescence Explorer)	Map vegetation fluorescence to quantify photosynthetic activity	High-resolution imaging spectrometer
Biomass	Accurate maps of tropical, temperate and boreal forest biomass	P-band synthetic aperture radar

Jan Cermak

Institute of Meteorology and Climate Research and Institute of Photogrammetry and Remote Sensing Karlsruhe Institute of Technology (KIT) Karlsruhe, Germany
jan.cermak@kit.edu

Jan Cermak has been Professor of Geophysical Remote Sensing at the Karlsruhe Institute of Technology, Germany, since 2016. Before that, he was a professor at Ruhr-Universität Bochum, Germany. He received his PhD from the University of Marburg, Germany, in 2006, after which he performed postdoctoral research at ETH Zurich, Switzerland. His main research interest is satellite climatology, focusing on clouds, fog, aerosols, and exchange processes in the boundary layer.

Isabel F. Trigo

Portuguese Institute for the Sea and the Atmosphere (IPMA) Lisboa, Portugal
isabel.trigo@ipma.pt

Isabel F. Trigo is a senior researcher at the Portuguese Institute for Sea and Atmosphere (IPMA), where she leads the Earth Observation Group. Her research focuses on applications of satellite observations to derive land surface variables, and on their use to better understand and model land surface processes. She coordinates the EUMETSAT LSA SAF, and has been involved in several international projects funded by ESA and European programs.

Julia Fuchs

Institute of Meteorology and Climate Research and Institute of Photogrammetry and Remote Sensing Karlsruhe Institute of Technology (KIT) Karlsruhe, Germany
julia.fuchs@kit.edu

Julia Fuchs is a research scientist at the Institute of Meteorology and Climate Research and the Institute of Photogrammetry and Remote Sensing at the Karlsruhe Institute of Technology (Germany), where she investigates the effects of urban areas on the lower atmosphere and the application of machine learning techniques to remote-sensing datasets. During her PhD, she used satellite remote sensing to map and quantify processes within the aerosol–cloud–meteorology system.

43. Atmospheric Measurements for Different Purposes

Bodo Wichura, Thomas Foken 

Meteorological measurements are performed by various types of stations, including synoptic weather and climate monitoring stations, agrometeorological stations, and stations that require meteorological data for other purposes, such as to monitor traffic or air pollution or for private use. This chapter describes the history of stations that carry out atmospheric measurements, as well as recent developments in this field, mostly involving the use of new technologies to measure meteorological parameters. The specifics of the installation of stations for different purposes and the main parameters measured are summarized. The accuracy of the atmospheric measurements and the sensor system maintenance required vary depending on the intended application of the data. Therefore, the requirements for the measured meteorological parameters may differ from those defined in the corresponding parameter-specific chapters of this Handbook.

Besides being used as classic weather stations, atmospheric measurements are utilized for many other purposes as well. Such data are used, for example, in research, by industry, in building services engineering, by public authorities, and by private users. Furthermore, some of the sensors in a variety of electronic devices (e.g., smartphones), can be used to measure meteorological parameters (see Chap. 44). Recommendations for the accuracy and availability of these measurements and for the maintenance of

the system that performs them may differ from those given in the corresponding parameter-specific chapters of this Handbook. Consequently, the quality and the areas of application of the resulting meteorological data differ from those of classical meteorological measurements performed at weather stations. This chapter aims to categorize the large number of applications of atmospheric measurements, and demonstrates how such data can be used for a range of purposes.

43.1 Principles of Atmospheric Measurement Station Classification

A general classification of the various types of stations used for atmospheric measurements is not yet available; indeed, such a classification could be rendered meaningless by the fast-growing number of reasons for performing atmospheric measurements and applications of them. Atmospheric measurement stations may be categorized according to the purpose of the station, the types of measurements performed, and the quality and availability of

the data. The representativeness of the measurements at various time and spatial scales can also be used as a criterion, as mentioned in Chap. 1.

43.1.1 General Overview of Station Types

A general overview of the quality of the measurements provided by various types of stations is shown in Ta-

Table 43.1 Proposed rough classification of station types; see Table 43.10 for data quality classification (high or extremely high for single sensors; medium or low for compact sensors; low or extremely low for simple sensors)

Station type	Data quality	Source of regulations
Synoptic weather and climate monitoring stations	High or extremely high	[43.1], this Handbook
Stations used for various purposes (see Sect. 43.1.2)	Medium to high	Partly [43.1, 2], this Handbook
Networks (combinations of different station types, possibly including crowdsourcing stations)	Low to high	Network internal regulations, partly defined in this Handbook
Industry, building services engineering	Low to medium	Internal regulation, partly defined in this Handbook
Crowdsourcing stations	Extremely low to low	No general regulations, partly defined in this Handbook (Chap. 44)

Table 43.2 Classification of atmospheric measurement stations [43.2, 9]

No.	Classification type	Features and recommendations	Relevant Handbook chapters
1	Microclimatological or micro-meteorological station	Miscellaneous applications with different instrumentations (e.g., biometeorological measurements)	Chapters in Part B
2	Micrometeorological station with turbulence measurements	Including eddy-covariance measurements for research purposes	Chapters in Part B and Chap. 55
3	Station for monitoring air pollution conditions	Determination of meteorological and boundary-layer parameters	Chapters in Parts B and C, Chap. 46
4	Station for immission measurements	Determination of air pollutant concentrations, along with additional meteorological measurements	Chapters in Part B and Chap. 54
5	Deposition measuring station	Determination of air pollutant concentrations in air and precipitation water, along with additional meteorological measurements	Chapters in Part B and Chap. 54
6	Landfill measuring station	Mainly for the determination of the water balance	Chapters in Part B and Chap. 57
7	Hydrological station	Mainly precipitation measurements	Chap. 12
8	Agricultural meteorological station	Miscellaneous applications with different instrumentations, (e.g., parameters for determining evapotranspiration [43.3–5])	Chapters in Part B and Chap. 57
9	Forest climate station	Measurement of meteorological elements in clearings and below trees [43.6]	Chapters in Part B
10	Urban climate station	Measurement of meteorological elements in urban locations such as street canyons, parks, etc.	Chapters in Parts B and C and Chaps. 50, 52
11	Spa climate station	Measurement of climate elements that are relevant to spa conditions	Chapters in Part B
12	Icing measurement station	Measurement of relevant meteorological elements (e.g., icing of power lines)	Chapters in Part B
13	Energy meteorological station	Measurement of parameters relevant to renewable energy (wind, solar, water)	Chapters in Parts B and C and Chap. 51
14	Noise pollution measuring station	Determination of meteorological parameters (mainly wind) that influence sound propagation [43.7]	Chapter in Part B
15	Traffic route measuring station	Measurement of meteorological elements that may affect traffic [43.8]	Chapters in Part B
16	Nowcasting station	Measurement of the current state of the weather, e.g., with present weather sensors	Chapters in Part B
17	Crowdsourcing	Measurement of meteorological elements with simple sensors (and usually not according to relevant installation instructions)	Chapters in Part B

ble 43.1. According to the data quality criteria given in Chap. 3, high and extremely high data quality are defined by a working or secondary standard established by the World Meteorological Organization (WMO) [43.1]. Medium data quality is defined according to the specifications given in the specific chapters of this Handbook. Low and extremely low data quality imply that the sensors and/or the installation do not comply with the quality specification for the specific parameter.

Furthermore, the WMO [43.1], Annex 1.B classifies stations into five classes depending on whether they fulfill the recommended siting conditions for temperature and humidity, precipitation, global and diffuse radiation, direct radiation and sunshine duration, and surface wind speed (for more in-depth discussions of siting conditions, please refer to the relevant chapters). According to this classification, a station may be assigned to different classes for different parameters (see also Chap. 45).

Data availability is high for most station types (Sect. 43.1.2) and most networks. It is still good in

industry and building engineering. However, for building engineering purposes, the sensors are often used to determine operating conditions only (by the use of corresponding limit values of meteorological parameters).

43.1.2 Classification of Atmospheric Measurement Stations According to Purpose

Classical weather stations that perform synoptic and climate monitoring measurements are described in detail by the WMO [43.1]. Other types of measurement stations can be categorized according their purpose, as shown in Table 43.2 (for more on this topic, see Sect. 43.3.1).

43.1.3 Networks of Different Station Types

The networks considered in this section are not mesoscale networks (Chap. 45) or specific atmospheric

Table 43.3 Some networks that were created to overcome deficiencies in atmospheric measurements

Name	Description	Links, references
Weather Observation Website (WOW)	WOWs are repositories for citizen weather data. They collect and share weather observations and weather impact information. WOWs are currently hosted in the UK, Netherlands, Australia, and New Zealand. Data from around the world are available. A site station description is required for continuous data upload. A basic level of data quality is ensured by community-driven reporting.	www.wow.metoffice.gov.uk , Accessed 15 July 2021
Citizen Weather Observer Program (CWOP)	CWOP is a network of private electronic weather stations that are mostly located in the United States, but data from around the world are also available. Network participants send automated surface weather observations to the National Weather Service (NWS). Temporal and spatial consistency checks are performed, and quality flags are stored.	www.wxqa.com , Accessed 15 July 2021
Community Collaborative Rain, Hail and Snow Network (CoCoRaHS)	CoCoRaHS is a network of volunteer weather observers in the United States, Canada, and the Bahamas. They report daily precipitation readings to a central data store. CoCoRaHS aims to provide accurate, high-quality precipitation data for end users.	www.cocorahs.org , Accessed 15 July 2021
Urban Meteorological Networks	There are a large number of urban meteorological networks with a wide range of research or operational objectives.	See [43.10] for a summary of these networks, including their objectives, data availability, management, and quality.
Aircraft-derived data (ADD): Automatic Dependent Surveillance (ADS)	ADS is a messaging regime used by aircraft (the standards are defined by the International Civil Aviation Organization, ICAO). ADS-Contract (ADS-C) data can be used to receive and/or derive both wind and temperature information at the aircraft's location. Additional parameters may also be available. Cooperation with either air traffic control (ATC), airlines, aircraft, or engine manufacturers is required to obtain the data, which involves data communication costs.	See [43.11] for a summary of data derivation, collection, and quality.
ADD: Mode-Selective Enhanced Surveillance Data (MODE-S EHS)	Mode-S EHS is a messaging regime used by aircraft (the standards are defined by the ICAO). Mode-S EHS data can be used to derive both wind and temperature information at the aircraft's location. Such data can be obtained using a local ADS-B/Mode-S receiver, and does not involve data communication costs.	See [43.11] for a summary of data derivation, collection, and quality.
ADD: Aircraft Meteorological Data Relay (AMDAR)	AMDAR uses the Aircraft Communications Addressing and Reporting System (ACARS) and the Aircraft Condition Monitoring System (ACMS) to provide meteorological datasets. The data is obtained through cooperation with airlines, which involves data communication costs.	See [43.11] for a summary of data derivation, collection, and quality.

(Chap. 63) or ecological (Chap. 64) networks, but networks that were created to overcome deficiencies in atmospheric measurements or to provide all available

information to another network (e.g., for nowcasting or warning systems). Table 43.3 lists a selection of some of these networks.

43.2 History

The history of synoptic weather and climate monitoring stations (as well as networks of them) is closely connected with the development of sensors (see Chap. 1 and the brief description provided in the following section). The first instructions for performing weather observations were given by *Robert Hooke* (1635–1703) [43.12], and the first stations were realized around 1660. These stations monitored the temperature, humidity, and pressure, carried out visual observations of cloud coverage (amount) and genera (type), and made other observations. Aided by *Karl Theodor*, Elector of Bavaria (1724–1799), who founded the first meteorological society—the *Societas Meteorologica Palatina* [43.13]—in Mannheim, *Johann Jakob Hemmer* (1733–1790) established a network comprising 36

stations in Europe, two in North America, and one at Greenland. Regular measurements were commenced in 1872 under the recommendation of the International Meteorological Conference at Leipzig. In 1951, the Commission for Instruments and Methods of Observation (CIMO) was founded [43.14]. The CIMO became responsible for international coordination and standardization in the field of atmospheric measurements, continuing activities that began in Leipzig 80 years earlier.

By contrast, no accounts of the historical development of other station types are available. However, the timelines of national and international recommendations or guidelines for implementing atmospheric measurements for various purposes may provide some historical information about these station types.

43.3 Theory

There is no general theory that can be applied to any meteorological station. Recommendations for the installation of a meteorological station are based upon the representativeness of meteorological parameters near the surface as well as upon experience (see Chap. 1). Some recommendations are given in [43.1], and lists of relevant parameters for different types of stations are compiled for instance in [43.2].

43.3.1 Recommendations for Synoptic Weather and Climate Monitoring Stations

The classical weather station with a Stevenson (or similar) temperature screen (see Chap. 7) comprising visual observations and a few instruments for measuring the wind, temperature, humidity, and precipitation has been widely replaced by automatic weather stations (AWS), which perform and transmit observations automatically. The general requirements, types, and locations of synoptic weather and climate monitoring stations as well as the composition, frequency, and timing of the measurements performed by them are described in [43.15, 16]. The meteorological elements required for manned and automatic surface synoptic weather stations are listed in Table 43.4. For other WMO station types, such as aeronautical or agricultural meteorological stations, see [43.16]. The specific requirements for measurements, site conditions, and measured data quality are given in [43.1] as

well as in the relevant chapters of this Handbook. In general, fewer meteorological parameters can be measured by an AWS than by a manned station. Therefore, there is a tendency to replace particular parameters with others, or to combine parameters (see Chap. 22).

Classical meteorological observing stations are designed to perform representative measurements. Thus, synoptic weather stations should permit observations that are representative for the synoptic scale, whereas stations used for other purposes can also determine values that are representative for more local conditions [43.1]. Synoptic weather or climate monitoring stations typically cover an area of at least 25 m × 25 m, covered with grass or a surface that is representative of the locality, and are surrounded by open fencing. Within this area, a patch of bare ground approximately 2 m × 2 m in size is reserved for soil-related measurements (see Chap. 61). All instruments should be installed according to the recommendations [43.1] given in the relevant chapters of this Handbook. Further recommendations for the siting of meteorological stations are provided in [43.17], and an example of such a station is shown in Fig. 43.1.

In general, the site for a particular type of observing station should be chosen based on the most stringent requirements for that station type [43.1, Sect. 1.3.3]. This means that requirements regarding the siting, the area, the surface conditions, and the area surrounding the station may differ from the corresponding requirements for

Table 43.4 Meteorological elements that are monitored by manned and automatic surface synoptic weather stations [43.16] (observables marked with a × are required, while those marked with a 0 are desirable but not required)

classical synoptic weather or climate monitoring stations.

43.3.2 Parameter Requirements for Different Station Types

Each type of station defined in Sect. 43.1.2 (see also Table 43.2) must monitor a specific set of parameters, while measurements of some other parameters are optional. These required and optional parameters are listed

for each station type in Table 43.5. The parameter symbols used in Table 43.5 are explained in Table 43.6, which also points to the Handbook chapters in which each parameter is discussed and to Table 1.1 in Chap. 1. The latter table lists the chapters that describe the in-situ and remote-sensing methods employed to measure the parameters. The set of parameters that are observed by a particular type of station depend on its purpose or the installation recommendations for that station type (Table 43.2).

Table 43.5 Parameters that are measured by different types of stations (station type numbers are defined in Table 43.2; parameter symbols are defined in Table 43.6; parameters marked with a × must be monitored, whereas it is not required but it is desirable to monitor those marked with a 0) [43.2]

43.4 Devices and Systems

Possible sensor combinations that can fulfill the measurement requirements of particular station types are discussed in this section, while the individual sensors are described in the relevant chapters of Part B of this Handbook.

43.4.1 Single-Sensor Stations

In principle, all of the station types listed in Table 43.2 can be implemented using single sensors. Nevertheless, the current trend is to use combined sensors

Fig. 43.2 Schematic of an automatic weather station (© Vaisala Oyj, Vantaa, Finland)

or even more specific configurations for some station types (Sect. 43.4.2). Only automatic synoptic weather and climate monitoring stations (i.e., AWS) and micrometeorological stations are typically installed with single sensors. This ensures that the highest data quality requirements of the WMO [43.1] will be achieved, and allows the sensor to be positioned precisely at the specified measurement height (e.g., 10 m for wind, 2 m for temperature and humidity, and 1 m for precipitation). The sensors used in AWS should be selected according to Table 43.4 [43.16] and regional standards. A schematic example of an AWS is shown in Fig. 43.2.

The configuration of a micrometeorological station or agricultural meteorological station is tailored to specific measurement requirements or research programs [43.5, 9]. Such stations are also used in ecological networks with region-dependent standards (see Chap. 64). More on this topic is provided in Chap. 55.

43.4.2 Stations with Compact Sensors

There is a fast-growing market for compact systems (multiparameter sensors) for measuring meteorological parameters. Such systems are easy to handle, mainly due to the fact that only one compact sensor block

must be mounted. The disadvantages of these systems are flow distortion effects on wind measurements and the need for different sensor heights to measure different parameters (e.g., wind and precipitation). In some compact sensor systems, wind and precipitation sensors can be installed separately. Most compact sensor systems are modular and combinable during the configuration process, and the user can select the most suitable sensors for the required measurements. Table 43.7 shows four examples of compact sensors. New compact sensor systems are continually in development. Therefore, the configurations and datasheets should be requested as needed. Measurement principles vary significantly depending on the system. Table 43.8 provides an overview of the most common principles.

For some specific station types the design has been modified to better achieve their aim. For instance, the spatial density of stations may not be high enough to measure the parameter of interest accurately, so mobile sensors are also used (see Chap. 50), e.g., for road and urban measurements.

43.4.3 Sensors for Networks of Different Station Types

A wide variety of sensors are used in networks of different station types. The sensors used depend on the purpose of the network and the participating parties, and vary from highly accurate measurement devices (see Sect. 43.4.1) to compact sensors (see Sect. 43.4.2) and simple sensors (see Chap. 44). In particular, in some networks such as ADS-C or Mode-S EHS (Table 43.3), a sensor is not needed to estimate the meteorological parameters of interest. In these cases, the required meteorological data are deduced from other information, such as aircraft flight parameters. Therefore, it is virtually impossible to summarize the sensors that are used in networks of different station types.

43.4.4 Sensor Comparison

The most appropriate sensor system to use in a station depends on the measurement quality required and the level of maintenance that is feasible. These should be decided upon before any system is applied (see Chap. 3). Quality assurance is therefore very important and should not be underestimated. Some basic information on the advantages and disadvantages of the sensor configurations used for different station types is given in Table 43.9.

Table 43.7 Some compact measurement systems (photos © OTT HydroMet Fellbach GmbH, Germany; Adolf Thies GmbH & Co. KG, Göttingen, Germany; Vaisala Oyj, Vantaa, Finland, Gill Instruments Ltd., Lymington, UK) [43.2]

Note that the devices shown here were selected to highlight that device construction can vary markedly. These types of devices are sold by many companies, who fit them with various equipment, meaning that this table should not be used for comparison purposes

Table 43.8 Measurement principles used for compact measurement systems [43.2]

Measured parameter	Measurement principle
Temperature	Thermocouple, thermistor, Pt100/Pt1000
Relative humidity	Capacitive
Air pressure	Capacitive
Wind direction	Ultrasound Wind vane
Wind speed	Ultrasound Cup anemometer
Precipitation	Acoustic, radar, tipping bucket (separated)
Global radiation	Semiconductor, thermopile
Brightness	Semiconductor
Lightning	Radio wave detector

Table 43.9 Advantages and disadvantages of the different sensor configurations (for data quality, see Table 43.10)

Configuration	Advantages	Disadvantages
Single sensor	Highly accurate measurements, easy to compare measurements between stations within a network	Expensive sensors, considerable maintenance required
Compact sensor	Easy-to-handle sensors, good price-to-quality ratio	Often do not comply with the WMO recommendations
Simple sensor for crowdsourcing	Inexpensive sensors or devices, readily available in large numbers/quantities	Data can only be used and compared with considerable mathematical effort (see Chap. 44)
Sensors for networks of different station types	Configuration has the advantages and disadvantages of the other sensor configurations (depending on the purpose of the network and the participating parties)	

Table 43.10 Measurement uncertainties and recommended installation heights for standard measurements performed using various station configurations (based on Table 1.5, Chap. 1)

Parameter	Typical sensor(s)	Recommended installation height (m) ^a	Typical measurement uncertainty		
			Single sensor	Compact sensor	Simple sensor ^b
Air temperature	Pt resistance with a radiation screen	2.0	1 K	1 K	2 K
	Pt resistance, ventilated with a radiation screen	2.0	0.1 K	0.3 K	
Humidity	Capacitive sensor	2.0	1%	5%	10%
Wind speed and direction	Cup anemometer with wind vane	10.0	0.2 m s ⁻¹ 3°		
	Sonic anemometer	10.0	0.1 m s ⁻¹ 2°	0.3 m s ⁻¹ 3°	
Pressure	Piezoelectronic sensor	Fixed height ASL	0.1 hPa	0.5 hPa	1 hPa
Precipitation	Rain gauge	1.0	0.1 mm resolution ≈ 10%	0.1 mm resolution ≈ 10%	
Global radiation	Pyranometer	≈ 2.0	5 W m ⁻²	20 W m ⁻²	

^a For standard measurements

^b Note that measurement uncertainties for simple sensors are estimated values (see Chap. 44)

43.5 Specifications

The general specifications for single sensors are described in the relevant chapters in Part B and Table 1.5 (Chap. 1) of this Handbook. The accuracies of compact sensors are slightly lower than those of single sensors (Table 43.10). A comparison of data from compact sensors with standard meteorological measurements is only possible if the recommendations for the measurement height and location are fulfilled when using compact sensors. Since these sensors are used in measurement stations for specific applications (Table 43.2), the specifications for standard meteorological mea-

surements are often not relevant for compact sensors. A common additional source of error for simple sensors used in crowdsourcing is inaccurate sensor installation, e.g., no radiation screen for temperature and humidity measurements, or different installation heights. Therefore, the main problem with these sensors is generally not their accuracy (see Table 43.10) but their installation. In principle, this issue can be resolved by selecting appropriate data from a large number of sensors (see Chap. 44) through the application of adequate filter techniques.

43.6 Quality Control

The principles of quality assurance and quality control (see Chap. 3) are valid for stations with single and compact sensors. The procedures followed for

the various meteorological parameters of interest are described in the relevant chapters in Part B of this Handbook.

43.7 Maintenance

The maintenance requirements are identical for stations with single and compact sensors, and similar for specific networks and industrial applications. The maintenance recommendations for specific sensors are given in the chapters of Part B of this Handbook. Table 43.11 provides a general overview of the maintenance re-

quirements for the station types listed in Table 43.1. For sensors used in specific networks (Table 43.3), for industrial applications, and for crowdsourcing, it is often cheaper to replace the sensor than to carry out costly maintenance work.

Table 43.11 Sensor maintenance for different types of stations (see Table 43.1)

Maximum interval	Single-sensor station	Station with compact sensors	Sensors in networks	Sensors used in industry and building engineering	Sensors for crowdsourcing ^a
1 week	Maintenance of special sensors if required				
	Check function and plausibility; if the sensor is not operating correctly, it must be serviced, replaced, or excluded from the network				
3 months	Check mechanical function, perform maintenance on special sensor types if required				Replace sensors with a permanent malfunction or exclude them from the network
2 years	Sensor calibration; replace sensors if necessary				
If a sensor check reveals a significant malfunction, the instrument should be replaced.					
^a Data need to be quality checked and corrected or deleted before further application					

43.8 Applications

Examples of how data for various meteorological parameters are used are described in the relevant chapters of Part B of this Handbook. The station types described in this chapter (see Table 43.1) cover practically every conceivable field of application of atmospheric measurements. Starting with classical weather stations for synoptic and climate monitoring measurements, Table 43.2 categorizes a large number of atmospheric

measurement station types according to their utilization in different areas of meteorology, hydrology, and environmental science. More recent applications include collecting and transferring all available information from atmospheric measurements to new networks or estimating atmospheric data from other networks. See Table 43.3 and Chaps. 63 and 64 for examples that can be accessed online.

43.9 Future Developments

Recently, there has been a trend for customers to choose less expensive sensors with medium to high data quality and data availability (see Table 43.10) and low maintenance costs. In order to comply with these requirements, manufacturers have been developing compact sensors (Sect. 43.4.2) that combine sensors and reduce the number of measurement principles utilized. This trend is likely to continue in the near future.

Single sensors will only be used in synoptic weather and climate monitoring stations or for research purposes due to their high accuracy, their specific requirements for maintenance, and their larger scope of measurements. It is likely that compact sensors will be increasingly used for atmospheric measurements at other stations. Due to their modular layout, they can be tailored to specific uses.

Networks that combine different station types (i.e., stations with private users, those with industrial users, and those with users from building services) will likely develop more rapidly due to the availability of inexpensive sensors with reasonable data quality and low maintenance costs. The ability to access the data generated

by many stations online, along with meta-information on their geographical locations, the characteristics of their surroundings, and sensor and installation heights, offers the ability to monitor atmospheric parameters to a much greater spatial density than some national monitoring networks can. In these cases, the accuracy of the sensors at the various locations is not the primary problem. The challenge is to develop software solutions for quality assurance and quality control that can distinguish between good and biased data, thus allowing a representative and sufficiently accurate spatial distribution of the atmospheric parameters to be derived and subsequently applied.

Nevertheless, climate monitoring stations, stations used for research purposes, and stations used for other purposes will continue to be utilized too, as only those stations can meet the requirements for data quality, long time series, and the collection of specific atmospheric data, respectively. Combining data from classical atmospheric measurement stations with atmospheric data measured and collected in new ways via inhomogeneous networks and crowdsourcing will be the most challenging and exciting task in the near future.

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

Crowdsourcing

44. Crowdsourcing

Matthias Budde 

Aside from classical meteorological measurements from a wide variety of weather stations, so-called crowdsourcing approaches have been applied to the collection of meteorological data, as well as generally atmospheric measurements in recent years. The topic of this chapter is crowdsourcing, but it is also a broad overview of sensors applied in crowdsourcing and corresponding projects. This chapter first introduces the definition and typology of the relevant terminology, along with a short history of crowdsourcing. We describe and discuss aspects of both the typically employed low-cost measurement technology, as well as human factors that emerge from laypersons carrying out the measurements. This includes general considerations concerning measurement uncertainty, as well as possible measures to improve the data quality in mobile nonexpert sensing. Devices and sensors, ranging from dedicated devices over do-it-yourself sensors to internal smartphone sensors are discussed, as are a number of applications and projects that illustrate in which ways crowdsourcing approaches have been applied to the measurement of atmospheric parameters and what type of challenges have been addressed and which ones remain.

Besides data collection from classical weather stations, gathering meteorological (or generally atmospheric) measurements has become possible with technology operated by nonexperts, as, e.g., citizens. So-called crowdsourcing approaches distribute tasks, such as, for example, data collection, to a group of individuals. This chapter provides an introduction of the general underlying concepts, the history of crowdsourcing, as well as an overview of low-cost measurement technology

and applications in atmospheric measurements. This includes an attempt to classify sensors and devices on the one hand and example projects on the other. In addition to presenting an overview of crowdsourcing in atmospheric measurements, this chapter discusses some specific aspects more deeply, such as measurement uncertainty, possible measures to improve the data quality in mobile nonexpert sensing, challenges and approaches, as well as possible future developments.

44.1 Measurement Principles and Parameters

Crowdsourcing has increasingly been applied in different ways and in different fields over the past two decades. Since the underlying concepts and the terminology employed are almost as diverse as the projects and the measurement technology employed, we begin this chapter by briefly introducing crowdsourcing as a general concept and present an overview of the atmospheric parameters that can be measured using crowdsourcing approaches.

44.1.1 General Overview

There are different notions of what crowdsourcing entails exactly. According to an integrated definition that was proposed in 2012 [44.1], crowdsourcing entails a task that is assigned online and uses the Internet, with a clear goal being carried out by a clearly defined crowd, which receives some form of recompense from a clearly defined crowdsourcer, who in turn receives some sort of compensation from the task being carried out. This definition, along with a typology of crowdsourcing systems, is discussed in more depth in Sect. 44.3.

Other concepts that are related to the notion of crowdsourcing include *citizen science (CS)*, *mobile crowdsourcing (MCS)*, *crowdsensing*, *participatory sensing (PS)* [44.2], *volunteered geographic information (VGI)* [44.3], *public participatory geographic information systems (PPGIS)*, *public–private partnerships (PPP)*, and others. They partially overlap and/or may also have differing definitions. Citizen science is a very broad term as well and does not necessarily include an online activity, and as the name says, it often involves the claim of contributing to science in some way. In this chapter, we include citizen science projects that have reached a certain scale. The concepts of participatory sensing (PS) and (mobile) crowdsensing both entail data collection with personal handheld devices, mostly smartphones. Another important factor in participatory sensing is the focus on the user, as the concept intrinsically involves empowering citizens [44.2].

44.1.2 Parameters

Measurement principles are highly variable for different systems, as are the capabilities in terms of meteorological parameters that can be detected, as well as, of course, the quality of the data provided by different instruments. In principle, any meteorological parameter could be measured with a crowdsourcing approach.

However, crowdsourcing is typically only feasible if the cost of the device is in a range that makes it either affordable for the crowdsourcer to fund it or possible that crowdworkers themselves cover the cost. This usually prohibits collecting data on parameters that can only be measured with intricate and expensive equipment. On the other hand, there are low-cost sensors for many meteorological parameters today.

Table 44.1 gives an overview of the meteorological parameters that can be typically covered with different devices and device classes, which we have roughly divided into five groups: *automatic weather stations (AMS)*, often commercially available *dedicated systems* (e.g., consumer devices), *do-it-yourself (DIY) platforms* that require some technical understanding and possibly assembly by the crowdworkers, and *smartphone accessories* that in some way interface with mobile phones and leverage its processing, storage, and/or communication capabilities. Finally, some approaches try to

Table 44.1 Data sources and meteorological and atmospheric elements of crowdsourcing

Data source	Atmospheric parameter	Relevant chapter
Internal smartphone sensors	Temperature Surface pressure Humidity	This chapter, Chaps. 7, 8, 10
Smartphone add-ons	Temperature Particulate matter Wind speed	This chapter
Cars	Temperature	Chap. 7
Venetian blind	Wind speed Shortwave radiation	Chap. 9, Chap. 11
Automatic weather stations (AMS)	Temperature Humidity Barometric pressure Wind speed Wind direction Precipitation etc.	Chap. 43, this chapter
Dedicated devices/personal weather stations	Temperature Humidity Barometric pressure Wind speed Wind direction Precipitation	This chapter, Chap. 43
Do-it-yourself (DIY) platforms	Temperature Humidity Particulate matter Wind speed	This chapter
Human observation	Qualitative data, e.g., on precipitation Data processing	This chapter

use *internal smartphone sensors* to directly assess parameters, such as temperature or atmospheric pressure. Section 44.4 lists examples of individual devices from each of these classes.

Besides these groups of technical systems, *human observation* is a notable data collection approach in crowdsourcing. This entails crowdworkers directly observing certain meteorological events and creating and submitting according reports. These are typically of a qualitative nature, i.e., observing precipitation events and reporting type and intensity. In addition to direct

observation, crowdworkers can also be employed for crowdanalyzing of tasks, i.e., in some way analyzing, classifying, or annotating existing data.

Whatever the underlying collection approach, crowdsourcing is typically impacted both by the measurement equipment and the humans involved. In the remainder of this chapter, we present possible measures to increase the quality of data collected by nonexpert users and discuss tradeoffs between the data quality of established measurement equipment and the scale of low-cost sensors.

44.2 History

While the term crowdsourcing is little more than a decade old, many related concepts existed before this. This section first briefly introduces the origin of the terminology. Subsequently, it presents a brief history of crowdsourcing, as well as of the hardware typically employed in crowdsensing. While, in principle, any level of device fidelity can be used, in most cases, low-cost sensors or consumer devices are, as other technology is prohibitively expensive and/or not obtainable by crowdworkers. The device history is related to the general development of meteorological sensors, as discussed in Chap. 1.

44.2.1 Evolution of Crowdsourcing

The term crowdsourcing is usually attributed to *Jeff Howe* who originally coined it in his article *The Rise of Crowdsourcing* [44.4] in *Wired magazine* in June 2006. It is a portmanteau of the words *crowd* and *outsourcing*, initially describing the business practice of literally outsourcing an activity to the crowd. It since has evolved and is used for all sorts of tasks being carried out by some group of people.

However, both the idea and the practice of using crowds to solve a challenging problem date back much further. In fact, according to the definition presented in Sect. 44.1.1 above, almost any announcement of a contest could be seen as a (competitive) crowdsourcing call. That is why early examples for crowdsourcing activities often include the Longitude Prize of 1714, the French Food Preservation Prize of 1795, or the Orteig Prize of 1919. An early example that is of a noncompetitive nature is the Oxford English Dictionary, which called for the submission of entries through newspapers in 1884.

However, as current crowdsourcing definitions typically include an activity that in some way involves usage of the Internet, the earliest examples that actually

qualify are probably the first online software sharing communities in the 1980s, in which so-called bulletin board systems (BBS) were used to collaboratively collect and modify source code. The first major crowdsourcing system that uses the Internet in today's sense is probably the community-driven Wikipedia project that was launched in 2001.

In 2004, *James Surowiecki* discussed the opportunities of crowdsourcing – still 2 years before the term was coined by *Jeff Howe* – in his book *The Wisdom of Crowds* [44.5]. Since then, a plethora of projects of different types have been realized. Countless online contests have leveraged the creativity of the crowd. Microwork platforms, such as the *Amazon Mechanical Turk* (launched in 2005) have emerged; some of them developed into general microtask markets, others specialized in tasks, such as software testing or graphical design. Platforms such as *Indiegogo* (2008) or *Kickstarter* (2009) have enabled diverse crowdfunded products, games, and even multimillion dollar movies. Moreover, in academia, countless research projects managed to engage volunteers for various purposes. Common applications of crowdsourcing in citizen science are both data processing as well as data gathering. Through crowdsensing, large volumes of data covering many geographical locations or moments in time can be collected today.

44.2.2 Low-Cost Sensors and Crowdsensing Hardware

In terms of the hardware employed, the origins of low-cost sensors, according communication technology and network intelligence have their roots in the advent of wireless sensor networks (WSNs) and, before that, in telemetric systems. The first academic WSN research was military driven, sponsored by the US Defense Advanced Research Projects Agency (DARPA),

and the first conference on the matter *A Workshop on Distributed Sensor Nets*, was held at Carnegie-Mellon University in December 1978. Back then, sensor nets were conceived differently from today, the emphasis lying mainly on distribution and less on miniaturization, mobility, or self-organization [44.2]. This workshop marks the starting point of approaches to sensor networks taken in the following years.

Over the course of the 1990s, advances in micro-electromechanical systems (MEMS) and system-on-chip (SOC) technologies allowed the development of small, generic, embedded devices with onboard sensors, short-range wireless communication, processing, and storage capabilities. The earliest attempts at developing such devices were the DARPA-sponsored UCLA programs *low-power wireless integrated microsensors (LWIM)* [44.6] and *wireless integrated network sensors (WINS)* [44.7], both initiated in the early 1990s. These projects resulted in the commercial production of the first inexpensive low-power sensor node platforms, which showed the integration of an embedded processor, wireless radio, and multiple sensors into a single device.

44.3 Theory

As already mentioned, crowdsourcing is neither entirely new, nor so well-defined that there would be one theory behind it. Instead, different aspects are of importance. We therefore begin this section with a definition of crowdsourcing and a typology of different classes of crowdsourcing approaches. Subsequently, we will go deeper into the peculiarities of crowdsourcing systems compared to classical measurement approaches, both in terms of challenges as well as potential benefits.

In the remainder of this section, we focus on approaches that involve data collection by nonexperts with nonstandard measurement equipment. The central issue in such systems is data quality, and the two factors that have the most impact on this are the user and low-cost sensing technology. We therefore shortly discuss ways in which humans may affect the quality in a crowdsourcing data collection system. Subsequently, a bit of mathematical theory is presented in order to enable a better understanding of the tradeoffs involved in using low-cost sensors at a large scale.

44.3.1 Definition and Typology

As was already briefly discussed in the introduction, detailed definitions of what exactly crowdsourcing

In 1998, DARPA initiated the *Smart Dust* program with the ambitious task of creating integrated sensor nodes measuring only 1 cubic millimeter by the year 2001. While this goal had not been reached by the end of the project, remarkable miniaturization was achieved, and the project fueled the development of WSN hardware and software outside the immediate scope of the program. In Europe, the EU project *Smart-Its* [44.8] developed a similar but more modular platform in 2000.

Around the same time, first projects that integrated mobile phones with sensor technology ushered in the era of mobile computing. The first one was the EU-project *TEA* (Technology for Enabling Awareness) in 1999 [44.9, 10] that extended a commercial mobile phone with various sensors similar to the ones we find in smartphones today, including, among others, a sensor for ambient temperature measurement.

Today, low-cost sensors, either standalone or available in inexpensive personal devices, enable unprecedented measurement networks and bottom-up citizen science approaches that have also started to influence and change the field of meteorological observations and analysis.

means – and what not – differ. While the term crowdsourcing originated in 2006 [44.4], there are earlier examples of the concept. In 2012, an integrated definition of crowdsourcing was proposed [44.1], which was formulated deliberately wide in order to cover most, if not all, of the (at the time) existing crowdsourcing processes. In verbatim, this definition is [44.1]:

Crowdsourcing is a type of participative online activity in which an individual, an institution, a nonprofit organization, or company proposes to a group of individuals of varying knowledge, heterogeneity, and number, via a flexible open call, the voluntary undertaking of a task. The undertaking of the task, of variable complexity and modularity, and in which the crowd should participate bringing their work, money, knowledge, and/or experience, always entails mutual benefit. The user will receive the satisfaction of a given type of need, be it economic, social recognition, self-esteem, or the development of individual skills, while the crowdsourcer will obtain and utilize to their advantage that what the user has brought to the venture, whose form will depend on the type of activity undertaken.

Table 44.2 Defining elements of crowdsourcing, according to an integrated definition [44.1]

No.	Description	Element
1	There exists a task with a clear goal	E2
2	There is a clearly defined crowd	E1
3	The recompense received by the crowd is clear	E3
4	The crowdsourcer is clearly identified	E4
5	The compensation to be received by the crowdsourcer is clearly defined	E5
6	It uses an open call of variable extent	E7
7	It is an online assigned process of participative type	E6
8	It uses the Internet	E8

Summing this up, the definition entails eight distinguishing elements (originally numbered E1–E8, Table 44.2). A task with (1) a clear goal being (2) carried out by a clearly defined crowd, which (3) receives some form of recompense from (4) a clearly defined crowdsourcer, who in turn (5) receives some sort of compensation from the task being carried out. Three additional constraints concerning the task are defined. First, that (6) the task is assigned via a somehow open call, second, that it (7) is an online assigned participative process, and third that it (8) uses the Internet.

If not interpreted too narrowly, the above definition covers all projects and applications featured in this chapter. However, depending on how strictly one takes the definition, individual ones could be seen as not meeting all of the eight conditions. Especially the latter constraints might exclude interesting systems. We adopt a broad interpretation here. Specifically, we do

not exclude projects that are not assigned online or do not involve an online activity. Passive sharing of meteorological data from personal weather stations could, for example, be seen as not being an online activity (or, for that matter, an activity at all). In addition, we include approaches that may not have a clearly defined crowdsourcer or in which the crowd and the crowdsourcer overlap or are identical. This is, for example, typically the case for bottom-up or grassroots projects that may initially both be started and worked on by the same set of people. Another aspect that may not always be met, especially with academic projects, is that of crowdworkers receiving some sort of recompense, or at least it may be individual rather than universally clear what this recompense entails. Besides money and other extrinsic motivators that may lead to people participating, the crowdworkers might only be intrinsically driven by creating something for their personal utility, expressing themselves, or simply gaining pleasure from their participation. We thus interpret *recompense* as including any such kind of motivation. Overall, if not interpreted too narrowly, we find the presented integrated definition very fitting and, therefore, adopt it here unaltered.

For typologies or taxonomies of crowdsourcing, the situation is a bit less clear. Only few papers have classified crowdsourcing types, one of which [44.11] proposed an integrated typology from individual ones from related work (e.g., [44.12–14]). As we find some of the presented classes ambiguous and/or partially orthogonal, we propose an adjusted typology of crowdsourcing (Fig. 44.1). As the main distinguishing characteristic, we chose the *type of activity* that is being carried out

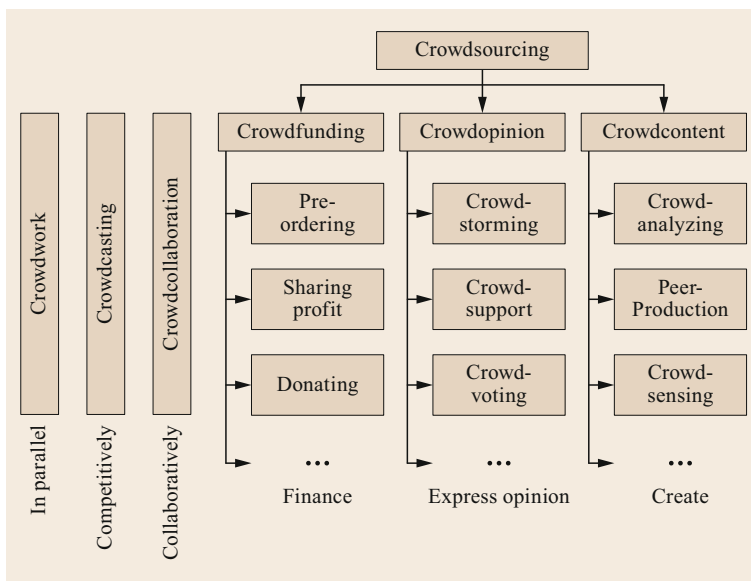

Fig. 44.1 Proposed typology of crowdsourcing. The distinguishing factor between the classes is the *type of activity* being carried out (financing, opinionating, or creating). Three orthogonal classes additionally allow categorization by the *level of collaboration* (in parallel, competitively, or collaboratively). Image © Matthias Budde

by crowdworkers. However, we do recognize that there are other dimensions along which categories could be distinguished. Additionally, we therefore also adopted three orthogonal classes that distinguish tasks by the *level of collaboration*. Any crowdsourcing task can fall in any of the classes, as well as either of the orthogonal classes. Of course, a crowdsourcing activity may also involve different tasks that cover multiple of the classes. This chapter contains multiple examples in which the same crowd, e.g., is involved in crowdfunding a platform and subsequently deploying and operating it (see the applications in Sect. 44.8). There have also been examples of multiple-tier crowdsourcing systems in which, e.g., the task of data acquisition is crowdsourced to one crowd, and the task of analyzing said data is crowdsourced to a different one [44.15, 16].

We would like to point out that while we adopted many of the names for the individual classes and their meaning from related work [44.11], many of the terms, in fact, have no clear definition and may also be defined or denoted differently in related work. As an example, neither *crowdopinion* nor *crowdcontent* are clearly defined terms, and our definitions may differ from those presented in other work.

On the first level of our typology, we distinguish three classes according to the type of activity that is being carried out. In *crowdfunding*, crowdworkers contribute by in some way financing an activity or project, in *crowdopinion*, they contribute something intangible, such as their knowledge or opinion, and in *crowd content*, their contribution is something more tangible, like for instance sensor data, labels, or even some sort of product.

On the second level, we list three exemplary classes each, including the classes from other proposed typologies, and add some that we believe to be important and that were missing before. However, there are literally dozens of other terms that could be used or added (e.g., *crowdrating*, *crowdsearching*, *crowdinvesting*, *crowdprocessing*, *crowdcreating*, *crowdcleaning*, *crowdsolving*, *crowdproduction*, etc.) and, as was pointed out above, many of them lack a clear definition. We do not intend to make this a comprehensive taxonomy, as we feel that this does not make sense or would be beneficial in any way.

Previous work distinguishes crowdfunding approaches as *preordering* and *profit sharing* [44.17]. Additionally, we include *donating* as a third category, in which people do not receive a direct reward (or the promise of one) for their money. Instead, they decide to contribute their funds no matter what, e.g., because they believe in an idea or would like to support some development voluntarily and unconditionally, a model

that was, for instance, common in early public domain (PD) software development.

Under *crowdopinion*, we added the class *crowdvoting*, which entails some rating activity. Additionally, we adopted and moved the two classes *crowdstorming* (online brainstorming sessions in which ideas can be raised) [44.11] and *crowdsupport* (user-to-user customer support systems) [44.11] from previous work into this branch of our revised typology, since we think that the defining factor is that crowdworkers express their opinion in some way, which does not necessarily need to involve working collaboratively.

In the third branch, *crowdcontent*, any activity that involves the creation of something is covered. This may lead from tasks like classifying or labeling a dataset (*crowdanalysis*) over the production of goods and services (*peer production*) to the collection of data using sensors or by making observations (*crowdsensing*). As crowdsourcing for atmospheric measurements often entails collecting data, we strongly focus on this last subcategory in the remainder of this chapter.

Since we think that, in principle, any of the presented activities can be carried out either by individual members of the crowd by themselves, or in competition between each other, or by working together, we included three orthogonal classes that additionally allow categorization by the *level of collaboration*. Depending on whether crowdworkers work on a task individually but in parallel, competitively, or collaboratively, we distinguish the classes *crowdwork*, *crowdcasting*, and *crowdcollaboration*.

44.3.2 Promises and Criticism

Whichever the term and detailed definition, the biggest benefits of crowdsourcing approaches usually named are always the same: scalability and cost effectiveness. Especially in data acquisition, crowdsourcing approaches enable unprecedented spatiotemporal resolution and often also (near) real-time data. This, in turn, allows, e.g., novel meteorological applications such as the identification of so-called urban heat islands and generally a better understanding of the urban climate and its dynamics.

An additional important aspect, especially of bottom-up or grassroots citizen science projects, is that of empowerment. The so-called democratization of technology has, for instance, brought forth open source software, accessible electronics platforms (like, e.g., Arduino), prototyping possibilities through three-dimensional (3-D) printers, and social media channels that facilitate building communities. All of these are tools that enable anyone to invent, design, implement,

and deploy novel systems that might potentially transform the world we live in [44.18].

On the other hand, crowdsourcing approaches have different issues as well. An often criticized aspect of systems that involve laymen carrying out tasks is that of questionable or at least unknown quality of the work result. Also, crowdsourcing approaches are not generally applicable to any problem, especially when trying to leverage the so-called *wisdom of the crowd* [44.5]. Depending on the task, it may, for instance, be difficult or even impossible to find and select appropriate crowdworkers, keep them engaged, and minimize uncertainty concerning the results of their work. A key factor for a successful crowdsourcing application is to always carefully consider the needs of the crowd. In commercial systems, further problems may include low wages, social dumping, and tax evasion. Paid microtasks may, e.g., circumvent minimum wage laws, as crowdworkers act like being self-employed (even if they, in fact, might not be). Apart from the legal and ethical questions involved, this again may have implications on quality.

Quality is especially an issue when the task involves crowdcontent. This is a topic that has been controversially discussed. The quality of content generated by crowdsourcing initiatives is often questioned or challenged, especially when it involves data collection [44.19, 20]. One extreme position even goes so far as to claim that while promising more truth and deeper knowledge, the possibilities of user-generated content and peer production actually destroy professionalism and ultimately lead to their disappearance [44.21]. However, this argument has, in turn, been criticized for being one-sided and suppressing positive examples. As so often in life, the truth is probably somewhere in the middle: crowdsourcing surely neither is the answer to all problems nor is it generally the source of unusable information. An important aspect is to be aware of and to acknowledge the shortcomings and deal with them as necessary for the application at hand. Otherwise, one might – maybe even inadvertently – contribute to the blurring between fact and opinion, especially when the collected data is made publicly available.

44.3.3 Human Factors in Crowdsourcing

Mobile and wearable devices – always being on, always online, always with the user, and context-sensitive – present a perfect platform for crowdsourcing, and, thus, crowdsensing applications. In contrast to the potential of such systems stand the many sources of systematic error that may affect data quality in nonexpert low-cost sensing [44.22]. That is why, as past research points out [44.19],

despite the wealth of information emerging from citizen science projects, the practice is not universally accepted as a valid method of scientific investigation. [...] At the same time, opportunities to use citizen science to achieve positive outcomes for science and society are going unrealized.

This goes to the extreme that data from laypersons is considered to be undesirable by experts or policy makers and may even be prohibited for official use [44.20]. On the other hand, research shows that laypersons can collect data of comparable quality to experts, if properly familiarized with the task [44.23]. The problem is that nonexperts are typically not, and thus cannot ensure standardized sensing processes. They may be [44.24]:

- *Untrained*: unfamiliar with the way the sensing process is intended to be performed
- *Overwhelmed*: uncomprehending or unable to recall the correct measurement procedure
- *Inattentive*: not paying attention to all details of the process (this is especially likely if participation is extrinsically driven, e.g., through monetary incentives or gamification)
- *Digital immigrants*: not digital natives, i.e., have little or no experience with mobile or wearable technology, or even
- *Malicious*: deliberately trying to influence the measurement process or *to play* the system.

We argue that in crowdsourcing applications, it is often neglected that, in fact, the user is often an important part of the technical sensing architecture, directly affecting the quality of the data generated or task performed. Research recognizes that [44.25]

[...] this application domain is poorly understood by most system designers who focus almost exclusively on empowering citizens rather than considering the needs of both citizens and civic authorities and establishing trusted relationships between these stakeholders.

By designing for both adequate data quality and intelligibility, this trust relationship between users and authorities is strengthened.

In previous work [44.24, 26], we studied mobile phone-based environmental sensing approaches and identified six main dimensions of human error in such systems (Fig. 44.2). These dimensions form a compilation of ways in which participants' behavior may adversely affect the eventual data quality. The purpose is to sensitize designers and facilitate the design of

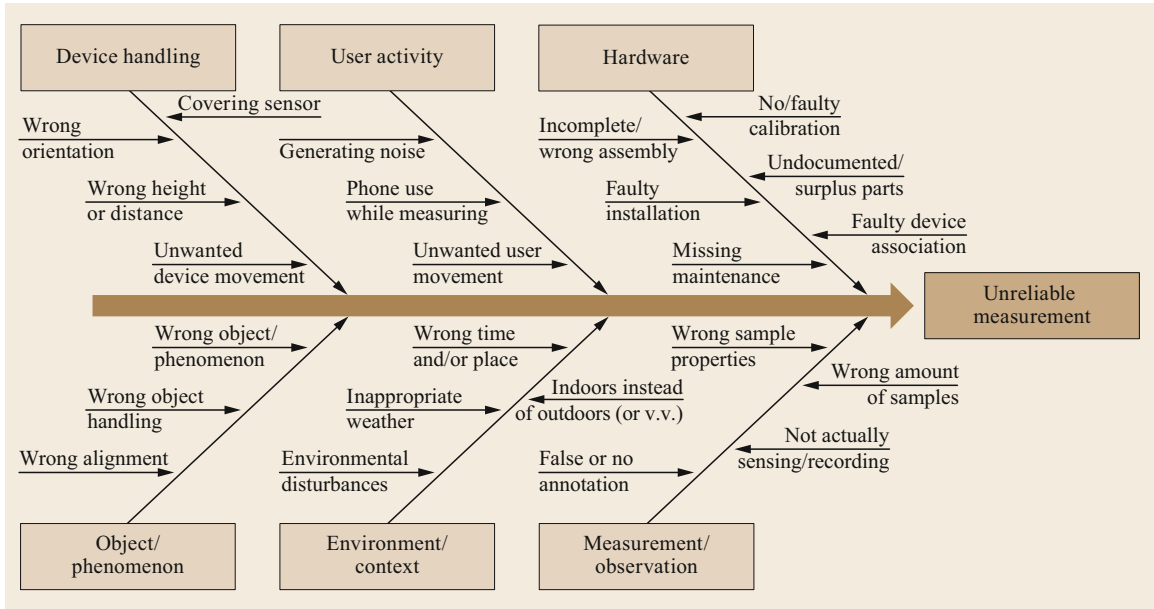

Fig. 44.2 Six dimensions of influence on data quality in nonexpert environmental sensing, as identified by previous research (image after [44.24] with permission from the ACM)

systems that are used by nonexperts to gather environmental data, such that they deliver a higher data quality.

Section 44.6 below discusses measures that can be taken to reduce uncertainty introduced by user error.

44.3.4 Measurement Uncertainty

Aside from the user, the most significant source of uncertainty regarding data quality in crowdsourcing is low-cost instrumentation (that is, for projects that employ sensors to make observations). Despite the often relatively low performance of such instrumentation in direct comparison to sophisticated, established equipment, the low cost allows measurements at a scale orders of magnitude above that of classical measurement grids. This scale in itself carries the potential to trade off uncertainty against spatiotemporal resolution (on the general topic of uncertainty see also Chap. 2).

For some natural number n , consider the data points x_1, \dots, x_n that each carry an error Δx_i . Now calculate the average value

$$\hat{x} = \frac{1}{n} \sum_{i=1}^n x_i. \tag{44.1}$$

The error of \hat{x} can be approximated by the error propagation formula

$$\Delta \hat{x} = \sqrt{\sum_{i=1}^n \left(\frac{\partial \hat{x}}{\partial x_i}\right)^2 \Delta x_i^2}. \tag{44.2}$$

Assuming the same errors for each data point

$$\Delta x_i = \Delta x = \text{const.} \quad \forall i \in \{1, \dots, n\}, \tag{44.3}$$

we get

$$\Delta \hat{x} = \sqrt{\sum_{i=1}^n \left(\frac{1}{n}\right)^2 \Delta x^2} = \frac{\Delta x}{\sqrt{n}}. \tag{44.4}$$

One can see here that any uncertainty in a measurement x_i can be lowered by conducting several independent measurements and averaging all of them. For 100 measurements, a reduction of an order of magnitude can be achieved. Figure 44.3 illustrates this fact.

The thin black line at $y = 5$ is the mean of the Gaussian distribution with $\mu = 5, \sigma = 1$ from which 1000 points (blue dots) were sampled. The colored, thick bars are the averages of batches of 100 points. We can clearly see that the spread of the colored bars around the black line is much smaller than that of the blue dots.

This reflects the strength of a large-scale crowdsourcing scenario with low-cost sensors. The fact that low-cost sensors are, in general, subject to numerous error sources can be alleviated by the sheer amount of sensors that can be deployed due to cost reduction. Statistical errors will be dampened in the average values of the whole sensor network. Systematic errors still need to be addressed differently. One approach to manage this is by calibrating the low-cost sensor network to a few high-cost reference devices, thus spreading high-cost accuracy over the whole network [44.27].

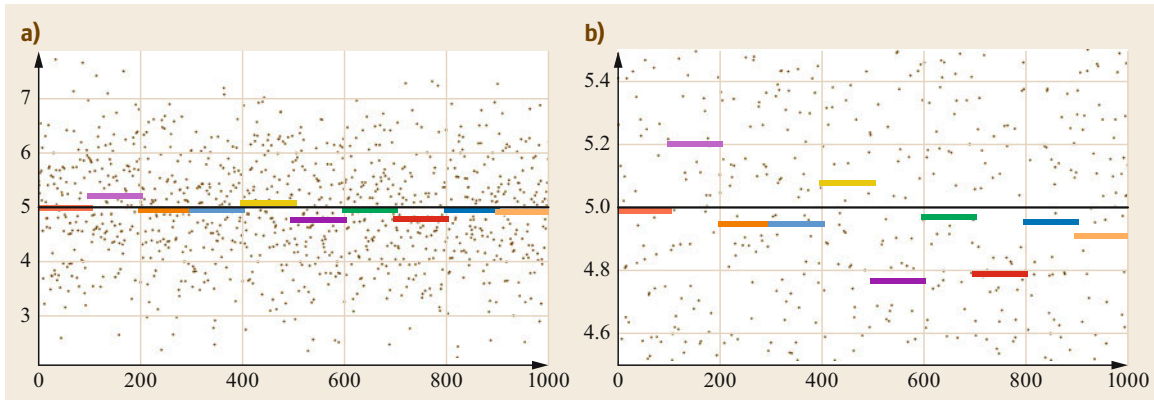

Fig. 44.3a,b Example of how a large scale can compensate for noisy data from low-cost sensors. By averaging over several independent measurements, the uncertainty can be lowered. In this example, averaging over 100 readings leads to a reduction of one order of magnitude (*dots* are readings, *colored bars* are averages; both images **(a)** and **(b)** show the same data on different scales)

As was already mentioned above, this approach still has some disadvantages. The act of averaging not only lowers the uncertainty but may destroy important information, too. For instance, averaging a time series will leave us with a worse time resolution of our (mean)

sensor reading. Similarly, a network average of, e.g., a whole city block will result in a worse spatial resolution. These two facts, reduction of uncertainty and loss of information, have to be thought of as an indisputable tradeoff in the act of averaging.

44.4 Devices and Systems

This section features examples of systems that are typically used in crowdsourcing for atmospheric measurements. We roughly group these devices into five classes: *automatic weather stations (AMS)* were already covered in Chap. 43. *Dedicated systems* cover consumer devices and personal systems, many of which are directly commercially available to the end-user. *Do-it-yourself (DIY) platforms* are usually low-cost for their respective capabilities, but demand some effort and/or technical understanding and possibly assembly on part of the user. *Smartphone accessories* are small add-on devices, often used to sense a single phenomenon, that leverage the processing, storage, and communication capabilities of modern mobile phones. Finally, some approaches try to use *internal smartphone sensors* to directly assess parameters such as temperature or atmospheric pressure. An overview of the meteorological parameters that can be typically covered with different devices or device classes was presented in Table 44.2 at the beginning of this chapter. We would like to point out that the list of devices and systems in this section is exemplary and is not meant to be comprehensive. Especially in the commercial sector, many consumer devices are available, and some of them are very similar.

44.4.1 Dedicated Devices

There are many different sensing platforms that can be used for crowdsourcing applications. The best known measurement devices are typically dedicated small networked weather stations that are designed as consumer products. A prominent example of these are, for example, products from the French company *Netatmo* [44.28], for which different modules exist, even to measure parameters such as wind or precipitation (Fig. 44.4).

There is a fast growing market of such compact systems to measure meteorological parameters. As they are designed for end-users, these systems are typically easy to set up and operate. Many of the systems – like *Netatmo* – are modular, letting the user select the sensors for his personal needs. Well-known examples for the measurement of gases and/or particulate matter include the open source *Air Quality Egg* (which was also crowdfunded and was named a *Best of Kickstarter 2012* project) or the *Laser Egg*.

44.4.2 Do-It-Yourself Platforms

In addition to commercial products, there exists today a wide range of *do-it-yourself (DIY)* projects. The ba-

Fig. 44.4a,b The networked *Netatmo* weather stations can (a) be extended with various modules, among them a rain gauge (b) to measure precipitation (photo © Netatmo. Photos Masaki Okumura, M-Agency, Marion Leflour, Fred Reynaud and 1988)

sis for these are usually single-board computers, such as *RaspberryPi*, *Arduino* platforms, or *ESP32* SOC microcontrollers. The *WeatherPi* project website, for instance, features manuals to set up a networked (optionally solar powered) *RaspberryPi*, which senses 20 different environmental values. *TheWeatherStation.com* shows a similar platform built on an *Arduino Uno*, and many more similar projects can be found on various pages on the Internet. These types of projects usually require users to read at least simple circuit diagrams, connect electronics accordingly – which may or may not include soldering – and load some kind of firmware onto the platform. Depending on the individual project, deeper electronics, operating systems, and/or programming skills may be required.

An example of a simple sensor used in DIY citizen science projects based on an *ESP* platform is the *Novafitness SDS011* particle sensor (Fig. 44.5). The low-cost nephelometer is available for currently just over US \$30 (as are other similar sensors as well), which is orders of magnitude below the cost of professional particle monitoring equipment. As is to be expected, the sensor has its shortcomings, but for its price it performs well under certain conditions [44.29].

Other than ready-to-use plug-in sensors, there is a variety of low-cost sensors available at very low cost due to the rise of smartphones and automotive sensor applications. Among these are inexpensive sensors for phenomena like temperature, humidity, or pressure, and increasingly also for gases. A recent report from the World Meteorological Organization (WMO) provides an overview of low-cost sensors for the measurement of the atmospheric composition [44.30]. In terms of their data quality, single sensors are of varying performance; some are very stable, others more noisy. An equally important aspect with these sensors is the

Fig. 44.5 The \$20-fine dust sensor SDS011 is (among other low-cost sensors of similar design) used in different crowdsensing campaigns around the world, such as the *luftdaten.info* project of the Open Knowledge Foundation Germany (image taken from Wikimedia under *CC0 1.0 Universal* license)

installation [44.24]. A decent temperature sensor, for instance, that is installed in direct sunlight will hardly be able to deliver adequate air temperature readings.

44.4.3 Smartphone Accessories

However, not only dedicated weather stations are available but also sensors and modules that can be used for mobile crowdsensing applications as accessories for or even integrated into smartphones. To realize truly large-scale pervasive sensing systems, it would be beneficial to carry out measurements directly with users' personal devices, especially smartphones. Different companies offer commercial smartphone anemometer apps that either wirelessly transmit data from small external wind meters to the phone or even directly from anemome-

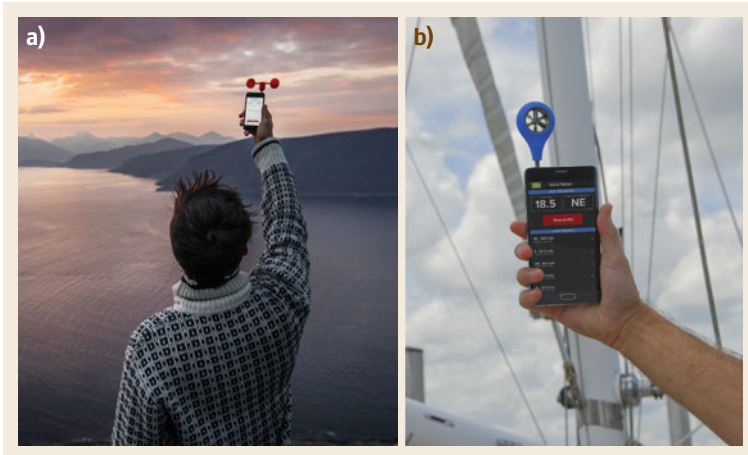

Fig. 44.6a,b The smartphone anemometers from the company *vaavud* (a) and the *WINDmeter* from *WeatherFlow* (b) are plugged into the microphone jack of an Android or Apple phone (photos © *vaavud* (a) and © *WeatherFlow* (b), used here with kind permission)

ter modules that are plugged into the microphone jack of an Android or Apple phone (Fig. 44.6). This allows both powering the accessory as well as sending the sensor data to an app on the phone. An example of this is the smartphone anemometer from the Danish company *vaavud*, which was later acquired by the company *WeatherFlow*, which offers a similar product under the name *WINDmeter*. The same technology approach is used for the *Thermodo* temperature sensing modules. These small plugs are also jacked into the microphone socket.

Other available products include visible light meters (*Lumu Power*), ultraviolet (UV) meters, and even Geiger counter modules (both from *Ftlab*). Some of these are fun gadgets rather than meaningful instruments. A general problem with data quality is again the user, as the measurement context greatly influences the validity of the readings [44.24]. The Geiger module, for example, requires the phone to be switched to airplane mode, as it can give false readings from the phone's own cellular and Wi-Fi radio frequency interference. Even if this is done, because we are today surrounded by many different sources of electromagnetic radiation, it remains hard to believe that meaningful accuracy can be achieved under uncontrolled conditions. For the *Thermodo* system, sensor performance is reportedly much less of an issue. However, as many smartphone users carry their phone in their pants or jacket pocket, body heat plays a role and, of course, influences the measurement results. So again, the correct measurement context is vital for achieving meaningful readings.

Apart from these commercial modules, several approaches that augment smartphones with accessories to measure different environmental parameters have been proposed in academia. These include, for instance, a system to measure black carbon (BC) with cellphones [44.31]. The aethalometry-based approach

involves BC aerosol collection on a quartz filter. The smartphone's camera is then used to capture the coloration of the filter, and the reading is transmitted to an analytics component for real-time evaluation.

Another interesting approach to measuring atmospheric dust in participatory sensing scenarios was presented by the Air Visibility Monitoring [44.32] and the *iSPEX* [44.33] projects. In the former, people use their camera phones to take pictures of the sky and upload them to a central database. The particle pollution then is estimated from the image luminance, the location, and other phone sensor data (such as, e.g., orientation). Cloudy skies and indoor environments present clear limitations to this approach. The *iSPEX* system is an ultra-low-cost (US \$3), mass-producible hardware add-on for the *iPhone* that enables crowdsourced spectropolarimetric measurements (Fig. 44.7). The system aggregates multiple readings for quantitative remote aerosol sensing [44.33]. It has been successfully used in single-day measurement campaigns on a large participatory sensing scale (Sect. 44.8).

The *FeinPhone* [44.26, 34] system is another approach that attempts to enable particulate matter (PM) sensing directly with smartphones using a clip-on module. It uses camera and flashlight functions that are readily available on today's off-the-shelf smartphones together with a passive hardware add-on based on light-scattering particle sensors. This direct, in-situ measurement distinguishes the approach from the former two. However, so far, *FeinPhone* is in a proof-of-concept stage and has not yet been used in realworld deployments.

Aside from modules that are directly (physically) attached to smartphones, there are a number of sensing modules that connect wirelessly to a phone, e.g., via Bluetooth (BT)/Bluetooth low energy (BLE). An example of this is, for instance, the *Qualcomm BLE*

Fig. 44.7a,b A citizen scientist is conducting a measurement (a) with the *iSPEX* clip-on module (b) clipped onto her *iPhone* camera (images after [44.24] with permission from the ACM)

Environmental Sensor Board, which carries different MEMS sensors, among them a temperature, humidity, and pressure sensor. The board is not intended to be an end-user device, but rather a development platform to prototype connected products that enable the Internet of Things (IoT). Dedicated wireless smartphone accessories exist as well: the *Plume Labs Flow* device, for instance, is intended to enable personal exposure tracking of a variety of parameters through a small device. There are many more such platforms of different fidelity available or under development.

44.4.4 Internal Smartphone Sensors

From a pure distribution perspective, the closer sensors come to being integrated into our phones, the better they can be employed for crowdsensing. Internal phone sensors are practically always with the user, inseparably tied to powerful processing and communication capabilities, as well as interfaces for control and visualization. In today's smartphones, a plethora of sensors is installed (Fig. 44.8).

Basically every smartphone has a 3-D accelerometer, gyroscope, magnetometer (compass), multiple microphones, as well as two or more cameras (newer models sometimes include depth sensors). Aside from the global positioning system (GPS) receiver, multiple radio interfaces can be used to obtain absolute or relative position information, through beacons, RF fingerprints, or cell trilateration. Many phones additionally feature pressure sensors and proximity (infrared (IR) light) and ambient light sensors. Smartphone batteries usually have an internal thermistor to monitor their temperature. Modern smartphones come with additional features, such as fingerprint sensors, retina scanners, or heart rate monitors.

Aside from the actual sensors, several so-called virtual sensors are available on today's smartphones. Their

readings are based on data fusion from the physical sensors, especially the inertial sensors. They range from simple ones, such as orientation/gravity sensors, over step counters/pedometers to context information, such as *running*, *standing still*, *on bicycle*, *in vehicle*, etc. While not directly usable for environmental observation, the inferred activities can maybe be used to rate and/or improve the data quality [44.24].

Individual smartphones even feature meteorological sensors. For instance, in 2013, the *Samsung Galaxy S4*, was the first smartphone equipped with ambient temperature and humidity sensors. One year later, the *Samsung Galaxy Note 4* featured the first UV light sensor. The waterproof *Caterpillar CAT S61* phone even includes a sensor to measure volatile organic compounds (VOCs) for indoor air assessment, a laser rangefinder, and a thermal imaging camera.

The most exotic sensor in a smartphone was probably built into the 2012 *Sharp Pantone 5 107SH*. The phone, which was only available in Japan, featured a radiation detector. However, this can probably be considered as serving a short-term niche market after the 2011 Fukushima disaster in Japan. At least, no further developments in this direction have been seen in later phone generations.

Aside from these sensors that are already available in smartphones today, efforts to enable, e.g., particulate matter sensing with small sensors that can be integrated into the housing of a smartphone have been made in the past. Researchers have proposed the design of a capacitive particle sensor that has the potential to be microfabricated and embedded into phones [44.35]. In a different approach, the direct measurement of the mass concentration of particles was enabled with an air-microfluidic microelectrical mechanical systems (MEMS) design [44.36]. These developments show both interesting approaches, as well as a promising performance under laboratory con-

Fig. 44.8 A current smartphone and examples of sensors found in different phones (no single smartphone features all of the listed sensors). Smartphones possess a plethora of integrated sensors, some of which can be (re)purposed for environmental measurements. More exotic ones feature sensors for ambient temperature and humidity, special cameras, or VOC (volatile organic compound) gas sensors

ditions. However, there may be one issue with the general approach of miniaturizing aerosol sensors that far, which is not a question of detection principle but rather one of statistics: the smaller the detector volume, i.e., the smaller the amount of air that can be sampled at a time, the more consecutive measurements need to be taken in order to make a statistically reliable statement concerning the mean concentration. This has implications, for example for air flow and measurement duration and frequency requirements [44.26, 37].

The most notable internal smartphone sensors that have actually been used for meteorological crowdsourcing applications are the battery temperature sensor and the pressure sensor. The respective applications are presented in Sect. 44.8.

44.4.5 Human Observation

Finally, we would like to point out that smartphone users themselves can be the sensor. This human-as-a-sensor approach is actually not uncommon in citizen science projects. Instead of measuring with some kind of device, users contribute qualitative observation(s). This is, in some cases, obligatory, if the information sought after is of a nature that can only – or a least much better – be determined by humans [44.38]. In other cases, it may simply enable a scale of observation that can otherwise be hard to achieve. This may be the case for direct active observation and reporting by the

user. Examples of this are, e.g., user-generated reports on precipitation events [44.39, 40] (Sect. 44.8).

Conversely, information can also be derived from indirect user reports. Through social media analytics (SMAs), public postings on platforms like Twitter can be analyzed to retrieve information. This has been done in the past for various applications in disaster situations, ranging from identifying active entities [44.41] over peer production of accurate maps in the aftermath of disasters [44.42] to real-time mapping applications [44.43].

Also, crowdanalyzing applications can be seen as another kind of human-as-a-sensor systems. In these, the task often involves data review and labeling rather than the collection of new data. Examples of this include the classification of cyclones or the analysis of historical weather reports from ship's logs, both on the *Zooniverse* Citizen Science Platform [44.44] (Sect. 44.8).

44.4.6 Comparison of Sensors

The choice of a sensor system depends on the crowd, the application, its quality requirements, and the effort required for maintenance. This should be decided before any system is applied (Chap. 3). The necessary process of quality assurance is, therefore, very important and should not be underestimated. Some basic information about advantages and disadvantages of the sensor configurations for the different station types is given in Table 44.3.

Table 44.3 Advantages and disadvantages of the different sensor configurations

Devices	Advantages	Disadvantages
Stations set up with single sensors	Highly accurate measurements Easily comparable measurements in networks	Expensive sensors High maintenance efforts
Compact sensors	Easy to handle sensors Good price-quality ratio	Often not in agreement with WMO recommendations
Simple sensors for crowdsourcing	Cheap sensors or devices Available in large amounts Tend to be small and low power and, thus, potentially mobile Possibility of collecting data with unprecedented spatiotemporal resolution accessible to almost anyone through open source drivers and single-board microcontrollers (democratization of technology): inexpensive tool for research purposes Enables novel applications	Often noisy sensors of varying data quality Sometimes cross sensitivity/selectivity Comparable information often only available with high additional effort (mathematical, organizational, etc.) Uncertainty in data quality Higher effort for writing consumer grade software and user interface

However, there are some peculiarities in crowdsourcing that may require looking at sensor performance and quality characteristics in a different way. Crowdsourcing enables unprecedented applications and quantities of data not possible in classical applications. One could argue – and depending on the application we think one should – that the definition of data quality on the device level is not adequate to describe such systems in the first place.

Comparing a single low-cost sensor against gold standard equipment is fine to characterize the short-

comings of cheap sensor technology, but it should not be the sole basis to rate a system using these sensors on a large scale. Taken as a whole, the emergent properties of such systems will likely differ from those of a single sensor, be it simply as an effect of scale (Sect. 44.3.4), or because data fusion and analytics enable new approaches to build models in a data-driven fashion. Therefore, we propose that the logical continuation of crowdsourced data acquisition is the fusion and analytics of this data with high-quality data available from different sources [44.45].

44.5 Specifications

For the specification of the single sensors see the chapters of Part B or Table 1.5 for general values. For compact sensors, the accuracy is slightly lower (Table 43.10). For simple sensors, like the ones typically used in crowdsourcing approaches, a general assertion concerning the uncertainty is difficult. As discussed in Sect. 44.4 above, there are small sensors that deliver little more than indicative readings, while others come close to or even exceed the accuracy of sophisticated equipment. Especially sensors that are used in the automotive sector, or those that are available in today's smartphones, offer remarkable performance characteristics, while being available at very low unit prices, because of the massive scale at which they are produced. An example of this is, for instance, the *Bosch BME280* integrated temperature, humidity, and pressure sensor, which shows high precision according to its data sheet [44.46]. On the other hand, there are many cheap sensors that claim a certain performance in their technical documentation but fail to deliver on that specification in real life. Increasingly, there are also cheap

copies of sensors on the market, mainly shipped from Asia, that are sold for a fraction of the price of the original sensor but under the same name. These imitations are sometimes indistinguishable on the outside but fail to achieve the performance of the original. In order to determine the suitability of a certain sensor, consulting related research or even conducting own validation experiments may be necessary.

For some sensors, characterizing the uncertainty is not a simple task, as they may perform very well under certain conditions, but not generally or in changing environments. An example of this is the *SDS011* particle sensor, which generally shows good correlation with reference equipment but fails to estimate concentrations correctly under high humidity or shifting particle size distribution [44.29].

For simple sensors in crowdsourcing, an additional problem is the often incorrect installation and/or operation of the sensor. This can entail, e.g., a missing radiation screen for temperature and humidity measurements, operation outside of a sensor's specifications,

Table 44.4 Overview of possible measures to improve the data quality in mobile non-expert sensing [44.24, 26]

Approach	Advantages	Disadvantages
Participant selection	Domain expertise/prior knowledge	Usually requires thorough analysis, high resource cost Selection success hard to verify
Training	Best/covers everything Trainer can assess success	High resource cost, experts needed continuously
Instruction (manual)	Clear	Mentally demanding Passive access
Instruction (in-situ)	Very clear Temporally close	Requires some sort of display
Reputation	Good for sorting out single users Helps against malicious intent	Can demotivate users May be hard to build
Verification	Ensures data quality	Infeasible for many tasks After-the-fact
Expert reviews	Ensures data quality	Infeasible for many tasks Experts needed continuously After-the-fact
Redundancy	Very simple	Only robust against statistical error, not systematic May be difficult to achieve Bad readings still contribute
Outlier/anomaly detection	Eliminates implausible readings	Prevents capturing <i>true</i> anomalies Ineffective against systematic error
Bayes filter	Adapts to available data	Needs basic models and multiple readings
Repetition	Simple	Only robust against statistical error, not systematic Needs to be triggered in some way
Context recognition	Potentially fine-grained control over measurements	Only a certain class of errors Maybe technically difficult
Reconstruction	Extremely robust	Only applicable in special cases
Data design	Provides structure	Mostly for textual data
Feedback	Supports user in verifying correct procedure himself Almost always possible	May overwhelm or frustrate user if not carefully balanced
Gamification	Motivates Increases hedonic quality May enhance measurement frequency	May distract from sensing task Can demotivate intrinsically motivated participants May promote quantity over quality

mobile sensing at speeds that compromise ventilation, or measuring background levels too close to a local source, etc. The problem is often not the accuracy of the sensor itself – given in Table 44.4 – but the installation. While incorrect procedure or installment are a problem that is independent of the technology employed, in crowdsourcing it is more likely to occur, because non-experts carry out the measurements.

On the other hand, crowdsourcing scenarios have a set of advantages that may potentially mitigate these drawbacks. The first one is scale. Because of the large

amount of sensors, inadequate measurements have less effect if multiple readings are averaged (Sect. 44.3.2). Additionally, as pointed out in Sect. 44.4.6, the definition of data quality on the device level may not be adequate to describe such systems accurately, because the emergent data quality may exceed that of a single sensor. Secondly, low-cost sensors and crowdsourcing enable novel applications that would not be possible otherwise. The accuracy requirements of these scenarios may differ. Examples are, for instance, hotspot detection or source identification and tracking.

44.6 Quality Control

The principles of quality assurance and quality control (Chap. 3) are valid for stations with single and compact sensors. For the different parameters, the procedures are described in the chapters of Part B.

For crowdsourcing, the situation is somewhat more intricate. As systems and approaches are very diverse, so are requirements and means for quality control. In crowd-based measurements, there usually are no

standard operation procedures (SOPs). There may not even be a clearly defined measurement process at all, or if there is, compliance with it may not be monitored. Apart from the measurement instrumentation employed, which is usually low-cost and in itself a source for unreliable readings, the human is the most important factor. In crowdsourcing projects, especially if they include data collection, the human is not only an operator of measurement equipment, but instead part of the technical sensing infrastructure.

Therefore, we will first discuss sensor calibration in this section, followed by an overview of approaches that can be employed to address issues with data quality that may stem from nonexpert users operating sensing equipment or otherwise contributing observations.

44.6.1 Calibration

As we have seen in Sect. 44.3.4, statistical error of low-cost sensors can be handled by averaging a large number of sensor readings. Suppose we are working now with mean sensor values that possess a low statistical deviation. The remaining relevant sources of error are systematic, i.e., they are stable with respect to different contexts, such as time, place, measurement setup, etc. Due to their stability, one can often apply calibration procedures in order to reduce them.

While research on sensor calibration often addresses the same issues, different terminology is used, some of it interchangeable, some entailing different meanings [44.26].

Generally, there are two main ways of calibrating a device:

- By exposing the device to a defined, often artificially created condition for calibration (usually in a lab environment).
- By comparison against another device in close proximity, typically one with a higher reliability.

As we are concerned with distributed sensing systems, we focus on *device-by-device* calibration, sometimes also known as *comparison calibration* [44.47] or *cross calibration*. Also, device-by-device calibration can either be carried out under factory or laboratory conditions or in the field. Other terms can be found for the distinction between calibration that is carried out by sensors autonomously (*auto* calibration) [44.48] in contrast to calibration that requires manual interaction (*manual* calibration) [44.49].

Regarding calibration with or without the existence of reliable, ground truth measurements, many terms can be found in the literature. So-called *blind* methods achieve calibration gain without ground truth reference

data [44.50]. In line with this, other work uses the term *semiblind* when referring to calibration with partial ground truth data and *nonblind* for calibration with full ground truth data [44.51]. In addition to this, the terminology *off-line* and *on-line* [44.52] can also be found when referring to calibration with or without ground truth data; the latter is sometimes also called *in-place calibration* [44.53]. The terminology *multihop* and *single-hop* [44.27] does not make a distinction regarding the availability of ground truth, but rather the quality of the reference. Single-hop calibration means calibrating directly against reliable reference sensors, while multihop calibration makes use of sensors whose calibration was propagated through several nodes. Another term is *virtual* in-situ calibration [44.54].

Regarding the level on which the calibration is carried out, i.e., whether on the sensing devices themselves or on a central instance that collects all data, also different terms are used. Some authors refer to *device-level* and *system-level* [44.55] calibration, while the terms *micro* and *macro* calibration are also found [44.56]. Calibration schemes without a central instance that use only peer-to-peer (P2P) communication are referred to as *distributed* calibration [44.57]. In addition, *local* calibration is also used in some works for calibration on the sensing devices themselves [44.55].

The general approach for device-by-device calibration is like this: given a set of pairs $(x_1, y_1), \dots, (x_n, y_n)$ of sensor readings x_i and reference values y_i , one tries to find an optimal fit function $f_\theta(x)$, such that a given loss function $L(f_\theta(x), y)$ is minimal. Here, θ are free parameters, e.g., polynomial coefficients or weights of a neural network. Obviously, the quality of calibration greatly depends on the right choice of the fit function f and the loss function L . Most often, a linear fit and a quadratic loss function are well suited

$$f_{a,b}(x) = ax + b, \quad (44.5)$$

$$L(f_{a,b}(x), y) = |f_{a,b}(x) - y|^2. \quad (44.6)$$

By optimizing this loss function, the differences between the calibrated values $f_{a,b}(x_i)$ and the reference values y_i are minimal. Given one value pair (x_i, y_i) we can derive the conditions for a minimum either analytically or by one of the numerous optimization algorithms available today. Because the above functions are so simple, we will do it analytically here

$$\frac{\partial L(f_{a,b}(x_i), y_i)}{\partial a} = 2(ax_i + b - y_i)x_i = 0, \quad (44.7)$$

$$\frac{\partial L(f_{a,b}(x_i), y_i)}{\partial b} = 2(ax_i + b - y_i) = 0. \quad (44.8)$$

The last equation implies the first one. So, in fact we only get a single minimum condition per value

pair. This is a general fact for polynomials and should be considered as a rule of thumb for other fit functions. Furthermore, if we consider all value pairs $(x_1, y_1), \dots, (x_n, y_n)$ we will have more conditions than parameters. The system is overdetermined and almost always unsolvable. Hence, we can try to construct an average solution, i.e., solve subsystems of two conditions and average the parameters over all such subsystems. If the fit function is not linear, a better approach is to minimize the average loss of all value pairs in order to combine the minimum conditions. Again, this corresponds to a specific choice of the loss function.

At the end of this procedure, we will have a set of parameters θ (here a, b), which will most likely not correspond to an exact match $f_\theta(x_i) = y_i$ but rather to some erroneous fit $f_\theta(x_i) = y_i + \Delta y(x_i)$, where $\Delta y(x_i)$ quantifies the error of the calibration at a given sensor reading x_i .

For distributed sensing systems, on-the-fly calibration (as, e.g., in [44.27]) is an interesting approach. If two sensors *meet* each other with respect to a given context, for instance (but not restricted to) time and space, one can apply a calibration method to *synchronize* both sensor readings. The above procedure describes the case where one sensor (the reference) has maximum trust, i.e., whose sensor readings are considered to represent the ground truth. There are different methods based on statistical models that can assign intermediate values of trust to each sensor and still try to match both sensor readings. For these scenarios, one aspect is very important: data dynamics. If the values measured do not vary enough during the meeting process, the scatter plot of points $(x_1, y_1), \dots, (x_n, y_n)$ will form a very narrow area. As has been said before, a single point can usually only determine one of the parameters. Hence, a narrow (point-like) area will most likely not contribute enough information to perform a good calibration [44.26].

44.6.2 Mitigating Human Influence

Numerous approaches have been proposed in the literature to mitigate the problem of low data quality. Some of these approaches are applicable to crowdsourcing, citizen science, and/or participatory sensing scenarios, some only under certain conditions, and some not. Mostly, this is because of one of the two following reasons: either, the approach may, in principle, be applicable, but does not scale to a crowdsourcing level, or the approach cannot be applied because it relies on information that is unobtainable in a practical setting. Still, the general need to ensure the viability of data from cheap sensors is recognized in the literature on mobile sensing [44.58]. However, only seldom, the focus is placed on the effects that the behavior of untrained

users may have on the quality of the collected data. Table 44.4 shows an overview of possible approaches.

Participant selection is an approach that has been used in different fields to identify and separate suitable personnel from such that is unfit for a task. Past research reviewed different methods of identifying people who are likely to perform successfully along with different measures of ability, albeit with a focus on assigning people to jobs [44.59]. However, by definition, crowdsourcing involves an open call and, therefore, often addresses everyday users, which conflicts with a pre-selection step. Additionally, at larger scale, screening may become prohibitively expensive.

The most intuitive approach to ensure that users perform a task correctly is *training* [44.23]. It has been reported that [44.60]

numerous studies have demonstrated that volunteers can successfully perform basic data collection tasks when given a half day or more of practical field training.

Unfortunately, this also highlights the biggest drawback of training sessions: a lot of resources (experts, facilities, etc.) are needed, and the approach does not scale. Slightly different forms of training that do not require the user to keep a mental model of the process are *instructions* (e.g., manuals or tutorials). The key difference to training is that instructions are typically given in writing or otherwise fixed form (video, etc.), which is used to make the nonexperts to understand the measurement process. Understanding is defined as the ability to hold and process all elements that define the measurement process simultaneously in working memory [44.61]. However, working memory is extremely limited in capacity [44.62] and in duration [44.63], in particular for novel information that needs to be processed in a novel way [44.61]. That is, people might fail to understand or completely recall new material if it is sufficiently complex, as may or may not be the case in crowdsourcing, depending on the application context. However, it is reasonable to assume that nonexperts will not have an in-depth understanding concerning the standard measurement procedures for a given meteorological parameter or the effects that deviations from a standard may have.

As a series of simple studies can show [44.24], even a seemingly easy task like recording an audio signal with a smartphone involves a complex measurement process for the user. Also, classic manuals are of little help, as people tend to not read them [44.64], especially if they do not encounter problems, as would be the case in a badly but (from the point of view of the nonexpert) successfully performed measurement

process. On the other hand, instructions can be given much *closer* to the actual task (spatially and temporally). In shorter form and in-situ, instructions provide an advantageous approach, up to providing a complete step-by-step walkthrough.

Another popular approach are *reputation systems* [44.65]. There are different flavors, ranging from picking users based on their reputation or skill level [44.66] over assessing it beforehand [44.67] to building it through data analytics. However, this again requires some kind of ground truth determined by expert users or a series of campaigns, making it an intricate option. In mobile crowdsensing systems, individual readings can usually not be reevaluated, and their classification as being correct or wrong after-the-fact is often infeasible, making reputation levels difficult to build. Additionally, *ranking users can backfire* [44.68], influence the participants' motivation, and paradoxically lead to the best performing participants dropping out, as they would feel they had *won the game*.

Verification of data entries is similar approach to increase data quality. Related work [44.69] differentiates between verified and direct citizen science. Entry verification can either be approached automatically by using some sort of computational recognition or simple sanity tests. The advantage of this sort of verification is that it can be performed in real time, and the user can be prompted before leaving the area, as proposed in past research (*Did you really just see 40 diesel trucks go by in 5 minutes?*) [44.2]. In community-based data validation [44.70], instead of revisiting their own data, participants verify data from their peers. This is obviously infeasible for sensor data, as the exact environmental conditions cannot be verified after the fact, at least not if they do not deviate so much as to become completely implausible (e.g., the observation of heavy rainfall on a completely sunny day). The same is true for *expert reviews* [44.2] of data. They also have the disadvantage that data has already been collected and can only be discarded, as the analysis takes place after the fact.

Computational approaches are diverse. The simplest ones are of a statistical nature: *redundancy* [44.71] and/or *repetition* [44.23] both lead to multiple instances of the same data, which can then, in turn, be processed, e.g., to remove outliers. These approaches only work, if the underlying assumption holds that the overall error is nonsystematic, i.e., people will on average perform the task correctly. However, as the exploratory studies that lead to the taxonomy in Fig. 44.2 indicate [44.24], there may be certain errors that the majority of people tend to make.

More sophisticated approaches like *outlier/anomaly detection* or *Bayes filtering* take the structure of the data

into account. Outlier detection is an approach that today is still largely carried out manually by experts that use their experience in order to remove implausible data sets. One of the drawbacks of automatically filtering out anomalies is that smoothing makes the approach less suitable for highly dynamic phenomena. If only few data points are available or no model can be constructed, filtering is also not applicable.

A different way of computationally addressing procedural errors is *context recognition*. Mechanisms may be as simple as performing simple plausibility checks, e.g., by detecting whether the GPS receiver is turned on, or the acceleration sensors of a device pick-up movement when there should be none, and range to integrating full-fledged activity recognition or applying other artificial intelligence (AI) techniques [44.72]. A robust way to deal with data afflicted with different unknown types of error is signal reconstruction from noise [44.22]. However, it is not generally applicable, as the measured phenomenon must be modelable as particles, among other constraints.

An interesting approach is *data design*, i.e., using methods from the field of human-computer interaction (HCI) not only to design interfaces but also to assess the needs of data consumers to collect reliable, standardized, and overall more useful data [44.73]. However, this works for observations that are reported in a free form (e.g., textual), but not so much for pure sensor data. Additionally, models have been developed to exchange, revise, and merge structured off-line data, e.g., from contributions that are accomplished via paper [44.74]. Finally, one of the most universal mechanisms is *feedback*. Since we can, in many cases, assume that users are actually interested in collecting and submitting high-quality data, it is important to make the measurement process as transparent as possible. Feedback (e.g., on the correct execution of a step, etc.) can greatly contribute to this understanding.

Some of the approaches discussed can be combined with *gamification* techniques. Researchers have, e.g., shown in the context of mobile experience sampling (ESM) that gamification can lead to an increase in amount and quality of participant contributions [44.75]. In other contexts, the location-based game *GeoSnake* [44.76] has been used to boost verification rates, the game *PhotoCity* gamifies training [44.77], and it has been proposed to use game contexts to ensure correct execution of a sensing task [44.78]. However, gamification approaches must be used with care, since they can have unintended side effects, such as perceived pressure that can have a negative effect on data quality [44.79]. It has also been discovered that extrinsic incentives can lessen or even replace intrinsic motivation or discourage certain peo-

ple. Again, knowing the crowd that is engaged in the task or activity is key here.

An underestimated aspect that indirectly may have an effect on data quality in systems involving individuals that collect data is privacy, or rather measures to ensure privacy. When collecting geolocated sensor data, people actually may submit a location trace of themselves along with the measurement data. If the data is made available online in real time, this can even enable live tracking of people. There are several measures that can be taken to ensure privacy, one of them being the obfuscation of the precise position of the measuring person and instead providing only a wider area in which the measurement was collected or artificially adding uncertainty to the location information. However, for some phenomena or analyses, precise location information may be important in terms of data quality. Therefore, it is prudent to determine which measures can be taken to protect the users' privacy while at the same time not sacrificing data quality. Other possibilities than direct obfuscation of the exact location may include only publishing analyzed data rather than raw data or relying on systems without mobility to circumvent the tracking issue. For device-to-device calibration, also several privacy-preserving approaches exist [44.80].

While the measures discussed may help to identify and control possible sources of error in large-scale crowdsensing systems, we already argued above that the definition of data quality on the device level may no longer be adequate to describe such systems in the first place. Instead, we propose that the logical continuation of crowdsourced data acquisition is the fusion and analytics of this data with available high-quality measurement data, as well as other relevant data from different sources, e.g., on traffic or urban topology [44.45]. Poor data quality remains a threat in such systems, as many possible sources of uncertainty potentially accumulate, and well-verified systems are still the exception in the scientific literature today.

On the contrary, increasingly there are systems emerging in which, e.g., machine learning or big data analytics approaches are used on questionable data in

order to produce data products such as animated maps or predictive applications. The danger is that people tend to accept values such systems provide without reflecting on data quality. Another danger is that they may judge the data quality in these systems based on the quality of presentation. If the visualization is professional, people may wrongfully place a higher level of trust in the data. Past research already reported this problem two decades ago: *Computer generated maps, a standard output of geographic information systems (GISs), generally imply an accuracy not warranted by the data* [44.81]. Therefore, a very important aspect of systems that involve users or that communicate observations to end users is that of finding adequate ways to visualize uncertainty and communicate clearly if there are doubts concerning the quality of the data presented.

This adds to the general problem that careful communication and education of users is important, especially in grassroots citizen science projects that may also have a political dimension. The use of low-cost sensors can form an increasing *threat* for the existing measurement infrastructure and the institutions that operate them. As people become aware of their existence and the fact that they are being operated by other citizens, they approach the institutions with queries like *why don't you use this technology?*, *why don't you measure in my street?*, and *why is your value for that parameter so much lower than what I measure here?*. While these are, in principle, legitimate inquiries, it is important that crowdsourcers also educate themselves and their crowdworkers concerning the limitations of the often imperfect technology they may be using, as well as the applications that can be used for and the conclusions that can be drawn from their raw data. Otherwise, they run the risk of their project discrediting itself and other similar efforts.

That being said, the large-scale sensing of environmental phenomena has the potential to bring forth unprecedented measurement systems that reveal previously undiscovered aspects and relationships, especially in urban environments. When properly assessed, actively managed, and properly communicated, data quality need not be an issue in these systems.

44.7 Maintenance

The requirements for maintenance are identical for stations with single and compact sensors and similar for specific networks and industry applications. For specific sensors, the maintenance recommendations are given in the chapters of Part B of this Handbook.

For cheaper sensors in specific networks, industrial applications and crowdsourcing sensors on the other hand, the replacement of the sensor is often cheaper than costly maintenance works. General statements about maintenance intervals are not possible, as

the variety of available sensors does not have uniform specifications (Sect. 44.5). Additionally, the application case also influences both maintenance requirements and feasibility. Besides the requirements for maintenance not being clearly defined, compliance with the requirements is hard to track, validate, and document in crowdsourcing systems. However, it is generally pru-

dent to at least somehow monitor sensor performance, so that the need for either the timely exchange of a sensor can be detected or other action can be taken.

Other maintenance efforts in crowdsourcing applications that may matter include keeping wireless systems powered (e.g., by regularly charging batteries) and ensuring connectivity or data upload.

44.8 Applications

Examples of applications for different parameters are given in the chapters of Part B, as well as in Chap. 43. For most of the station types described in this chapter, a huge amount of applications is available. Therefore, in the following, only a few examples of station types according Table 44.1 are given. All of the projects and applications listed in this section employ crowdsourcing in some way. Table 44.5 shows an overview of projects, indicating for each project which property is observed or which task is performed and which sensors (if any) are used for this. For each entry, the table further shows whether the project is academic, civic, or commercial, which scale the project has reached (in terms of community size and/or data points), and whether extrinsic incentives are offered. Finally, for each row, the type of task is indicated, as well as the interfaces over which the crowdworkers interact with the system.

There have been multiple surveys on crowdsourcing in the past, some general and at least one specific to crowdsourcing in meteorology, presenting a survey on crowdsourcing for climate and atmospheric sciences [44.82]. It features a plethora of atmosphere, weather, and climate-related crowdsourcing projects and techniques. Many of the applications featured in that work are presented here as well. Table 44.5 shows an overview of all projects described in this section. As was already the case with the list of crowdsourcing technology in Sect. 44.4, this is not intended to form a comprehensive list but rather an overview of different projects and approaches.

For each crowdsourcing application, the column *Observed Properties* indicates which data is collected or created in the respective project. The column *Sensors* holds the class of device or system that is used to do this, according to the classification from Sect. 44.4. Under *Purpose*, we list the type of project (academic, public, commercial, grass-roots), and the column *Scale* describes the level the project has reached, in terms of number of devices, volunteers, and/or data points. Under *Incentives*, the table shows whether the application relies on intrinsically motivated participants or features

some kind of incentivization method, monetary or other. The column *Type (task)* indicates the type of activity the crowdworkers are involved in according to the typology presented in Sect. 44.3.1, as well as information on the task itself (e.g., observation, classification, maintenance, prediction, etc.). Finally, the table lists the *Interface(s)* over which the crowdworkers perform the tasks, upload the data, and/or access the results, if applicable.

The *Old Weather* project [44.83] has the goal of making historical weather data that is *hidden* in ships' logs available for research by crowdsourcing the task of extracting, labeling, and digitizing the data. It is hosted on the *Zooniverse* citizen science platform [44.44]. The ultimate goal is to better understand what the weather is going to be like in the future by analyzing how it has been in the past. To this end, crowdworkers extract all kinds of weather data from millions of pages of nineteenth century and World War I ships' logs.

There are two activities crowdworkers can choose from: *marking* and *transcribing*. Marking is used to identify specific pieces of data (like time, date, location, what kind of sea ice happened to be around the ship, etc.) in digital images of each of the logs' pages (Fig. 44.9). Transcribing is the activity of digitizing marked information by typing it into corresponding text input fields, a task in which humans outperform automated approaches handwritten entries.

The project was initially launched in 2010. By 2012, more than one million log pages had been transcribed and in 2016, the project reported that more than 4 million observations had been digitized by a total of more than 20 000 participants [44.84]. In terms of incentives, the platform relies on the intrinsic motivation of participants to contribute to science, as well as, apparently, learn about historical seafaring. *Blaser and Ridge* [44.85] report that

many users have commented in the Old Weather forum that as a result of the project, they were buying books and enrolling in courses to enhance their knowledge further.

Table 44.5 Overview of example crowdsourcing projects and applications that collect meteorological and/or other atmospheric data. While most projects involve data collection (crowdsensing), some entail classifying or annotating existing data (crowdanalyzing)

Project/application	Observed properties	Sensors	Purpose	Scale	Incentives	Type (task)	Interface(s)
Old weather	Historical weather data from ships' logs	Human observation	Academic	> 20,000 volunteers, > 4 million data points (2016)	Intrinsic; extrinsic (gamification)	Crowdsensing (observation), crowdanalyzing (classification)	Website
Cyclone Center	Cyclone classification	Human observation	Academic	> 16,000 active users, > 900,000 data points, > 44,000 images complete (2018)	Intrinsic	Crowdanalyzing (classification)	Website
mPING	Qualitative precipitation (rain, snow, ...), selected events (flood, tornado, mudslide, ...)	Human observation	Academic/public	> 30,000 downloads, > 860,000 reports (2015)	Intrinsic	Crowdsensing (observation)	App, website, application programming interface (API)
RainRadar	Qualitative precipitation	Human observation	Academic	N/A (inactive)	Intrinsic	Crowdsensing (observation)	Twitter, website
UK Snow Map	Qualitative snowfall	Human observation, (camera)	N/A	N/A	Intrinsic	Crowdsensing (observation)	Twitter, website, app
Snow Tweets	Snow depth	Human observation, ruler	Academic	N/A (inactive)	Intrinsic	Crowdsensing (observation)	Twitter, website
CoCoRaHS	RR, qualitative condition reports	Human observation, high quality manual rain gauges	Academic/public	> 20,000 volunteers, \approx 10,000 reports/day (2018), > 31 mio. reports total	Intrinsic	Crowdsensing (observation)	Website, app
Citizen Weather Observer Program (CWOP)	t_a , R, p, RR, dd, u_h (varies)	Automatic stations (AMS); consumer stations; DIY platforms	Public	> 13,000 stations, > 100,000 reports/hour	Intrinsic	Crowdfunding, crowdsensing (observation, maintenance)	API
Netatmo	t_a , R, p, CO ₂ , RR (optional), u_h (optional)	Dedicated commercial consumer stations	Commercial	> 100,000 stations	Extrinsic (service)	Crowdfunding, crowdsensing (observation)	Website, API, app

Table 44.5 (Continued)

Project/application	Observed properties	Sensors	Purpose	Scale	Incentives	Type (task)	Interface(s)
Weather Underground	t_a , R , p , RR , dd , u_h , and others (depends on personal weather stations (PWSs))	Heterogeneous consumer stations/PWS	Commercial	> 250 000 consumer stations	Intrinsic, extrinsic (service)	Crowdfunding, crowdsensing (observation, maintenance)	Website, multiple apps, API
AirBox	PM_{10} , $PM_{2.5}$, t_a , R	Dedicated commercial platform with low-cost sensors	Commercial/civic/grass-roots	> 4000 sensor stations	Intrinsic	Crowdfunding, crowdsensing (observation)	Website, API, app
luftdaten.info	PM_{10} , $PM_{2.5}$, (t_a , R)	Dedicated DIY platform with low-cost sensors	Civic/grass-roots	> 5000 sensors installed worldwide (2018)	Intrinsic	Crowdfunding, peer-production (DIY sensor), crowdsensing (observation, maintenance)	Website, API
SenseBox/OpenSenseMap	t_a , R , p , E_v , UVR, PM_{10} , $PM_{2.5}$	Dedicated DIY platform with low-cost sensors	Academic/civic/commercial	> 3000 sensors	Intrinsic	Crowdfunding, peer-production (DIY sensor), crowdsensing (observation, maintenance)	Website, API
CurieuzNeuzen	NO_2	Diffusion tubes	Academic/public	Campaign with > 20 000 users, > 17 000 data points (2018)	Intrinsic	Crowdfunding, crowdsensing (observation, maintainable)	Snail mail, website
iSPEX	TSP (total suspended particles) (indirect)	Internal smartphone camera with smartphone clip-on module	Academic	Campaign with > 1000 participants in one day, > 6000 data points	Intrinsic	Crowdfunding, crowdsensing (observation)	App
PressureNET	P	Internal smartphone sensors	Academic/commercial	> 100 000 hourly smartphone pressure readings across the USA	Intrinsic, extrinsic (service)	Crowdsensing (observation)	App, website
OpenSignal/Weather Signal	t_a (and others)	Internal smartphone sensors	Academic/commercial	> 270 000 downloads, hundreds of millions of data points	Intrinsic, extrinsic (service)	Crowdsensing (observation)	App(s), website

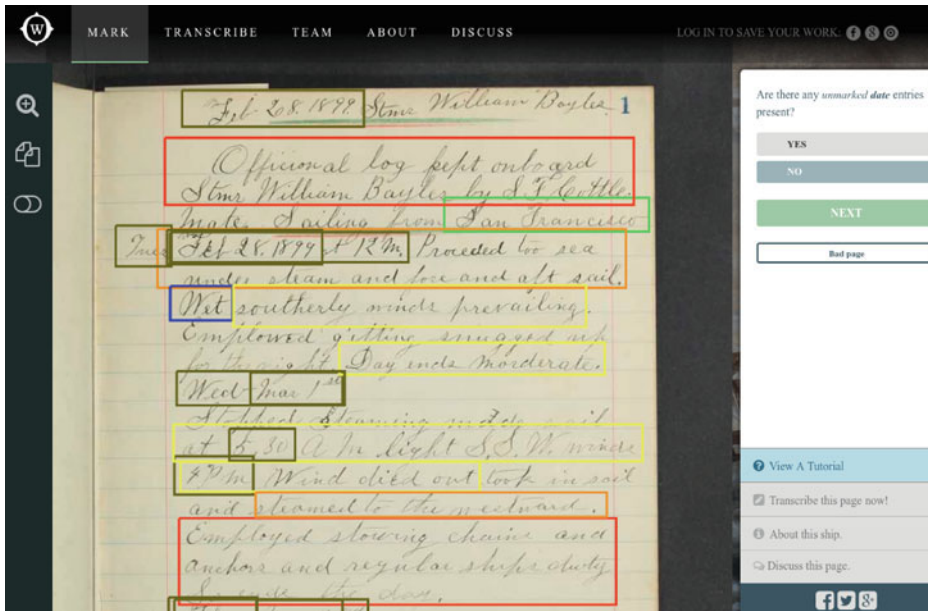

Fig. 44.9 The *Old Weather* project crowdsources the task of digitizing historical ships' logs to extract weather observations by marking and transcribing relevant data (screenshot after [44.83])

As an additional extrinsic incentive, gamification techniques were employed [44.86]. Through a ranking system, participants could earn promotions: when 'joining a ship', i.e., starting to transcribe weather observations for one particular vessel, volunteers started with the rank of cadet, working their way up to lieutenant. The person with the most contributions for that particular ship holds the rank of captain, which can be lost once another volunteer takes the first rank. In some research [44.86], these competitive game elements were partially perceived as being problematic, as they contributed to participants choosing quantity over quality, as well as to the decision of discontinuing participation for some users. They conclude that competitive and personal achievements should be balanced and that, generally, the appeal of game elements varies between participants and over time.

The *Cyclone Center* [44.87] is another *Zooniverse* project that uses crowdworkers to label atmospheric data. In this case, infrared images from weather satellites are analyzed. These images carry information on the cloud-top temperatures, which in turn give an indication of the height of the clouds. Crowdworkers analyze these satellite images according to the so-called *Dvorak Technique* [44.88], developed by *Vernon Dvorak* in the 1970s and early 1980s. For this, two satellite images of whirlwinds are presented to the user at a time, prompting the decision as which one is stronger. Subsequently, the crowdworkers are asked to mark the center of the system and to select which type of cloud pattern best describes it. They are further asked to indicate how organized or intense the cloud pattern is, and whether the

system looks stronger or weaker than on a satellite image from 1 day earlier. From this information, the type and intensity of that tropical cyclone can be approximated.

The *Cyclone Center* project has close to 300 000 satellite images of tropical cyclones dating back as far as 1978 available that need to be analyzed, more than 44 000 of which have been completely analyzed by crowdworkers so far.

While in the former two projects, crowdworkers analyze existing data and create labels for it, most crowdsourcing projects in this section deal with the collection of new data. In the *mPING* project (short for *Meteorological Phenomena Identification Near the Ground*) [44.39] for example, smartphone users collect public weather reports for the *National Severe Storms Laboratory* (NSSL) of the *US National Oceanic and Atmospheric Administration* (NOAA) through a free app. Released in 2012 in collaboration with the University of Oklahoma, by 2015 the app had been downloaded more than 20 000 times, and over 860 000 observations had been collected [44.90]. Users can select the type of observation (rain/snow, hail, wind damage, tornado, flood, mudslide, or reduced visibility), some of them being subcategorized further (e.g., by size). The observations purely report occurrence though, not intensity.

The *RainRadar* project [44.40] of the University at Buffalo and the Ohio State University employed Twitter as a medium through which users could both pose queries to inquire about the precipitation at a certain location (e.g., @RainRadar? Weather Loc:Buffalo, NY), as well as post answers to respective queries relayed

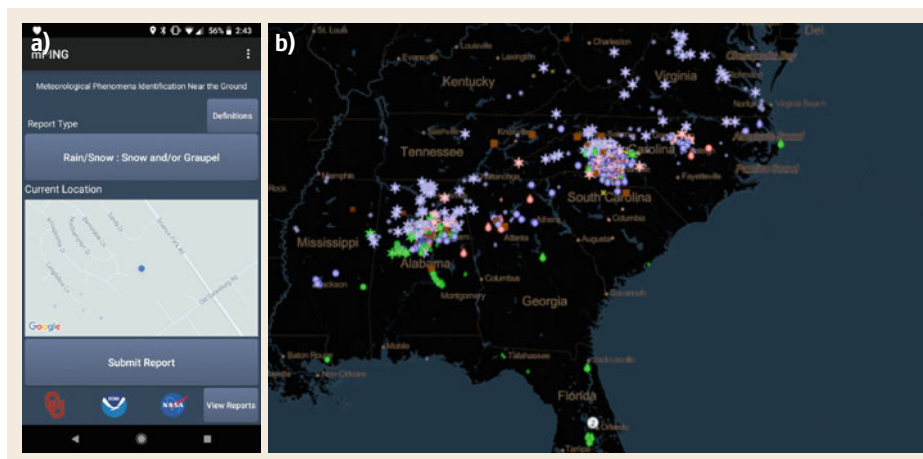

Fig. 44.10a,b In the *mPING* project, crowdworkers report the occurrence and type of precipitation events via an (a) app or (b) web interface (screenshots of (a) mobile app and (b) web interface, after [44.89])

to them based on their current location. The research project also featured a sensing component that automatically read out sensor data and sent it via Twitter. Additional components, such as mining tweets, exploiting social network structures, or adding incentives were envisioned as future work. However, the research project seemed to only have been a case study in 2009, and the respective Twitter account does not show much activity since 2010, so it can be assumed that this project is no longer active.

The *UK Snow Map* project [44.91] follows a similar approach. To indicate that it is snowing, users send a tweet with the hashtag *#uksnow*. The tweet should either be geotagged or contain the first half of the UK postcode of the user's location, as well as a snow intensity rating ($x/10$). A live map is displayed online, along with pictures that users attach to their reports. Another project that works similarly is the *Snow Tweets* project of the University of Waterloo, the difference being that the property observed is not snowfall but snow depth, simply using a ruler. However, since the original website is down, and the current website shows no data points at all, the project can be considered discontinued.

While the previous projects all collect qualitative reports from human observation, many projects use technology to obtain quantitative measurements. The *CoCoRaHS (Community Collaborative Rain, Hail & Snow Network)* [44.92] project ([44.93], Fig. 44.11) is a large citizen science observation network in North America, in which volunteer participants manually submit reports on precipitation and other events. CoCoRaHS volunteers use low-cost, high-quality manual rain gauges to measure precipitation. The project was officially initiated in 1998 at the Colorado Climate Center at Colorado State University (CUS) and has since then been running continuously for more than 20 years, scal-

ing up to more than 20 000 active volunteers who have submitted over 30 million reports in total [44.94].

The *Citizen Weather Observer Program (CWOP)* is a Public Private Partnership that collects data from privately owned electronic weather stations. Unlike CoCoRaHS, measurements are not carried out manually, but instead by automatic stations (AMS, see Sect. 44.4 and Chap. 43). More than 8000 stations are maintained in North America alone, and more than 13 000 across the world. The CWOP originated in the amateur (ham) radio community, but today also includes stations that are connected via the Internet. The connected stations are not all of the same type; any station that implements the APRS (automated packet reporting system) protocol can be configured to connect to the CWOP server. Therefore, the properties observed and the quality of data varies between stations.

A growing number of systems and projects exist that, in contrast to the CWOP program, employs small dedicated Internet of Things (IoT) measurement devices. The technology of the commercial *Netatmo* system was already described in Sect. 44.4. Users can configure whether their data should be made publicly available. If so, the data can be accessed via the public *Netatmo Weathermap* [44.95], as well as an API. Worldwide, more than 100 000 Netatmo personal weather stations transmit their data to the system. This data is freely accessible by anyone.

Data from Netatmo stations has also been analyzed for scientific projects. Researchers have analyzed crowdsourced data from over 1100 Netatmo stations in the city of Berlin and the surrounding area from a period of 6 months (from January to June 2015) [44.96]. Their results indicate that crowdsourced atmospheric data can be valuable for urban climate research, provided faulty data is filtered out. Causes for bad raw data

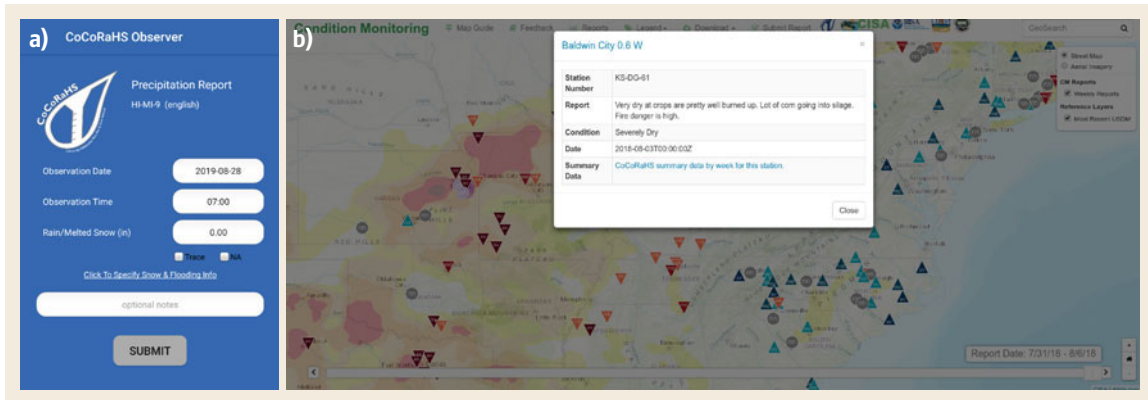

Fig. 44.11a,b The *CoCoRaHS* (*Community Collaborative Rain, Hail & Snow Network*) project has been collecting volunteer precipitation measurements and qualitative condition reports since 1998 (screenshots of **(a)** mobile app and **(b)** web interface (after [44.93] licensed under Creative Commons Attribution 3.0))

were, among others, intermittent connectivity, wrong or incomplete meta data, and faulty installation (e.g., outdoor module operated indoors). After five filtering steps, linear correlation coefficients between reference stations and the *Netatmo* data ranged from 0.80 to 0.99. The daily number of stations that provided data on this quality level dropped to between 350 and 831 stations. For Berlin, this was still sufficient to greatly increase the spatial density of available stations and enable further analysis. However, the authors stress that standardized, calibrated, and quality-checked reference stations are essential in order to validate such systems. An extended version of the research on 1 year of data basically yielded the same conclusions [44.97].

Another scientific project based on *Netatmo* data was conducted in the city of London [44.98]. It characterized the urban heat island effects for a study area from 287 *Netatmo* stations and seven standard reference sites for validation. Among others, the study authors observed a temperature bias probably caused by improper siting of stations, resulting in a systematic deviation of several Kelvin in the temperature readings. Overall, the study concludes that there is clear potential in using crowdsourced data from Internet-connected weather stations for meteorological studies, as long as the challenges of quality assurance and control are properly addressed.

There are other commercial services that integrate data collected by individuals operating personal weather stations, some that sell their own devices, others that integrate data from anyone who registers their station with them. An early example of the latter is the *Weather Underground* (or for short, *Wunderground*; [44.99]). *Wunderground* is a commercial service that evolved from initially being an academic

project at the University of Michigan into a major commercial weather provider. The notable aspect that distinguishes *Weather Underground* from classic weather providers is that it early on integrated data from personal weather stations (PWS) and reached an impressive scale of sensors through that. In 2012, *Weather Underground* was acquired by the *Weather Company*, which in turn sold its B2B, mobile and cloud-based web properties, including *Weather Underground*, to *IBM* in 2015. Also in 2015, *NetAtmo* stations were added to the *Wunderground* map. Today, over 250 000 personal weather stations submit their data into *Weather Underground* [44.100]. *Wunderground* invites people to upload their data but does not distribute their own sensors and, instead, features a PWS buying guide on its website. Incentives to upload one's data were mainly intrinsic in the early days and today include services such as the provision of dashboards and graphs of one's personal station data. Various research papers used weather data from *Wunderground* in their evaluations, either working directly on the dense data (e.g., [44.101]) or using it as supplemental meteorological data (e.g., [44.102, 103]).

Airbox [44.104] is a Taiwanese project for large-scale $PM_{2.5}$ sensing, which started with the deployment of 150 devices in Taipei city in 2016 [44.105]. Since then, a total of more than 4000 devices has been deployed in over 30 countries [44.106], though most of the devices are located in Taiwan (Fig. 44.12). *Airbox* is a mixture of a commercial and a citizen science project. While the *Airboxes* are today manufactured and sold for profit by a company, the project has its roots in a citizen science project LASS (location-aware sensing system [44.107]), the devices of which were directed at makers. The *Airbox* website aggregates both data from

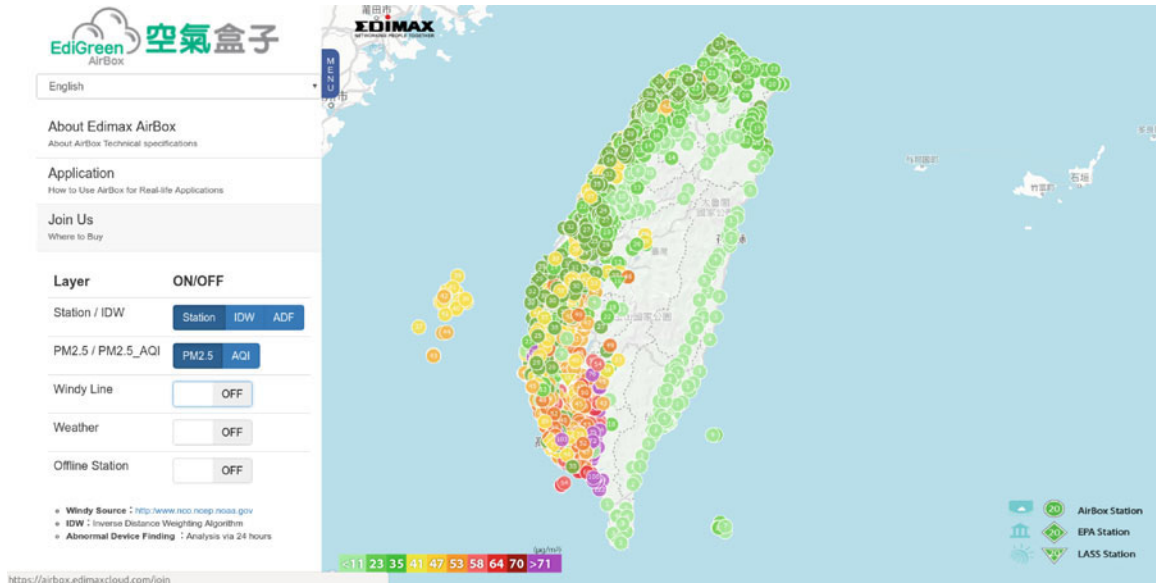

Fig. 44.12 The Taiwanese *Airbox* project provides access via an open API to the data from over 4000 commercially sold *Airbox* devices that measure fine dust (screenshot after [44.104] reprinted with permission from Edimax Technology Co., Ltd)

the LASS devices, as well as from *Airboxes*. Access to the data remains free; it can be accessed either after applying for an access token and downloading the data from the *AirBox* manufacturer's backend database or by using the data API provided by the LASS community to download the measurement data directly [44.105]. Apart from the open data API, the manufacturer donated almost 1000 *Airboxes* to elementary schools in four major Taiwanese Cities, making a substantial contribution to the fine-dust measurement community in Taiwan.

Other notable grass-roots projects have sprung out of citizens' growing consciousness for air quality in the last decade. *Sensor Community* [44.108] is a project affiliated with the Open Knowledge Foundation Germany. Started for the monitoring of PM_{10} in Stuttgart, Germany, sensors are today deployed across the world, though the vast majority is located in central Europe. Luftdaten.info provides a construction manual that describes how to build a PM sensing node out of a low-cost dust sensor, a microcontroller platform, and an external temperature/humidity sensor. Apart from information on which hardware to purchase and how to connect it, open firmware is provided for downloading. After deploying, configuring, and registering the node, it sends PM data to the luftdaten.info servers, from which the raw data is visualized as a heat map on a website (Fig. 44.13). The data is also available through an open API. More than 5000 sensors currently contribute data in this way. This is especially impressive, since the

project is a pure grass-roots effort that has been built and scaled up by a group of environmentally conscious citizens without an institution behind it.

A very similar project is *OpenSenseMap* [44.109], or *SenseBox* [44.110]. In contrast to the grass-roots origin of luftdaten.info, *SenseBox* developed out of an academic project of the Institute for Geoinformatics at the University of Münster, Germany. The *SenseBox* hardware [44.111] developed through several iterations and is today available in two different versions: *SenseBox:home*, which is a modular sensor device directed at citizens, and *SenseBox:edu*, which targets schools, universities, and educational institutions. Both versions are developed and sold by the company *re:edu*, which is a startup that grew out of the *SenseBox* project. A notable aspect of the *SenseBox* project is its strong emphasis on education. Around the hardware and the data platform, many resources on experimentation with sensors, visual programming of the devices, planning workshops, and hackathons, etc., are available. The *OpenSenseMap* platform [44.112] is open not only to data from the *SenseBoxes* but also other registered sensing devices. In total, more than 6000 *SenseBoxes* currently send their data to the *OpenSenseMap* (Fig. 44.14). There are multiple other projects that provide manuals for DIY measurement nodes (Sect. 44.4.2) and open APIs to collect and visualize the data.

In addition to continuous measurements, impressive scales have also been reached by campaign-style

Fig. 44.13 The grass-roots *luftdaten.info* project collects and provides raw data from a network of Citizen Science fine-dust sensors, which are built from off-the-shelf components bought by the users and open software provided by volunteers of *luftdaten.info* (screenshot after [44.108])

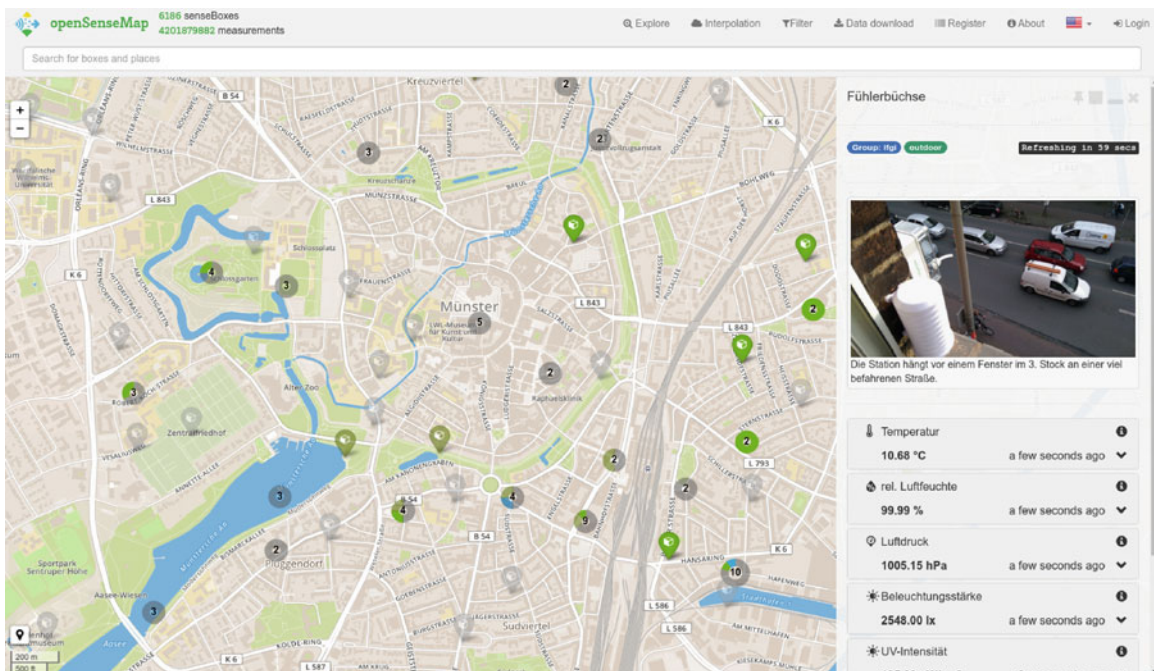

Fig. 44.14 The *SenseBox/OpenSenseMap* project provides an open API that also allows registering devices other than the *SenseBox* hardware to upload and visualize data (screenshot after [44.109])

projects with custom sensor technology. *Curieuzen* [44.113] is a Flemish citizen science project to measure nitrogen dioxide (NO_2) in ambient air. In order to do this, participants are asked to install a pair of diffusion tubes outside their home, on a window facing the street. To ensure a standardized setup for the mea-

surement, the samplers are installed inside a v-shaped window sign, which participants receive as a ready-to-install kit. After a 4-week measurement campaign, they collect the tubes and send them via snail mail to be analyzed in the lab. The results of all measurements are then calibrated against official measurement

stations and jointly analyzed and eventually made public. Two campaigns have been run so far, one in 2016 with 2000 participants (Curieuzeneuzen Antwerp) and one in 2018 with 20 000 participants (Curieuzeneuzen Flanders). The latter eventually managed to collect over 17 000 valid readings and gained interesting insights, e.g., that *the centres of rural villages, which were thought to have pure air, in fact have high levels of traffic-related air pollution* [44.114]. Besides crowdsourcing the measurement, the project also partially uses crowdfunding to cover the cost of the measurement. While 75% of the costs are covered by the project partners, 10 € per measurement are covered by each participant. Additionally, donations are accepted, e.g., to provide free measurement kits to schools.

Another campaign-style citizen science project that reached an impressive scale is the *iSPEX* project [44.33] from Leiden University in The Netherlands. The technology that was developed for and employed in the project was presented above (Sect. 44.4.3). A small clip-on module for the *iPhone* camera enables spectropolarimetric measurements, which are aggregated between multiple users to enable quantitative remote aerosol sensing. The parameter that is derived from the camera recordings is the aerosol optical thickness (AOT). As with other projects we have seen before, users contribute not only the time and effort to make recordings with the system but also part of the cost (only a couple of Euros) of the ultra-low-cost clip-on modules, adding a crowdfunding aspect to the academic *iSPEX* project. Multiple 1-day campaigns have been conducted in The Netherlands, involving up to more than 1000 volunteers in a single day.

While the *iSPEX* project relies on a passive clip-on module in combination with a smartphone camera, some projects attempt to only use the internal sensors of a smartphone. The *PressureNET* project [44.115] collects data on surface pressure from smartphones with internal barometric pressure sensors. The GPS-tagged data from multiple smartphones is sent to a server and processed to support numerical weather prediction. Range and dynamics checks can be used to filter out obviously false data, and movement can be detected through the GPS signal or rapid changes resulting from vertical movement. *PressureNET* experienced some difficulties in the beginning with many users uninstalling the free app quickly after having installed it. When surveying their user base for the reasons, many reported that they did not understand the results the app displayed. One of the problems also seemed to be that in the early phase, *PressureNET* could not yet provide very much direct value to the user and had little more to offer besides the promise to make the weather forecast better. *PressureNET* was acquired by the Sunshine

company in 2016. It is unclear whether *PressureNET* may have been discontinued, as the website no longer seems to be available.

Another project that built on data from internal smartphone sensors concerns itself with deducing urban air temperature based on data from *OpenSignal* [44.116] on smartphone battery temperatures [44.117]. Using mathematical transformations, the battery temperatures from a group of phones in the same vicinity were used to calculate the outdoor air temperature. The research was conducted on a subset of a large worldwide 1-year data set consisting of 220 million battery temperature readings. From this, 2.1 million data points for eight major cities spanning half a year were selected, and after filtering, 1.3 million readings remained. Since many assumptions needed to be made (e.g., people usually carry their phones in their pockets, the majority of readings is recorded outside, etc.), the application of the developed heat transfer model delivered only an estimate of the actual areal average air temperature. Still, the study shows a relatively high accuracy, provided that the number of readings is high enough and model coefficients are adapted to season and location. Following this academic research, *OpenSignal* released *WeatherSignal* in 2013, a specialized Android crowdsourcing app dedicated to collecting information relevant to meteorology in real time from native smartphone sensors, such as barometers, hygrometers, thermometers, magnetometers, and lux meters, with the aim of creating live weather maps. While the app initially seemed to be a success, today neither the website nor the app are available.

In summary, we can see many projects that involve crowdsourcing in atmospheric sciences in some way. The list presented only features examples, with no claim of comprehensiveness. Nevertheless, these examples illustrate the diversity of projects and applications. While most of the crowdsourcing projects focus on data collection and can, thus, be classified as crowdsensing projects, some also involve annotating or classifying existing data, making them fall into the category of crowdanalyzing. Additionally, both academic and commercial projects sometimes involve financial support by the crowd, adding a crowdfunding dimension to them. Some projects entail continuous measurements, others are campaign-style projects that focused the collection period on a short timeframe. Projects may be organized by academic institutions, companies, or bottom-up in a grass-roots fashion by concerned citizens. The technology employed ranges from full-scale automated meteorological stations (AMS) over personal weather stations, both commercial as well as do-it-yourself (DIY) devices, to attempts at gaining useful information from internal smartphone sensors.

Devices can be stationary or mobile, and the sensing procedure may either involve an active role of the user or be rather passive sampling [44.118]. Every project

has its very own challenges, be it scaling up to a certain level, filtering out unwanted data, or creating sustained engagement.

44.9 Future Developments

There is a general trend that people are becoming more concerned and interested in measuring environmental data in the cities they live in, among them the weather and the air quality. For this, they are in need of low-cost sensing equipment with low maintenance effort. Besides individual measurements, the network connection of such devices enables providing novel services such as real-time data visualization, cross calibration, or small-scale exposure assessment and prediction. The possibility to perform individual exposure assessment is particularly interesting for research purposes, potentially complementing, e.g., classical tools of epidemiological researchers, such as regression models to estimate personal exposure. In the long run, the combination of the Internet of Things (IoT) devices and big data analytics has the potential to improve forecasts both in terms of quality and resolution and enable completely novel applications and services.

These developments involve both risks and chances, as well as challenges that need to be addressed. The projects and applications presented in this chapter have shown that low-cost networked sensing systems have the potential to bring science deeper into society. This so-called *democratization* of technology will bring forth new challenges, such as the need to educate citizens concerning the peculiarities of the measurement of certain environmental phenomena, as well as the informative value of the raw data collected. On the other

hand, it is important to collect information on the needs of citizens and user requirements to develop adequate solutions.

This is closely related to the data quality and measurement uncertainty of the measurement technology employed. It remains important to at least document the measurement context and to establish methods to filter out erroneous data. In networked sensing systems that involve big data fusion and real-time analytics, it may be prudent to judge the quality of the data in question not on the single device level but rather view it as data products that are the result of fusing data from heterogeneous sensors, models, etc. Such systems are yet unprecedented, which is why validation strategies are needed that can holistically assess the quality of such systems [44.45].

One of the biggest challenges still seems to be to build sustainable systems that can be maintained over long periods of time, rather than prototypes that are eventually discontinued. Besides appropriately incentivizing participation on the one hand, new business models are needed on the other hand to sustain long-term network operation, data storage, and processing.

Acknowledgments. This chapter was written while during the author's employment at and with the support of the Chair for Pervasive Computing Systems/TECO at Karlsruhe Institute of Technology (KIT), Germany.

Matthias Budde is a consultant and senior research scientist at Disy Informationssysteme GmbH in Karlsruhe, Germany. Before that, he was a postdoctoral scholar in the TECO/Pervasive Computing Systems group at Karlsruhe Institute of Technology (KIT), Germany, where he received his PhD degree in Computer Science (2018) for work on low-cost, non-expert environmental sensing and its data quality. Matthias has worked on a variety of projects in ubiquitous computing with the research foci environmental sensing, mobile computing, the Internet of Things (IoT), human-computer-interaction and context and activity recognition.

Mesometeorological Networks

Jerald A. Brotzge , Christopher A. Fiebrich 

Real-time environmental monitoring and numerical weather prediction at high resolutions are now made possible by the deployment of mesometeorological networks. Mesometeorological networks are designed in a manner to optimize sampling across mesospatial (3–100 km) and temporal (minutes to hours) scales. A given number of weather stations are similarly sited, instrumented, and deployed with appropriate spacing across a broad geographic area in order to provide simultaneous, comparable measurements across a region. Each station is comprised of a platform, sensors, and a datalogger, equipped with a power source and communications; the system utilizes centralized software for networking, quality control (QC), and dissemination. Raw data are archived, along with appropriate metadata and QC flags. Ideally, the network operates continuously and indefinitely with routine maintenance including regular sensor cleaning, repair, and calibration. As mesometeorological networks become more widespread and reliable, data from these networks are consumed by emergency management, agriculture, transportation, and utility sectors, among others. Technological advances in computing and networking allow for continued expansion and adoption of these networks worldwide.

We live in a period of history often referred to as the Information Age where data drives decision-making in all areas of life. In meteorology, weather data is the fundamental building block for understanding the past, analyzing the current state, and predicting the future. Yet in order to use data properly, we must understand its errors and uncertainties. Measurement errors can arise from faulty sensor design, siting issues, and sampling

mistakes, among others. But one way to minimize errors among many measurements is to create a common network with similar siting standards, sampling methods, sensors, transmission, quality control, and archival methods. To satisfy this need, mesometeorological networks have developed across those regions around the world with the greatest requirements for high-quality, real-time weather information.

45.1 Measurement Principles and Parameters

Mesometeorological networks (often abbreviated “mesonets”) are a series of stations deployed in a manner that allows *mesoscale* features (Chap. 1) to be sampled in real time over a relatively large area. Mesoscale phenomena range in size from 3 to > 100 km and may evolve rapidly on the order of minutes. In general, all sites within a network have a common infrastructure, set of sensors, and sampling methodology. All data are collected together, quality controlled, and then archived and disseminated.

45.1.1 Purpose

The unique purpose of a mesometeorological network is to collect similar variable observations simultaneously in time and space across a mesoscale region. For most research and operational applications, these measurements must be done with a high level of accuracy and precision on a continuous, real-time basis. To fulfill these functions, each network must be designed carefully in a way that can best satisfy these requirements (Chaps. 3 and 4).

Table 45.1 Common parameters of a standard mesometeorological network

Parameter	Typical height (m)	Stations per 100 km ²	Chapter

45.1.2 General Description

Specifically, each network configuration must be designed in a way that enables it to observe mesoscale features. In addition, each station should be sited in a way that collects observations most representative of the region, thereby limiting microscale influences. Each site must be equipped with the proper equipment, such as a platform, sensors, power, and communications, installed at standardized heights at high spatial density

45.2 History

The Bureau of Aeronautics in the US Navy began to develop automated weather stations (AWS) in 1939, thereby advancing the technology needed to collect real-time environmental data at numerous locations at high temporal resolution [45.1]. The expansion of automated weather stations continued through the twentieth century, as meteorologists and decision-makers became increasingly reliant on the data.

45.2.1 Growth, Spread of Technology for Communication and Observation

The US Federal Aviation Administration and the National Weather Service developed automated weather stations for widespread use at airports in the 1970s [45.2–4]. With advances in microelectronics, computers, and communication technologies, automated weather stations grew in use throughout the 1980s. By 2001, the National Oceanic and Atmospheric Administration's automated surface observing system

(Table 45.1), and be adequately maintained and calibrated to retain high quality performance with limited down time. A central processing center is needed in order to collect, process, quality control, archive, and disseminate data from the network of stations to users of the data. Extensive metadata should accompany the data and include detailed descriptions of the site locations and characteristics, site configuration, sensor properties, and quality control standards. A typical mesometeorological station is shown in Fig. 45.1.

(ASOS) was the largest network of automated sites in the United States. Many regional to statewide mesonets were established also in the 1980s and 1990s and into the early part of this century [45.5–7]. Many of these mesonets were a result of efforts at colleges and universities [45.8].

45.2.2 Automated Networks – Growth and Examples of Current Networks

By 1992, large-scale networks of automated stations were becoming widespread [45.9]. The Nebraska Automated Weather Data Network, the California Irrigation Management Information System, and the Oklahoma Mesonet constituted some of the earliest, largest networks of stations [45.10]. The Climate Reference Network [45.11] was established nationwide in 2008 with over 100 stations to provide long-term, homogeneous observations to monitor climate change. By 2017, 1619 mesonet stations were active across the US. [45.8].

45.3 Theory

Several features are common to mesometeorological networks to enable them to monitor mesoscale features accurately and in real time. These features include common siting standards, similar instrumentation, automated real-time sampling and communications, and regular quality control, maintenance, and calibration.

45.3.1 General Requirements

An essential element of mesometeorological networks is that local differences are minimized in order to more accurately monitor the evolution of mesoscale features in time and space. To minimize differences between sites, each site should conform to similar sit-

ing standards; these are discussed in more detail in the next section (Chaps. 3 and 43). Furthermore, each site should be designed with the same station configuration, be equipped with the same model and brand of sensors, and have the same signal processing applied [45.12].

A second functional requirement of most mesometeorological networks is the need to provide data in real time. Many networks supply data to weather operations or emergency service providers where real-time analyses are critical for time-sensitive warnings and response. Thus, most networks must have the ability to not only collect observations frequently and repetitively, but also to transmit these data on the order of minutes. A reliable communication network is essen-

tial. In addition, for many applications, data are needed 24 hours a day, 7 days a week, at high frequency intervals (e.g., every 5 min), something few human networks can provide. Importantly, automated sensors have been shown to be more accurate by reducing some types of errors in measurements [45.13].

A final essential element expected from most mesometeorological networks is the ability to produce high-quality data. Regularly applied quality assurance and quality control routines applied to the data can be used to identify sensor errors early and minimize sensor downtime (Chap. 3). Routine preventive and responsive maintenance can ensure the continuity and reliability of the network. Regular calibration of sensors against known international standards can ensure the accuracy and precision of the data. Archiving all operations and maintenance metadata can improve the monitoring of long-term sensor performance. Even field experiments that deploy mesonets on a relatively short-term basis can benefit from site standardization, real-time data access, automated quality control, and attention to sensor calibration.

45.3.2 Siting Requirements

To adequately monitor mesoscale features, mesonet stations must have an average spacing distance between stations on the scale of ≤ 30 km apart. In general, the network topology should be as uniformly distributed as possible to minimize gaps in coverage. Special care should also be taken to include stations across a variety of landscapes as representative of each region. When covering a large area, the variability in topography, vegetation, land use, and soil types common across the region should be well represented by the network. For example, in complex terrain, stations should be placed in both valleys and hills to the extent that these locations can still satisfy World Meteorological Organization (WMO) standards for siting [45.14]. Network spatial density may need to be greater in areas of complex terrain, near large bodies of water, and in urban areas.

One factor that separates many high-quality networks from lesser quality ones is how well each station is sited. Many site-dependent factors can bias otherwise accurate measurements, and this is especially critical in a mesometeorological network where data are to be compared and possibly averaged across multiple stations simultaneously. For example, local terrain features can impact a station's winds, and nearby trees can shade its pyranometer. Nearby concrete surfaces and local bodies of water can bias local temperature and moisture measurements. To help minimize these issues, the

WMO has provided a set of guidelines for station siting [45.14]. Network scientists should work to limit these issues when siting each station, and where possible, all station properties should be captured within exhaustive metadata.

45.3.3 Basic Building Blocks of a Network

The four primary building blocks of a mesonet include the infrastructure and resources associated with data collection, data integration, data dissemination, and network operations and maintenance.

Each network must have the field infrastructure and sensors that measure and collect the sensible weather observations. The network infrastructure may include a tower or mast, power equipment, and weather sensors. Field data are collected automatically and remotely. Often, a sensor will collect a voltage, current, pulse, or digital reading, which is then converted into the correct units, as representative of a weather variable. A datalogger is often used to distribute power, make the necessary conversions, and store data on site. Network infrastructure is discussed in more detail in Sect. 45.4.

Integration of the data is necessary in order to analyze the mesoscale features of interest. Data are collected in real time from all sites and then transmitted to a central processing center. A reliable communication network, such as cellular, radio, or satellite, is necessary for data transmission. Site communications are discussed in more detail in Sect. 45.4.5. One or more servers are needed at the central processing site for the data ingest and subsequent quality control; these servers can be set up for automated retrieval of archived data from field sites when real-time data transmissions are interrupted.

Once processed, data may be disseminated to a variety of users. Data may be disseminated through several avenues, including file transfer protocol (FTP), local data manager (LDM), application program interfaces (APIs), or the Internet. Many networks utilize phone apps and engage users through social networks and other online media. Additional value-added products and displays can be created for specific customers [45.15].

A final but critical building block of a network is the continual operations and maintenance of the system. Continuous monitoring of all data is recommended to flag erroneous data and to alert field technicians of needed repairs. Regular firmware upgrades and sensor calibrations keep sensors within instrument specifications. Software must also be maintained and updated regularly.

45.4 Devices and Systems

Mesometeorological networks vary largely as a function of their original purpose and financial support. Networks may be mobile or fixed, simple or complex. Nevertheless, they have many common elements. These elements include

- (i) A platform
- (ii) Sensors
- (iii) A central processing unit
- (iv) A power source
- (v) Communications
- (vi) Quality assurance and quality control
- (vii) Regular calibration and maintenance.

45.4.1 Platform

A collective suite of sensors that comprises a weather station must be mounted on a platform from which to operate (Chap. 6). A platform provides the mounting structure for the sensors and associated infrastructure, such as a datalogger and access to power and communications. A platform can be mobile or stationary. Many field programs utilize weather instrumentation mounted on vehicles [45.16] (Chap. 50). This provides a flexible network that can move with the feature of interest. For most long-term networks, stationary, fixed towers are used. These towers may vary in height; many are at least 10 m tall in order to collect wind measurements at the 10 m level. Some networks, primarily used for agriculture or transportation, may utilize shorter towers. Some towers are fold-over or hinged to allow easier maintenance without climbing. Some towers are free standing, while others are guyed. Most towers are manufactured using steel or aluminum. Steel towers are sturdier and allow for heavier payloads and greater wind loading. Aluminum towers are cheaper and of lighter weight and are adequate for most purposes, though they may not be climbable. Overall, the platform used should be designed in such a way to minimize overall impact on the variable(s) being measured. For towers, the lattice should be as open and minimal as possible so as not to block or disturb the wind flow. All platforms should be well grounded for lightning protection.

45.4.2 Sensors

A wide variety of sensors are deployed across mesometeorological networks. The most common variables measured include air temperature, relative humidity, wind speed and direction, atmospheric pressure, and precipitation (see the chapters in Part B). Other less common variables include solar radiation, soil temper-

ature and moisture, leaf wetness, snow depth, and snow water equivalent. Some networks measure the surface energy budget, including shortwave and longwave radiation, photosynthetically active radiation (PAR), as well as sensible, latent, CO₂, and ground heat fluxes (see the chapters in Part F). Some networks are beginning to expand beyond surface measurements to collect vertical profiles, such as temperature, moisture, and wind profiles to augment the radiosonde record [45.17] (see the chapters in Part C). Now with high bandwidth available from commercial cellular communications, cameras are being deployed to provide imagery along with standard meteorological data. Photographic data provide important visual verification of sensible weather and act as an excellent quality-control tool for understanding unusual weather events.

All sensors should be mounted in a way that minimizes instrument errors, platform interference, and local siting impacts. While it is not always possible because of power and budgetary constraints, temperature sensors should ideally be mounted in aspirated shields in order to minimize radiational heating errors. This is especially important in areas where sunny, light wind conditions ($< 2 \text{ m s}^{-1}$) are common. Aspiration fan speeds should be monitored to ensure a uniform air flow across the sensor. Humidity sensors should be placed in a radiation shield to prevent direct solar radiation from heating the sensor. Barometers are often mounted in a weatherproof enclosure with a pressure tube extending to the outside of the enclosure to minimize pressure changes and differences with the outside environment. Wind sensors should be mounted on top of a mast or tower such that there are no obstacles impacting the winds impinging upon the sensor. Precipitation is often measured using either a tipping bucket gauge or weighing gauge. Both types of gauges require a single or double Alter shield placed ≈ 1.2 to ≈ 2.4 m around the gauge, designed to minimize the acceleration of air at the gauge orifice, which could lead to an underestimation in precipitation if not used [45.18]. Pyranometers should be mounted level on a cross arm on the south side of a tower, or independently away from a tower on an independent platform, such as a tripod, to minimize shadows or reflectance from the platform. Soil sensors must be installed level in undisturbed soil, and preferably at multiple locations within a site to provide a collective average due to soil inhomogeneities. For most purposes, soil sensors should be placed under naturally occurring vegetation representative of the site area; however for some applications such as agriculture, soil data collected under bare soil may be needed. Soil sensor measurements are often collected

at several depths in order to provide a vertical profile. The WMO recommends soil data collection at 5, 10, 20, 50, and 100 cm. Some networks may collect measurements at 25 or 75 cm. Near-surface rock may inhibit some lower soil depth measurements.

The data collection requirements of most mesonets demand a relatively high data collection rate. Most variables sample at a 1 or 3-second rate; others may sample at a 12 or 60-second rate (e.g., barometer). Typically, these samples are averaged within a central processing unit or datalogger to produce 1-minute and/or 5-minute averages. For some variables, such as maximum rainfall rate and wind gust, a maximum sample is retained. Most sites report 5-minute to hourly averaged observations computed from the higher-frequency sampling.

Redundant sampling yields a more robust data record. Multiple, same type sensors allow for exact, real-time comparisons to ensure good calibration. Multiple sensors that use different measurement techniques, such as the use of a propeller vane and sonic anemometer, can provide even greater confidence in an observation. Extreme weather events can create doubt in a measurement when just one sensor is available. Multiple sensors enable long-term drift to be detected earlier than when just one sensor is used. Whenever sensors are upgraded across a network, it is advisable to collect at least 1 year of simultaneous field measurements with both the old and new sensor at select locations in order to document any unforeseen changes or biases with the upgrade. Furthermore, all networks should be compared against independent network systems whenever possible in order to identify any systematic errors or biases that may be present.

45.4.3 Datalogger

Each station has a central processing unit (CPU), typically referred to as a datalogger (Chap. 2). The datalogger is often multifunctional; it can be used to convert voltages to meteorological units, apply averaging and calibration coefficients, distribute power to sensors, temporarily archive data, and bundle data for transmission. Dataloggers can handle either digital or analog sensors. Dataloggers also provide on-location storage and, depending upon the amount of data generated, can store up to months of data at a time. This is useful whenever communications are interrupted, and archived data can be retrieved once communications are reestablished such that no data are lost in the archive.

45.4.4 Station Power

Siting requirements often limit mesonet stations access to utility power. Many stations are deployed in remote,

wide-open areas away from utility poles. Solar power is now a viable alternative used to power a majority of mesometeorological sites. A solar power system is comprised of one or more solar panels, a charging system, and one or more batteries for power storage. In general, higher-latitude sites require more and larger panels due to the lower winter sun angle and more sensors requiring heating.

One complication with powering a weather station is the distribution of power from the panels to the sensors. Some sensors require 24 V, while others require 12 V. Some sensors are sensitive to the regularity of the current. A distribution system may be needed to regulate and distribute power from the solar panels and datalogger to the sensors and supporting equipment.

45.4.5 Station Communication

At the site, data are bundled by the datalogger and then sent to a modem for transmission. Again, largely due to siting requirements, most stations do not have easy access to line (e.g., Ethernet) communications. As an alternative, many sites use either line-of-sight radio telemetry, or increasingly cellular communications. The proliferation of cellular communications is aiding the collection of data from remote stations; however, the use of cellular requires some costs paid to a third party, private network. For those networks deemed critical for emergency management in the United States, hourly transmissions are allowed free of charge through the geostationary operational environmental satellite (GOES). A limited 30-second transmission is allowed once per hour from each station and provides critical environmental information during emergency situations.

Ideally, all data are collected, processed, and then transmitted in near real time from network stations simultaneously, where data are then collected at a central processing unit. At the receiving end, a single server or cluster will ingest this raw data, where additional processing, such as quality control, may be applied. The entire process, including data collection, transmission, data processing, and dissemination to customers, can ideally be completed in several minutes.

One increasingly critical issue with regards to communications is cyber security. Public internet protocols (IP)s should be used with caution when setting up any communication network.

45.4.6 Operations and Maintenance

Once established, the focus of resources in a mesometeorological network quickly becomes aimed at regular operations and maintenance. Some regular staff should be dedicated to the continuous upkeep of both net-

work field hardware, as well as the central processing center servers and software. A number of automated tools can be utilized for the standard data collection, transmission, quality control, and dissemination steps. Nevertheless, direct human intervention is needed when

problems arise, and a manual review of data is highly recommended even on a daily basis in order to more reliably detect subtle errors or sensor drift that may arise. Site maintenance is discussed in greater detail in Sect. 45.7.

45.5 Specifications

Fortunately, years of study and experience operating mesonets worldwide have now yielded reliable guidelines for station siting and sensing standards. These general recommendations are reviewed below.

45.5.1 General Guidelines for Siting

As discussed in Sect. 45.3.2, the WMO provides a classification scheme for siting guidance based on station site properties [45.14]. These properties include land use type, slope, vegetation height, roughness, and the presence of large bodies of water, heat sources, and obstacles. The ideal site is classified as “Class 1”, which means that the weather measurement incurs minimal, generally insignificant impacts as a function of the site properties. In contrast, station properties at a “Class 5” site overwhelm the measurement to a significant degree. However, note that each site classification is variable dependent. A Class 1 site for measuring rainfall could be a Class 5 site for monitoring solar radiation. For more details, see Chaps. 7, 9, 11, and 12.

Ultimately, the location of a site will depend upon many factors; however, the site properties will have a direct impact on data quality. If very high data quality is required, then a Class 1 site (for as many variables as possible) should be selected. If data quality is less of a concern, then lower class sites can be considered. In general, the more restrictive the class category is, often the fewer the options available for placing a station will be.

45.5.2 General Sensor Guidelines for Automated Stations

As with station siting, many factors determine which sensors are best suited for use in any given mesometeological network. For example, data quality requirements, power constraints, communication availability, and sensor costs may all impact the selection of sensors. In general, high-quality, low-power, robust (low-maintenance) sensors are best for use in mesonets. A list of sensors used in the New York State Mesonet and their corresponding properties is provided in Table 45.2 as an example of a typical system (Chap. 43).

Table 45.2 Sensor specifications for the New York State Mesonet, as an example of a standard mesometeological network

Parameter	Sensor	Operating range	Sampling rate (s)	Accuracy
Temperature	R.M. Young 41342 Platinum RTD	−50 to +50 °C	3	±0.3 °C (at 23 °C)
Humidity	Vaisala HMP155	−80 to +60 °C, (0–100% RH)	3	±1% RH (0–90% RH) ±1.7% RH (90–100% RH)
Pressure	Vaisala PTB330	500–1100 hPa	12	±0.25 hPa (−40 to +60 °C)
Precipitation (weighing gauge)	Pluvio ² 200 by Ott	−40 to +60 °C, (up to 50 m s ^{−1})	60	±0.05 mm (amount) 0.01 mm (resolution)
Wind speed, wind direction (sonic anemometer)	Lufft V200A	0–75 m s ^{−1} , 0–360°	3	±0.3 m s ^{−1} or 3% of reading, wind direction: ±3°
Wind speed, wind direction (vane propeller)	R.M. Young wind propeller 05103	0–100 m s ^{−1} , 0–360°, −50 to +50 °C	3	±0.3 m s ^{−1} or 1% of reading, wind direction: ±3°
Solar radiation	LiCor LI-200SA	−40 to +65 °C	3	Approximately ±5%
Soil temperature and moisture	Stevens Hydra Probe II	−30 to +55 °C	60	±0.1 °C
Snow depth	SR50A	−45 to +50 °C	3	±1 cm, or 0.4% of distance to target
Camera	Hikvision	−30 to +60 °C	5 min	–

RH: relative humidity

45.6 Quality Control

The high-resolution nature of data from mesometeorological networks is often an advantage during the quality control process (Chap. 3). In general, data are tested for internal, spatial, and temporal consistency. The challenging aspect of quality control for mesonets is oftentimes the diversity of observations collected (e.g., soil temperatures, solar radiation) and phenomenon detected (e.g., heat bursts, mesolows; [45.19]). Proper siting (Sect. 45.5), the use of calibrated sensors, and routine maintenance (Sect. 45.7) are considered paramount in the quality-control process. Once those conditions are met (or at least documented in the metadata), a number of automated and manual techniques can further refine the assessment of data quality.

45.6.1 Automated Algorithms

The general automated algorithms for mesometeorological data consist of range tests (both based on sensor specifications and on climate thresholds), temporal tests that evaluate observation-to-observation consistency, and spatial tests that compare data from neighboring stations [45.20]. Range tests based on climatological extremes may need to be updated periodically as a meteorological network's data archive grows. Temporal tests can identify anomalous data that have changed either too rapidly during sequential observations (e.g., a temperature decrease of more than 9 K in 5 min) or too slowly (e.g., a temperature change of less than 0.1 K in 60 min). Spatial tests take advantage of neighboring sites to identify sensor drift, bias, or other quality issues. Automated tests for spatial consistency oftentimes include dynamic thresholds based on the standard deviation of the variable tested. For instance, during stormy weather, greater variability may be allowed than during quiescent times. Depending on the data available, many additional, sensor-specific automated algorithms can be employed. For instance, multiple measurements of the same parameter at various heights can be compared to test for expected gradients. For some measurements such as pressure and relative humidity, it is more appropriate to derive sea-level pressure and dewpoint before performing automated spatial comparisons (Chaps. 8 and 10).

45.7 Maintenance

It has often been remarked that the best performing sensor is the best maintained sensor. In other words, it is possible to get accurate data from a well-maintained,

45.6.2 Manual Review

While automated algorithms are invaluable for screening data in real time, a manual review is required to accurately flag erroneous data in the archive. For instance, an automated spatial check may identify a subtle sensor bias that has finally grown large enough to be detected. In that case, a manual edit to the metadata would be required to accurately flag the observations back to the true start of the sensor problem. Thus, rather than manually reviewing hundreds of thousands of observations that might be collected on a given day, a suite of automated tests can pinpoint the dozen or so observations that require manual review. Oftentimes during manual review, external datasets can be exploited. For instance, visible satellite data can be compared to solar radiation data to identify problematic pyranometers. Likewise, radar data can be used to identify failing precipitation sensors. Because these remotely-sensed observations are not necessarily direct measurements, a subjective eye is often required during these manual comparisons.

45.6.3 Metadata and Documentation

Metadata and documentation are critical to the quality review process. Station properties, such as topography and roughness, can have a major influence on sensible observations. For example, a site's elevation in relation to neighboring stations may explain why temperature observations are anomalously cold (due to a relatively low elevation) or warm (due to a relatively high elevation) on a night with a strong low-level inversion. Likewise, panoramic photos of a station may help explain an anomalously low wind speed at a station when the flow is from a direction that has obstructions (e.g., trees) on the horizon. Real-time photos collected by a station can be especially helpful when determining if and when precipitation, fog, or even human or animal vandalism occurred. A well-documented record of all calibrations, sensor changes and rotations, firmware upgrades, and regular maintenance visits provide data users (and quality control managers!) with a wealth of valuable information.

inexpensive sensor. Likewise, it is possible to get poor data from a neglected, expensive sensor. Regular maintenance of mesometeorological networks typically

Table 45.3 General sensor rotation guidelines for automated stations [45.21]. For more details, see Chaps. 7–12

Sensor	Rotation interval (month)
Temperature	60
Humidity	24
Pressure	48
Precipitation (tipping bucket)	60
Wind (propeller vane)	48 (speed); 60 (direction)
Solar radiation	24–36

consists of performing vegetation maintenance in and around the sensors, performing sensor rotations, cleaning and inspecting sensors, performing in-field sensor tests, and documenting site characteristics with photographs [45.21].

45.7.1 General Sensor Rotation Rate

Optimal sensor rotation rates are dependent on a number of factors. The sensor manufacturer often has general guidance on the typical sensor drift rate or life expectancy. Such intervals vary based on manufacturing quality and environmental exposure. For instance, a humidity sensor may drift faster in a moist, coastal environment in comparison to one deployed in a dry, desert environment. While the manufacturer’s guidelines are a good starting point, each network will likely adopt rotation intervals based on typical drift and time-to-failure rates observed in their particular environmental

conditions. As an example, Table 45.3 lists rotation periods based on sensor drift and failure rates experienced across Oklahoma, a region that spans moist, humid conditions in the southeast and dry, arid conditions in the northwest. Some networks choose not to preventatively rotate soil sensors (e.g., soil temperature, soil moisture, soil heat flux), since disturbing the soil structure is often more damaging to the data archive than simply waiting for the soil sensor to fail before replacing it.

45.7.2 Maintenance Schedule

Routine, scheduled maintenance provides an efficient way to perform standard work at each station, as well as complete sensor rotations and collect and update metadata. Oftentimes, vegetation growth is a driving factor in how often routine maintenance is needed. A survey of maintenance schedules at various networks found a range from monthly to annually [45.21]. Tables 45.4 and 45.5 provide example maintenance schedules for a typical mesometeorological network.

Not all maintenance can be scheduled in advance, and the ability to repair failed sensors quickly is critical to minimizing gaps in the data record. Sites and sensors can fail from a myriad of causes, including normal sensor aging, dirt and dust, vandalism, wildlife (e.g., mice chewing wires), snow and ice buildup, extreme temperatures, rain, wind, and lightning. Table 45.6 lists various precautionary recommendations and common problems often observed by field networks.

Table 45.4 General maintenance schedule for automated weather stations

Maximum interval	Site in general	Temperature	Humidity	Wind (propeller vane)
2–4 weeks (growing seasons)	Cut grass within site area			
6 months	Clean all sensors, inspect wiring, check for bugs and critters	Inspect sensor, aspirator fans	Clean sensor tip	Test speed and direction
1 year	Inspect tower, fencing			
2 years			Rotate, recalibrate	
3 years				
4 years				Rotate propeller, recalibrate
5 years		Rotate, recalibrate		Rotate vane, recalibrate

Table 45.5 General maintenance schedule for automated stations, additional variables

Maximum interval	Pressure	Precipitation (tipping bucket)	Precipitation (weighing gauge)	Solar radiation
2–4 weeks (summer)				
6 months	Inspect pressure port	Clean debris from top	Fill antifreeze (fall); empty antifreeze (spring); test weighing device	Clean sensor, check leveling
1 year				
2 years				Rotate, recalibrate
3 years				
4 years	Rotate, recalibrate			
5 years		Rotate, recalibrate		

Table 45.6 A list of common operational issues often encountered by mesometeorological networks

Variable	Guidance
General site	<ul style="list-style-type: none"> • Vegetation should be maintained such that the vegetation height does not interfere with the measurements. Vegetation type should match vegetation outside the station when possible • Beware of wildlife chewing cabling; consider burying all cabling within rodent-proof conduit. Adequate fencing around site to keep domestic animals and large game away from sensors • Site should be well grounded to minimize damage from lightning
Temperature	<ul style="list-style-type: none"> • Sensors must be protected against radiation, preferably housed within aspirated shielding. Air ventilation within shielding be $\approx 3 \text{ m s}^{-1}$
Humidity	<ul style="list-style-type: none"> • Sensitive to dirt and pollutants; require filtering on most sensors • Sensors must be protected against radiation, preferably housed within shielding
Pressure	<ul style="list-style-type: none"> • Sensitive to temperature, drift, vibration, and exposure • Sensors should be housed within a protected enclosure; if housed within a sealed container, a pressure tube must be used
Precipitation	<ul style="list-style-type: none"> • Tipping bucket gauges must be kept clear of debris • Weighing gauges require antifreeze during the winter months • Portions of some gauges should be heated with temperatures $< 0^\circ \text{C}$ • Wind shielding should be used to reduce under-catchment
Wind	<ul style="list-style-type: none"> • Propeller anemometers are susceptible to ice buildup; recommend heating if possible • Sonic anemometers may fail during moderate to strong winds and precipitation
Solar radiation	<ul style="list-style-type: none"> • Sensitive to dirt accumulating on the sensor • Sensitive to leveling
Soil temperature, soil moisture	<ul style="list-style-type: none"> • Be aware of water channeling along the cabling; include a drip loop in installation • Should be installed in undisturbed soil and remain as undisturbed as possible • Estimates sensitive to the soil properties
Snow depth	<ul style="list-style-type: none"> • Sensitive to snow drifting • Data quality may fail during precipitation

45.8 Applications

Dense networks of observations in the near-surface and lower boundary layer have been shown to improve analysis and short-term prediction [45.22]. Sites in particularly remote areas provide significant value to large-scale numerical weather prediction models [45.23]. Stations in urban areas are critical for decision-makers in transportation, energy, and emergency management. These applications point to the need for more observations, which has driven the proliferation of new and expanded mesonets across portions of the United States, Canada, South Korea, and many parts of the world. A growing number of industries and sectors recognize the value for more accurate, more precise analysis and prediction, as these improved weather output translate to more efficient, more cost-effective services and products.

Many early mesometeorological networks were deployed primarily for research, and many networks still retain a research component. For instance, Oklahoma Mesonet data have been used in over 500 peer-reviewed journal articles and over 400 theses and dissertations [45.24]. Research-oriented networks may be mobile and/or transitory.

Access to highly localized, high-temporal weather information is critical for emergency management. Emergency management is harnessing mesometeorological network data for aiding storm preparation and response [45.25, 26]. Improved short-term prediction allows for more efficient prestaging of resources, and real-time information allows for faster postevent response. Observations of precipitation, snowfall depth, and snow water equivalent aid in hydrological forecasting and flood response. Temperature, wind, and pressure data aid in monitoring severe weather. Temperature, humidity and wind data also help with fire management (e.g., remote automatic weather stations (RAWSS) network; [45.27]). Drastic wind shifts can be a matter of life and death for firefighters on the front lines [45.15].

Local and frequent weather information is critical to many ground transportation operations. Some state and federal transportation agencies operate their own networks, often sited along roadways (roadway weather information systems (RWISs)); e.g., the Iowa State University's environmental mesonet, <https://mesonet.agron.iastate.edu/RWIS/>, Accessed 20 July 2021). Real-time weather data are used for winter

weather operations and road closures, while climate archives can be useful for long-term planning [45.28].

Aviation is highly sensitive to meteorological conditions. While weather radar is the primary tool used by aircraft, surface networks and boundary-layer sensing networks provide necessary ground truth of radar data and improve overall weather analyses and prediction. Furthermore, networks of short-range radars and vertical profiling sensors, such as gap-filling (X-band) weather radars, lidars, and microwave radiometers, fill a void in sampling the lower-level boundary layer (0–3 km) largely missed by large (C- and S-bands) radars. The value of mesometeorological networks can be expected to increase as more localized, frequent data are needed as the operation of near-surface drones becomes more widespread.

Utility companies rely increasingly on local weather networks to optimize power load predictions [45.29]. Energy production costs are lower when peak demands are correctly forecast; access to local weather information can save utilities millions of dollars. Weather data are also used for improving short-term prediction of high-impact weather in order to prestage resources to minimize outage times. Power grids are particularly susceptible to lightning, high winds, and ice storms, and the

analysis and prediction of these can be improved with the use of local, dense weather networks. As utility companies become more dependent on renewable energies, energy production and grid operations will become even more sensitive to weather extremes and variability.

Arguably the most weather savvy community is the agricultural sector, and a majority of current mesometeorological networks have an important agricultural component. Farmers utilize weather data for a variety of uses including planting, fertilizing, and harvesting of crops and modeling of plant disease and pests (e.g., the Network for Environmental and Weather Applications (NEWA); [45.30]). The use of weather information can be economically beneficial [45.31].

Data from mesometeorological networks continue to find many other uses. Public health is beginning to utilize networked data to explore the spread of infectious disease and to monitor public health issues, such as asthma. Criminologists are exploring weather information to predict criminal activity. Forensic meteorologists utilize local weather information for use as evidence in court cases. Data from mesonets are becoming increasingly important as more personalized, more efficient, and autonomous infrastructure is adopted that requires frequent, local weather input.

45.9 Future Development

Several current trends portend future growth and utilization of mesometeorological networks. These trends include:

1. Continued expansion of networks worldwide as resources permit
2. Continued increase in the number of variables measured and the frequency at which they are measured
3. Expansion in observations from the surface to include lower-level boundary layer sensing
4. Increasingly automated end-to-end networks with adaptive sampling features
5. Diversification in how mesometeorological networks are funded and operated.

The last decade has seen a proliferation of mesonets across the US; over 20 states now host some type of mesometeorological network [45.8]. Networks have also expanded in their capabilities as new sensors are developed and made cheaper and more reliable. Sensors to measure snow depth, snow water equivalent, pavement temperatures, PAR, and soil moisture are becoming more common. Cameras may be added to more networks as bandwidth and power become more easily accessible.

To extend measurements into the vertical, the New York State Mesonet hosts a network of 17 profiling stations, each equipped with a lidar, microwave radiometer, and environmental sky imaging radiometer (eSIR). The West Texas Mesonet has several sodars deployed, whereas the Oklahoma Mesonet is experimenting with drone technologies. As the costs of these sensors come down, and as the technology continues to advance, we can expect more of these and other vertically penetrating sensors to be deployed.

Nearly all networks collect data at fixed, regular intervals. However, with increasingly adept artificial intelligence algorithms, more networks will integrate adaptive sampling, which may automatically adapt their scanning strategies as a function of the evolving environment.

Finally, it is an important reality that the deployment and operation of a mesometeorological network is expensive. As the expectations from these networks rise, the cost burden also increases. Increasingly, these costs are shared among the public and private sectors, with some active networks already utilizing a combination of public and private funding.

45.10 Further Readings

Listed below are two overarching papers that describe the need for mesometeorological networks and make recommendations on how they should evolve to facilitate future needs:

- W.F. Dabberdt, T.W. Schlatter, F.H. Carr, E.W.J. Friday, D. Jorgensen, S. Koch, M. Pirone, F.M. Ralph, J. Sun, P. Welsh, J.W. Wilson, X. Zou: Multifunctional Mesoscale Observing Networks, *Bull. Amer. Meteorol. Soc.* **86**, 961–982 (2005)
- National Research Council: *Observing Weather and Climate from the Ground Up: A Nationwide Network of Networks*, Washington D.C., National Academies Press, 250 pp. (2009)

Most mesonets are well documented, and below are several papers describing some exemplary networks:

- R. McPherson, C. Fiebrich, K. Crawford, R. Elliott, J. Kilby, D. Grimsley, J. Martinez, J. Basara, B. Illston, D. Morris, K. Kloesel, S. Stadler, A. Melvin, A. Sutherland, H. Christopher A. Fiebrich is the Associate Director of the Oklahoma Climatological Survey and Executive Director of the Oklahoma Mesonet at the University of Oklahoma. He is also Adjunct Faculty with the School of Meteorology at OU. His areas of expertise are in mesoscale meteorology and climatology, meteorological instrumentation, and applied meteorology and climatology.

Aerological M

46. Aerological Measurements

Holger Vömel , Masatomo Fujiwara 

Many aerological measurements rely on compact radiosondes, which are carried into the atmosphere using rubber balloons. Radiosondes measure essential atmospheric state parameters: pressure, temperature, humidity, and winds. Although sensor technology is similar to the sensors used in ground-based measurements, sensors used on radiosondes must be able to measure a much wider range of conditions and to operate in difficult environments. Many different technologies for radiosonde sensors exist. Here, common sensor technology in modern radiosondes is described. Radiosonde pressure measurements either use specialized small solid-state sensors or rely on pressure derived from global navigational satellite system (GNSS) height measurements. Temperature measurements either use small thermistors or wire resistance thermometers. Coatings to minimize solar radiative heating and accumulation of water on the sensor reduce measurement artifacts. Modern humidity sensors are almost exclusively based on thin film polymer sensors, which are optimized for atmospheric observations under a wider range of conditions and may have heaters implemented to reduce icing problems. Wind measurements are based on GNSS signals received onboard the radiosondes. Radiosonde technology is also used on dropsondes, which are deployed from aircraft for targeted observations of severe weather and hurricanes, as well as on tethered systems. Data sharing through international systems is an important component in the distribution and use of global radiosonde data. Technical specifications, quality control, and maintenance considerations, as well as an outlook on applications and future developments are presented.

Weather and climate, which we experience on the surface of our planet, are largely controlled by the processes in the air above us. Meteorology started to develop as a specialized discipline of physics, when early

scientists developed the capabilities to observe the state parameters of the atmosphere above us. From the drive to understand the state of our atmosphere and the details of atmospheric processes, these observations led

to a solid foundation of meteorology and atmospheric physics and enabled the important field of weather forecasting, on which we rely every day.

From the humble beginnings of measurements of the lower and middle troposphere on balloons and kites by few dedicated scientists, aerological measurements have developed into a complex system of observations and data sharing. The technology needed to be developed to lift instruments into the air. With balloon technology, which was developed over 100 years ago, soundings today routinely reach altitudes well above 30 km or well into the middle stratosphere. Sensor technology needed to be developed to enable more accurate observations and reduce the environmental influences on the measurements. As remote-sensing technologies were developed, in-situ sensing technologies were required for validation and even calibration of remote-sensing methods. Aircraft meteorological observations complement the observations on small balloons but have not replaced them, due to aviation safety reasons. Simultaneous measurements of pressure, temperature, humidity, and winds are still the core aerological observations, but technological developments now allow observations of many more parameters onboard small balloons.

The large-scale dynamics that drives our atmosphere requires meteorological observations covering large regions, crossing national borders and oceans. With the development of the observation technologies and platforms, a system of cooperation and data sharing needed to be developed to study the processes, which affect everyone. International cooperation started with personal contacts between scientists and developed into the World Meteorological Organization (WMO) within the framework of the United Nations. To share data specialized formats had to be agreed upon, a data-sharing infrastructure had to be built, types and frequencies of observations had to be defined, and developments meeting needs had to be enabled.

Today, aerological observations play a central part in weather forecast, climate studies, and research of atmospheric processes around the globe. Few scientific research areas are as globally interconnected as aerological observations. New observational technologies are being developed, new platforms to carry sensors into the air are built, and new questions arise about how our atmosphere works. Here, we provide an overview of the history and the current state of aerological measurement technology, and how aerological observations fit into the larger field of global meteorology.

46.1 Measurement Principles and Parameters

Aerological observations refer to measurements of the thermodynamic variables pressure, temperature, relative humidity (water vapor), and winds in the free atmosphere, covering the vertical range up to the middle stratosphere. Balloon-borne in-situ measurements have been a core technique since the beginning of aerological observations, and current radiosonde balloon soundings are among the most important technologies to characterize the atmospheric state (Fig. 46.1).

46.1.1 Measured Parameters

Soundings are carried out worldwide, and, therefore, the instruments must to be able to cover a large range of atmospheric conditions. Table 46.1 lists the ranges for pressure, temperature, humidity, water vapor mixing ratio, and wind, which sounding instruments may encounter. The altitude range is assumed to be up to ≈ 35 km, corresponding to ≈ 5 hPa, which is the al-

Table 46.1 Range of atmospheric parameters measured in aerological observations

Parameter	Minimum	Typical region of minimum	Maximum	Typical region of maximum
Altitude (m ASL)	0	Some sounding sites are below sea level	35 000	Typical ceiling maximum for sounding balloons in the middle stratosphere
Pressure (hPa)	5	Typical ceiling maximum for sounding balloons in the middle stratosphere	≈ 1065	Typical pressure at the elevation of the Dead Sea at 430 m BSL
Temperature ($^{\circ}\text{C}$)	≈ -90	Tropical tropopause over the Western Pacific, Antarctic winter stratosphere	> 40	Dry desert regions
Relative humidity (%)	< 1	Stratosphere	≈ 100	Clouds, fog
Water vapor mixing ratio (mg kg^{-1})	< 1	Tropical tropopause	$> 25\,000$	Tropical monsoon region
Wind (m s^{-1})	0		> 100	Jet streams, hurricanes, tornadoes

Fig. 46.1 Radiosonde launch at the DWD Meteorological Observatory Lindenberg, Germany ►

titude range that is easily reached by balloon-borne soundings. The relative humidity (over liquid water) and mixing ratio are two measures of the atmospheric water vapor concentration. Almost all radiosondes report relative humidity, from which the mixing ratio can be calculated (Chap. 8).

All radiosondes are capable of measuring pressure and temperature over the required range (Sect. 46.3). However, radiosonde humidity sensors are limited to tropospheric measurements only, with decreasing capabilities at colder temperatures. Stratospheric humidity is measured with only few scientific sounding instruments at a few select stations (Sect. 46.8.2).

A typical tropical profile of pressure, temperature, relative humidity, and winds is shown in the Skew-T/Log-P diagram shown in Fig. 46.2. The temperature in this example ranges from about 17 °C at the surface to -78 °C at the tropopause. Relative humidity ranges from near saturation in the boundary layer to about 2% RH at 6 km. Typical for tropical wind profiles is the high variability of wind directions across the profile. The boundary layer top is indicated by a very strong thermal inversion ≈ 1.6 km above ground.

Aerological observations are also taken from commercial and research aircraft, which are limited to the ceiling altitude of the aircraft and to weather conditions,

Table 46.2 Atmospheric parameter and current and historic radiosonde sensor technology

Parameter	Sensor	Notes
Temperature	Small bead or disk thermistor	Calibration over the entire temperature range required
	Wire resistance	Current state of technology
	Glass-ceramic capacitor	Thermocap [®] technology of the Vaisala RS80, RS90, and RS92 radiosondes
	Bimetal strip	No longer in use
	Thermocouple	Very rarely used
Pressure	Piezoresistive strain gauge and capacitive sensor	Large relative uncertainty in stratosphere
	GNSS altitude	Larger uncertainty in boundary layer, requires independent surface pressure
	Radar height	Large uncertainties especially at far distances
	Aneroid can and Bourdon tube	No longer in use
	Hypsometer	No longer in use
Humidity	Thin film capacitor	Tropospheric humidity only
	Cryogenic frostpoint hygrometer	Scientific instrument for tropospheric and stratospheric water vapor
	Lyman- α hygrometer	Scientific instrument for stratospheric water vapor only
	Carbon hygristor	Used on only few sondes
	Goldbeater's skin	No longer used on radiosondes
	Hair hygrometer	No longer used on radiosondes
Wind	Psychrometer	No longer used on radiosondes
	GNSS	Current state of technology
	Radar	Large uncertainties especially at far distances
	Radio navigation (LORAN and Omega)	Obsolete
	Optical theodolite	May still be used on pilot balloons

which are safe for aviation (Chap. 43). Aircraft observations complement the observations by radiosondes and are used in dedicated research projects. Aerological observations are also taken from long duration balloons at constant density. These measurements are used for research purposes only and provide a detailed representation of the dynamics of a single air parcel.

46.1.2 Principles of Measurements

Sensors to measure pressure, temperature, humidity, and winds typically found on current and his-

toric radiosondes are listed in Table 46.2. For pressure measurements, some radiosondes allow combining in-situ measurements with GNSS or radar altitude measurements. Stratospheric humidity currently can only be measured with specialized scientific instruments, such as frostpoint and Lyman- α hygrometers. Some of the technology that is no longer used on radiosondes may still be in widespread use for surface-based measurements. Refer to the respective chapters for more information. A detailed description of historic instrumentation can be found in [46.1].

46.2 History

The term *aerology* refers to the branch of meteorology that uses aeronautical means for the scientific study of the upper air. This term was coined by *Wladimir Köppen* (1846–1940) [46.2] in the early years of the twentieth century and was quickly adopted as scientific

discoveries and technological developments in this field progressed at a rapid pace. Until the end of the nineteenth century, atmospheric observations had been taken largely from the surface, except for few occasional observations from manned hot-air or gas

balloons. In 1894, Abbot *Lawrence Rotch* (1861–1912), who 10 years earlier had founded the Blue Hill observatory near Boston, MA, USA, flew the first kite equipped with a recording instrument to measure a profile of the atmospheric conditions [46.3]. This moment marks the beginning of systematic upper air observations. In 1898, Leon Teisserenc de Bort (1855–1913) founded the observatory at Trappes near Paris, France, where he pioneered gas-filled hydrogen balloons as observational platforms. In 1899, *Richard Assmann* (1845–1918) founded the Aeronautical Observatory at Reinickendorf near Berlin, Germany, which in 1905 was relocated to Lindenberg, Germany, and which has continued until today to be a preeminent institute for atmospheric observations. Assmann used kites and tethered balloons but also free-flying *registering* instruments, for which he had invented rubber balloons [46.4]. The instruments used in these measurements were sophisticated barothermohydrographs, better known at the time as meteorographs. They typically measured pressure using aneroid cans, temperature using bimetal strips, and humidity using hair hygrometers. Measurements were recorded on mechanical strip charts, and in the case of free-flying registering balloons, the instrument had to be recovered to retrieve the data. Registering balloons and the simpler pilot balloons, which did not carry any instruments, were also tracked by one or two optical theodolites to measure wind profiles aloft. The discovery of the stratosphere by *Léon-Philippe Teisserenc de Bort* (1855–1913) and Assmann in 1902 [46.5, 6] constituted a seminal milestone of upper air observations [46.7]. *Arthur Berson* (1859–1942), who worked with Assmann at Reinickendorf and later at Lindenberg, was responsible for almost all of the manned balloon ascents. In 1901 he flew on a gas-filled balloon, taking manual Assmann psychrometer observations to confirm the measurements by a parallel-flying registering balloon. This validation measurement was an essential part in the discovery of the stratosphere [46.8]. With this flight, Berson also set an altitude record of 10.8 km for open-basket balloon ascents, which still holds today.

John Wise (1808–1879), an avid balloonist in the middle of the nineteenth century, noticed very strong winds in the middle troposphere. By the early decades of the twentieth century, a network of upper-air stations had been established in Europe and in the USA performing regular soundings for weather forecasting. In Japan, *Wasaburo Ooishi* (1874–1950) founded the first meteorological upper-air observatory at Tateno, in 1920 [46.9]. Ooishi traveled to Lindenberg in 1911 to learn about upper air observations and returned to Japan in 1913. Due to World War I, the creation of his observatory was significantly delayed; however, by the mid 1920s, Tateno was a well-established observatory.

Between March 1923 and February 1925, Tateno measured 1288 profiles, which is nearly two soundings by kite or pilot balloon per day. *Ooishi* observed unusually strong winds in the upper troposphere, and he published these observations in Esperanto [46.10]. This publication is effectively the first climatology of what 13 years later *Heinrich Seilkopf* (1895–1968) called *Strahlströmung* [46.11] or jet stream in its English translation. In Europe, *Vilhelm Bjerknes* (1862–1951) used the upper-air network and coordinated ascents at 18 stations in a set of four different case studies. The last of these [46.12] also found narrow regions of high wind speeds and put these into a much more theoretical context. Further approaches for a theoretical explanation of the jet stream followed in the 1940s [46.13–15]. *Carl-Gustaf Rossby* (1898–1957) and collaborators [46.16] created 5-day averages of synoptic chart at 3 km over North America over several years to extend weather forecasts by investigating these slower variabilities. They identified and theoretically described upper-level stationary troughs and long waves, which would later be known as Rossby waves.

Profiling by kites was very labor-intensive work. Despite a number of improvements (e.g., *Grund's* self-regulating kite [46.17]), breaking wires and escaping kites were common and dangerous occurrences. Furthermore, observations by kites were limited to the lowest few km of the atmosphere. Typical operational profiling heights done at Lindenberg were generally up to 4 km, with occasional ceilings up to 7.5 km. In 1919, a string of eight kites raised at Lindenberg reached an altitude of 9750 m, a record still standing today [46.18]. To measure the atmosphere above that altitude required flying registering devices on free-flying balloons, which were not always recovered. This motivated the development of instruments that were able to send their data by radio transmission rather than recording data in situ on paper charts, which had to be recovered. Early developments of balloon-borne transmitters for meteorological work started at Lindenberg in the early 1920s, followed by work in the Soviet Union, France, and in the USA [46.1]. In 1924, *William Blair* (1874–1962) at the US Signal Corps laboratory at McCook Field, Ohio, built and flew what can be considered the first radiosonde, which, however, only included a temperature measurement. This work was abandoned when Blair was reassigned and was not published until 1931. The first published radiosonde launch was likely conducted in 1929 by *Robert Bureau* (1892–1965) in France, who also coined the term *radiosonde*. His first sonde also contained only a temperature sensor, but he soon added an aneroid pressure sensor. In 1930, *Pavel Molchanov* (1893–1941) built a similar design in Russia, and *Paul Duckert* (1900–1966) in Lindenberg followed with

a design that was similar to Blair's. Duckert soon added a sensor for humidity to complete the sensors still used in today's radiosondes. In 1930, *Vilho Väisälä* (1889–1969), a Finnish engineer, started a design for a radiosonde after seeing one of Molchanov's radiosondes [46.19]. Väisälä's sonde used capacitive sensors for pressure, temperature, and humidity, and combined these with fixed capacitive references to characterize the transmitter. His design principle was more innovative and could be implemented at lower cost. This basic design principle lasted through most of Väisälä's radiosondes for nearly 80 years.

Many radiosonde designs followed and allowed a significant expansion of the upper-air network. By the late 1940s almost all kite-based profiling had transitioned to observations by radiosondes [46.18]. Measurements of winds, however, still required tracking of the balloon by optical theodolites, which limited wind measurements to fair weather or below cloud base. The invention of radio-theodolites and radar tracking offered two alternative solutions to this problem, which would both be weather independent. Both techniques led to the now outdated term *rawinsonde* (radar-wind sonde) for radiosondes. Both systems for radio wind finding were implemented by different manufacturers, and some are still in use today in Russia and China. Later wind finding systems were based on radio navigation systems such as LORAN and Omega, which have meanwhile been replaced by GNSS, such as the American Global Positioning System (GPS), the European Galileo system, the Russian Global Navigation Satellite System (GLONASS), or the Chinese BeiDou Navigation Satellite System (BDS). These systems allow measurements of temperature and winds well into the stratosphere independent of weather and are one of the backbones of global upper-air observing systems.

In 1908, Berson led an expedition to East Africa to study monsoons. During this campaign, kite observations were taken from several ships, and registering and pilot balloons were launched well into the stratosphere. The soundings launched during this campaign found that the tropopause in the tropics is much higher and colder than at mid latitudes. They also discovered westerly winds in the stratosphere, which were opposite in direction to the easterly winds that had been deduced from the dispersion of ash in the stratosphere following the Krakatoa eruption in 1883. *Clarence. E. Palmer* (1911–1973) [46.20] called these winds *Berson's westerlies* and *Krakatoa winds*, and assumed easterlies overlying westerlies to be a feature of the lower tropical stratosphere, although he pointed out that *technical difficulties of observation are very great, the accumulated data almost insignificant*. With the expansion of the radiosonde network in tropical regions, in particular in

the context of nuclear tests, stratospheric observations became more abundant and provided a better dataset for the analysis of tropical stratospheric dynamics. The analysis of stratospheric winds from radiosonde launches in Nairobi, on Canton Island, and on the Christmas Islands between 1955 and 1960 [46.21, 22] showed that wind reversal descends with time throughout the lower stratosphere in what became known as the quasi-biennial oscillation [46.23–25]. A first theoretical explanation of the QBO was provided by *Lindzen and Holton* [46.26], who proposed a new idea of wave mean-flow interaction, which could generate a reversing wind pattern independent of the annual solar cycle.

A dramatic warming of deep layers of the stratosphere, with temperature increases of several tens of kelvin over a few days, accompanied by a wind reversal from strong westerlies to easterlies was discovered in the 1950s by upper air observations first at Berlin and then over the American radiosonde network [46.27, 28]. These sudden stratospheric warmings (SSW) are occasionally observed over the northern winter polar region and rarely over the southern winter polar region. SSWs are caused by the interaction of the mean flow with planetary scale waves in the troposphere.

In-situ soundings over oceans, which cover 2/3 of our planet, have been notoriously difficult due to the logistical effort to launch soundings away from land and, more importantly, the dangers of launching soundings in storms. Nevertheless, these measurements are most needed when storms threaten populated regions on land. In 1943, *Colonel Joseph B. Duckworth* (1902–1964) flew into the eye of a hurricane near Houston, thereby starting the era of hurricane reconnaissance. However, since flights through severe storms are inherently dangerous for aircraft, measurements were soon done by launching instruments from aircraft into storms. Early dropsondes still used chart recorders and had to be recovered [46.29]. In the late 1960s, the National Center for Atmospheric Research (NCAR) at Boulder, CO, USA, developed a dropsonde system, which could be deployed from aircraft into thunderstorms [46.30]. Wind finding based on the Omega global navigation system was added in the early 1970s [46.31]. LORAN wind finding and later GPS and more advanced sensors were added [46.32]. Dropsondes have become an essential instrument for hurricane surveillance and have significantly improved the ability to forecast how hurricanes develop and which regions they may affect [46.33]. They fill an important gap for many research programs that rely on targeted observations in data-sparse regions.

Ionizing radiation had been discovered by the end of the nineteenth century, and it was well understood that many materials might emit this mysterious radiation. To understand the nature of this ubiquitous radiation,

Victor Hess (1883–1964) tried to measure vertical profiles of this radiation. In the last of his manned balloon flights, which reached an altitude of 5380 m and landed not far from Lindenberg, he found that the radiation increased nearly fourfold over that measured at the surface [46.34]. He had discovered cosmic rays, for which he received the Nobel Prize in Physics in 1936. Most measurements above this altitude required heavier instruments and pressurized gondolas for the observer. In the 1930s, a race to greater heights using manned balloons ensued with programs in Russia, Europe, and the USA. In the early 1930s, balloonist *Auguste Piccard* (1884–1962) used rubberized cotton balloons to fly to altitudes of ≈ 16 km in a steel pressure capsule. One of his scientific goals was to continue the study of cosmic rays. However, most efforts went to sustaining high-altitude life support in the nascent space program with little value for the atmospheric sciences. His twin brother *Jean Piccard* (1884–1963) was first to develop lighter plastic balloons [46.35], which could carry much heavier payloads into the stratosphere. However, World War II interrupted most of these developments. In 1945, the German engineer *Otto C. Winzen* (1917–1979) partnered with Jean Piccard to make plastic balloons using polyethylene for manned stratospheric flights. The development of these balloons culminated in the record-breaking parachute jump from an altitude of 102 800 ft (31 300 m) by *Joseph Kittinger* (*1928) in 1960. However, this work also provided the technology to lift heavy instruments into the stratosphere and to break into a region of the atmosphere that had previously been out of reach. In 1961, the National Scientific Ballooning Facility (NSBF) was founded; it was initially operated by NCAR to provide scientists access to altitudes up to well above 30 km. The same year, the French National Center for Space Studies (Centre national d'études spatiales, CNES) was founded and started a similar ballooning program. Vincent Lally (1922–2005), who was the first NSBF director, initiated the Global Horizontal Sounding Technique (GHOST) balloon program to study tropospheric and stratospheric winds [46.36]. This program demonstrated that specialized superpressure balloons could stay afloat for many months, measuring winds at constant density levels, and led to a number of follow on programs by NASA, NCAR, and CNES. Many hundreds of balloons were launched as part of these programs, and they stayed afloat for many months, with a record of 744 days. Data collected from these balloons provided the first representation of winds covering the tropics and nearly the entire Southern Hemisphere [46.37].

In addition to remote-sensing techniques, monitoring of stratospheric ozone requires frequent in-situ observations. Few instruments for small balloons

were available in the 1960s when *Walter Komhyr* designed the electrochemical concentration cell ozone sonde [46.38]. This instrument has been used extensively on small rubber and plastic balloons and is recognized as the in-situ reference instrument for vertical profiles of ozone in the troposphere and lower to middle stratosphere. It is the only in-situ instrument that provides accurate measurements of the vertical extent of the annual ozone hole.

In the early 1940s, *Alan W. Brewer* (1915–2007) made the first observations of stratospheric water vapor on meteorological research flights of the Royal Air Force over England. These measurements were largely in support of WWII military efforts in understanding the formation of aircraft contrails. However, they revolutionized the understanding for stratospheric dynamics. Brewer and *Gordon M.B. Dobson* (1889–1975) deduced that tropospheric air enters the stratosphere from the tropics [46.39, 40]. Their model was the first description of the general stratospheric circulation. However, it took another 20 years before stratospheric water vapor measurements in the tropics could be taken. In the late 1950s, work on stratospheric frostpoint hygrometers were taking place at a number of locations. *H. John Mastenbrook* (1919–2010) at the Naval Research Laboratory developed a cryogenically cooled frostpoint hygrometer, which was small enough to be launched on rubber balloons [46.41]. Due to the size of the balloon and the instrument, he found that unlike normal temperature measurements, water vapor measurements on ascent were usually contaminated due to the water vapor carried with the balloon and the payload itself. To avoid this issue, he developed a method for the controlled release of gas from small rubber balloons, which allowed water vapor measurements on descent. This instrument flew over several Pacific islands, in India, as well as Trinidad [46.42, 43], where he achieved a 2-year dataset of tropical stratospheric water vapor, which would not be repeated for another 40 years. These measurements confirmed the stratospheric dryness, hypothesized by Brewer and Dobson. In 1980, this instrument was transferred to NOAA in Boulder, CO, USA, where some derivatives of the original instrument are still flown. This continuing program represents the longest data series for stratospheric water vapor worldwide [46.44] and is a sensitive indicator for climate change [46.45].

With the miniaturization of instruments, it is now possible to build lightweight payloads for small sounding balloons, which measure a multitude of parameters. The combination of frostpoint hygrometers and ozone sondes flown across the tropical tropopause provides important measurements on mechanisms for troposphere–stratosphere exchange or Antarctic dehydration [46.46, 47]. Small versions of cloud backscatter

sensors, icing probes, and aerosol counters have been built with sufficient quality to obtain scientific observations with high vertical resolution using small sounding balloons. This technology is highly flexible and can be transported to even the most remote locations.

International coordination was an important step for large-scale meteorological observations. Following a proposal by *Buijs Ballot* (1817–1890) [46.48], the International Meteorological Organization (IMO) was formed in 1873. In 1896, the IMO proposed simultaneous upper-air observations using kites, manned balloons, and unmanned registering balloons at different observatories, and initiated the International Committee for Scientific Aeronautics to coordinate upper-air observations and the exchange of observational data [46.49]. In 1951, the WMO succeeded the IMO as specialized agency within the United Nations (UN). While the IMO was an organization of scientists, the WMO has full support of the governments of all member countries of the UN. Unchanged from the founding periods, measurements are conducted by each national hydro-meteorological service, with coordinating efforts by the WMO, such that measurements follow accepted procedures and data standards and may be best used for regional and global weather prediction and climate monitoring [46.50]. Today, the global radiosonde network coordinated by the WMO Global Observing System comprises about 900 stations, more than two-thirds of which launch soundings twice daily (00:00 UTC and 12:00 UTC). As a subset of this network, the Global Climate Observing System (GCOS) Upper-Air Network (GUAN; Chap. 63) was established in the early 1990s, with 170 stations as of 2014, for long-term high-quality measurements for climate monitoring purposes [46.51]. Furthermore, the GCOS Reference Upper-Air Network (GRUAN; Chap. 63) was established in 2008 with a dedicated Lead Center within the German Meteorological Service, with 26 sites at the end of 2017. The goal of GRUAN is to lay the foundation for long-term climate records based on well-characterized upper-air observations using high-quality instrumentation.

46.3 Theory

In-situ soundings onboard balloons, kites, and unmanned aircraft systems use similar instrumentation and sensors as surface-based measurements. However, due to weight restrictions and the need for low-cost equipment, sensors for these platforms may have different performance characteristics than those used in surface-based measurements. In addition, airborne platforms lift sensors into very different environmental

The question of how well different instruments at different stations provide comparable observations has been a challenge since coordinated observations started. The comparability of upper-air instrumentation was an important topic in the discovery of the stratosphere [46.7], and some simultaneous tests were done early on. The International Aeronautical Congress in 1902 already proposed formal intercomparisons of different instrumentation [46.49], and the WMO has conducted international radiosonde comparison campaigns since 1950 [46.52] to characterize the differences between instruments. The latest of these intercomparisons took place in 2011 at Yangjiang, China [46.53].

In recent years, research groups have developed homogenized radiosonde temperature datasets for climate research purposes by correcting jumps in time series due to instrumental and other changes, using various homogenization methods (a list of such datasets can be found, e.g., in [46.54] for a list of such datasets). Some of these datasets have been used in global atmospheric reanalysis data sets, which combine global *re-analyzed* observations and a fixed, numerical forecast-assimilation system (e.g., [46.55] for a list of reanalysis data sets). The homogenization efforts benefit from efforts such as GRUAN to characterize measurement uncertainties and to avoid artificial jumps in data records to the extent possible.

In-situ upper-air observations using small and large balloons continue to play an important role in atmospheric research, weather forecasting, and climate change studies. In particular, for small sounding balloons, great emphasis is being placed on how changes in sensor technology, data processing, and operating procedures affect time series of upper-air parameters. Standardization of procedures and a detailed quantification of measurement uncertainty are essential elements in providing in-situ upper-air observations. A detailed understanding of the technology, operational procedures, and how data are used is essential for future progress in this field.

conditions and require that sensors cover a larger range of observed parameters, which creates additional challenges that must be considered in aerological measurements.

Operational stations launch radiosondes on fixed schedules under all weather conditions, which do not pose a safety hazard to the observers and the sounding equipment. Radiosonde stations are located in all cli-

mate zones from the southernmost station at the South Pole to the northernmost at Alert, NU, Canada (83° N). Sounding instrumentation needs to be able to operate in surface temperatures exceeding 30 °C and at the tropical tropopause with temperatures well below –80 °C and needs to provide accurate measurements in very dry and very wet conditions. Radiosondes may be launched in rain or snow and may pass any type of clouds as well as icing conditions within supercooled liquid clouds. In-situ soundings are expected to provide an accurate representation of the atmospheric state across this large range of challenging conditions.

Balloon-borne soundings generally last between 1 and 2 h, and typical sounding instrumentation is rarely exposed to the atmosphere for longer than that. This reduces the need for long-term stability under extreme conditions and relaxes some requirements that may exist for surface-based instruments that may be operated continuously for a long time.

Almost all current balloon-borne sounding systems report measurements once per second. At a typical ascent rate of 5 m s^{–1} this represents a vertical resolution of 5 m. For some parameters, the effective vertical resolution may be less due to a slower response time or the need to filter out unwanted signals.

46.3.1 Temperature

In-situ observations of temperature on sounding balloons use electronic sensors similar to some sensors used for surface-based measurements (Chap. 7). Almost all modern radiosondes use resistive temperature sensors, which can be grouped into two categories: thermistors and wire resistors. Capacitive elements, which until recently had a significant market share, and thermocouples are much less common today.

Thermistors are made of semiconductor material, whose resistance changes strongly with temperature. These sensors are typically manufactured as small beads or disks with diameters down to < 1 mm. The temperature dependence is highly nonlinear, and the resistance of these sensors may increase by two to three orders of magnitude between the temperature at the surface and the coldest temperature near the tropopause.

Resistance wires are most commonly made of platinum, but tungsten wires have also been used for atmospheric observations. The resistance of these materials also depends on temperature; however, the temperature dependence is much weaker and highly linear.

The WMO requires an uncertainty of < 0.4 K at two standard deviations for tropospheric temperature measurements and < 0.8 K for stratospheric temperature measurements > 16 km [46.56]. The Global Climate Observing System [46.57] specifies an uncertainty re-

quirement of 0.5 K at two standard deviations for this Essential Climate Variable (ECV) throughout the entire profile. In addition, GCOS specifies a long-term stability requirement of 0.05 K decade^{–1}. These requirements present some challenge for the calibration of in-situ temperature sensors, which should be calibrated to at least this requirement over the entire temperature range.

The calibration of thermistors is typically based on the *Steinhart–Hart* equation [46.58]

$$\frac{1}{T} = A + B \ln(R) + C [\ln(R)]^3, \quad (46.1)$$

where R is the resistance in Ω at temperature T in K. The coefficients A , B , and C are the Steinhart–Hart coefficients, which are determined during calibration, typically at three calibration temperatures spanning the expected temperature range. Higher-order polynomials of $\ln(R)$ may be added to this equation to reduce the deviation of the fit curve from the true temperature between the calibration temperatures. However, using higher-order polynomials leads to larger calibration fit errors outside the range over which the thermistors were calibrated. Therefore, thermistors should be calibrated over the entire temperature range over which they will be used to achieve the required uncertainty and stability requirements.

Platinum and other wire-resistance temperature sensors have a nearly linear dependence of resistance on temperature and are considered more stable [46.59, 60]. For the calibration, the *Callendar–Van-Dusen* equation [46.61]

$$R(t) = R(0) [1 + At + Bt^2 + C(t - 100)t^3] \quad (46.2)$$

may be sufficient to achieve a better calibration fit over the atmospheric temperature range compared to thermistors. Here, t is temperature in °C and R the resistance in Ω .

Unlike in typical surface measurements, temperature sensors on radiosondes are exposed to solar radiation, leading to heating of the sensor, which increases with decreasing pressure. The balloon ascent provides reliable and measurable ventilation, and highly reflective coatings reduce the sensor heating by sunlight as much as possible (Fig. 46.3). At lower pressures, sensor heating is the most significant source of uncertainty. Solar radiation correction algorithms remove most of this measurement error using the solar elevation angle, the ambient pressure, and the ascent rate of the balloon as input parameters. Currently, no manufacturer provides algorithms that consider cloud cover, surface or cloud albedo, and all algorithms assume a climatological radiation field to estimate the amount of radiative heating

Fig. 46.3 Temperature and humidity sensor of the Vaisala RS41 radiosonde. Note the highly reflective coating of the sensor boom and the temperature sensor to right of the sensor boom

(e.g., [46.62]). Changes in coatings by the manufacturer require changes in the correction algorithm to avoid artificial signals in long-term climate records. Changes in the climatological albedo may also lead to artificial temperature trends, although this effect is generally ignored.

Most modern radiosonde temperature sensors are sufficiently small and at typical balloon rise rates equilibrate with ambient conditions fast enough. At the typical data rate of 1 Hz, a correction for sensor lag may not be needed or may provide only a small correction.

Exposure to moisture inside clouds may cause some temporary bias in atmospheric temperature measurements after a radiosonde exits a cloud. The evaporation of water or ice, which has accumulated around a temperature sensor inside supercooled liquid clouds, will cause evaporative cooling of the temperature sensor and indicate a temperature well below the true atmospheric temperature in the dry layer above the cloud. The bias may be large enough to indicate apparent superadiabatic lapse rates [46.63]. This effect cannot be avoided, but it can be minimized through hydrophobic coatings and by reducing the total surface area around the temperature sensor that may accumulate water or ice. Temperature errors of 2 K or more are possible in layers up to 300 m or more above the top of a cloud [46.53].

The presence of the balloon may also affect the temperature measurement by the radiosonde below the balloon. Solar heating of the balloon can strongly raise the temperature of the lifting gas inside the balloon, while nearly adiabatic expansion without solar heating at night can cool the lifting gas to well below ambient temperature. These effects may create wakes of warmer air during daytime and of colder air during nighttime below the rising balloon [46.59]. The turbulent motion around the balloon may also generate a wake of reduced ventilation. These warm and cold spikes can be detected by fast temperature sensors and may be filtered out by

the radiosonde processing software [46.62]. To minimize these effects, the string separating balloon and radiosonde should be at least 20 m in length in the troposphere and 40 m in the stratosphere [46.56]. Some manufacturers provide unwinder strings longer than the minimum recommended value to reduce the risk of temperature spikes further.

The uncertainty requirements for temperature measurements are a significant challenge, in particular, the stability requirement of $0.05 \text{ K decade}^{-1}$ by GCOS. Small changes in sensor coating and sensor calibration may introduce systematic changes larger than this requirement into the production of radiosondes. Operational procedures such as changes in the length of the unwinder string and changes of the balloon size may induce subtle effects in the temperature spike filter.

46.3.2 Pressure

Radiosonde-based pressure measurements use technologies similar to surface-based pressure measurements (Chap. 10). However, radiosondes require low cost sensors, which are capable of measuring absolute pressure over a range from 1000 hPa at the surface to $< 5 \text{ hPa}$ in the stratosphere. Piezoresistive strain gauges and capacitive sensors are currently the leading technologies for these sensors. Common to all technologies is that they need to be calibrated over the entire pressure range and that they need to operate over a large temperature range.

Operating procedures for Vaisala radiosondes include a one-point recalibration of the pressure sensor prior to launch; all other manufacturers offering pressure sensors rely on their factory calibration.

Geopotential height is calculated from the measurements of pressure, temperature, and humidity using the hypsometric equation (Chaps. 1 and 10)

$$\Delta z = \frac{R_d T_v}{g_0} \ln \left(\frac{P_0}{P_1} \right), \quad (46.3)$$

where Δz is the layer thickness in meters, $R_d = 287.058 \text{ J kg}^{-1} \text{ K}^{-1}$ is the specific gas constant for dry air, T_v is the mean virtual temperature of the layer in kelvin, P_0 and P_1 are the pressure at the base and the top of the layer, and $g_0 = 9.80665 \text{ m s}^{-2}$ is the standard gravitational acceleration. The integration of this equation over the profile of pressure, temperature, and humidity gives the profile of geopotential height. Offset errors in pressure or temperature add to increasing biases in geopotential height. Small pressure offsets are inconsequential for most applications in the troposphere but may lead to significant errors in the calculations of height and mixing ratio of trace gas species

in the stratosphere [46.64–66]. Accurate integration of (46.3) requires small integration steps and, thus, data with high vertical resolution. Large data gaps may cause significant biases for all geopotential heights calculated beyond any data gap.

Recently, many radiosonde manufacturers have been replacing a direct pressure measurement with pressure derived from GNSS height measurements. The basis of this technology is again the hypsometric equation, which can be inverted to

$$P_0 = P_1 \exp \left[-\frac{\Delta z g(z, \varphi)}{R_d T_v} \right]. \quad (46.4)$$

In contrast to (46.3), here, the measured height z is geometric height measured by GNSS, and $g(z, \varphi)$ is the height and latitude dependent gravitational acceleration. Using this equation, the pressure profile can be integrated from a profile of geometric height, temperature, and humidity. However, (46.4) requires that the surface pressure at the launch site is well known, which requires a pressure measurement from an independent surface reference, which must be fed into the sounding system. Errors in the surface pressure mostly affect the tropospheric pressure profile and become small in the stratosphere.

Height errors from GNSS are considered random and may add noise to the calculated pressure profile but do not contribute to any systematic bias. In the lower to middle troposphere, the GNSS-induced pressure noise is typically larger than that from a measured pressure profile, and a possible bias depends on the quality of the reference pressure. In the stratosphere, bias and random noise induced by the GNSS height measurements are less than those from true pressure measurements.

Equation (46.4) makes the implicit assumption of hydrostatic stability. In storms and in strong gravity wave activity, vertical up and downdrafts speeds may reach up to several tens of meters per second. Under these conditions, hydrostatic stability is no longer valid and using (46.4) leads to significant pressure errors.

Currently, the best pressure profile observations rely on a combination of measured pressure in the lower to middle troposphere and GPS derived pressure in the upper troposphere and stratosphere. This combined observation scheme has been employed by GRUAN [46.62].

Uncertainty requirements for pressure provided by the WMO [46.56] range from 2.0 hPa at 1 km (≈ 900 hPa) to 0.1 hPa at 32 km (≈ 10 hPa) at a confidence level of two standard deviations. In the lower troposphere, directly measured pressure by the best radiosondes may achieve these requirements. In the stratosphere, GNSS derived pressures achieve these requirements, if the surface-based reference pressure sensor used in the

initialization of the pressure profile has been properly maintained.

Pressure observations, whether from a pressure sensor or derived from GNSS altitude, are considered fast and in equilibrium with the ambient pressure. No lag correction is applied to pressure measurements; however, smoothing of noise, either from GNSS or pressure sensor noise, may be applied, slightly degrading the effective vertical resolution.

46.3.3 Relative Humidity

All humidity measurements on modern radiosondes use thin-film capacitance sensors [46.53]. Other technologies for humidity measurements that may be found in surface-based measurements (Chap. 8) are not practical or are too expensive for almost all radiosonde applications. The thin-film technology is based on work by *Suntola* [46.67], who first described thin-film capacitive elements with sufficient stability for radiosonde applications. It was first introduced by *Vaisala* in the radiosonde model RS-80 in the 1980s. These sensors make use of the ability of polymer or other materials to absorb water vapor, thereby changing their dielectric constant (Sect. 9.4.3). Polymer materials, such as polyimides or cellulose acetate, are easily manufactured as thin films between permeable electrodes that allow ambient water molecules to move into and out of the material (Fig. 9.9). Thin-film capacitive sensors for radiosondes need to be sufficiently fast to provide good vertical resolution on a rising balloon. They also need to be able to operate over a large temperature range, must be able to operate at saturated conditions as well as very low humidity conditions, and must show minimal hysteresis.

The capacitance of the polymer material changes nearly linearly with ambient relative humidity. However, calibration of the sensor over the entire humidity and temperature range is required for high-accuracy measurements on radiosondes.

While the basic principle is the same for all manufacturers, sensors differ by a number of characteristics. Thinner polymer films allow faster measurements but also allow stronger calibration drifts and require better electronics to measure lower capacitance values. Some materials are less susceptible to contamination by other gases, in particular volatile organic compounds, but are also less sensitive to water vapor. Production processes in the manufacturing of the devices play an important role in maintaining stable and consistent response. The choice of polymer material influences the hysteresis that a sensor exhibits. The best humidity sensors currently in use on radiosondes show a hysteresis of significantly less than $\pm 1\%$ RH.

Fig. 46.4 Humidity sensor of the Chang Feng CF-06-A radiosonde underneath its protective cap

Older technologies, such as carbon hygriators, may still be found in some national radiosonde networks and are mentioned here just for completeness. These technologies are inferior to thin-film capacitance sensors and are not discussed further.

Historically, icing of humidity sensors has been a significant issue. Icing may occur in supercooled liquid clouds and even in colder ice clouds. If significant amounts of ice accumulate around the humidity sensor, it may lose exposure to the atmosphere and no longer report accurate humidities. This condition may last until most of the accumulated ice on the sensor has evaporated above the cloud layer and may lead to considerable parts of the profile, where artificially high humidity readings are reported.

For accurate measurements, most humidity sensors require that the sensor be in thermal equilibrium with the atmosphere or that the temperature of the sensor is measured. Sensors that are warmer than their surroundings report low biased relative humidity readings, if their temperature is assumed to be ambient. In typical radiosonde applications, most humidity sensors are protected by a highly reflective cap to minimize solar heating of the sensor (Fig. 46.4).

Furthermore, this cap reduces the risk of icing of the sensing element but also reduces ventilation around the sensor, which may not be desired.

Some manufacturers have included heating elements in the humidity sensors that prevent or at least minimize icing of the sensor. The older Vaisala RS92 radiosonde employed a pair of humidity sensing elements, in which one element was set to measurement mode, while the other was in heating mode. At regular intervals, the elements were switched, which provided one continuous humidity profile and minimized the risk for icing and contamination. Since both sensing elements were exposed to solar radiation, this sensor design suffered a significant dry bias [46.68], which required an empirical correction.

Several newer humidity sensors also include a temperature sensor in the humidity-sensing element

Fig. 46.5 Heated humidity sensor of the Internet iMet-54 radiosonde showing the polymer film and electrodes in the center, surrounded by a heater coil/temperature sensor

(Fig. 46.5). This allows simultaneous active heating and measurement of the humidity sensor temperature. Raw humidity readings are reported at sensor temperature and are corrected for the difference between sensor temperature and air temperature in signal processing using

$$R_{\text{ambient}} = R_{\text{Sensor}} \frac{E_w(t_{\text{sensor}})}{E_w(t_{\text{ambient}})}, \quad (46.5)$$

where R_{ambient} is the ambient relative humidity of the surrounding air at the ambient temperature t_{ambient} , and R_{sensor} is the relative humidity measured by the sensor at the elevated sensor temperature t_{sensor} ; E_w is the saturation vapor pressure equation over liquid water (46.6).

Measurement errors in heated sensors are amplified by the ratio of the vapor pressures in (46.5). This requires a compromise between the benefits of sensor heating and limiting additional measurement errors. For well-calibrated temperature sensors, this can be done without significantly compromising the overall measurement uncertainty. The inclusion of a temperature measurement in the humidity element, furthermore, eliminates the need for a protective cap, since solar heating no longer represents a problem for the actively heated sensor.

The response time of thin-film humidity sensors is highly temperature dependent. Sensors for radiosondes may have response times $\ll 1$ s at 20°C but > 60 s at -60°C . Some manufacturers correct the slow sensor response using specialized time-lag algorithms (e.g., [46.53, 62]). Especially at low temperatures, this correction improves the representation of the atmospheric humidity profile. Unfortunately, the time-lag correction also amplifies noise in the raw signal, which must be filtered before correction. This reduces the effective vertical resolution of humidity measurements especially at cold temperatures.

Contamination by other gases, in particular volatile organic compounds, may interfere with the absorption of water vapor into the polymer material and permanently change the calibration of the sensor. Therefore, exposure of the sensor to contaminants should be min-

imized during storage. Sensors with integrated heating elements may be capable of driving off contaminants by applying high amounts of heat for some time and thereby restoring the original calibration.

Operational uncertainty requirements for humidity range from 6% RH above -50°C to 10% RH below that. Uncertainty requirements for climate are more stringent with 5% of a reading (not 5% RH) and a stability of $0.3\% \text{ decade}^{-1}$ [46.57]. The operational uncertainties may be met by some manufacturers using modern thin-film sensors; however, the more demanding uncertainty requirement for climate may require improvements in sensor technology and operational procedures.

Some of the best performing sensors report reliable humidity values well below -60°C . By convention, relative humidity is reported as relative humidity over liquid water at all temperatures, extending to very cold temperatures, where liquid water no longer exists. This may cause confusion for the conversion of relative humidity to other measures of water vapor (e.g., mixing ratio), which make use of the saturation vapor pressure equation. Different formulas for saturation vapor pressure over liquid water are in use, which may lead to significantly different results at cold temperatures. At -60°C , different vapor pressure equations may differ by as much as 10% and at -80°C by more than 20%, which exceeds the stated uncertainty of some of these sensors (see [46.69] and [46.53] for more details).

The proper solution to this challenge would be to use the same saturation vapor pressure equation that the manufacturer used in the calibration of their sensors. However, this information is usually not available, and some manufacturers may not share calibration details. Nash et al. [46.53] recommended three formulations: Wexler [46.70], Hyland and Wexler [46.71], and Sonntag [46.72]. These three formulations agree with each other to within less than 0.5% over the entire atmospheric temperature range. Preference may be given to the formulation by Sonntag [46.72], which is based on the ITS90 temperature scale and given in (46.6),

$$\begin{aligned} \ln(E_w(T)) = & -6096.9385T^{-1} + 16.635794 \\ & - 2.711193 \times 10^{-2}T \\ & + 1.673952 \times 10^{-5}T^2 \\ & + 2.433502 \ln(T), \end{aligned} \quad (46.6)$$

where T is in K and E_w is the water vapor pressure over liquid water in hPa. The range of validity for this formula is given as $173.15 \leq T \leq 373.15 \text{ K}$.

The Magnus formula [46.56, Annex 4.B, Eq. 4.B.1], which is also referenced in Chap. 8, should not be used for radiosonde applications at temperatures colder than -45°C , since the difference to the equations used by

most manufacturers increases rapidly below that temperature.

46.3.4 Winds

The horizontal motion of a rising balloon is a direct indication of horizontal wind speed and direction. The balloon ascent rate is considered slow enough so that the inertia of the balloon train in wind shear can be neglected. Most current radiosonde systems track the payload motion using GNSS. Tracking through radio theodolites and active radar tracking is currently done only in Russia and China.

The implementation of GNSS winds may differ between different manufacturers. Modern GNSS receivers are capable of calculating and reporting winds independent of position. Some systems may simply report position and calculate winds as its derivative.

The use of differential GNSS, where GNSS signals are received both by the ground station and by the radiosonde, allows reducing some errors related to GNSS positioning and thereby improving wind and position estimates. This technology is implemented by some systems.

Since position and wind are measured by the radiosonde itself, these measurements include the pendulum motion of the radiosonde underneath the balloon. This pendulum motion needs to be filtered from the data using appropriate filters in processing on the ground. Manufacturers need to take great care to filter only the pendulum motion and not to smooth the wind profile excessively. A typical unwinder length is 30 m, which would allow a pendulum period of $\approx 11 \text{ s}$. Immediately after launch, however, the pendulum period is much shorter and changes quickly as the unwinder releases the string, forcing swinging of the sonde underneath the balloon. These launch-induced sonde oscillations may take 1 min or more to dampen. At a typical ascent rate of 5 m s^{-1} , the balloon reaches an altitude of 300 m. This implies that wind measurements with an unwinder in the lowest few hundred m of the profile may have only poor vertical resolution and may not represent the wind gradients near the surface well.

Almost all GNSS wind-finding radiosondes specify uncertainties of $< 0.5 \text{ m s}^{-1}$ for wind speed and 2° for wind direction, which meets the requirements for GCOS essential climate variables and for WMO operational observations [46.56, 57]. Aside from GNSS for measurements of wind, two older systems are still in use to measure the track of the balloon: radio-theodolites and radar.

Radio theodolites or radio direction finders (RDF) only track the azimuth and elevation angle from which the transmitter signal is received. With height from

a pressure measurement onboard the radiosonde, the horizontal position can be derived. Uncertainties and biases in the pressure measurements may lead to errors in position, especially at low elevation angles, and may cause significant errors in the determination of winds.

Radar as a wind finding method uses a ground-based radar to track the radar reflection off a dedicated radar reflector, which may be part of the parachute. Radar measurements provide the azimuth and elevation angles, as well as the distance of a balloon, from which horizontal position and height can be derived. In radar and radio-theodolite tracking, wind speed and direction are simply calculated as the change in position.

Russian and Chinese radiosondes utilize a radar-transponder combination (secondary radar), in which the radar signal is received by the sonde, which, in turn, sends out its own data in reply. Radio direction finding provides azimuth and angle, while the radar return provides the distance and meteorological parameters. Russian radiosondes do not carry pressure sensors but calculate the pressure from the hypsometric equation using radar heights as input.

Early radiosondes including GNSS were significantly more expensive than those without, providing a significant cost advantage for these secondary wind-finding systems. In modern radiosondes, the cost of GNSS receivers has decreased dramatically, and only some national manufacturers produce sondes without GNSS receivers. Both Russia and China have started a transition to GNSS-based radiosondes, but GNSS-based radiosondes were not yet operational in either country in 2018.

Radar tracking and radio theodolites require a high level of maintenance of the ground equipment and regular calibration of the direction finding. Poor main-

tenance and calibration errors may lead to significant errors in wind and height measurements. Furthermore, the temporal resolution of wind measurements is limited. Uncertainties in wind speed and direction are considered significantly larger compared to those from GNSS measured winds.

Profiles of wind speed and direction may also be observed by tracking pilot balloons (pibals), which carry only a transmitter or no instrumentation at all. These balloons may be followed by a radio theodolite or an optical theodolite, where azimuth and elevation angle are recorded at regular intervals. Although height is not measured, it may be estimated by assuming a suitable ascent rate of the balloon [46.73] and recording the time of the measurements. Uncertainties in the height of the measurement and in calculated wind increase with altitude as the height errors compound. However, the simplicity and low cost of this method makes it attractive for some applications.

Since the southernmost sounding station is at the South Pole, reporting wind directions at that site and, in fact close to both poles, requires a special convention. At both poles the conventional wind directions are not defined, which would cause problems in the reports of wind direction. By historical agreement, wind directions within 1° of the poles are reported with respect to *grid north*, which is an artificial convention that defines the direction *north* on the azimuth ring as the direction of the 0° Greenwich meridian, *south* as the opposite direction, i.e., of the 180° meridian, *east* as the 90° meridian, and *west* as the 270° meridian. Upper-air wind directions measured by soundings should be reported using this convention, as long as the launch site is within 1° of the poles, even if the balloon travels outside of this circle [46.56].

46.4 Devices and Systems

Aerological sensors are not only installed in radiosondes but also in dropsondes, which are deployed from aircraft, in tethered systems, and more recently, in unmanned aircraft systems (UAS). A reliable balloon technology is an essential component in aerological measurements up to the middle stratosphere. Standardized data formats underpin the widespread exchange of aerological observations and are often overlooked.

46.4.1 Radiosondes

Currently, there are more than 20 radiosonde manufacturers worldwide, some with many decades of experience, and some that were established relatively

recently. Table 46.3 lists manufacturers, countries of origin, the current radiosonde model(s), and the technology to measure temperature, humidity, pressure, and wind. There may be more radiosonde manufacturers producing radiosondes, and Table 46.3 may not be complete, since information from some countries is difficult to collect or may not be shared with the WMO. Some manufacturers offer variants of their radiosondes with different transmission frequencies, optional sensors, and other modifications, which are too numerous to list here. Previous models, which are no longer produced, or which are currently being phased out, are also omitted. As example, three modern radiosondes are shown in Fig. 46.6. The last formal WMO

radiosonde intercomparison took place at Yangjiang, China [46.53]. Most radiosonde models that participated in that campaign are no longer produced and have been replaced by newer models using more recent technology. This level of movement in the radiosonde

market highlights the need for regular intercomparisons as well as standardized procedures of observation. The report by [46.52] and the references therein provide an overview of formal intercomparisons preceding the Yangjiang campaign. Comparisons of different sonde

types are being conducted by a number of research groups for different purposes ([46.74–77]).

In both China and Russia, radiosondes are produced for the specific needs of the respective National Hydro-Meteorological Service (NHMS) and used only there. In each country, very similar radiosondes are produced under the same product code by different manufacturers. In Russia, radiosondes use secondary radar tracking for winds and pressure. In China, radiosondes use secondary radar only for winds, while the pressure is measured with a dedicated pressure sensor. In both countries, sensors may change without notice, hindering traceability and making identification of sondes by the numerical forecast centers difficult.

The recent trend is not to equip the radiosonde with a dedicated pressure sensor but to use GNSS geometric height measurements to calculate pressure and geopotential height data. Due to the large pressure range, small solid-state sensors may have significant biases in the stratosphere, while the GNSS method gives much better pressure and geopotential height data in this altitude region. However, in the lower troposphere, in-situ measured pressure may have lower uncertainties compared to the GNSS calculated pressure. For that reason, a number of manufacturers offer radiosondes with optional pressure sensors for customers who require the higher accuracy levels. In addition, using radiosondes with pressure sensor relaxes the need for an independent surface pressure measurement needed to initialize the GNSS pressure calculation and, thereby, relaxes operational requirements. For the most accurate measurements, the pressure sensor is typically recalibrated prior to launch using an external reference pressure sensor.

Radiosondes operate in two frequency bands allocated for meteorological applications: 400.15–406.0 MHz and 1675–1695 MHz. The majority of, but not all, GNSS tracking radiosondes operate in the 400 MHz band; almost all secondary radar systems operate in the 1680 MHz band. These frequencies are among the essential wavelength bands reserved for meteorological applications.

Currently, three different temperature sensor types can be found in operational radiosondes. Most radiosonde manufacturers use small bead or disk thermistors. These may differ slightly in size, but are all considered reasonably fast for atmospheric soundings. Most Chinese and some Russian sondes still use a rod thermistor (see [46.78] for details on this sensor), which is considerably slower and may require a time-lag correction in processing. Vaisala uses a platinum resistance wire with a response time comparable to that of bead and disk thermistors. Since radiosonde temperature sensors are completely exposed, the level of solar

shortwave heating and atmospheric long-wave heating/cooling of the sensor is determined by sensor size and by the reflective coating that the manufacturers apply to the sensors. Smaller sensors and highly reflective coatings minimize radiative heating biases but cannot eliminate them. The WMO [46.56] recommends that the coating be a metallic coating that is reflective also in the infrared range. Some manufacturers still use white-painted sensors, which have a significant radiative cold bias at night due to their high infrared emissivity. The coating of the temperature sensor and sensor boom should also be hydrophobic to minimize evaporative cooling errors after passage through wet clouds. Little information is available from the manufacturers regarding their coatings, often due to its proprietary nature. The effectiveness of these coatings is evaluated during formal intercomparisons. Some efforts have been undertaken to quantify the influence of radiation on radiosonde temperature measurements using multiple thermistors with different coatings [46.79]; however, these efforts have not found widespread use.

Almost all humidity sensors are based on the thin-film technology. However, there are significant differences between the different sensors. Vaisala and Meisei manufacture their own sensors, while all other companies use various third-party sensors. Currently, only Vaisala and Internet Africa use humidity sensors that are heated. The temperature range over which humidity sensors operate varies significantly between the different radiosonde manufacturers. Some manufacturers have implemented a time-lag correction algorithm into the processing software to correct for the slow response time of polymer thin-film sensors at cold temperatures.

Russia and China have started evaluating GNSS-based radiosondes, but as of 2018, secondary-radar tracking remains the dominant wind-finding method for these countries.

Most modern radiosondes require communication with the ground system during sounding preparation to exchange calibration information, to set the transmitter frequency, and to perform some instrument checks and calibrations prior to launch. This communication may be done through serial cable and increasingly wirelessly through near field communication.

46.4.2 Dropsondes

Targeted in-situ observations for specific meteorological conditions, especially in remote locations such as in tropical storms over oceans, are taken using small instruments that are dropped from research aircraft. Dropsondes (historically also called dropwindsonde or dropwinsonde) measure the same parameters as radiosondes using very similar technology. An overview

Table 46.4 List of dropsonde manufacturers

Manufacturer	Dropsonde model(s) (sounding system)	Country
Vaisala/NCAR	RD41, NRD41 (AVAPS)	USA
KIT	KIT-Sonde	Germany
Meisei	iMDS-17	Japan
Modem	Dropsonde	France
Yankee	XDD (HDSS)	USA

of dropsonde manufacturers is shown in Table 46.4. Dropsonde systems are installed on aircraft of more than 12 research organizations worldwide, including aircraft such as the US Air Force WC-130J and NOAA WP-3D hurricane hunters, the NASA RQ-4 Global Hawk high-altitude UAS, or the NCAR G-V research aircraft, among others.

Airborne Vertical Atmospheric Profiling System (AVAPS[®]) dropsondes have been developed by NCAR, based on their work dating back to the 1960s [46.32]. These sondes have been licensed to Vaisala, who market these to the meteorological community. These sondes are the most widely used dropsondes and are deployed operationally for hurricane and severe weather forecast,

**Fig. 46.7** Image of the NCAR NRD41 dropsonde

in US university and government supported research and internationally for typhoon research and meteorological research. Currently, two versions of this sonde exist, which differ largely only in their geometry to fit two different launch systems. Both sondes use the Vaisala RS41 sensor module but a special GPS module for high-resolution wind measurements. The RD41 uses a launch system dating back to the 1980s, while the newer NRD41 (Fig. 46.7) is about half the weight and about half the diameter. This sonde had been developed for remote controlled release onboard the NASA Global Hawk but may be used also on the NCAR G-V, NCAR C-130, NOAA G-IV, and NOAA WP-3 aircraft. The automated launch system for the NASA Global Hawk is shown in Fig. 46.8.

The KIT-sonde was developed by the Karlsruhe Institute of Technology (KIT), Germany, based on the Graw DFM-09 radiosonde [46.80]. This dropsonde consists of four sondes, which separate after release to provide higher spatial coverage than regular dropsondes. KIT-sondes have been tested on the German DLR HALO G-V aircraft and the Dornier Do 128 of the Technical University Braunschweig, Germany.

Meisei developed the iMDS-17, which is currently deployed from a Diamond Air Service (DAS) Gulfstream-II aircraft for typhoon research [46.81].

**Fig. 46.8** NCAR-AVAPS automated dropsonde launch system for the Global Hawk UAS (NASA photo/Tony Landis)

Modem [46.82] has developed a dropsonde based on their M10 radiosonde model, which has not yet seen wider use.

Yankee [46.83] has developed the Expendable Digital Dropsonde (XDD) for their High-Definition Sounding System (HDSS). These dropsondes have been deployed from the Center for Interdisciplinary Remotely Piloted Aircraft Studies (CIRPAS) Twin Otter, the NASA DC-8, and the NASA WB-57 high-altitude aircraft.

Despite their similarity, there are some significant differences to radiosondes. Dropsondes need to be mechanically robust, since they experience a strong mechanical shock when they are deployed out of aircraft at speeds of up to 200 m s^{-1} . This represents a significant challenge for small lightweight sensors. Their descent is typically slowed using small parachutes or special geometries that increase their drag. Fall rates typically range between 25 m s^{-1} at 14 km altitude and 10 m s^{-1} near the surface. Although dropsondes may report at data rates of 2 Hz or higher, the lag of the sensors at the higher vertical speeds compared to radiosondes is significant. Some algorithms dedicated to dropsondes have been implemented in the processing of these data to remove response lag artifacts in temperature, humidity, and winds (e.g., [46.84]). In particular, humidity measurements are subject to significant response lag due to the considerable time constants at cold temperatures and faster vertical speed of dropsondes compared to radiosondes.

Many dropsonde applications require a higher spatial and temporal coverage of observations. This requires that dropsonde systems be capable of receiving multiple sondes simultaneously. AVAPS systems allow up to 8 simultaneous sondes and HDSS allows up to 40 simultaneous sondes.

The geopotential height for dropsondes using (46.3) may be calculated downward using aircraft observations to initialize the integration. The geopotential height may also be calculated upward using the last dropsonde observations before landing for initialization. Downward integration is less desirable, because uncertainties in aircraft pressure, temperature, and altitude, and less reliable dropsonde data immediately after deployment may lead to significant height uncertainties in the profile. Upward integration may be preferable, as long as telemetry data have been received up to the landing of the sonde. In severe weather such as hurricanes, this may not always be the case.

Unlike radiosondes, dropsondes do not suffer much from sensor icing. This is largely due to the fact that dropsondes fall from colder into warmer regions and into temperatures above freezing, where any accumulated ice will melt and be blown off by the airflow.

Furthermore, dropsondes fall through critical regions faster, exposing them to icing conditions for less time. Properly coated temperature sensors are unlikely to be subject to evaporative cooling after exiting clouds.

Dropsondes, which mostly use temperature sensors based on operational radiosonde models, are less likely to be subject to radiative heating temperature biases. The downward pointing of the sensors with the main sonde body above and shading by parts of the dropsonde lead to a smaller actinic flux compared to radiosondes where the sensor is fully exposed. The two to four times faster vertical speed provides much stronger ventilation of the sensor, and the highly reflective coating reduces the heat absorption of the temperature sensor. When these factors are combined, radiative heating of the temperature sensor is considered negligible for dropsondes.

Air-traffic control regulations may lead to some operational limitations for the deployment of dropsondes. While observations within hurricanes encounter few conflicts with other aircraft, observations of winter storms over the Atlantic generally require close air-traffic coordination due to the proximity of the North Atlantic flight corridors between Europe and North America. Dropsonde releases over land may be possible but are more restricted than releases over remote oceans.

46.4.3 Tethered Sondes

Observations on tethered balloons and kites were made at the very beginning of upper-air observations. This technology is still in use today, although almost exclusively for focused research projects and no longer for routine observations. The most significant limitation for tethered platforms lies in their inherent danger for aviation, which limits these platforms generally to low altitudes within the boundary layer and to restricted or closely controlled airspaces.

Tethered systems consist of a winch, a tether, and a balloon. The winch has to be strong enough to be able to reel in the balloon or kite even under significant wind load. The winch has to coil the tether in a safe fashion, such that the tension on the tether due to buoyancy and wind load does not damage the tether on the spool. The tether has to have a high tensile strength and must not break even under excess load. The load on the tether needs to be monitored during operation to avoid breakage of the tether. Unlike sounding balloons, tether balloons are typically not made out of natural rubber but out of a number of different materials and fabrics, which are coated for gas tightness, weather resistance, and other purposes. Many tether systems are equipped with an automatic rapid deflation device, which activates if the balloon escapes its tether. Tether balloon operations are generally not allowed close to cloud base

or inside clouds and are usually restricted in height. Flying in special-use airspaces may allow operation of tether systems outside of these limitations. Balloons for tethered operations may have special shapes (blimp, helikite, and others) to maintain their orientation into the wind and possibly to provide additional lift. Operators are required to monitor the atmospheric conditions constantly to be able to bring a tethered balloon back to the ground if atmospheric conditions change such that the operation is no longer safe for the balloon or the operators on the ground. Different types of balloons have different surface wind limits under which they can be launched.

The most common use of tethered systems is for observations in the lower troposphere and boundary layer, rarely exceeding 1 km above the surface. These systems allow placing sensors at relatively fixed heights for extended periods and allow observing changes in atmospheric conditions over hours to days. Sensors may include typical radiosondes, turbulence probes, particle instruments, radiation sensors, icing sensors, chemical sensors for air pollution, and others. Wind measurements require lightweight anemometers, typical cup anemometers and wind vanes for direction, or sonic anemometers (Chap. 9), which have to be corrected for the movement of the balloon. Tethered balloons may also be used to lift one end of optical fibers as part of the distributed temperature sensing (DTS; Chap. 20; [46.85]) to measure continuous vertical profiles of air temperature.

Raising and lowering tethered balloons at regular intervals provides vertical profiles of the measured parameters. Winch speeds are typically less than $0.5\text{--}1.0\text{ m s}^{-1}$, allowing high-resolution profiles of the parameters measured.

Sensor ventilation may vary significantly over the range of operating conditions. Therefore, the influence of solar heating and of nearby heat sources needs to be carefully analyzed and corrected. Since the sensors may remain at a constant altitude and, therefore, at near constant conditions for an extended amount of time, icing, rain, and the accumulation of pollutants may interfere with the measurements. Data need to be carefully screened for these artifacts.

Kite observations ended largely with the introduction of radiosondes into the operational network. Some research on kite technology has taken place since then [46.86]; however, few if any research projects currently use kites for atmospheric science.

46.4.4 Balloons

Modern meteorological balloons are made of thin rubber, and their size is conventionally expressed by their

Fig. 46.9 Balloon inflation building (*right*) and hydrogen room (*left*) at the sounding station at Yangjiang China

mass in grams. For single radiosonde soundings, balloons between 100 and 600 g are typically used, depending on the desired ceiling height of the profile (e.g., 18 or 32 km, respectively). For soundings with slightly larger payloads, such as ozonesondes, frostpoint hygrometers, and other scientific instrumentations (Sect. 46.8.2), 1000, 1200 g, or larger balloons may be used to reach altitudes ≈ 32 km. Larger balloons can lift heavier payloads and may reach higher altitudes but use larger amounts of fill gas. The volume of the balloon expands during its ascent into lower pressures, up to points where the rubber envelope is stretched to its maximum, and where the balloon finally bursts (see [46.87] for an image of a bursting balloon at the DWD Observatory Lindenberg and GRUAN Lead Center). After bursting the remains of the balloon and the payload fall back into the lower atmosphere and the surface. Equipping the payload with a parachute, which is usually attached below the balloon but in some cases may already be provided inside the balloon by the balloon manufacturer, substantially reduces the fall speed and risk of damage on the ground and may be required by national code to achieve fall rates near the surface of 6 m s^{-1} or less [46.56].

Meteorological balloons are filled with either hydrogen or helium. Most operational stations use a special building with one or several large doors (Fig. 46.9) for inflation; some operations inflate balloons in an open space outside. Although pure methane produces some lift as well, it is not sufficient to reach higher altitudes. Handling these gases requires diligent safety precautions, and improper handling may result in injury or even death. The WMO [46.56] provides a more detailed discussion of gas handling and balloon inflation-related safety topics than can be provided here.

Helium and hydrogen gas can be provided to most stations in high-pressure gas cylinders. A pressure regulator gauge should be used when a balloon is inflated.

Table 46.5 Typical balloon performance

Balloon weight (g)	100	200	350	600	1000	1500
Payload weight (g)	100	250	250	250	250	1000
Free lift (g)	500	500	600	900	1100	1300
Gas volume (m ³)	0.67	0.91	1.15	1.68	2.26	3.65
Rate of ascent (m min ⁻¹)	250	300	300	300	300	300
Maximum height (km)	18	21	26	31	34	34

Helium is inherently safer than hydrogen, since it is an inert gas and will not combust. However, pure helium gas should not be breathed in because of the risk of suffocation due to the lack of oxygen, which requires some safety measures for inflation in closed shelters.

Hydrogen gas is significantly cheaper but forms explosive mixtures with air. Static electricity and any open flame must strictly be avoided during balloon inflation and handling of the inflated balloon. Some stations, where delivery of gas cylinder is not feasible, generate hydrogen on site using dedicated hydrogen-generation systems usually based either on the electrolysis of water or using a number of chemical systems.

The appropriate amount of gas depends on the mass of balloon and payload and on the target ascent rate (typically ≈ 300 m min⁻¹ or 5 m s⁻¹). The gross lift L_g expressed in grams is

$$L_g = m_b + m_p + L_f, \quad (46.7)$$

where m_b is the mass of the balloon, m_p is the mass of the payload (including instrument(s), unwinder, and parachute), and L_f is the free lift.

A number of studies exist to estimate the balloon ascent rate based on balloon size, payload weight, and other parameters [46.88, 89]. The ascent rate also depends on the balloon manufacturer, the balloon shape, the drag coefficient, and in parts also on the atmospheric temperature profile. Therefore, it is difficult to provide exact equations for the relationship between the free lift and the desired ascent rate. An approximate empirical relationship [46.56] between the ascent rate v in m min⁻¹, free lift L_f , and gross lift L_g (both in g) can be given as

$$v = k \frac{\sqrt{L_f}}{\sqrt[3]{L_g}}. \quad (46.8)$$

Here, k is a factor depending on the balloon manufacturer and on balloon types (size and color) and may be approximately in the range between 130 and 150. In practice, the actual set of L_f , L_g , and v is obtained empirically by test launches for a specific set of balloon type and payload weight at a particular station.

Some stations measure the amount of fill gas not by the nozzle lift but by the volume of gas used to fill the

balloon. Assuming that the gross lift is due to hydrogen or helium in a pressure-dependent volume V throughout the sounding ascent, we obtain the following relationship between the gas volume V and the gross lift L_g

$$V = \beta L_g, \quad (46.9)$$

and

$$\beta = \frac{1}{M_{\text{air}} - M_{\text{gas}}} \frac{RT}{P}, \quad (46.10)$$

where M_{air} is the molar mass of air (29×10^{-3} kg mol⁻¹), M_{gas} is the molar mass of the fill gas (2.0×10^{-3} kg mol⁻¹ for hydrogen and 4.0×10^{-3} kg mol⁻¹ for helium), R is the molar gas constant (8.3 J K⁻¹ mol⁻¹), T is the temperature in K, and P is the pressure in Pa. With $T = 288$ K and $P = 1000$ hPa, the factor β becomes 0.89 m³ kg⁻¹ for hydrogen and 0.96 m³ kg⁻¹ for helium. Since industrial gases are typically not pure gases and contain small amounts of air, this factor is typically slightly larger than the values given here.

Typical balloon performance values for different balloon sizes and payloads are given in Table 46.5. Larger balloons for the same payload size will reach higher ceiling altitudes. Increasing the free lift and gas volume for the same balloon and payload will increase the ascent rate and decrease the ceiling height. These parameters may be adjusted for specific performance and operational requirements. Larger balloons for radiosondes are used to observe higher into the stratosphere. GUAN typically uses 600 or 1000 g balloons to reach well > 30 km.

In very cold environments, especially in the dark polar winter stratosphere and the nighttime tropical tropopause region, the balloon rubber may change to a glassy state through a glass transition (e.g., [46.90]), resulting in a much higher risk of early balloon burst. During normal soundings, the generally warmer balloon gas and solar heating during daytime flights keep the rubber above this transition point. Some balloon manufacturers offer special models with a different mixture of rubber materials for extremely cold temperatures, likely using a material with a lower glass-transition temperature.

Some polar stations use regular soundings balloons during winter that are treated with kerosene prior to launch. This method has also been used in tropical soundings at night by the Sounding of Ozone and Water in the Equatorial Region (SOWER; e.g., [46.91]). In this treatment, the balloon is dipped into a bucket of kerosene, which is absorbed into the rubber, and then hung on a laundry pole to dry before inflating the balloon. It is speculated that the chemical bonds between rubber molecules are modified such that the glass transition is delayed. However, the treatment may also start to break down the balloon material, such that many hours after the kerosene treatment, balloons are considered degraded and may not be useful for any sounding. Diesel or gasoline fuel, instead of kerosene, may also work. For example, during some SOWER tropical campaigns and at Syowa, Antarctica, kerosene has been used, while at the AWIPEV Arctic Research Base at Ny Ålesund, Svalbard, a mixture of 40% diesel, 40% kerosene, and 20% motor oil has been used.

In addition to the kerosene treatment, stations such as Ny Ålesund and Lindenberg, Germany, store balloons in a warm storage (55–60°C) for hours to days, which makes the balloons softer and more flexible. After being taken out of storage, the balloons are inflated and flown immediately.

Plastic balloons (Fig. 46.10) are a completely different type of balloon, and are generally used for much larger payloads than radiosondes. However, these shall be mentioned here as well, since at the South Pole, plastic balloons are also used for meteorological soundings, in particular for ozone soundings. Plastic balloons are made of thin inelastic polyethylene film. Unlike rubber balloons, whose size is given as the weight of the balloon, plastic balloon sizes are given by their volume at complete inflation, which they reach at their target al-

Fig. 46.10 Plastic balloon launch at McMurdo, Antarctica

titude. At inflation, the fill gas takes up only a small fraction of the available volume, leading to the typical teardrop shape at launch. The material does not stretch and withstands all atmospheric temperatures. Plastic balloons are used for reliable stratospheric observations, for long duration flights lasting from many hours to many months (Sect. 46.9), and for lifting heavy payloads up to a few tons.

Small plastic sounding balloons are typically over-inflated, such that the balloon breaks due to overpressure when reaching the ceiling altitude. Larger balloons are equipped with pressure control and pressure relief devices, which actively control the balloon behavior. Due to their high cost, plastic sounding balloons are only used in special situations, such as the investigation of the Antarctic ozone hole.

46.4.5 Autolaunching Systems

In recent years, some stations have deployed autolaunching systems for radiosondes to reduce personnel expenses. Different manufacturers are providing different models, but in general, the systems are similar. A small compartment inside a container is used to load radiosondes, balloons, and unwinders into a moving system of trays. These trays contain the communication hardware between sonde and main computer, as well as the inflation hardware. Once the balloons, radiosondes, and filling gas are situated within the system, all procedures (ground check, gas filling, launch, data acquisition, and data transmission) happen automatically at a preprogrammed schedule or may be initiated through remote control. At the scheduled launch time, the trays transport radiosonde and balloon to the filling section of the autolaunching system, which may be inside the main container or outside. Balloons are inflated using a prescribed amount of gas. When the balloon is ready, a retractable roof or cover is opened to release the balloon. Depending on the model, between 12 and 60 sets of radiosondes and balloons can be loaded at once. At stations with twice-daily soundings, these systems require service visits to refill sondes and balloons at schedules between once per week and once every four weeks. Automation may be an important step for the future of aerological measurements, but some questions need to be investigated carefully. The data quality for radiosondes from autolauncher systems, including balloon burst height statistics, should be comparable to that for manual launches. If not, further system improvements need to be considered. For example, if autolaunches under strong surface wind conditions tend to be unsuccessful, the obtained data records may have biases compared to the manual-launch data records. Maintenance costs need to be carefully monitored be-

cause the system is much more complicated than that for manual launches, and additional maintenance costs may be required. A number of issues may be aggravated in autolaunching systems, such as corrosion in coastal and small-island stations, insects in stations near forests and wetlands, or prolonged open storage of the balloon inside the launcher, which may lead to early balloon burst. Other site-specific issues may negatively affect the overall performance of a site and require changes in setup or additional maintenance. Furthermore, if an autolaunch system stops functioning, no sonde releases are possible at a site, until a service technician addresses the problem, which lowers the availability of upper-air data, in particular under bad weather conditions, when issues are more likely to occur.

46.4.6 Data Transmission and Formats

Radiosonde and dropsonde observations are heavily used in near real-time weather forecasting and weather advisories. Observations are distributed to the national meteorological centers (NMC) through the WMO Global Telecommunication System (GTS). Data sent through this network are highly regulated and require adherence to strict formatting requirements.

In-situ sounding profile data are mainly sent in two different format conventions [46.92]. The WMO [46.93] defines coded messages for meteorological data and other geophysical data relating to meteorology, which are transmitted through the GTS. For radiosondes and dropsondes, alphanumeric code forms have been defined: FM-35 TEMP (fixed land-based station), FM-36 TEMP SHIP (ship-based station), FM-37 TEMP DROP (dropsonde released from carrier balloon or aircraft), and FM-38 TEMP MOBIL (mobile land-based station). The origin of these messages dates back to the late 1940s, when compact data formats were a necessity and, therefore, they contain highly compressed data with limited vertical resolution and a minimal set of metadata. Modern computer and communication systems are capable of handling much larger data files, and alphanumeric code messages are currently being phased out.

46.5 Specifications

Accuracy specifications by the manufacturers cover a large range of observed conditions and do not necessarily meet the requirements by all user communities.

Uncertainties of upper-air measurements are influenced not just by the performance of the sensor but also by how well environmental influences, foremost solar radiation, are minimized through appropriate coatings and correction in postprocessing algorithms. Most

To meet the need for more comprehensive representation of observations, in 2005 the WMO decided to migrate from the traditional alphanumeric code (TAC) forms to table-driven code forms (TDCF) using the binary universal form for the representation of meteorological data (BUFR) format, a process which has not yet been completed. For radiosonde and dropsonde observations, the BUFR format allows storing observations up to 1 s resolution, including location and time information with each data point, and adding significantly more metadata, which may be used in the interpretation of the observations. At present, both formats, TAC and TDCF, are still in widespread use. Templates have been defined for both radiosonde data [46.94] and dropsonde data [46.95]. These templates describe the exact content that radiosonde and dropsonde data files in BUFR format should contain. Both formats were defined by the meteorological community, but only few software tools exist in the general research community to work with the BUFR format. This is likely to change as more software tools become available, such as those developed by the European Centre for Medium-Range Weather Forecasts (ECMWF, [46.96]), and as the benefits of the higher information-content BUFR data are becoming obvious.

In addition to these WMO standard formats, a large zoo of formats for radiosonde and dropsonde data exists. Most manufacturers provide their own ASCII output, which has been tailored to the needs of their customers. Some data centers, such as GRUAN, the Earth Observing Laboratory (EOL) of NCAR, and the Atmospheric Radiation Measurements (ARM) program of the US Department of Energy have started using netCDF (network common data form) formatted data files for radiosondes, some of these implementing the Climate and Forecasting (CF) metadata conventions to improve interoperability of these data. The netCDF format has the advantage that libraries for many software packages are freely available and that this format is in use well beyond the meteorological community. Properly coded netCDF files are self-describing and may contain extensive metadata to support the use of these data.

manufacturers provide uncertainty estimates for the instruments; however, the methods by which these estimates have been determined are not standardized, and large differences may exist in the methods by which manufacturers determine their uncertainties.

Independent intercomparisons provide a real-world snapshot of the instrument performance and uncertainties of measurements at the time of the intercompari-

Table 46.6 Uncertainty and requirements matrix. See text for more explanations; *n/d* stands for *not defined*

Variable	Manufacturer specifications	WMO optimum radiosonde	WMO optimum parameter	GCOS climate	GCOS stability
Temperature at 0–16 km (K)	0.2–0.5	0.4	0.6–1.0	0.5	0.05 K decade ⁻¹
Temperature > 16 km (K)	0.3–1.0	0.8	1.0	0.5	0.05 K decade ⁻¹
Humidity troposphere at 40 to –50 °C	3–5%	6%	2–4%	5%	0.3 % decade ⁻¹
Humidity troposphere at –50 to –90 °C	3–7%	10%	4%	5%	0.3 % decade ⁻¹
Pressure near the surface (hPa)	0.3–1.2	2	n/d	n/d	n/d
Pressure near 32 km (hPa)	0.04–2.0	0.1	n/d	n/d	n/d
Wind speed (m s ⁻¹)	0.15–2.0	1	1–2	2	0.5 m s ⁻¹ decade ⁻¹
Wind direction (°)	1–5	2	n/d	20	5° decade ⁻¹
Geopotential height (m)	8–15	20–60	24–100	n/d	n/d

son. The WMO has organized intercomparisons since 1950, with the last happening in 2010 at Yangjiang, China [46.53].

The WMO has compiled different sets of requirements for upper-air measurement uncertainties, depending on the target of the observations [46.56, Annexes 12.A and 12.B]; [46.57]. Different requirement levels have been specified, depending on the intended use of the measurements. The most lenient requirement is the uncertainty at which measurements become useful. Measurements with uncertainties larger than this threshold may be considered not meaningful for numerical weather prediction or for climate monitoring. The most stringent requirement is the uncertainty below which no further improvement in scientific result is expected. The WMO also specified a breakthrough requirement, which is an intermediate level at which significant improvement in scientific usefulness over the threshold requirement is expected. In addition, GCOS [46.57] has specified a stability requirement, which describes the required stability of the measurement system over decades, so that possible drifts in the measurement system are less than the expected climate change signals over long periods. Some level of random uncertainty is allowed over long periods, but, on average, any change in systematic bias must be below this stability requirement. Other requirements for process studies and campaign-based observations may exist but are not discussed here.

Table 46.6 lists the range of uncertainties specified by most manufacturers and the WMO and GCOS uncertainty requirements. Column *WMO optimum radiosonde* lists the optimum requirements for measurements by radiosondes based on the technological capability assessed after the 2010 international radiosonde intercomparison at Yangjiang [46.56, Annex 12.A]. Column *WMO optimum parameter* lists the optimum requirements for measurements by any system based on the WMO rolling review of requirements of upper-air observations [46.56, Annex 12.B]. These two columns are targeted for numerical weather prediction. Column

GCOS climate lists the requirements for measurements by any system targeted for climate observations [46.57]. Column *GCOS stability* lists the stability requirements for climate observations.

All uncertainties and requirements combine estimates of repeatability and of systematic bias. It is assumed that the distribution of measurements under identical conditions is Gaussian and all specifications and requirements are expressed as two standard deviations of this distribution (95% confidence level).

Russian and Chinese manufacturers have been excluded from the range of manufacturer specifications in Table 46.6 and from the discussions below, due to the sparseness of publicly available information. The few available specifications for temperature for these manufacturers range between 0.6 and 1.8 K and for humidity between 5 and 10%. No specification for pressure, wind, and height are available, as these depend largely on the performance of the secondary radar system, not on the radiosonde itself.

The manufacturer specifications need to be treated with caution, since not all manufacturers have the ability to rigorously evaluate the performance under all conditions, and some may overstate their specifications. Independent formal intercomparisons, such as those by the WMO or characterizations in independent laboratories, are vital for proper evaluations of the performance of radiosondes.

The geopotential height and stratospheric pressure derived from GNSS measurements may satisfy all requirements. In most cases, GNSS altitude uncertainties are in the range of 10–20 m, which is consistent with the manufacturer's specifications. Near the poles, GNSS height uncertainties on radiosondes may be larger due to the unfavorable geometry of GNSS satellite orbits [46.97]; however, this has not been evaluated yet.

GNSS derived pressure profiles near the surface critically depend on the reference pressure sensor used to initialize the profile. Proper placement and calibration of the reference pressure sensor are additional

influences on the uncertainty estimate at a given station. Operational procedures must take proper maintenance and calibration of the reference sensor into account.

GNSS-derived wind measurements meet all requirements, including stability requirements for long-term climate observations. The lower uncertainty range provided by manufacturers may be overestimating the GNSS performance, in particular considering that filtering of the balloon pendulum motion is an important step in the derivation of winds. Changes in the processing of GNSS winds, such as GNSS filter modes, balloon pendulum filters, or reception of additional GNSS systems, may lead to small changes in the reported values; however, these changes are likely to be within the most restrictive requirements.

Temperature measurements at nighttime do not suffer from solar radiation but depending on coating may be subject to long wave cooling, which is considered a small to negligible effect for most modern sensors. The uncertainties at nighttime should largely reflect the uncertainties of the calibration and measurement electronics. Daytime observations need to be corrected for solar radiation error and have larger uncertainties due to variations in the effectiveness of the reflective coating, due to the quality of the correction algorithm, and due to variations of the actinic flux due to varying albedo.

Humidity measurements by a number of modern polymer thin-film sensors meet the uncertainty requirements in the lower and warmer troposphere. However, calibration and a slow response time at cold temperatures in the upper troposphere still presents a significant

challenge for accurate humidity measurements for most sensors. Stratospheric humidity is outside the capabilities of almost all radiosonde humidity sensors.

The stability requirements for upper-air observations for climate are very stringent and are probably not met by most instruments (except for GNSS upper-air winds). Stability requirements affect all aspects of radiosondes, from sensor hardware to radiosonde production, to sensor calibration, to operational procedures. Small changes in any of these areas may not significantly change the overall combined uncertainty and, therefore, not degrade the usefulness for numerical weather prediction, but may degrade the usefulness of some systems for climate research, because many climate signals are small. Technological advances and improvements in operating procedures may bring more radiosondes within range for observations of small climate signals.

Almost all sondes rely on the factory calibration for their sensors, and no manufacturer, except Vaisala with the RS41 pressure sensor, currently performs a one-point calibration check or one-point recalibration to capture the extent of possible calibration drifts. To support climate observations, GRUAN is implementing independent ground-check measurements for pressure, temperature, and humidity in a controlled environment prior to launch [46.62]. Understanding the changes in calibration between production and use of the sondes, and possible changes in manufacturing itself, is an essential component in reducing uncertainties of long-term trend estimates using radiosondes.

46.6 Quality Control

Upper-air observations from radiosondes are usually processed automatically and sent to the numerical weather prediction (NWP) centers with only little human oversight. Therefore, the first level of quality control is performed automatically within the software provided by the radiosonde manufacturers. The details differ greatly between manufacturers, and only some general descriptions can be provided, without assumptions that these procedures are actually implemented in the software.

On all parameters, a physical range check assures that reported measurements are within physically possible limits. Bad values failing this test are more likely due to telemetry errors but may also be caused by failures of electronic components. Outlier filters make sure that changes over short time periods (neighboring data points) are within physical limits. Outliers may be caused by telemetry errors but may also be caused by temperature spikes in the stratosphere as the instru-

ments swings through the balloon wake and do not represent the state of the atmosphere. Outliers and physically impossible readings may simply be ignored, and neighboring readings may be interpolated to fill in gaps. Some sounding systems can specify the extent of the gap over which the software may interpolate data.

Some sounding systems may require that pressure be monotonically decreasing, i.e., that the balloon constantly rises to produce a uniform vertical profile. This may eliminate data during some periods of a sounding, when a balloon is descending, either due to strong icing on the balloon and payload inside a storm cloud, or possibly due to strong gravity wave activity in the stratosphere. Such a temporary descent may introduce a small temperature discontinuity at the transition from rising to temporary sinking of the balloon.

The temperature profile within the atmosphere is largely limited by the adiabatic lapse rate. Vertical gradients in temperature exceeding the adiabatic lapse rate

in the middle and upper troposphere are suspicious and may be flagged as invalid. One cause for a reported superadiabatic lapse rate may be evaporative cooling of the temperature sensor after exiting a cloud. A superadiabatic lapse rate near the surface may be possible under some conditions and may or may not be removed.

For sondes using GNSS to determine pressure, large vertical updrafts inside storms due to hydrostatic instability may lead to large pressure biases. The vertical rise rate of the balloon may be used to remove or flag pressure values that have been calculated during and above instability conditions.

Relative humidity measurements are poorly constrained and range between 0% and about 100%. Most manufacturers truncate relative humidity values to 100%, although small amounts of supersaturation above liquid water may be possible in updrafts. However, the typical uncertainty of most relative humidity sensors is larger than the range of possible supersaturation in the lower to middle troposphere. Unheated humidity sensors may accumulate sufficient amounts of ice such that they are no longer exposed to the atmosphere. These sensors may incorrectly report high relative humidity values well beyond the extent of a cloud. Complementary observations or expert knowledge may be required to identify observations impacted by icing that may not be filtered out operationally.

Wind measurements using GNSS may be invalid, if the GNSS receiver does not receive a sufficient number of satellites to calculate position and winds properly. These data may be interpolated, if the period of loss of satellite reception is short.

National meteorological services may have additional quality control procedures implemented to detect suspicious observations before transmitting data through the GTS. These additional quality control procedures have the ability to make use of other nearby observations to check the consistency of observations. The details of these additional quality control procedures depend on the capabilities of the meteorological service.

Some meteorological services perform essential corrections, such as solar radiation correction, calculation of the geopotential height, and others, not as part of the radiosonde sounding system but as part of the data processing chain within the service.

Numerical weather prediction (NWP) centers have additional quality control procedures after receiving data through the GTS. During data assimilation into the NWP model, all observations, including radiosonde observations, are compared with the atmospheric state calculated by the NWP model (called *background*). If the difference between observation and background is too large, then the observation may be flagged and ignored. If, over a period of time, a substantial fraction

of observations coming from a station or from a particular radiosonde model is flagged by the NWP center, then these data may be flagged permanently, and all observations from this station or this radiosonde model may be ignored. Large NWP centers may also evaluate the performance of each radiosonde type in comparison to their model background based on the information provided with the observations. This model comparison needs to be cognizant of the model errors itself and cannot replace a direct evaluation of the radiosonde types, but it does provide information about the limitations of different radiosonde types [46.98].

Meteorologists issuing weather forecasts or radiosonde data for other research purposes may analyze individual radiosonde profiles and use their expert knowledge about the radiosonde system and the atmospheric conditions to flag, correct, or ignore profiles or parts of profiles. In particular, for significant weather events, a detailed understanding of the radiosonde system and the atmospheric situation is essential to avoid misinterpretation of either the observation or the output of the NWP model.

GRUAN implemented additional manufacturer-independent ground checks into the operational procedures. In this network, radiosondes prior to launch are compared against well-characterized references under controlled conditions. These tests may identify small but significant calibration problems that cannot be identified any other way. Since this step may be labor intensive, it will be limited to small, dedicated networks. For long-term climate monitoring, this quality check is considered essential.

In addition to the actual measurements by the radiosonde, the metadata accompanying these observations also require quality control. Metadata include the information about the site, such as location, latitude, longitude, altitude, and station identifier, and about the instrumentation, such as manufacturer, sonde type, system configuration, etc. For regular observations, this quality control may need to be done only during configuration of the site; however, regular reviews of this information avoid errors in the description of the observation.

At well performing stations, the quality-control information is collected and analyzed to help improve the collection of observations. Most quality problems are most likely due to either specific atmospheric conditions or other rare circumstances. However, recurring quality concerns may point to deeper problems that need to be rectified. Frequent quality problems may be due to operational procedures, weaknesses in the instrumentation, or problems in the manufacturing of the radiosondes. Addressing these root causes should improve the overall data collection process.

46.7 Maintenance

Most radiosondes are single-use instruments. These instruments should be stored in a dry environment and kept in the manufacturer-sealed bag until they are used. The sensor calibration may drift slightly over the course of storage. Manufacturer-recommended procedures to restore the original factory calibration should be followed, where they are available.

Modern electronic ground systems require little maintenance. Operational sites may need to keep spares of key components in case of failure. Electrical connections that are exposed to severe weather conditions, especially corroding environments with high humidity and high concentrations of sea-salt spray, may need to be inspected regularly.

Updates of the sounding software need to be carefully evaluated before installing them in the sounding system. In particular, changes in any of the calculations need to be carefully evaluated, since they may negatively affect the ability for long-term trend detection.

Systems that track radiosondes by mechanically moving antennas may require regular inspection of all moving parts of the system. Stations using these systems should follow the maintenance protocol provided by the manufacturer.

The gas handling equipment needs to be inspected regularly. High-pressure gas cylinders holding either helium or hydrogen are normally connected to a pressure regulator and a fill valve. All components must be in good working order and not create any safety hazard. The maintenance protocol of the manufacturer should be followed for these systems. Gas systems handling hydrogen must also be electrically grounded to minimize the buildup of static electricity. The grounding connections need to be inspected to assure that all components are properly grounded. Proper safety gear should be worn by the operators and should be available at the launch site.

Inflation buildings should be properly ventilated, and shelters used for hydrogen inflation should be built following the appropriate safety codes. Regular inspection may be required to assure that the inflation shelter and the gas handling system are still operating within safety regulations.

Balloons typically have a short shelf life and should not be stored much beyond 1 year. They should be stored in a dark, cool place, since ultraviolet light quickly deteriorates the natural rubber material.

46.8 Application

Operational sounding data are shared in near real time by national and international meteorological services through the GTS of the WMO, together with meteorological data taken at surface stations and obtained onboard aircrafts and by satellites [46.99]. These data are used for meteorological analyses, in which they are compiled to generate a best estimate of the global meteorological fields during the analysis period as initial conditions for NWP at all participating national and international NWP centers. Since operational radiosonde data provide simultaneous information about vertical profiles of pressure, temperature, humidity, and winds, they are one of the key components of the global weather forecasting systems.

The historical record of radiosonde observations collected through the GTS since the 1950s may be an important basis to analyze upper air climate change. However, these real-time radiosonde data are generally not sufficiently homogeneous to be used for the detection of temperature trends of the order of $0.1 \text{ K decade}^{-1}$ [46.100]. Changes in instrumentation (radiosonde types and manufacturers), in operational procedures, and even in station location (e.g., a move

within a city with a significant station altitude change) in a timescale of decades may easily have caused larger changes than the possible atmospheric trend. To remove these possible artifacts in radiosonde temperature data, researchers have created different *homogenized* radiosonde temperature products for climate research using different methodologies [46.54, 101]. Global atmospheric reanalyses compile all available observations to generate a best estimate evolution of the atmospheric state over the period covered by the reanalysis. Instead of using the original real-time radiosonde data, most of these reanalysis projects use homogenized radiosonde temperature data sets [46.55].

Radiosondes are also used for studies of specific atmospheric processes and for the validation of ground-based and satellite remote-sensing instruments. For these purposes, radiosondes may be launched in intervals as short as 30 min to capture short-period variabilities; their launch may be timed with satellite overpasses, or radiosondes may be coordinated with observations from other platforms, such as aircraft, for simultaneous measurements. Radiosondes are also flown with specialized atmospheric sensors to measure parameters that

are not measured by radiosondes. Recent technological advances have allowed a significant expansion of the use of radiosondes for many upper-air applications that were previously out of reach.

46.8.1 Sounding Networks

Coordinated aerological observations provide a snapshot of the atmospheric state over large regions using similar technology and standardized practices. These networks are part of the overall coordinating efforts of the WMO and are described in greater detail in Chap. 63.

The global operational radiosonde network as part of the WMO Global Observing System (GOS) contains approximately 900 stations, which are operated by national meteorological services and research institutions. The WMO coordinates these observations through the infrastructure commission, which oversees the implementation and operation of the observing systems and data communication and management. The infrastructure commission also provides technical guidance on the instrumentation, as well as on operational procedures. More than two-thirds of these stations launch radiosondes twice daily at 00:00 UTC and at 12:00 UTC.

GUAN [46.50] is a subset of the larger operational radiosonde network, which was defined in the mid-1990s. GUAN includes stations with long-term, high-quality radiosonde observations that follow the GCOS climate monitoring principles to establish an upper-air climate monitoring network. To resolve synoptic-scale weather disturbances, stations on land are spaced approximately at 5°–10° latitude. By 2014, GUAN had grown to 170 stations worldwide.

In recognition of the need for stronger technical leadership within the network, GRUAN was started in 2008 [46.87, 102]. This network included a dedicated lead center, hosted at the German Meteorological Service, which coordinates research activities on various aspects of the upper-air climate measurements within the network. One of the essential characteristics of all GRUAN data products is vertically resolved uncertainty estimates attached to every data point. This effort has stimulated numerous research activities both within GRUAN, as well as within different suppliers of upper-air instrumentation. GRUAN currently consists of 26 high-quality, long-term, upper-air observing stations that are built on, but not confined to, the GUAN. Of these stations, 10 have been certified, and 16 are awaiting certification (as of 2018).

Radiosondes for operational weather forecast are also launched from commercial ships as part of the Automated Shipboard Aerological Program (ASAP), which is coordinated by the Joint WMO-IOC (Inter-

governmental Oceanographic Commission) Technical Commission for Oceanography and Marine Meteorology (JCOMM). Radiosoundings from commercial ships partially fill the large gap of missing in-situ observations over the oceans. These soundings may be done through autolaunching systems or through manual launches by a ship's crew [46.103]. The operations are supported by several national meteorological services in Europe, Asia, and South Africa.

46.8.2 Scientific Soundings

Radiosondes provide an ideal platform for additional scientific sounding instruments to measure the vertical distribution of atmospheric parameters for thermodynamics, composition, and radiation, up to 30–35 km. Over the last decade, a new de-facto interface standard (XDATA, [46.104]) has been implemented by several radiosonde manufacturers, which allows the transmission of additional channels for external instruments through the telemetry stream of operational radiosondes. This technology allows simultaneous measurements of parameters such as ozone, stratospheric water vapor, cloud backscatter, aerosol size distribution, supercooled liquid-water content, long-wave and short-wave radiation, SO₂, and others, in addition to the basic meteorological parameters. Special care is needed in developing external instruments for radiosondes, because environmental parameters may change relatively quickly (e.g., temperature from +30 to –80 °C in 45 min and pressure from 1000 to 10 hPa in 90 min), and because radiosondes may cause significant radio-frequency interference due to their proximity to the scientific instrument.

Most external instruments are used in short research campaigns, but ozonesondes are a notable exception. These instruments are flown operationally by many national meteorological services stations to monitor the ozone layer and tropospheric pollution and to validate satellite-based ozone measurements. The WMO Global Atmosphere Watch (GAW) coordinates the operational ozonesonde network, and its data are archived at the World Ozone and Ultraviolet Radiation Data Centre (WOUDC) hosted at Environment and Climate Change Canada. Worldwide, there are about 70 operational ozonesonde stations with weekly soundings in many cases. The Southern Hemispheric Additional Ozonesondes (SHADOZ) network is a subset of the global ozone sonde network, which focuses on ozone observations in the Southern Hemisphere and, most importantly, the tropics [46.105].

Two types of ozone sondes are currently in use: the electrochemical concentration cell (ECC) ozonesonde [46.38], which is produced by two man-

Fig. 46.11 Scientific sounding launched at the DWD Meteorological Observatory Lindenberg, Germany, on 08.10.2018. The instruments launched as part of this payload are the Vaisala RS41 radiosonde, the ECC ozone sonde, the CFH water vapor sonde, and the COBALD backscatter sonde. The temperature is shown in red, the backscatter ratio at a wavelength of 455 nm in light blue, the measured water vapor mixing ratio as a solid line in dark blue, the calculated saturation mixing ratio as a dashed line in dark blue, and the ozone mixing ratio in green

ufacturers, and the Brewer–Mast sonde, which is produced on a small scale by only one manufacturer. ECC ozonesondes are supported by several radiosonde types, where the ground-system software processes the data coming from the ozone sonde. These instruments consist of a small pump and a cell, in which ozone pumped through a solution of potassium iodide converts iodide to iodine. This reaction generates an electrical current within the cell that can be measured [46.38]. See [46.105] and the references therein for more information on the ozonesonde.

All radiosonde relative humidity sensors measure tropospheric water vapor concentration, with decreasing capability in the cold upper troposphere, but currently none of them have the capability to measure stratospheric humidity. However, the concentration of stratospheric water vapor can be measured by small frostpoint hygrometers, such as the cryogenic frostpoint hygrometer (CFH, [46.106]) or the NOAA frostpoint hygrometer (FPH [46.107]), or by optical hygrometers based on the Lyman- α fluorescence method [46.108]. Currently, there are fewer than ten stations worldwide that measure stratospheric water vapor routinely using cryogenic frostpoint hygrometers [46.107, 109]; most

of these are coordinated within the Network for the Detection of Atmospheric Composition Change (NDACC; Chap. 63). These instruments operate on the chilled mirror principle, where the temperature of a mirror is controlled such that condensation forms on the surface of the mirror and remains constant. The condensation on the mirror may be dew or ice, which determines whether the instrument measures the dewpoint or frostpoint temperature. The condensate on the mirror is measured by an optical detector and used in a feedback controller to regulate the mirror's temperature. The use of cryogenic liquids in these instruments allows them to measure the very cold frostpoint temperatures corresponding to stratospheric water vapor concentrations.

Scientific instruments exist to measure aerosol and cloud particles onboard small radiosonde balloons ([46.110, 111] and references therein). These instruments focus on upper tropospheric cirrus clouds and aerosols in the upper troposphere and lower stratosphere. These instruments may be combined with newly developed sensors for sulfur dioxide [46.112] to measure, for example, volcanic emissions.

A profile of tropospheric and stratospheric water vapor, ozone, and the cloud backscatter ratio using the

balloon-borne backscatter sonde COBALD (Compact Optical Backscatter and Aerosol Detector, [46.113]) measured at the DWD Meteorological Observatory Lindenberg, Germany, is shown in Fig. 46.11. These profiles are measured regularly as part of the monitoring activities of GRUAN and NDACC and to better understand the details of upper tropospheric and stratospheric chemistry and dynamics.

The content of supercooled liquid water in clouds can be measured using vibrating wire sensors [46.114] onboard small radiosonde payloads. In-situ measurements of this kind are notoriously difficult due to the risk of icing for aircraft.

46.9 Further Development

Although remote-sensing observations from space and from the ground have dramatically expanded our ability to observe the global atmosphere, in-situ observations on small balloons continue to play a very important role. Radiosondes remain the only technology to observe all atmospheric state variables at the same time and at the same location and thereby help reducing observational errors due to poor spatial and temporal correlation between remote sensing observations. Radiosondes are one of the most important observing systems contributing to forecast skill of global NWP models, and their degradation has immediate impacts on weather forecast [46.117].

The improvement of radiosonde sensors is driven by the need for better traceability of observations and for standardizations of procedures. A significant amount of research is invested in better characterizing sensor performance in their atmospheric environment, not just under laboratory conditions. The close cooperation with national standards laboratories is currently leading to a better quantification of measurement uncertainties and the recognition of their importance in atmospheric observations.

Technological progress has significantly improved the observations of upper tropospheric humidity and it is expected that observations of lower stratospheric humidity may be significantly expanded through developments of new sensors and improvements of existing sensors. The adoption of the XDATA protocol by many commercial radiosonde manufacturers allows adding new sensors, thereby significantly expanding their capabilities. This de-facto interface standard has laid the foundation for a strong upper air research community.

For measurements of carbon dioxide and other long-lived greenhouse gases in the stratosphere, the cryogenic whole-air sampling method with large plastic balloons has been used ([46.91, 115] and references therein). Over the last decade, a new approach called *AirCore* has been developed to measure the vertical distribution of carbon dioxide and methane and other constituents [46.116]. For both air-sampling methods, the air samples are recovered, and the composition is analyzed in the laboratory using the nondispersive infrared gas analyzers, gas chromatographs, and mass spectrometers. *AirCore* is the first whole air sampler small enough to fly on small radiosonde balloons.

In-situ observations from UAS (Chap. 49) and commercial aircraft (Chap. 43) provide great spatial coverage. These systems complement radiosondes, which are capable of reaching much greater altitudes than these systems and are not biased by the need to avoid aviation hazards. UAS platforms require small, lightweight, and highly accurate sensors. Many synergies exist between UAS technology and radiosonde technology for mutual benefit. Most UAS lack the capabilities to reach much above the boundary layer, for technical and logistical reasons. Some projects have combined small balloons and UAS to achieve the altitudes of balloons and to maintain the ability for control of UAS. For example, *Kräuchi* and *Philipona* [46.118] launched a dedicated glider, equipped with pressure, temperature, humidity, GPS, and radiation sensors on a small sounding balloon. At 24 km, the glider was released from the balloon and returned autonomously back to the launch site. Winds were measured only on ascent, while the other parameters were measured throughout the flight. This development has the potential to reduce costs for soundings, which are more complex than normal radiosondes. However, coordination with civilian air traffic is a significant hurdle in the development of these systems and adds significant logistical overhead. As regulations and UAS technology further develops, it is expected that UAS will be better integrated into regulated airspace.

Long-duration plastic balloons such as those during the *Concordiasi* project [46.119], which have been launched since the 1960s, have the ability to stay afloat for several months in the lowermost stratosphere. These projects provide a unique Lagrangian view of the atmosphere, as they drift with the prevailing winds.

46.10 Further Readings

A reference for aerological technologies and observations is the Guide to Meteorological Instruments and Methods of Observation of the WMO Commission for Instruments and Methods of Observations [46.56]. This guide is regularly updated by a panel of experts from the operational and research community. Part I, Chap. 12 of this guide deals with measurements of upper air pressure, temperature, and humidity; Part I, Chap. 13 deals with measurements of upper air wind.

The formal intercomparisons organized by the WMO present a review of the current state of radiosonde technology at that time. The most recent inter-

comparison took place at Yangjiang, China [46.53] with next intercomparison planned in 2022 at the GRUAN Lead Center, Lindenberg, Germany.

The GRUAN documents (<https://www.gruan.org/documentation/>, Accessed 20 July 2021) provide detailed information on a number of specific topics relating to upper air observations. This network manages upper air observations for climate and relies on a detailed understanding of the observing technology.

Other important works for upper air observations have been published, many of which are listed in the references below.

Holger Vömel

Earth Observing Laboratory
National Center for Atmospheric Research
Boulder, USA
voemel@ucar.edu

Holger Vömel is a scientist at the National Center for Atmospheric Research at Boulder, CO, USA. He graduated in Physics from the University Heidelberg, Germany in 1990 and received a PhD in Chemical Physics from the University of Colorado at Boulder in 1996. His research interests focus around high-quality observations of atmospheric parameters such as water vapor, ozone, temperature, pressure, and winds, to provide reliable data for studies of climate change and atmospheric processes.

Masatomo Fujiwara

Faculty of Environmental Earth Science
Hokkaido University
Sapporo, Japan
fuji@ees.hokudai.ac.jp

Masatomo Fujiwara is Associate Professor of the Faculty of Environmental Earth Science at Hokkaido University in Japan. He received a PhD in Science in 1999. His research interests include atmospheric dynamical and chemical processes in the upper troposphere and lower stratosphere and upper-air climate observations, based on balloon measurements, development of balloon-borne instruments, and data analysis and evaluation of global atmospheric reanalysis data sets.

47. Composite Atmospheric Profiling

Christoph Kottmeier , Bianca Adler , Norbert Kalthoff , Ulrich Löhnert , Ulrich Górsdorf

Each observation system that vertically profiles one or several atmospheric parameters by performing in-situ or remote-sensing measurements has its own distinct characteristics in terms of vertical range and resolution, temporal resolution, and height-dependent error. Combining several profiling instruments of the same type or different types—known as composite atmospheric profiling—bypasses the limitations of using those instruments separately, allowing additional information on the state of the atmosphere to be retrieved, thus enhancing the retrieval accuracy and the temporal and/or spatial resolution of atmospheric parameters. New quantities with added value can also be obtained using this approach. In this chapter, the state of the art in composite vertical atmospheric profiling is discussed. It is described how multiple systems that measure different parameters and have different height ranges as well as vertical, temporal, and spatial resolutions can be optimally combined. Some examples from recent research are presented to demonstrate the successful implementation of composite profiling techniques.

Composite atmospheric profiling is the practice of combining instruments and techniques in a manner that yields enhanced vertical and temporal resolution, vertical range, accuracy, and information content compared to those provided by any of the instruments individually. It can be considered an offshoot of three-dimensional composite observation that focuses on mea-

surements in the vertical direction, where changes are typically largest. Such composite information is needed to:

- Understand vertically coupled atmospheric processes at scales ranging from the microscale to the mesoscale

- Drive and validate numerical models of such processes
- Validate data from satellites
- Assimilate data into weather prediction models at high resolution
- Retrieve statistical information (e.g., relating to renewable energies)
- Monitor the climate.

The instruments that are combined in composite atmospheric profiling can be of the same type or different types. Some lidar and radar systems have scanning capabilities, meaning that they can retrieve data from various directions, not just the vertical, potentially providing quasi-hemispherical coverage. Such coverage is provided by a variety of integrated observation platforms and networks around the world, including the KITcube [47.1] and atmospheric radiation measurement (ARM) mobile facilities [47.2] as well as LACROS [47.3]. Fixed platforms or networks that possess this ability include the Richard Aßmann Observatory (MOL-RAO) in Lindenberg, Germany [47.4], the CESAR observatory in Cabauw, Netherlands [47.5], the JOYCE observatory in Jülich, Germany [47.6], and the CNR-IMAA observatory in Potenza, Italy [47.7]. Fixed stations are often operated by national weather services, and different systems are often combined in order to improve weather forecasts and enhance climatological studies [47.8]. The mobile systems mentioned above have been utilized in various international field campaigns to provide comprehensive high-resolution data for limited time periods, facilitating process studies and model evaluation; for instance, the ARM mobile facility was used in African Monsoon Multidisciplinary Analysis (AMMA) [47.9] and Convective and Orographically-induced Precipitation Study (COPS) [47.10, 11], the KITcube was used during the Hydrological Cycle of the Mediterranean (HYMEX) campaign [47.12], and the KITcube and LACROS were

operated in the HD(CP)² Observational Prototype Experiment (HOPE) [47.13].

The objectives of composite atmospheric profiling are to:

- Extend the measurement range and/or temporal resolution compared to those achieved with individual instruments
- Enhance temporal and/or spatial resolution in the horizontal and vertical directions
- Obtain parameters that cannot be accessed with a single instrument.

For the first objective, the profiles provided by different instruments are either simply concatenated and analyzed in parallel without performing any calculations [47.14], or they are merged via interpolation/extrapolation or variational analysis in overlapping regions, taking into account error characteristics (e.g., by integrating microwave radiometer (MWR) measurements with water-vapor lidar data [47.7, 15] or combining in-situ and remote sensing systems to retrieve wind and temperature profiles [47.16]). The second objective can be achieved by combining systems of the same type (e.g., by applying the virtual tower method [47.17, 18] or the coplanar scan technique [47.19] to Doppler lidars), combining instruments that perform measurements under different atmospheric conditions (e.g., a Doppler lidar that provides wind information in cloud-free regions and a cloud radar that yields data on wind in clouds [47.20]), or combining different types of systems that have different resolutions or spatial coverages (e.g., water vapor data from radiosondes and information from a global navigation satellite system, GNSS [47.21]). The third objective involves the use of complementary variables to retrieve added-value quantities such as convection indices, turbulent fluxes, or micro- and macrophysical cloud properties (as performed by Cloudnet [47.22], for example).

47.1 The Relevance of Composite Atmospheric Measurements

Composite atmospheric profiling is required when no single instrument or observation system can probe all of the parameters needed to fully characterize the state of the atmosphere. This is important when attempting to study complex process interactions or to initialize models. Any physical measurement principle (whether based on mechanical, acoustic, or thermodynamic variations, changes in electrical conductivity or capacity, or on radiation emission, absorption, or scattering; see Chap. 1) can only be used to investigate particular properties, and those properties can only be studied under specific at-

mospheric conditions or in certain regions in which the physical measurement process is effective. For example, an aerosol Doppler lidar requires backscatter caused by the presence of small particles (e.g., aerosols and ice crystals), so it is only rarely able to provide any information on the free atmosphere where the aerosol content is low. Depending on the purpose for which measurements are made, quite different instruments can be applied. For example, the wind measurements that are needed to assess the wind energy potential at a particular site differ considerably from the wind measurements that are

required to calculate turbulent fluxes in micrometeorology. Instruments are therefore designed by the manufacturer to achieve a specific sensitivity, resolution, and range, and to be used in particular operating conditions. In addition, the platform on which the instrument is installed (e.g., the ground, a mast, a tower, a balloon, an aircraft, or a satellite) imposes certain geometric constraints on the height range that can be accessed, and operational issues (e.g., frequency of radiosoundings, orbital period, and the observation geometry of the satellite) limit the temporal resolution.

In this chapter, we discuss composite atmospheric profiling by in-situ sensing and ground-based remote sensing. Ground-based remote sensing offers many possibilities for combining data from different instruments to obtain more accurate or additional information, and overviews of this topic are also provided in [47.8, 23]. Composite vertical profiling from satellites is not treated in this chapter, although height-resolved satellite data may usefully complement in-situ- and ground based vertical profiling. The spatial and temporal resolution, the satellite orbit characteristics and the instrument viewing angles strongly differ between satellite sensors, and optimum merging of data normally needs data assimilation within a full four-dimensional model.

This section gives an overview of common instrument combinations. In one type of combination, the measurement range is extended and/or the temporal resolution of temperature, humidity, and wind measurements is increased (Fig. 47.1a–c). Table 47.1 summarizes the strengths and weaknesses of important instrument types in terms of vertical resolution, temporal resolution, coverage of the free atmosphere, spatial coverage, and performance in the presence of clouds. The limited vertical range of tower-based instruments (Chap. 6) can, for example, be extended by combining them with remote-sensing instruments such as lidars (Chaps. 26, 27) or radar wind profilers (Chap. 31). Research aircraft (Chap. 48), radiosondes (Chap. 46), and certain unmanned aircraft systems (UASs; Chap. 49) can provide

temperature, humidity, and wind profiles throughout the troposphere. However, these profiles are not continuous; they are snapshots of the state of the atmosphere. All of the instrument types considered in the table have particular advantages and disadvantages (see the relevant chapters in Parts C–E of this Handbook for details). For example, while lidars cannot obtain measurements from optically thick clouds, while aerosol lidars cannot obtain measurements inside clouds, cloud radars provide information on the vertical cloud structure inside optically thick clouds. Using Doppler lidar and cloud radar, also combined wind profiling below and inside clouds is possible, the vertical resolution of a profile retrieved using a microwave radiometer (Chap. 29) or an infrared spectrometer (Chap. 28) is rather coarse and not suitable for resolving sharp gradients, but the temporal resolution of the profile data is quite high. Raman lidars (Chap. 25) generally perform better at night than during the day. Even high towers (up to 300 m high) can only measure the wind vector, temperature, and humidity in the lowest few hundred meters of the atmospheric boundary layer (ABL). To cover the whole ABL (which is typically ≈ 1 km thick), it is necessary to use a Doppler lidar (Chap. 27), Raman lidar, or differential absorption lidar (DIAL, Chap. 26). Sodar (Chap. 23) and radar wind profilers (Chap. 31) can probe winds at heights of up to about several hundred meters and several kilometers, respectively. Adding a radio acoustic sounding system (RASS) to a sodar or radar wind profiler allows temperature variances to be obtained along with wind variances.

It has been demonstrated that combining passive with active remote sensing [47.15] and in-situ with remote sensing [47.16] leads to improved profiling. For instance, integrating GNSS with radiosonde measurements increased the spatial resolution of the retrieved humidity information compared to the corresponding information obtained from a single instrument [47.21]. Combining microwave radiometer data with radiosonde data yields temperature and humidity data with increased vertical and temporal resolution [47.24, 25].

Table 47.1 Strengths and weaknesses of selected instruments in terms of vertical resolution, temporal availability (i.e., the temporal resolution for remote-sensing instruments and towers, and the time interval between individual soundings or profile flights for radiosondes, UAS, and aircraft), free atmosphere coverage, spatial coverage, and performance in the presence of clouds

Parameter	Tower	Lidar/ DIAL	Microwave radiometer	Infrared spectrometer	Radar wind profiler/RASS	Sodar/ RASS	Cloud radar	Radio- sonde	UAS	Aircraft
Vertical resolution	–	+	–	–	+	+	+	+	+	+
Temporal availability	+	+	+	+	+	+	+	–	–	–
Free atmosphere coverage	–	–	+	+	+	–	+	+	–	+
Spatial coverage	–	–	–	–	–	–	–	–	+	+
Clouds	+	–	+	–	+	+	+	+	–	+

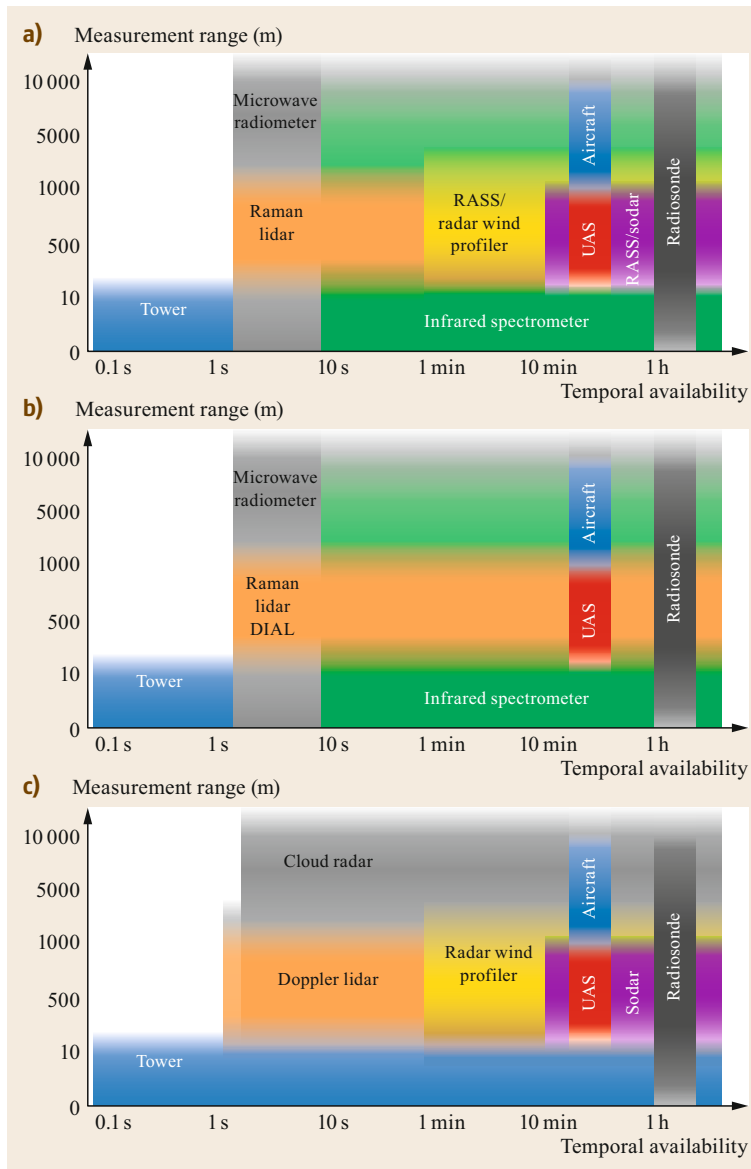

Fig. 47.1a–c Typical temporal availabilities and height ranges of common instruments that are used to measure temperature (a), humidity (b), and wind (c). For remote-sensing instruments and towers, the left margin of the colored section indicates the minimum time interval between profiles (i.e., minimum integration time) under very good measurement conditions, although the sampling rate may be considerably higher than the temporal resolution. For UAS, aircraft, and radiosondes, the temporal availability indicates the typical time interval between soundings or profile flights (diagrams © B. Adler)

Another type of instrument combination permits the retrieval of quantities that cannot be measured with a single instrument. Examples of these *added-value* or *compound* quantities and the instrument combinations that can access them are given in Table 47.2. For instance, flux profiles can be derived by combining Doppler lidar with Raman lidar or DIAL [47.26]. The ABL height is often obtained from a lidar or radiosonde profile, but the applicability of each method strongly depends on the atmospheric conditions present [47.27]. As radiosondes measure temperature, humidity, and wind at the same time, convection indices can be estimated from radiosonde profiles [47.28]. Micro- and

macrophysical cloud properties can be determined by combining active and passive remote-sensing data with in-situ information [47.22, 29].

The site requirements for composite measurements are similar to those for the individual instruments themselves. To achieve a spatial overlap or to perform dual observations (such as dual-Doppler lidar or dual-Doppler radar), the scanned volumes must be free of obstacles. It has been shown, however, that adequate site conditions can be found even in urban environments (Sect. 47.8.1) and large valleys [47.25].

Methods that can merge datasets from different instruments in order to derive the best estimate for the

Table 47.2 Selected added-value quantities and instrument combinations that are used to probe them

Added-value quantity	Instrument combination
Sensible and latent heat flux profiles	Doppler lidar and Raman lidar or DIAL [47.26]
ABL height	Doppler lidar and radiosondes [47.27]
Convection indices (e.g., convectively available potential energy (CAPE), konvektiv-index (KO), lifted index (LI), bulk Richardson number	Radiosondes with temperature, humidity, and wind measurements [47.28]
Vertical cloud structure characteristics (microphysics, turbulence, precipitation fluxes)	Cloud radar, ceilometer, microwave radiometer, Doppler lidar, radiosondes [47.22, 29]
Humidity profile	Raman lidar and microwave radiometer [47.30, 31] Microwave radiometer and radar wind profiler [47.32]
Bulk cloud properties	liquid water path (LWP) from microwave radiometer and infrared (IR) measurements [47.33, 34] Cloud radar and microwave radiometer for cloud liquid water content (LWC) profile retrieval [47.35]
Temperature profile, humidity profile, and bulk cloud properties	Microwave radiometer, infrared spectrometer, and ceilometer [47.36, 37] Microwave radiometer, cloud radar, and ceilometer [47.38]

state of the atmosphere at a site (the site atmospheric state best estimate, SASBE) are available. Such methods allow the spatial and temporal resolution of the measurements to be enhanced [47.14, 39, 40] or can be used to generate a data product that best meets the research needs of specific data users [47.41].

Water-vapor profile retrievals can be improved by combining wind profiler and microwave radiometer measurements [47.32] or by combining Raman lidar with microwave radiometer measurements. A physically consistent method of enhancing the retrieval of low-LWP clouds by combining an infrared spectrometer with a microwave radiometer was introduced in [47.33], whereas a similar method that utilized a robust neural network approach, a two-channel broadband IR radiometer, and a microwave radiometer is reported in [47.34]. Radiative closure studies highlight the advantages of com-

posite measurements. Also, active remote-sensing measurements of liquid clouds obtained with a cloud radar can be constrained by the column-integrated liquid water path retrieval from a microwave radiometer to achieve improved estimates of the cloud liquid water content (LWC) in non-drizzling clouds [47.35]. A microwave radiometer, an infrared spectrometer atmospheric emitted radiance interferometer (AERI instrument [47.42]), and a ceilometer [47.36] represent a very powerful combination for simultaneously retrieving temperature, humidity, and bulk cloud properties (optical depth, effective radius) in a physically consistent manner. Finally, the spatial coverage and temporal resolution of wind information can be enhanced by combining multiple Doppler lidars (e.g., by applying the virtual tower technique [47.17, 18] or performing coplanar scans [47.19]) or by combining Doppler winds from a lidar and a cloud radar [47.20].

47.2 History

The history of composite atmospheric profiling can be traced back to the early Age of Enlightenment at the end of the eighteenth century, when much innovative research on natural phenomena and processes was initiated. New measurement techniques were invented and applied in research during subsequent decades.

The desire to perform observations from altitudes above buildings or mountains expressed by scientists in the eighteenth century. Although a kite experiment was carried out in 1749 to study lightning and electricity [47.43], measurements of the atmosphere at high altitudes necessitated a form of transportation that could carry instruments up to the altitude of interest and return those instruments safely back to earth for data recovery. The first air transportation of this kind to be invented

was the tethered balloon. The same year, 1783, saw the invention of both the manned gas-filled balloon, by *Jacques Alexandre César Charles* (1746–1823), and the manned hot-air balloon, by two brothers: *Joseph-Michel Montgolfier* (1740–1810) and *Jacques-Étienne Montgolfier* (1745–1799) [47.44]. Thus, starting in the late eighteenth century, instruments that had already been used to perform measurements on the ground were taken aloft by balloons to obtain measurements and the first vertical profiles up to high altitudes.

By the end of the nineteenth century, there was a need for greater knowledge of the ABL, given the increasing popularity of aviation. Driven by this need, *Hugo Emil Hergesell* (1859–1938), *Richard Aßmann* (1845–1918), and *Wladimir Köppen* (1846–1940) performed

various observations in the ABL as well as the free atmosphere above the ABL, and are therefore regarded as the founders of aerology. Aerological measurements (Chap. 46) of more than one variable can be considered an early example of composite vertical profiling.

The advent of gliders [47.45] and motorized aircraft [47.46] in the early twentieth century allowed heavier instrumentation to be carried, including sensors of properties other than the classical parameters of temperature, humidity, and pressure. A multitude of other instruments that measured, for instance, the electric field strength, radiation flux, cloud liquid water, aerosols, ice particles, turbulence, and icing conditions at high altitudes or that performed visual photography were tested and applied for research purposes [47.47, 48].

Over the last 70 years there has been—and there continues to be—rapid development in the instrumentation used for ground-based remote sensing in the visible, infrared, and microwave bands. The physical base of interaction of electromagnetic waves with atmospheric matter (gases and particles), such as the Rayleigh and Mie scattering theories developed in the late 19th and early 20th century, or the description of the dielectric properties of liquid phase water molecules in 1929 [47.49] has been laid already decades before. But only the development of detectors for very low level amplitude signals, e.g., the microwave radiometer invented and described in 1947 [47.50], and various theoretical improvements regarding absorption spectra, in particular line shape models, temperature and humidity weighting functions at different frequencies, as well as calibration methods, allowed for this progress.

Recent decades have seen major progress, particularly in radar and lidar technology for atmospheric remote sensing. The remote sensing of macro- and microphysical cloud properties and associated processes has been possible since the mid-1990s [47.51]. The first combination of a microwave radiometer with wind profiler auxiliary sensors for humidity profiling was also reported [47.52].

Early examples of composite techniques included sodar/RASS and radar wind profiler/RASS techniques for coincident measurements of horizontal wind and temperature. An overview of the wealth of sensors available for combination is given in Parts B and C of this Handbook, while a comprehensive account of the synergetic use of sensors is provided in [47.8].

A new era in vertical composite atmospheric profiling began in the mid-twentieth century with the arrival of satellite-based remote sensing (see Chap. 37). While it has some similarities to surface-based remote sensing in terms of its physical basis (radiative transfer calculations, absorption and scattering by gases and aerosols, and detector and calibration requirements), satellites represent a completely new source of regular global

Fig. 47.2 Obtaining integrated vertical profiles with a 45 m high mast and a kite-mounted tethered sonde at the German Antarctic Neumayer Station in 1983 (after [47.55] photo © Ch. Kottmeier)

observations of the atmosphere. The system of geostationary satellites and polar orbiters has become the backbone of data acquisition for weather prediction. Cloud coverage and surface conditions as well as the gas-phase composition of the upper atmosphere can be observed at unprecedented detail from satellites. However, the horizontal and vertical resolution of measurements by satellites remains quite limited, meaning that such data will tend to be used in conjunction with complementary data from other systems, although the latest generation of Meteosat satellites provide rapid-scan information every 15 min. Some satellite series such as the afternoon train (A-Train) constellation [47.53] are designed to acquire synergetic information to improve cloud surveys, for example. Specifically, there have been many studies of clouds and their radiative effects based on composite atmospheric profiling using data from the A-Train satellites CloudSat (cloud radar) and CALIPSO (backscatter lidar) [47.54].

Several historical developments are still relevant to operational weather services and climate monitoring, as well as for specific research purposes.

High instrumented masts have been operated for decades. The Boulder Atmospheric Observatory (BAO) [47.56] was the first research facility to study the plan-

etary boundary layer and to test and calibrate atmospheric sensors. This facility includes a 300 m tower instrumented with fast- and slow-response sensors, a variety of remote-sensing systems, and a real-time processing and display capability that greatly reduces the time required for scientists to analyze current or archived data. In the past four years of operation, the BAO has been involved in several large cooperative experiments and numerous smaller ones. The 200 m mast of the KITcube has been operated since 1986 and is equipped with extensive instrumentation at 7 heights. Mean and turbulence data are continuously collected and are used for environmental monitoring and climate studies.

High instrumented masts have been also equipped with movable sondes for profiling [47.56, 57], and have been used in combination with tethered balloons and kites in boundary-layer research in Antarctica (Fig. 47.2).

The international network of about 800 radiosonde stations provide the foundations for numerical weather prediction (see Chap. 46). Aircraft-based measurements have steadily improved, and reconnaissance flights are conducted by a fleet of aircraft with quite different purposes, instrumentation, ranges, and durations (Chap. 37). High-altitude jet aircraft such as the National Center for

Atmospheric Research (NCAR) high performance instrumented airborne platform for environmental research (HIAPER) and the German high altitude and long range research aircraft (HALO) can carry a variety of in-situ and remote-sensing instruments simultaneously around the world and up to the lower stratosphere.

Information from surface-based remote-sensing stations is acquired by and distributed across large national and international networks of instruments. Operational use is already being made of C-band precipitation radars, ceilometers, and aerosol robotic network (AERONET) stations. Regional networks that include, for example, radar wind profilers, radiosondes, and ceilometers have also been established and successfully operated.

Data provided by surface and upper air (radiosonde) networks as well as by surface-based remote-sensing stations (e.g., precipitation radars) and various remote-sensing satellites are funneled into the data assimilation cycles of numerical weather prediction models. The results of numerical analyses performed after each data assimilation step can be considered the best estimate of the global state of the atmosphere and—in a sense—the most advanced example of vertical composite atmospheric profiling.

47.3 Theory

In this section, we introduce methods and algorithms that can be used to:

- Enhance the spatial (vertical or horizontal) and/or temporal resolution of data
- Provide added-value parameters.

Higher spatial and temporal resolution is targeted for parameters such as temperature, humidity, and wind. An example of an added-value quantity are turbulent flux profiles in the ABL.

47.3.1 Example of the Application of Composite Atmospheric Profiling to Extend the Measurement Range and Increase Spatial Resolution: The Dual-Doppler Technique

Combining several lidar systems allows us to simultaneously derive spatial information on the three-dimensional wind with high temporal resolution. The dual- and triple-Doppler lidar techniques utilize two or three lidars located at different physical locations. The technique follows simple geometrical arguments, which are demonstrated below by considering two Doppler lidars labeled 1 and 2, respectively. To apply

the technique, the radial velocity must be measured simultaneously by the two lidars at a particular point in space. This allows the two-dimensional wind vector at the crossing point in the plane spanned by both beams to be retrieved provided that the beams are not parallel. First, the data for the region in which both lidar beams overlap are mapped onto a Cartesian grid and aggregated at each grid point. The vector $\mathbf{rv} = (rv_1, rv_2)^T$ contains the radial velocities measured by both lidars in the range gate around the point where the beams intersect. If $\mathbf{u} = (u, v, w)^T$ is the Cartesian wind vector at this point and \mathbf{A} is the lidar projection matrix containing the directional unit vectors describing the plane spanned by the lidar beams, we can write

$$\mathbf{rv} = \mathbf{A} \cdot \mathbf{u} . \quad (47.1)$$

For example, if we consider a plane parallel to the ground in which az_1 and az_2 are azimuth angles, the equations for the u and v components in that plane are, respectively,

$$u = \frac{rv_1 \cos(az_2) - rv_2 \cos(az_1)}{\sin(az_1 - az_2)} , \quad (47.2)$$

$$v = \frac{rv_2 \sin(az_1) - rv_1 \sin(az_2)}{\sin(az_1 - az_2)} . \quad (47.3)$$

Fig. 47.3 Application of the dual-Doppler technique. The locations of the lidars are indicated by *triangles* and the scan sectors are shown as viewed perpendicular to the plane. The *vertical axis* of the plot shows the height from the crater floor, and the *horizontal axis* shows the distance from the highest point on the rim in the scan plane. The *rectangular grid* represents the plane in which the two-dimensional wind vector is retrieved. The *inset* provides a view of the crater from above, showing the location of the plane for coplanar scans and the relative positions of the two lidars (after [47.19])

More detailed information on this technique is given in [47.58].

A proven way to combine measurements from two lidars is to perform a fixed beam scan in which both lidar systems stare at the same point in space [47.59]. In [47.17, 18, 60], the virtual tower method was applied to two lidars that retrieved horizontal wind and turbulence profiles at selected locations in space, while three lidars were used in [47.61, 62] to retrieve virtual towers of the three-dimensional wind and turbulence. The dual-Doppler technique also yields information on the spatial two-dimensional wind field. Two scan types are often used to achieve this: low-elevation plan position indicator (PPI) scans are performed to obtain the horizontal wind components and range height indicator (RHI) scans are implemented to retrieve the vertical velocity and the horizontal wind component in the vertical plane spanned by both lidars. An application of this method is illustrated in Fig. 47.3 [47.19]. In this application, RHI scans were performed to retrieve the wind field in a meteor crater [47.63]. Other applications can be found in [47.64]. Those authors assembled radial velocity measurements from independent Doppler lidars into velocity vectors in the vertical plane using a least squares retrieval method. In [47.60], the coplanar scan technique was employed to investigate coherent structures in a horizontal plane over homogeneous terrain. The great advantage of applying the dual-Doppler technique is that information on the spatial distribution of wind in layers that can

only otherwise be probed with aircraft or radiosondes can be obtained with high temporal resolution (on the order of minutes or less) and spatial resolution (on the order of a few tens of meters). When selecting the lidar sites for dual-Doppler scans, it is important to ensure that the angle Δaz between the laser beams of the lidars in the targeted atmospheric volume is not too large or too small to avoid too large propagation errors (it should be approximately $30^\circ < \Delta\text{az} < 150^\circ$). Also, when performing coplanar horizontal PPI scans to investigate the horizontal wind field, the lidars must be installed at the same height above sea level.

47.3.2 Example of the Derivation of Compound Quantities: Sensible and Latent Heat Fluxes

The sensible and latent turbulent heat fluxes are parameters that characterize the conditions in the convective boundary layer. To obtain their profiles, it is necessary to perform simultaneous turbulence-resolving measurements of vertical velocity and temperature or humidity in approximately the same atmospheric volume and with roughly the same temporal resolution (see also Chap. 55). For example, the kinematic latent heat flux is calculated as

$$\overline{w'q'} = \frac{1}{N} \sum_{i=1}^N (w - \bar{w})(q - \bar{q}), \quad (47.4)$$

where N is the number of samples, q is the specific humidity, and w is the vertical wind speed. Alternatively, the flux can be computed using the covariance spectrum Co_{wq} via

$$\overline{w'q'} = \int_{f=\frac{1}{T}}^{\frac{n}{2T}} \text{Co}_{wq}(f) df. \quad (47.5)$$

The volume should be no larger than a few tens of meters cubed, and the temporal resolution should be on the order of seconds. So far, most flux measurements have been derived from aircraft-based in-situ observations [47.65], meaning that data are only available from extensive field experiments. Airborne vapor and Doppler lidar systems have been used in combination to derive latent heat flux profiles based on the covariance spectrum [47.26]. Much progress has been made in obtaining variance and higher order measurements of water vapor, temperature, and wind [47.66, 67]. However, the extraction of reliable vertical flux profiles from synergetic, turbulence-scale-resolving remote-sensing measurements of vertical wind, temperature, and humidity is still a major challenge in boundary-layer research.

47.3.3 Example of the Application of Composite Atmospheric Profiling to Increase Spatial and Temporal Resolution: Humidity Profiles

Humidity often shows high spatiotemporal variability at the mesoscale. This high variability is known to be a crucial influence on the timing and location of moist convection development [47.21]. However, most observation systems have either high temporal resolution but low or no vertical resolution (e.g., a microwave radiometer or GNSS) or high vertical resolution but low temporal resolution (e.g., radiosondes). Other systems, such as water-vapor lidars or DIALs, are not yet incorporated into networks with sufficient horizontal density. Since single systems are not able to resolve this high spatiotemporal variability, different methods have been introduced to increase the spatiotemporal resolution of humidity.

For example, in [47.21], high vertically resolved water-vapor profiles from radiosoundings were combined with integrated water-vapor (IWV) data from GNSS stations [47.68, 69], which are continuously measured and available with high horizontal resolution. In a first step, the GNSS-driven IWV data $\text{IWV}^g(x_g, y_g)$ were combined with the radiosonde-derived IWV data $\text{IWV}^r(x_r, y_r)$ to generate an IWV

field on a high-resolution grid, $\text{IWV}^{g,r}(x, y)$. In the second step, the water-vapor profiles from radiosondes, $q^r(x_r, y_r, z)$, were interpolated to the same high-resolution grid, yielding the profiles $q^r(x, y, z)$. A new IWV field $\text{IWV}^r(x, y)$ on the high-resolution grid was then estimated from these interpolated $q^r(x, y, z)$ profiles. Except for radiosonde sites, the $\text{IWV}^r(x, y)$ and $\text{IWV}^{g,r}(x, y)$ data did not necessarily agree. The difference between them was used to adjust the interpolated $q^r(x, y, z)$ profiles to get new water-vapor profiles

$$q(x, y, z) = q^r(x, y, z) + \text{AF}(x, y)q^r(x, y, z), \quad (47.6)$$

where $\text{AF}(x, y)$ is an adjustment function that is calculated via [47.21]

$$\text{AF}(x, y) = \frac{\text{IWV}^{g,r}(x, y) - \text{IWV}^r(x, y)}{\text{IWV}^r(x, y)}. \quad (47.7)$$

The resulting highly resolved water-vapor profiles and accompanying convection-related indices highlighted the areas in which deep convection occurred.

Radiosonde and microwave radiometer data have also been successfully combined to enhance the vertical and temporal resolution of humidity profiles [47.25]. In this scheme, a ground-based scanning microwave radiometer that provided IWV^m was used to determine the vertical distribution of water vapor between radiosonde ascents, $q(z, t)$. Multiplying the linearly temporally interpolated water-vapor field detected by radiosondes, $q^r(z, t)$, by the ratio of $\text{IWV}^m(t)$ to the linearly interpolated $\text{IWV}^r(t)$ yielded

$$q(z, t) = q^r(z, t) \frac{\text{IWV}^m(t)}{\text{IWV}^r(t)}. \quad (47.8)$$

The integrated profiling technique (IPT [47.24, 38]) is a variational technique for deriving temperature and humidity profiles at high temporal and vertical resolution based on microwave radiometry and radiosonde ascents. The advantage of microwave radiometers is that they provide low-resolution water vapor profiles at high temporal resolution (≈ 1 s). Although the accuracy of IWV^m is very good ($\approx 0.5 \text{ kg m}^{-2}$), the signal only has approximately two degrees of freedom [47.37], which means that only two independent height intervals of water vapor can be distinguished. This is due to the fact that microwave radiometer radiance observations (also expressed as *brightness temperatures*) are purely passive (i.e., they only receive radiation emitted by the gases—mostly water vapor and oxygen—themselves). The temperature profile can be retrieved with ≈ 4 degrees of freedom, and the best vertical resolution is obtained in the lowest 1 km of the atmosphere.

By combining radiosonde and microwave radiometer data, IPT can add significant profile information to the time period between two subsequent operational radiosonde ascents, regardless of whether both sets of measurements are performed at the same site or different sites. Depending on the density of the radiosonde network, a ground-based profiling station has the potential to significantly improve the quality of the network or even to substitute specific radiosonde stations.

Ground-based Raman lidar water-vapor profiles and microwave radiometer brightness temperatures can be used synergetically to enhance the vertical resolution of humidity. Due to the fact that a water-vapor Raman lidar measures atmospheric backscatter at a slightly different frequency than the emitted laser pulse, these observations deliver a water vapor extinction profile that can be directly related to a high vertical resolution atmospheric humidity profile. However, strong extinction due to hydrometeors hinders water vapor profiling of Raman lidars within or above clouds. In addition, incomplete overlap of the transmitter and the receiver telescope near the surface as well as the decrease in the signal-to-noise ratio with height limit height coverage.

A retrieval algorithm that combines the advantages of both instruments in an optimal estimation approach, which allows the uncertainty in the estimated humidity profile to be determined directly, has been reported [47.30]. The analysis showed that accurate lidar retrieval dominated the accuracy within the range of the lidar, but information gain was achieved through composite atmospheric profiling beyond this range, especially during the daytime, when the vertical range of the lidar was limited by a low signal-to-noise ratio. A similar variational retrieval based on a Kalman filtering approach showed that water-vapor profile retrieval is also possible in cloudy conditions [47.31]. As mentioned above, other composite profiling studies that combine radiometer and radar wind profiler data have also been reported [47.32].

47.3.4 Example of the Derivation of Compound Quantities: Cloud Properties and Hydrometeor Classification

Besides the thermodynamic and dynamic properties of the ABL, it is very important to probe the micro- and macrophysical cloud properties. One reason why this is important is that clouds and their associated microphysical properties actively regulate the radiation budget and the hydrological cycle. However, nearly

all remote-sensing systems have limitations regarding measurements in clouds. For example, lidar signals normally only penetrate thin cloud layers. Cloud radars are not able to detect the cloud base due to the *large droplet issue* (i.e., a few small droplets from drizzle dominate the radar signal and obscure backscatter from smaller cloud droplets). Microwave radiometers have poor vertical resolution and only provide estimates for the liquid water path (LWP) of clouds. Therefore, different algorithms have been developed to determine cloud properties by applying a combination of different sensors. One of these algorithms, Cloudnet [47.22], determines cloud properties from ground-based observations. The core instruments used in the cloud retrievals are a Doppler cloud radar, a ceilometer, a microwave radiometer, a rain gauge, and the output of a numerical weather prediction (NWP) model. Cloudnet algorithms can provide various meteorological products: the cloud base height and target classification (e.g., aerosol, insects, ice, melting ice, cloud droplets, drizzle, rain, and clear sky), the liquid water content (LWC), and the ice water content (IWC). Furthermore, in principle, the turbulent kinetic energy (TKE) and the eddy dissipation rate can be derived. Within the framework of the European aerosols, clouds and trace gases research infrastructure (ACTRIS) research initiative, Cloudnet algorithms are applied to a number of permanent cloud observatories such as Chilbolton (UK), CE-SAR (Netherlands), Palaiseau (France), CNR-IMAA atmospheric observatory (C-IAO, Italy), and JOYCE & MOL-RAO (Germany). Combining the various remote-sensing systems was found to considerably enhance operational observations of liquid water clouds. The Cloudnet software is for example implemented at the KITcube, where additional remote-sensing systems are available (Sect. 47.4.1).

Another method of obtaining cloud properties is to extend the integrated profiling technique to retrieve not only temperature and humidity profiles from microwave radiometers and radiosondes but also profiles of cloud liquid water content and cloud droplet effective radius [47.29]. This can be achieved by adding reflectivity profiles from cloud radar data as well as the cloud boundaries derived through the Cloudnet target classification. Microphysical properties of warm clouds have also been derived by applying the SYRSOC (synergistic remote sensing of cloud) technique, as described in [47.70]. This technique involves combining cloud radar, microwave radiometer, and lidar/ceilometer data to derive profiles of liquid water content and cloud droplet number concentration.

47.4 Observation Platforms

Various integrated observation platforms are deployed around the world. While many of the instruments used in these integrated platforms are similar (e.g., ceilometers, Doppler lidars, microwave radiometers, cloud radars, radiosonde stations; see Tables 47.1 and 47.2), the platforms do differ in the purpose and main scientific objectives of the site. It is possible to distinguish between mobile platforms, which are mainly deployed for limited periods during field campaigns, and fixed platforms, which are operated for long periods at the same location. Without any claim to be complete, a selection of mobile and fixed observation platforms are introduced in the following (see also Table 47.3).

47.4.1 Mobile Platforms

Some prominent examples of mobile platforms currently operated by certain institutions worldwide are described below. These platforms are evolving due to technological progress, and are partly already operated in an information environment comprising a high-resolution model with assimilation of data (Table 47.3).

The ARM Mobile Facilities (AMFs)

The ARM Mobile Facilities are primarily used to investigate the phenomena that control radiative transfer in the atmosphere. In order to explore research questions that are not addressed by ARM's fixed atmospheric observatories [47.2], scientists can propose a field campaign that utilizes one of the three AMFs to collect atmospheric and climate data from undersampled regions around the world. Each AMF is designed to operate in any environment—ranging from the cold of the Arctic to the heat of the tropics—during cam-

paigns that typically last about a year. The ARM Mobile Facilities consist of several portable shelters, a baseline suite of instruments, and communication and data systems. When deployed for a field campaign, an experienced project management and engineering team travels with the AMF to set up and modify the shelters and instruments and to train and manage the staff who will continuously operate the facilities. Scientific and infrastructure staff are also available for collaborative planning activities, as is local on-site or virtual support for scientists who are using an AMF for their research. An overview of AMF deployments is given in [47.2].

The AMFs have instrumentation and data systems that are similar to those in fixed atmospheric observatories. About 50 instruments are deployed with each facility, enabling continuous measurements of clouds, aerosols, precipitation, energy, and other meteorological variables. Measurement capabilities of the AMFs include standard meteorological instrumentation, a broadband and spectral radiometer suite, and remote-sensing systems, including lidars and cloud radars.

The instrumentation available with AMF2 is, with a few notable exceptions, the same as that available with AMF1 and AMF3. Because AMF2 was designed to support shipboard deployments, its baseline suite of instruments is marine-focused. The AMFs are also designed to host guest instruments or collaborate with experiments from other agencies, making them ideal platforms for conducting joint research anywhere in the world. Data from these facilities undergo quality checks and are made freely available to the international research community in near real-time through the ARM Data Center via Data Discovery.

Table 47.3 Examples of mobile and permanent observation platforms and their key instruments (bolded entries indicate core instruments that are relevant to Cloudnet retrievals)

The Karlsruhe Observatory for Convection Studies (KITcube)

KITcube (Fig. 47.4) is an advanced integrated atmospheric observation system operated by the Karlsruhe Institute of Technology (KIT). It is designed to be deployed and operated in international measurement campaigns involving boundary-layer, convection, and atmospheric transport studies over heterogeneous terrain defined by e.g. changes in surface properties and orography [47.1]. The mobile KITcube includes various remote-sensing and in-situ systems that permit the observation of process (chain) of convection including the energy exchange at the Earth's surface, the evolution of the ABL, exchanges of heat, moisture, and aerosols between the ABL and free troposphere, and the development of moist shallow and deep convection. The spectrum of interest ranges from the micro- to the mesoscale, and KITcube is designed to effectively probe cross-scale interactions in particular. One specific highlight is the deployment of several powerful scanning Doppler lidars that have been successfully used in dual-Doppler [47.58, 60] and multi-Doppler [47.71, 72] lidar studies of the spatial distribution of wind. Examples are given in Sect. 47.8.1. Other highlights of the studies performed with KITcube include the

application of a Doppler lidar and cloud radar in combination to measure the vertical wind below and within clouds [47.1, 20] and the synergetic utilization of a Doppler lidar and scanning microwave radiometer to analyze moisture transport [47.25].

The Leipzig Aerosol and Cloud Remote Observations System (LACROS)

LACROS [47.3] (Table 47.3) is designed to investigate unresolved questions concerning the interaction between aerosol particles and clouds and the corresponding indirect effects on precipitation and radiative transfer. Synergetically extracting information about cloud and aerosol properties from multi-instrument and hence multi-sensor observations is key to overcoming our current lack of knowledge in this area. LACROS comprises a set of active and passive remote-sensing instruments that are partially available for use in field campaigns. The active remote-sensing instruments span the wavelength range from the UV to microwave radiation. Passive instrumentation is included to help interpret the active remote-sensing measurements. The system also includes meteorological surface, radiation-balance, and radiosonde stations that enable it to fulfill the criteria of the Baseline Surface Radiation Network (BSRN).

47.4.2 Permanent Platforms

Permanently operated platforms at fixed locations are used to monitor processes and various atmospheric changes. They also provide data for comparison with satellite data. Some of the main facilities are described below.

The CNR-IMAA Advanced Observatory for Atmospheric Research (C-IAO)

The Istituto di Metodologie per l'Analisi Ambientale of the Italian National Research Council (CNR-IMAA) operates the C-IAO (the CNR-IMAA Atmospheric Observatory) [47.7]. This advanced atmospheric observatory is located in Tito Scalo, close to Potenza in southern Italy. Its main scientific objective is to perform long-term measurements of water vapor, aerosols, and cloud properties. The observatory's equipment consists of ground-based remote-sensing instruments for aerosols, water vapor, and clouds, including active and passive sensors (Table 47.2). The observation strategy is to provide quality-assured measurements for satellite validation and model evaluation. The measurements obtained with the active and passive instruments are also used synergetically to improve atmospheric profiling and integration algorithms (e.g., water-vapor profiling using Raman lidar and microwave radiometer data). The C-IAO database is utilized in satellite data validation programs. The station additionally hosts two European aerosol research lidar network (EARLINET) multiwavelength Raman lidars, one of which acts as the mobile reference for the network [47.73]. A detailed description of the C-IAO infrastructure, its scientific activities, and its observation strategy is given in [47.7].

The CESAR Observatory in Cabauw

The Cabauw Experimental Site for Atmospheric Research (CESAR [47.5]) is located in the southwest region of the Netherlands. At CESAR, a large set of instruments are employed to study the atmosphere and its interaction with the land surface. CESAR focuses on monitoring long-term trends in atmospheric changes, studying atmospheric and land-surface processes for climate modeling, validating spaceborne observations, and developing and implementing new measurement techniques. The observatory collaborates with several Dutch universities and major research institutes and is involved in intense international cooperation. Besides the instruments listed in Table 47.3, a 213 m high tower is used to investigate the links between land-surface conditions, the state of the ABL, and general weather conditions. A scanning X-band radar operated by Delft University of Technology is located on top of the tower. The remote-sensing systems are located ≈ 300 m from the tower.

The Richard Aßmann Observatory

The Lindenberg Meteorological Observatory—Richard Aßmann Observatory (MOL-RAO) of the German Meteorological Service (DWD) was founded in 1905 [47.74]. It is situated in Lindenberg, eastern Germany. For over 100 years, the main focus of the work carried out at this observatory has been vertical atmospheric profiling. This was originally done using captive balloons and kites, which were replaced in the 1930s with radiosondes (from 1947 on, the observatory released radiosondes four times a day). With the beginning of the 1990s, the observatory has increasingly used ground-based remote sensing methods such as radar, lidar, and microwave radiometer to enhance the profiling [47.75].

Currently, its research activities also encompass measuring programs to study solar and terrestrial radiation as well as interaction processes between the Earth's surface and the atmosphere [47.76, 77]. The data derived from the measurement systems operated at the observatory are used to produce a reference dataset, the *Lindenberg Column*, which characterizes the vertical structure of the atmosphere from the ground up to the stratosphere [47.4, 78]. Additionally, the MOL-RAO is the lead center of the Global Climate Observing System (GCOS) Reference Upper-Air Network (GRUAN), and it also acts as a testbed for other networks such as BSRN.

The data from the observatory, which are also obtained through sensor synergy [47.16, 79], contribute significantly to efforts to monitor the Earth's climate. They are also used to validate satellite sensors and to verify weather prediction and climate models. In addition, the observatory is testing new sensors and observing systems that will potentially be incorporated into the DWD's measuring network.

The JOYCE Observatory

The Jülich Observatory for Cloud Evolution (JOYCE [47.6]) in Jülich, Germany was established to probe boundary-layer cloud development, including the impacts of factors such as dynamics, thermodynamics, and aerosols, as well as interactions with vegetation and the Earth's surface. Another focus of the observatory is precipitation generation, including the ice phase [47.80] and drizzle production during the warm rain process [47.81]. In 2016, JOYCE was funded to become a DFG (Deutsche Forschungsgemeinschaft) core facility, with the goal being to provide users from the scientific community with regulated access to the observation facility and the continuous datastream. JOYCE is part of the European ACTRIS observatory network for monitoring the atmospheric column, and is evolving into the ACTRIS topical center for microwave radiometers. This topical center shall define ACTRIS-

wide harmonized procedures for measurement configuration, calibration, quality control and retrieval development and application. To achieve these aims, JOYCE is equipped with a variety of in-situ and remote-sensing instruments (Table 47.3). Composite profiling at JOYCE is complemented by measurements of two scanning X-Band radars, one located on a close-by pit-mining hill (Sophienhöhe), the other located at the University of Bonn. JOYCE was also selected for the HOPE field campaign [47.13], which focuses on ABL clouds.

47.5 Specifications

In this section, we discuss the specifications of instruments that are used for integrated profiling. The instruments considered are those described in the rel-

This campaign served as the observational basis for the critical evaluation of high-resolution models (< 1 km). JOYCE exploits instrument synergy to implement integrated profiling techniques [47.29], which are used to retrieve physically consistent profiles of temperature, humidity, LWC, and the effective radius of the water cloud droplets, along with the corresponding uncertainties. Finally, long-term observational data from JOYCE are used to improve the parameterization schemes of numerical weather and climate prediction models.

evant instrument-focused chapters of this Handbook (in Parts B, C, and D); we do not consider any other instruments here.

47.6 Quality Control

Composite atmospheric profiling is a field that is generally characterized by rapid development in terms of both the underlying measurement systems used and the fusion techniques applied. A general methodology for quality control or international standardization in this field appears to be missing from the literature, although some subcommunities that focus on specific instrumentation (e.g., for cloud parameters) have recently started to address this issue. Therefore, we now present some quality-control considerations for basic types of composite profiling.

When composite atmospheric profiling is applied to extend the measurement range and to increase spatial and temporal resolution (Sect. 47.3.1), quality control can be achieved by comparing the various parameters (e.g., temperature, humidity, and wind speed) in layers of overlapping redundant measurements. For example, profile measurements from towers can be used to check profiles from scanning wind lidars by collocating measurements and comparing data for the lidar range gate next to a tower instrument. Furthermore, integrated information can be exploited to assess the quality of observations (e.g., IWV data from GNSS, radiosondes, and microwave radiometers) (Sect. 47.3.3). When composite atmospheric profiling is employed to derive compound quantities such as turbulent heat and moisture flux profiles (Sect. 47.3.2), the quality of the resulting data can be assessed by comparing them with values obtained from in-situ measurements that have known uncertainties, such as data from high towers with instruments to measure the turbulence-resolving temperature, humidity, and wind, or data from aircraft equipped with turbulence-probing systems [47.82].

The variational retrieval frameworks used when performing composite atmospheric profiling are frequently based on Gaussian statistics, i.e., the random uncertainties in atmospheric parameters and observables are assumed to follow a normal distribution. Variational retrievals require prior knowledge of the random uncertainties (not only the uncertainties in the signal observables but also their covariances). If a forward model is applied (i.e., there is a conversion from atmospheric state space to measurement space), the random uncertainty in this model must also be considered. While observational uncertainty can be determined largely through the application of calibration standards, model uncertainty is difficult to quantify, as the true state of the atmosphere is seldom known.

Aside from prior knowledge of random errors, quality-controlled, bias-free observations are crucial when performing composite atmospheric profiling in variational retrieval approaches (such as optimal estimation). If the observations include errors due to unidentified systematic bias, the retrieval results will most probably be affected in a nonlinear way. Thus, bias error must be identified and removed beforehand if possible. While it may be possible to compare the observations to independent data sources, remote-sensing approaches often also offer inherent quality checks. For instance, a microwave radiometer spectral consistency check that can be applied directly to brightness temperature measurements and can reveal channels strongly affected by bias has been developed [47.29]. Obviously, in such an approach, spectral consistency statistics must be known a priori. In addition, the results of the variational retrieval itself can serve as

a further quality check of the observations, particularly in clear-sky cases; nonconvergence or physically

inconsistent solutions may hint at measurement offset errors.

47.7 Maintenance

The maintenance that must be performed on the observation systems used in composite atmospheric profiling is the same as that described in the relevant instrument-focused chapters of Parts B, C, and D of this Handbook.

There is little information in the literature about additional maintenance requirements or common standards, such as maintenance intervals, when instruments are used for composite profiling.

47.8 Applications

A wide range of applications of composite atmospheric profiling have been proposed in the last few decades. We focus on a few prototypical examples below.

region of Stuttgart. Note the spatial variability of the horizontal wind field over hilly terrain.

47.8.1 Dual-Doppler Lidar Measurements: The Virtual Tower Technique

An example of the application of the so-called virtual tower technique is displayed in Fig. 47.5. One way to use this technique is to have two Doppler lidars perform coordinated stop-and-stare scans [47.83]. In this configuration, both lidars measure simultaneously at discrete points in space for approx. 10 s. By varying the azimuth and elevation angles, virtual towers can be placed at different locations over otherwise inaccessible terrain. Figure 47.5b shows the horizontal distribution of wind profiles obtained with the virtual tower technique in the

47.8.2 Dual-Doppler Lidar Measurements: Coplanar Scans

An example of the retrieval of a wind field in a vertical plane from dual-Doppler lidar measurements is given in Fig. 47.6. The data were measured during an experiment in a meteor crater in Arizona [47.63], where two scanning Doppler lidars were located on the crater's north rim and the floor of the crater, respectively. The dual-Doppler retrievals were calculated from continuous coplanar RHI scans. The lidar on the rim scanned at elevation angles ranging from -10° to 20° . The scan resolution of this lidar was 0.75° , and the range gate length was 15 m. The lidar on the crater floor scanned at eleva-

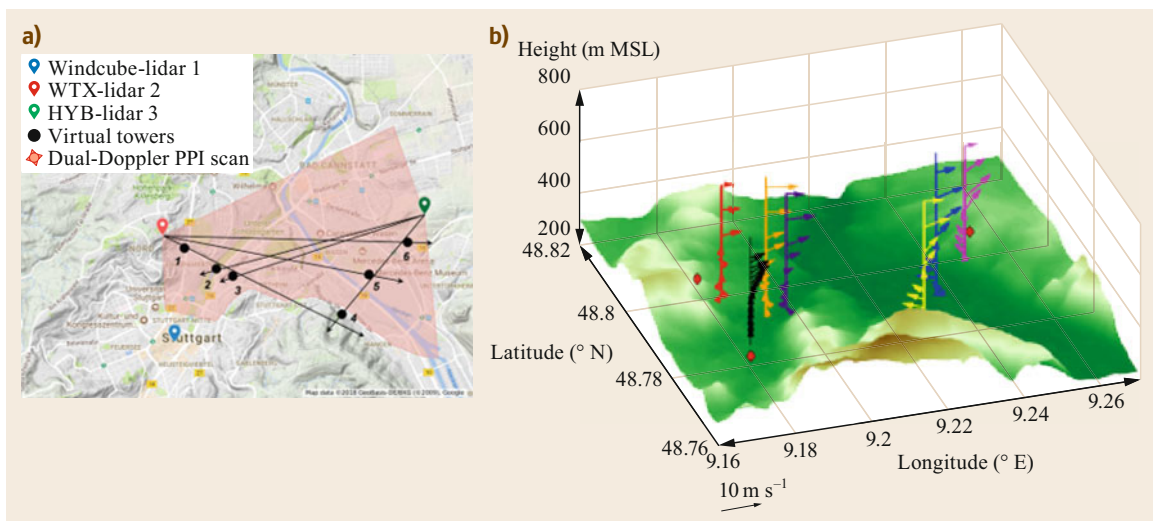

Fig. 47.5 (a) Schematic of the intersecting lidar beams used in an application of the virtual tower technique, and (b) some vertical profiles of horizontal wind measured at different virtual tower sites (measurements were performed at 06:00–07:00 on 19.07.2017; schematics from current project work at KIT © B. Adler)

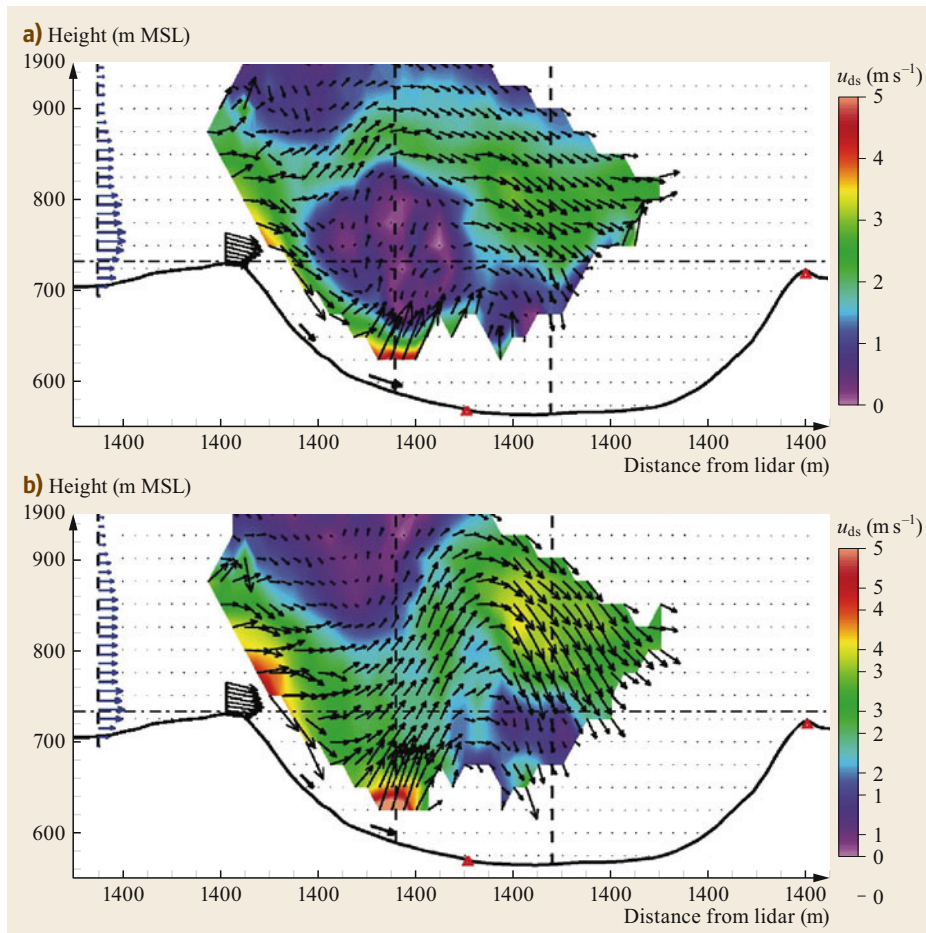

Fig. 47.6a,b Two-dimensional wind field in a vertical plane above the Meteor Crater in Arizona, USA, based on dual-Doppler lidar measurements. An abrupt change in flow structure between the bifurcation and warm air intrusion phases can be seen from the 2.5-min-mean dual-Doppler wind retrievals obtained at 22:40 MST (**a**) and 22:52 MST (**b**). The positions of the two Doppler lidars (crater floor and on the rim) used for the dual-Doppler lidar measurements are indicated by *red triangles* (after [47.84] with permission from the American Meteorological Society)

tion angles ranging from 10° to 150° . The scan resolution of the lidar on the crater floor was 1.4° and the range gate length was 24 m. The data were interpolated onto a $25\text{ m} \times 25\text{ m}$ grid [47.84]. The dual-Doppler lidar wind field retrievals allowed the development of a hydraulic jump in the atmosphere above the crater to be studied in detail. At 22:40 MST (Mountain Standard Time) (Fig. 47.6a) there was a bifurcation of the wind flow, with a cavity separating the warmer upper and colder lower currents and a hydraulic jump on the lower slope. However, an unsteady lee wave was present in the statically stable upper current. By 22:52 MST (Fig. 47.6b), the cold and warm air currents had merged, eliminating the cavity between the two currents and bringing warm residual-layer air down into the basin. The merging of the two currents and the stable layers increased the downslope wind speeds as well as the layer depth.

The hydraulic jump strengthened (Fig. 47.6b) as the flow became more negatively buoyant relative to the adjacent warm air and as momentum was transported downward into the stable layer from the warm air intrusion. The warm descending air over the upwind sidewall was actually the descending branch of the first wave of a two-wave train that extended across the basin with a wavelength approximately equal to the basin radius and an amplitude of approximately twice the basin depth.

47.8.3 Latent Heat Flux Profiles

As described in Sect. 47.3.2, extracting reliable vertical sensible and latent heat flux profiles for the ABL is still a major challenge due to the need for simultaneous measurements of wind and temperature or humidity with high vertical and temporal resolution. One of the

Fig. 47.7 Latent heat flux profile, Q_E from airborne lidar data and in-situ results for the same leg. The measurements were taken at about 11:00 UTC. The average top of the convective boundary layer (CBL) was at ≈ 1500 m ASL. Included are sampling (*thin dashed*) and noise (*thin dotted*) uncertainty ranges, plus an in situ results (*black dot with sampling uncertainty bar*) (after [47.26] with permission from Wiley and Sons)

few studies that successfully obtained latent heat flux profiles [47.26] used an airborne nadir-pointing differential absorption lidar (DIAL) and a $2 \mu\text{m}$ Doppler lidar to derive profiles of latent heat flux and then compared them to the latent heat flux profiles calculated from in-situ measurements performed with the Do 128 research aircraft [47.82, 85]. The measurements were performed over hilly terrain. On average, the latent heat fluxes obtained with remote-sensing instruments agreed with the in-situ values (Fig. 47.7). The latent heat flux values in the ABL (i.e., $\lesssim 1500$ m ASL) varied between 100 and 500 W m^{-2} . This example illustrates the considerable

potential of remote-sensing instruments to study turbulent exchange processes in the ABL, which requires knowledge of the sensible and latent heat flux profiles.

47.8.4 Increasing the Vertical and Temporal Resolution of Humidity Profiles

By combining high temporal resolution IWV measurements from a microwave radiometer with high vertical resolution humidity profiles from radiosoundings, it is possible to explore the evolution of the humidity profile between individual radiosoundings [47.25]. Figure 47.8 shows humidity profiles for a valley on the mountainous island of Corsica that were retrieved with this method. The arrival of a sea breeze at the measurement site at around 12:30 LT (local time)—as indicated by an increase in humidity in the region up to 1000 m—was detected due to the high temporal resolution of the profiles. It would not have been possible to detect the exact arrival time of the sea breeze using only the radiosonde profiles (obtained every 3 h) or by simply interpolating linearly between the radiosonde profiles.

47.8.5 Humidity Profiles from Active and Passive Remote Sensing

A water-vapor Raman lidar and a microwave radiometer were used during HOPE to retrieve atmospheric humidity profiles in the lowest 3 km of the atmosphere. A variational retrieval (as defined in [47.30]) was applied to the lidar-only, microwave radiometer-only, and composite microwave radiometer and lidar observations, with both instruments located within a few meters of each other. As expected from the physics underpinning these measurements, the derived lidar-only retrieval uncertainty during cloud-free conditions ($< 0.2 \text{ g m}^{-3}$) with a sufficient signal-to-noise ratio was significantly bet-

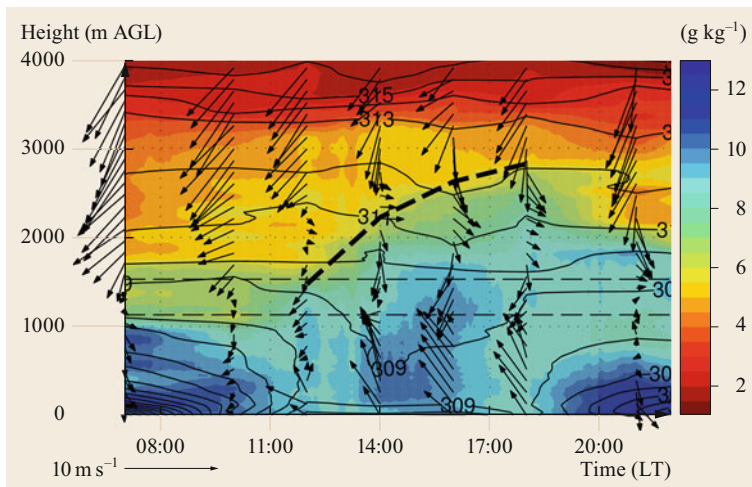

Fig. 47.8 Specific humidity (*color-coded*), potential temperature (*black isolines*), and horizontal wind vector (*arrows*) measured by radiosondes at Corte on the island of Corsica on 19 August 2012. The specific humidity was interpolated from microwave radiometer and radiosonde data, and the potential temperature was linearly interpolated from the radiosoundings (after [47.25])

Fig. 47.9a–c Vertical profiles of the random uncertainty (theoretical error) in the absolute humidity retrieved from water vapor lidar and/or microwave radiometer measurements for 100 clear-sky cases during HOPE. **(a)** Water vapor lidar only, **(b)** microwave radiometer only, and **(c)** combination of both lidar and microwave radiometer (composite profiling). The dashed horizontal lines indicate levels of full hypothetical lidar attenuation due to the presence of cloud or a signal-to-noise ratio that is too low. The corresponding colored lines (bold) show the uncertainty when there is no lidar signal above the dashed line (after [47.86])

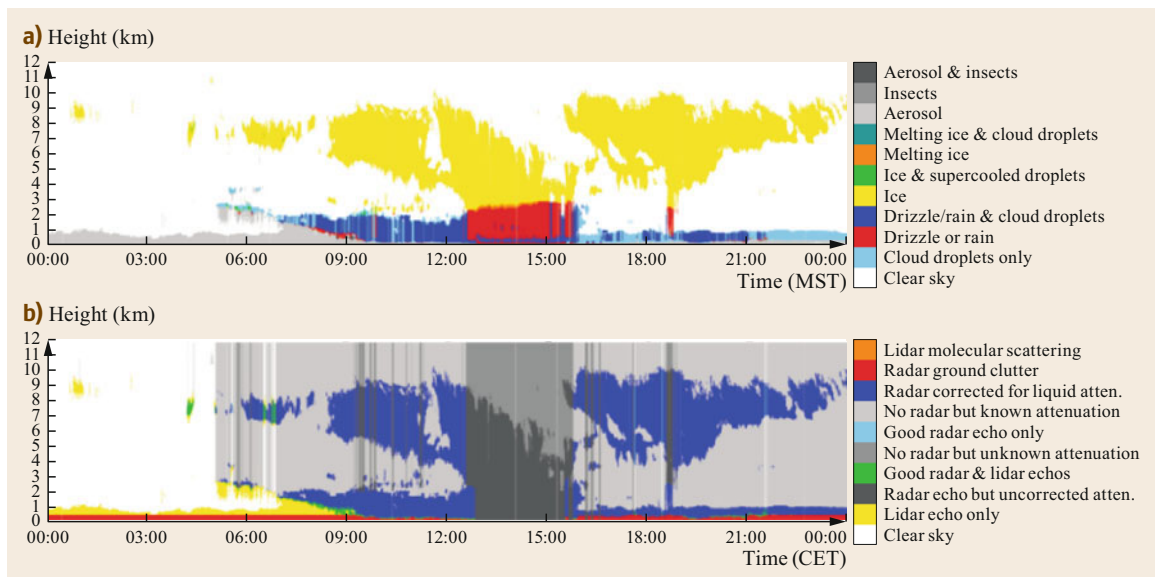

Fig. 47.10a,b Examples of **(a)** target classification and **(b)** radar and lidar detection status for measurements from Chilbolton Observatory using Cloudnet on 17 November 2003 (after [47.22] with permission from the American Meteorological Society)

ter than the microwave radiometer-only retrieval uncertainty ($0.6\text{--}0.8\text{ g m}^{-3}$; compare Fig. 47.9a,b, red lines). However, above the height where the Raman lidar signal dropped off because the maximum range of the lidar had been exceeded or due to the presence of a liquid cloud, the lidar-only retrieval uncertainty increased with height towards the background humidity profile assumed (the so-called a priori profile). Due to the vertical correlation of humidity at the different height levels considered in the optimal estimation retrieval, the uncertainty increases gradually and not in an ad-hoc manner. The benefit of composite atmospheric profiling is shown in Fig. 47.9c. At heights above the detection threshold of the lidar signal, the retrieval uncertainty stays well below the lidar-only and microwave radiometer-only values (up

to 0.3 g m^{-3}). The degrees of freedom (DOF) for the signal in the microwave radiometer measurements are used to improve the profile above the height of the lidar detection threshold, whereas these DOF are used to retrieve the full profile in the microwave radiometer-only case. This underlines the added value of composite profiling.

47.8.6 Target Classification with Cloudnet

One of Cloudnet's products is a target classification. Utilizing the fact that a radar and a lidar are sensitive to different particle sizes and concentrations, the atmospheric targets of each radar/lidar pixel are categorized into classes. One example of the target classification provided by Cloudnet is given in Fig. 47.10.

47.9 Future Developments

Currently, most composite atmospheric profiling methods combine only two or a few different sensors or sensor systems. However, given that this is a rather new and rapidly growing research field, we can expect considerable advances in such methods in the near future. These advances will likely involve enhancing the temporal and spatial resolution of variables and retrieving new variables. [47.87] outlines how higher order moments and fluxes can be derived from high-resolution lidar measurements as well as future directions in this field. Differential absorption lidars (DIALs, Chap. 26) for retrieving water-vapor profiles with temporal resolutions of approximately 20 s to 20 min are being developed which are not sufficient for fluxes but allow to obtain high vertical resolution profiles in the boundary layer [47.88], and will probably become commercially available soon.

A more comprehensive approach to combining many observed variables can be realized by extending the site atmospheric state best estimate (SASBE) method [47.39, 40]. Variational approaches for optimal merging, as in Sect. 47.8.5, with known systematic and stochastic errors have a big potential for synergistic use of multiple sensors.

This is actually what we have shown above applying the optimal estimation approaches for optimal merging with known systematic and stochastic errors characteristics of different have a big potential for synergistic use of multiple sensors.

In addition to ground-based observations, satellite sensors will also bring a wealth of additional information into tropospheric research. Composite profiling of ground-based and satellite-based remote sensing for atmospheric stability retrieval, e.g., has been successfully carried out [47.89]. The EarthCare mission [47.47, 90] provides an excellent example of a future spaceborne mission to measure aerosols, clouds, rain, and radiation.

Beyond composite atmospheric profiling, it is easy to predict that there will be rapid progress in the assimilation of observed data from many different kinds of instruments into numerical models. Future networks of lidar, radar, and passive remote-sensing systems will allow much more detailed analysis and predictions of the state of the atmosphere, particularly at the mesoscale and in relation to convection modeling, for both urban and mountainous areas.

47.10 Further Reading

A summary of combinations of different ground-based remote-sensing stations is given in COST (European Cooperation in Science and Technology) Report 720:

Christoph Kottmeier

Institute of Meteorology and Climate Research, Department Troposphere
Karlsruhe Institute of Technology (KIT)
Karlsruhe, Germany
christoph.kottmeier@kit.edu

Christoph Kottmeier is professor of meteorology and headed the Institute of Meteorology and Climate Research (Department Troposphere) at the KIT until 2020. His conducts tropospheric research by applying advanced observation techniques (aircraft, automatic buoys, lidar, and radar) as well as numerical modelling with COSMO and ICON model systems. He initiated the construction of the KITcube facility for integrated observation.

Bianca Adler

CIRES, University of Colorado Boulder
Boulder, CO, USA

NOAA/Physical Sciences Laboratory
Boulder, CO, USA
bianca.adler@noaa.gov

Bianca Adler was an atmospheric scientist in the Land Surface and Boundary Layer research group at the Institute of Meteorology and Climate Research (Karlsruhe Institute of Technology, Germany). Since 2020, Bianca Adler is a research scientist at CIRES in Boulder working at the NOAA Physical Science Laboratory (PSL). Her research focuses on multiscale processes in the boundary layer over complex terrain and the synergistic use of remote sensing, in-situ measurements, and high-resolution numerical simulations to gain the best possible insights into atmospheric conditions and processes.

Norbert Kalthoff

Institute of Meteorology and Climate Research, Department Troposphere
Karlsruhe Institute of Technology (KIT)
Karlsruhe, Germany
no.kalthoff@web.de

Norbert Kalthoff is group leader of the Land Surface and Boundary Layer research group at the Institute of Meteorology (Department Troposphere) and Climate Research at the Karlsruhe Institute of Technology in Germany. He received his PhD in meteorology in 1986 from the University of Bonn, Germany. His research team contributes to several national and international field campaigns worldwide, investigating land–surface processes and its impact on the atmospheric boundary layer as well as on the initiation of moist convection. His main scientific focus is on processes over complex terrain.

Ulrich Löhnert

Institute for Geophysics and Meteorology

ulrich.goersdorf@dwd.de

Ulrich Görzdorf is a research associate in the Remote Sensing Group of the Lindenberg Meteorological Observatory, operated by the DWD. He studied meteorology at the Humboldt University in Berlin, and obtained his PhD in radar wind profiling in 1999. His current research focuses on the assessment and evaluation of cloud radar and ceilometer measurements.

48. Aircraft-Based Flux Density Measurements

Raymond L. Desjardins , Devon E. Worth, Ian MacPherson, Matthias Mauder , Jens Bange 

This chapter presents aircraft-based methods of measuring the flux densities of sensible and latent heat, carbon dioxide, ozone, nitrous oxide, methane, and other trace gases. The main techniques and sensors that are used to measure flux densities with an aircraft are briefly described. Factors that affect the accuracy of those flux density measurements are discussed, including analysis techniques, run lengths, sampling heights, surface and environmental conditions, and data quality assessment. The use of aircraft-based flux density measurements to evaluate the representativeness of tower-based flux measurements is examined. The versatility of aircraft to act as sensor platforms under a wide range of conditions is demonstrated using several interesting examples. Future potential research directions are mentioned.

Aircraft are versatile sensor platforms that have the ability to measure surface-atmosphere exchange throughout the planetary boundary layer and can be rapidly deployed to areas of interest. Such flux measurements complement tower-based flux measurements (Chap. 55)

that provide data for long periods of time at one location. This combination of flux measurements has been widely used for ecosystem studies and for developing and validating atmosphere-biosphere models.

48.1 Measurement Principles and Parameters

This section briefly presents the main techniques for obtaining flux density measurements using aircraft-based systems as well as the variables measured and parameters calculated.

48.1.1 Flux Measurement Techniques

Several techniques have been used to measure the vertical fluxes of momentum, sensible heat, water vapor, and other scalars using aircraft-based systems. The eddy covariance (EC) technique provides the most direct measurements of mass and energy exchange at the land–atmosphere interface. Wavelet analysis, which yields wavelet cross-scalograms between vertical wind and various scalars, provides spatial information that makes it easier to relate flux density measurements to surface characteristics along a flight track. Both of these techniques require fast-response (10–20 Hz) sensors. For gases such as nitrous oxide (N₂O), volatile

organic compounds (VOCs), and agrochemicals, for which fast-response analyzers are unavailable on an aircraft, the relaxed eddy accumulation (REA) technique has proven to be extremely useful (Chap. 56). Mass balance, inverse modeling, and tracer gas techniques have also facilitated the quantification of gas emissions from large sources such as urban centers, landfill sites, and leakages from natural gas infrastructure. All these flux-measuring techniques complement each other, and the best choice depends on the types of gas and source involved.

48.1.2 Measured Variables and Parameters Calculated

Summaries of the variables measured and the parameters calculated for aircraft-based flux-density measurements are presented in Tables 48.1 and 48.2, respectively.

Table 48.1 Variables measured for aircraft-based flux density calculations and chapters in which they are discussed in this Handbook

Parameter	Description (sensor)	Symbol	Unit	Relevant chapter
Horizontal wind components	Scalar components of horizontal wind speed (multiport pressure transducer)	u, v	m s^{-1}	Chap. 9
Vertical wind velocity	Vertical component of wind speed (multiport pressure transducer)	w	m s^{-1}	Chap. 9
Air temperature	Air temperature (heated or unheated total air temperature probe)	T	K	Chap. 1
	Potential air temperature (total air temperature, pitot static systems)	θ	K	
Mass density	Mass of constituent per volume air (various gas analyzers: infrared differential absorption, cavity ring-down spectroscopy, off-axis cavity output spectroscopy)	ρ_s	kg m^{-3}	Chaps. 16–18
Air density	Mass air per volume air (wet: thermometer, air pressure; dry: thermometer, hygrometer, air pressure)	ρ_a, ρ_d	kg m^{-3}	Chaps. 7, 8, 10, 16
Pressure	Atmospheric pressure (pitot static systems)	p	hPa	Chap. 10

Table 48.2 Other variables and parameters calculated for aircraft-based flux density measurements and chapters in which they are discussed in this Handbook

Parameter	Description	Symbol	Unit	Relevant chapter
Shear stress	$\tau = \rho \sqrt{(\overline{w'u'})^2 + (\overline{w'v'})^2}$	τ	$\text{kg m}^{-1} \text{s}^{-2}$	Chaps. 1, 55
Friction velocity	$u_* = \sqrt{(\overline{w'u'})^2 + (\overline{w'v'})^2}$	u_*	m s^{-1}	Chaps. 1, 55
Sensible heat flux	$Q_H = c_p \rho \overline{w'T'}$ or $Q_H = c_p \rho \overline{w'\theta'}$, where c_p is the specific heat at constant p and $\theta = T \left(\frac{1000}{p} \right)^{\frac{2}{7}}$ to correct for changes in flight altitude	Q_H	W m^{-2}	Chaps. 1, 55
Latent heat flux	$Q_E = \lambda \rho \overline{w'q'}$, where λ is the specific heat of vaporization	Q_E	W m^{-2}	Chaps. 1, 55
Trace gas flux	$Q_{\chi_{sm}} = \rho_d \overline{w'\chi'_{sm}}$, where χ_{sm} is the dry mixing ratio (kg kg^{-1} dry air) of the gas being measured	$Q_{\chi_{sm}}$	$\text{g m}^{-2} \text{s}^{-1}$	

48.2 History

Since the dawn of aviation, aircraft have been used for both civilian and military purposes. Environmental and meteorological observations have been made by aircraft since World War I [48.1]. The speed, payload flexibility, and ability of aircraft to provide an aerial perspective has consistently provided value to a variety of industries. These same capabilities have proven to be extremely useful for atmospheric flux measurements.

48.2.1 Initial Flux Density Measurements

Aircraft-based EC measurements have been carried out in the planetary boundary layer for almost five decades. Early aircraft-based measurements quantified the fluxes of momentum and heat [48.2]. This was shortly followed by measurements of water vapor (H_2O) flux during the Barbados Oceanographic and Meteorological Experiment (BOMEX) [48.3], a study of the structure of turbulence in the lower atmosphere [48.4], and measurements of the variations in the turbulent fluxes of momentum, heat, and moisture over Lake Ontario at several altitudes [48.5]. Later, the average vertical flux of ozone (O_3) over a distance of 100 km was evaluated [48.6] (measurements over such a large distance were required because of the small correlation coefficient between ozone and vertical wind velocity). Aircraft-based flux measurements of CO_2 collected for a wide range of ecosystems showed that repeatable flux measurements could be obtained by making several passes 4–5 km in length over a given site, and that the frequency response of the sensors was adequate to perform EC flux measurements at altitudes as low as 25 m [48.7, 8].

48.2.2 Importance of Large-Scale Field Experiments

Soon after these initial flux studies, aircraft became essential flux-measuring platforms for many large-scale field experiments. The Amazon/Arctic Boundary Layer Experiments (ABLE), which took place from 1985 to 1990, used a combination of tower-based and aircraft-based flux measurements to study ecosystems that were considered to strongly influence atmospheric chemistry globally [48.9, 10]. Two major ecosystems studied were the rain forest of Brazil during the dry and wet seasons and the northern wetlands of the Hudson Bay lowland. The focus was on quantifying the rate of exchange of mass between the Earth's surface and the atmospheric boundary layer. In 1986, the Hydrologic Atmospheric Pilot Experiment (HAPEX)-MOBILHY

experiment in France attempted to characterize the hydrological budget of an area 100 km by 100 km [48.11]. In this experiment, instrumented aircraft were used to obtain simultaneous measurements of atmospheric fluxes and remotely sensed properties of the Earth's surface. In 1987 and 1989, the First ISLSCP (International Satellite Land Surface Climatology Project) Field Experiment (FIFE), carried out in Kansas (USA), set out to develop methodologies to study a grassland ecosystem at a scale of 15 km by 15 km using a variety of measuring systems [48.12]. It was designed to obtain satellite and ground observations for the development and validation of models relating surface fluxes to spectral data [48.13]. Aircraft flights over the FIFE research area provided the data required to evaluate the various terms in the conservation equation and to elucidate that the underestimation seen in aircraft-based flux measurements was mainly due to the undersampling of long-wavelength contributions and the divergence of flux with height [48.14, 15].

Between 1994 and 1996, the Boreal Ecosystem–Atmosphere Study (BOREAS) was undertaken to examine the role of the boreal forest in global environmental changes [48.16]. The region selected covered an area of 1000 km by 1000 km. In order to characterize the heterogeneity of the boreal landscape, a flux-unmixing method based on aircraft-based flux measurements was developed, along with a land-cover map derived from the Landsat thematic mapper and tower-based flux measurements from eight cover types [48.17]. Using this information, they were able to derive flux data for cover types for which there were no tower-based measurements. Several additional large-scale studies soon followed, such as the Southern Great Plains (SGP) hydrology experiment, which was motivated by the scientific interest in estimating soil moisture conditions at the continental scale using remotely sensed data [48.18], whereas the Large-Scale Biosphere–Atmosphere (LBA) experiment in Amazonia focused on how tropical forest conversion affects carbon and nitrogen dynamics as well as trace gas fluxes [48.19]. These large-scale experiments were an excellent opportunity to develop more sophisticated technology and data analysis techniques for aircraft-based flux measurements. It soon became clear that it was easier to get comparable flux measurements between aircraft [48.20] than between aircraft and tower-based systems [48.21] because of different averaging periods, different footprints, and the divergence of flux with height.

Table 48.3 Important milestones in aircraft-based flux measurements and chapters in which they are discussed in this Handbook

Year	Milestone	Reference(s)	Relevant chapter
Early 1970s	First reported aircraft-based EC measurements of sensible and latent heat fluxes	[48.2, 3]	Chap. 55
1980s	First reported aircraft-based EC CO ₂ flux measurements	[48.8]	Chap. 16
1990s	First reported aircraft-based flux measurements of agrochemicals and VOCs with REA	[48.22, 23]	
2000s	Wavelet transform used for obtaining aircraft-based flux measurements over short distances	[48.24, 25]	Chap. 56
2010s	Aircraft-based EC and REA (CH ₄ , N ₂ O) flux measurements	[48.26–29]	

48.2.3 Flux Density Measurements from Smaller-Scale Experiments

Aircraft-based flux density measurements were also obtained during many smaller-scale experiments. The prime focus of the California Ozone Deposition Experiment (CODE) was to improve estimates of the absorption of ozone by crops [48.30]. The Mackenzie GEWEX Study (MAGS) focused on the hydrological cycle and energy fluxes of the Mackenzie River Basin [48.31]. This was an area for which there were few measurements, so it was important to develop land-surface algorithms based on satellite data. Another part of the global energy and water exchange (GEWEX) project, the GAME-Siberia (GEWEX Asian Monsoon Experiment), conducted aircraft-based flux measurements in the Yakutsk region that highlighted the spatial variability in flux estimates for a forest-grass landscape in spring [48.24], and completed pioneering work to apply wavelet transforms to aircraft-measured turbulence and turbulent fluxes [48.32]. Also, aircraft measurements obtained during the GAME-Siberia project helped to identify the conditions in which local circulation patterns [48.33] exacerbate the common problem of flux underestimation observed by tower-based measurement systems [48.34]. The Soil Moisture Atmosphere

Coupling Experiment (SMACEX) was designed to use a combination of aircraft-based and tower-based flux measurements, satellite data, and models to help understand the impact of spatial and temporal variability in vegetation cover, soil moisture, and other land-surface states on atmosphere–surface interactions across a wide range of scales [48.35]. Many other small-scale experiments were carried out. For example, methane (CH₄) and VOC emissions over shale gas production regions were measured [48.36]. In that study, the EC technique was applied to measure the fluxes of CH₄ and benzene. Results indicated that in the two regions studied, 10% of the facilities contributed 40% of the CH₄ emissions. Aircraft-based measurements have been used to quantify CH₄ and ammonia emissions from a beef feedlot [48.37] and to apportion the emissions to appropriate sources (cattle, effluent ponds, and manure piles) within the feedlot. Recently, a suite of commercial and custom instrumentation was employed to acquire the fluxes of CO₂, CH₄, sensible heat, and latent heat at high spatial resolution in order to gain new insights into biophysical and biogeochemical processes [48.26].

Some milestones in the development of aircraft-based flux methods are given in Table 48.3. A common theme is that techniques developed for tower-based systems were adapted for use on aircraft-based systems.

48.3 Theory

Several techniques have been successfully used to obtain aircraft-based flux measurements. The EC technique (Chap. 55) is the most frequently used of these techniques, but others such as wavelet analysis, relaxed eddy accumulation, and mass balance have all provided useful information.

48.3.1 Eddy Covariance (EC) Technique

The EC technique (Chap. 55) is widely used for the measurement of mass and energy exchange at the land–atmosphere interface [48.38]. In this technique, the flux density is integrated over time for a tower-based system and over space for an aircraft-based system. The aircraft is flown at a constant velocity and altitude and

the covariance between the vertical wind and the scalar of interest is calculated, i.e.,

$$F_c = \frac{1}{N} \sum_{i=1}^N (c_i - \bar{c})(w_i - \bar{w}) = \frac{1}{N} \sum_{i=1}^N (c'_i w'_i), \quad (48.1)$$

where the mixing ratio of the scalar c_i is the sum of the mean mixing ratio \bar{c} and the deviation from the mean c'_i ; similarly, the vertical air velocity w_i is the sum of the mean vertical wind \bar{w} and the fluctuations from the mean w'_i . These values are measured at constant time intervals over a certain time period or a certain distance. Reasonably stationary conditions, negligible horizontal advection, and an absence of chemical reac-

tions involving the gas of interest within the air column below the measuring system are required for accurate flux measurements. Ignoring these conditions leads to flux divergence with height, causing the surface flux to be underestimated.

In a tower-based EC system, wind and scalar measurements are closely collocated in space to ensure that the same eddies are being sampled. This is often not possible in aircraft-based EC systems: there is substantial physical separation (on the order of one to several meters) between the vertical wind and scalar measurements. Therefore, to compute aircraft-based fluxes, the data must be adjusted for the time taken for a parcel of air to pass from the nose boom, where the air velocity is measured, to the other sensors [48.39]. This adjustment is particularly important for measurements performed at low altitude, where the spacing of the sensors can become a significant fraction of the typical eddy size [48.40]. The mean must be calculated to determine the flux using the EC technique. This can be done by either block averaging, linear detrending, or high-pass filtering the time series. The practice of comparing the flux estimates obtained from raw, linearly detrended, and high-pass-filtered time series has proven to be a useful screening technique for identifying non-stationary conditions [48.21, 39].

48.3.2 Relaxed Eddy Accumulation (REA) Technique

For many years, only the fluxes of heat, momentum, and a limited number of gases (e.g., CO₂, H₂O, and O₃) were measured using the EC technique on aircraft. This was the case because there were no fast-response analyzers for most of the other gases. The eddy accumulation (EA) technique was suggested by [48.41] as a potential solution to this problem (Chap. 56). In this technique, air is collected in one of two reservoirs using fast-response valves [48.42]. The reservoir used for collection is selected based on whether a vertical wind anemometer detects ascending or descending air, and the rate at which air is collected depends on the vertical wind speed. The air collected over a half-hour period was subsequently analyzed using a slow-response gas analyzer such as a mass spectrometer [48.41]. Several years later, the REA technique was proposed [48.43]. This technique is simpler to implement than the EA technique and gives similar results [48.44]. With the REA technique, the flux density (FC_{REA}) is equal to the product of the difference between the mean concentrations of the gas of interest in the ascending (\bar{C}^+) and descending (\bar{C}^-) air, the standard deviation of the vertical wind σ_w (m s⁻¹), the air density ρ_d , the ratio of the molar mass of the scalar $M(C)$ to the molar mass of air

$M(\text{Air})$, and an empirical parameter A [48.45]; in other words,

$$\text{FC}_{\text{REA}} = A\sigma_w\rho_d \left(\bar{C}^+ - \bar{C}^- \right) \frac{M(C)}{M(\text{Air})}. \quad (48.2)$$

This technique has been used successfully on aircraft to measure the fluxes of agrochemicals, VOCs, N₂O, and CH₄ [48.22, 23, 27, 29]. Similar to the discussion in Sect. 48.3.1, there can be significant physical separation between the vertical wind measurements and the pump, tubing, and valve assembly needed to partition the gas samples in the REA technique. Thus, the time lag between the wind measurements and the gas partitioning must be precisely determined, otherwise the flux can be significantly underestimated [48.46].

48.3.3 Wavelet Covariance

Wavelet analysis [48.47], which is a powerful tool for signal analysis in the frequency and time domains, has been increasingly used to estimate turbulent fluxes obtained using aircraft-based sensors [48.25, 32, 48–50]. The wavelet method provides estimates of the spectra and cospectra over a larger scale interval than the Fourier transform. It also provides both frequency and spatial localization. This information is important in studies connecting flux measurements to surface characteristics. The Morlet wavelet has been used to show the various scales that contribute to the fluxes of mass and energy exchange along a nonhomogeneous transect over a boreal forest [48.25]. In general, a continuous wavelet transform of a discrete sequence $x(n)$ is defined as the convolution of $x(n)$ with a wavelet function,

$$W_x(a, b) = \sum_{n=0}^N x(n)\psi_{p,a,b}^*(n), \quad (48.3)$$

where $W_x(a, b)$ are the wavelet coefficients as functions of the scale or dilatation parameter a and the shift or translation parameter b , and $\psi_{p,a,b}^*$ is the complex conjugate of a wavelet function. Averaging the cross-scalogram matrix $W_x(a, b)W_y^*(a, b)$ yields the wavelet cross-spectrum [48.51]

$$E_{xy} = \frac{\delta t}{C_\delta} \frac{1}{N} \sum_{n=0}^{N-1} W_x(a, b)W_y^*(a, b), \quad (48.4)$$

where δt is the time step of the time series. The factor C_δ originates from a delta (δ) function that was used to reconstruct the band-pass filtered original time series from the wavelet transform, and is a constant for each wavelet function [48.47].

Table 48.4 Advantages and disadvantages of the main aircraft-based flux measurement techniques

Measuring technique	Advantages	Disadvantages
Eddy covariance	Provides the most direct measurement of turbulent flux	Requires measurements over long distances, fast-response sensors, complex instrumentation, and synchronization of the data collected
Wavelet covariance	Provides spatially resolved flux estimates, including long-wave components	Requires EC instrumentation
Relaxed eddy accumulation	Enables flux measurements of gases for which there are no aircraft-compatible fast-response analyzers	Cone of influence: edge effects reduce confidence in flux estimates Precise determination of the time lag between a wind gust and gas sampling is essential Due to the nature of the sample collection, it is not possible to perform corrections ex post facto
Mass balance	Simpler instrumentation and calculations; provides flux density estimates for sources of various sizes	Requires nontrivial assumptions regarding the wind direction, boundary layer height, background concentration, and even mixing

The covariance of two signals x and y can be calculated from the real part of the cross-spectrum,

$$\text{cov}_{xy} = \delta j \sum_{j=0}^J \frac{\text{Re}(E_{xy}(j))}{a(j)}, \quad (48.5)$$

where δj , a nondimensional factor, determines the spacing between discrete scales of the wavelet transform [48.47].

48.3.4 Mass Balance

The mass balance computation of the flux of trace gases depends on the assumptions that winds are steady in the horizontal direction, that the atmospheric boundary layer is well developed, that there is complete and even mixing, and the measurements are taken upwind and downwind of the source. The difference between what goes into and out of an area is the magnitude of the emission. In general, the flux (mols s^{-1}) of a scalar (FC_{MB}) is calculated as

$$\text{FC}_{\text{MB}} = U \int_{-p}^p \Delta C \left(\int_{z_{\text{ground}}}^{z_{\text{pbl}}} n_{\text{air}} dz \right) \cos \gamma dx, \quad (48.6)$$

where U is the mean horizontal wind speed, the increase in the concentration of the scalar above the background (ΔC) is integrated over the total measured plume width ($-p$ to p), n_{air} is the average molar density of air between the ground surface (z_{ground}) and the planetary boundary layer (z_{pbl}), and γ is the angle between the mean horizontal wind direction and a line normal to the aircraft flight direction. Therefore, along a flight track of length x , $\cos \gamma dx$ is the distance that is perpendicular to the mean horizontal wind.

This technique has been used to quantify urban emissions for a wide range of gases [48.52, 53]. Constant wind conditions are very important, and while accurate mean emissions can be obtained, emission estimates from individual flights have a high uncertainty [48.54]. Convective boundary layer budgeting has also been carried out to estimate fluxes using concentration profiles. Regional-scale CH_4 emissions from a predominantly agricultural area were estimated using aircraft-measured concentration profiles [48.55]. Methane fluxes calculated under strong wind conditions were shown to be consistent with bottom-up estimates.

A brief overview of the advantages and disadvantages of these techniques for measuring the flux density is presented in Table 48.4.

48.4 Devices and Systems

A variety of aircraft ranging from a small single-engine ultralight [48.56] to larger multiengine aircraft [48.8, 24, 28] have been used to conduct flux measurements. These aircraft can carry a wide array of instrumentation to measure positions, air motions, temperatures, trace-gas concentrations, and radiative exchange.

48.4.1 Flux Aircraft

Aircraft have become elaborate measuring platforms for obtaining flux density measurements of mass and

energy over a wide range of ecosystems [48.24, 28, 40, 56]. Many different types of flux aircraft have been used [48.20, 26, 32, 56]. It has been found to be easier to get agreement between aircraft than between aircraft and tower-based systems. It is possible to have relatively similar footprints for two aircraft, but this is not possible in aircraft-to-tower comparisons [48.20, 21, 56]. In a comparison of the measurements from four aircraft, some differences were noted, but generally the fluxes and variances did not differ by more than expected given the separation of the aircraft [48.20].

Fig. 48.1 The NRC Twin Otter Aircraft as configured for flux measurements (after [48.57] photo is presented courtesy of the Flight Research Laboratory of the NRC Canada)

However, since each flux aircraft is unique, generalizations regarding aircraft type, the instrumentation used, and the positioning of that instrumentation are not possible. A typical setup features nose-mounted wind-speed and temperature sensors complemented by cabin-mounted gas-sampling and radiation equipment. Alternatively, wind and temperature measurements can be performed in a wing-mounted pod, as described in [48.58]. Figure 48.1 provides an example of instrumentation onboard the National Research Council (NRC) Canada Twin Otter flux aircraft for measuring the position and altitude of the aircraft, three wind components, the air pressure, the air and dewpoint temperatures, and the concentrations of H_2O , CO_2 , O_3 , and CH_4 . Data acquisition and computer systems for real-time data analysis and a video camera are also shown, as well as a wide range of multispectral sensors for measuring the incoming and reflected solar radiation, net radiation, surface temperature, and the greenness of vegetation using various satellite simulators. Unmanned aircraft systems (UASs)—another type of aircraft—are also used to obtain flux density measurements (see Chap. 49).

48.4.2 Aircraft Position and Altitude

Many different systems have been used on aircraft to measure location. The Twin Otter used sensors such as the Litton LTN-90-100 IRS, Trimble GNSS TNL-8100,

and Novatel GNSS RT-20 [48.57]. Global navigation satellite systems (GNSSs) represent the current standard for location measurements. When operated in nondifferential mode, the accuracy of a GNSS is about 5 m, although centimeter accuracies can be achieved if the system is operated in the differential mode, where signals recorded by an accompanying ground station are incorporated. In this mode, GNSS also provides accurate measurements of the height of the aircraft above mean sea level.

The absolute altitude can also be measured with many different instruments. Radio and laser altimeters can be used to measure the absolute height above the terrain (Fig. 48.1). Altimeter measurements can be combined with pressure–altitude or GNSS altitude data to produce records of the height and roughness of the terrain over which the flux measurements are being made.

48.4.3 Wind Measurements

Flux aircraft are instrumented to measure the three-dimensional meteorological wind vector \mathbf{v} at a frequency range of more than 10 Hz. The wind vector can be calculated from navigation, flow, and attitude measurements in the Meteorological Orthonormal Coordinate System (MONS, index m) using the relation [48.59]

$$\mathbf{v} = \mathbf{v}_{\text{gs}} + \mathbf{M}_{\text{mf}} (\mathbf{v}_{\text{tas}} - \boldsymbol{\Omega} \times \mathbf{s}_{\text{L}}). \quad (48.7)$$

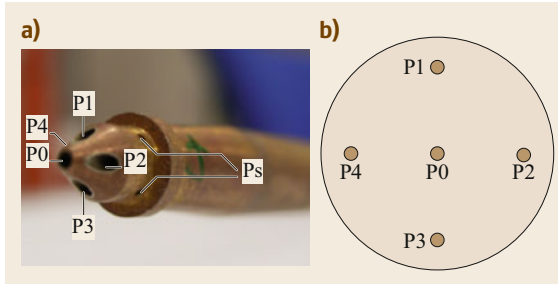

Fig. 48.2 (a) Five-hole probe manufactured by the Institute for Fluid Dynamics, TU Braunschweig (after [48.60]); (b) schematic of a FHP showing pressure ports P0 through P4 (in a head-on perspective, i.e., starboard is on the left side from this point of view)

Here, the ground-speed vector \mathbf{v}_{gs} describes the movement of the origin of an aircraft-fixed coordinate system known as the Aircraft-Fixed Orthonormal System (ACONS; index f) with respect to the Earth's surface, and is determined using the onboard inertial navigation system (INS), which is usually an inertial measurement unit (IMU) combined with a GNSS via a Kálmán filter.

The true airspeed vector \mathbf{v}_{tas} is the flow vector measured by the in-situ flow probe (e.g., a five-hole probe, FHP; see Fig. 48.2) on a nose boom, and is therefore defined with respect to the FHP. Thus, for a fast-flying aircraft with $|\mathbf{v}| \ll |\mathbf{v}_{tas}|$, the true airspeed is oriented more or less towards the ground speed.

The location of the FHP in relation to the origin of the ACONS is described by the lever-arm vector $\mathbf{s}_L = (x_p, y_p, z_p)$. The vector of angular body rates $\boldsymbol{\Omega} = \Omega_p, \Omega_q, \Omega_r$ contains the angular velocities (roll, pitch, yaw) of the ACONS in relation to the MONS, and is among the primary output data of the IMU.

The vector sum $(\mathbf{v}_{tas} - \boldsymbol{\Omega} \times \mathbf{s}_L)$ describes the measured airflow vector with respect to the ACONS, and is transformed into the MONS via the operator \mathbf{M}_{mf} in (48.7). Since the (relatively small) meteorological wind vector is obtained by combining two large vectors in (48.7), the challenge is to determine \mathbf{v}_{tas} and \mathbf{v}_{gs} with very high precision. While the ground speed \mathbf{v}_{gs} is measured by the INS in an Earth-fixed coordinate system, the second term in (48.7) requires more attention. Please see the Appendix for further details regarding the calculation of the meteorological wind vector, as well as [48.61, 62].

48.4.4 Scalar Sensors

A wide range of fast-response sensors (Table 48.1) have been fitted to flux aircraft to measure the air temperature, the dewpoint, and the H_2O , CO_2 , O_3 ,

and CH_4 concentrations [48.63, 64]. Rosemount fast-response heated (or unheated) probes mounted on the nose of the aircraft are frequently used to determine air-temperature fluctuations. Humidity is usually measured using a dewpoint sensor (Chap. 8). Several kinds of infrared gas analyzers have been used to measure carbon dioxide and water vapor fluctuations (Chap. 16). Ozone fluctuations have been measured using chemiluminescence-based sensors and UV absorption sensors have frequently been used to determine absolute ozone concentrations [48.65]. Cavity ring-down spectrometers and integrated off-axis cavity output spectrometers are now available for accurate measurements of CH_4 fluctuations [48.63, 66].

48.4.5 Solar Radiation Sensors and Satellite Simulators

A variety of sensors have been used to measure solar radiation (Chap. 11). Thermopile-type pyranometers with a typical spectral range of 300–2800 nm have been used to measure downwelling ($S \downarrow$) and reflected ($S \uparrow$) solar radiation. Software routines have been developed that can continuously correct the $S \downarrow$ measurements on an aircraft for the mounting alignment and for variations in the pitch and roll attitude, heading, latitude and longitude, and time of day throughout each flight [48.57, 58]. The net radiation (Q_s^*) on the Twin Otter has been calculated at intervals of 1/32 s using downwelling and reflected solar radiation and long-wave radiation derived from the surface temperature (T_0 in K, measured with an infrared thermometer) and the air temperature (T in K) using the equation

$$Q_s^* = S \downarrow - S \uparrow + [1.20 \sigma T^4 - 17] - [0.98 \sigma T_0^4], \quad (48.8)$$

where the last two terms represent the incident and reflected long-wave components estimated using the Stefan–Boltzmann constant $\sigma = 5.6924 \times 10^{-8}$ and a surface emissivity of 0.98. The net radiation has also been measured with a Kipp and Zonen CNR-1 net radiometer housed in a specially modified port wingtip (Fig. 48.1). The CNR-1 consists of two CM3 pyranometers with a spectral range of 305–2800 nm and two CG3 pyrgeometers with a spectral range of 5000–50 000 nm.

Spectrometers with spectral ranges that are similar to those of specific satellites have also been used on aircraft during flux campaigns to attempt to collect data that can be used to adjust satellite data to correspond to the time that flux density measurements were made. The Twin Otter aircraft carried several upward- and downward-looking spectrometers. The Skye Indus-

tries greenness indicator, which is based on the ratio of near-IR (730 nm) to red (660 nm) radiation, indicates the amount of green vegetation beneath the aircraft. Another instrument used on the Twin Otter to measure vegetation characteristics is the downward-looking Exotech 100BX satellite simulator. This simultaneously measures the reflected radiation in four wavelength bands, and can be configured to simulate two modes of Landsat operation—the Thematic Mapper (TM) and the Multispectral Scanner (MSS)—as well as the Satellite Pour l’Observation de la Terre (SPOT). Hyperspectral reflectance measurements offer increased flexibility, allowing the selection of custom spectral ranges that are matched to corresponding satellite measurements [48.67]. When mounted on a low-flying flux aircraft, these spectral sensors provide information on only a narrow strip directly under the aircraft, but the data can be compared and integrated with wider scenes provided by various satellites. In most large-scale experiments, many kinds of spectral data have been collected. For example, in the Southern Great Plains (SGP) 1997 Hydrology Experiment, wide-angle sensing spectrometers such as the ESTAR (Electronically Scanned Thinned Array Radiometer) on the National Aeronautics and Space Administration (NASA) P-3 measured surface characteristics that could be directly superimposed on the footprint sensed by the flux aircraft [48.18].

48.4.6 REA System

Fast-response sensors are not available for some trace gases such as agrochemicals, VOCs, N_2O , and CH_4 ; gas chromatographs and slow-response gas analyzers have been used to measure the fluxes of these gases using REA systems. A variety of gas-collection devices have been used: polyurethane foam plugs for agrochemicals [48.22], stainless steel canisters for CO_2 and isoprene [48.23, 68], and polytetrafluoroethylene (PTFE) bags for N_2O and CH_4 [48.29, 69]. Basically, air is drawn by two diaphragm pumps and is then split between up and down channels. The air flow is maintained constant by two mass flow controllers. Two

fast-response switching three-way valves allow the flow to be directed to either sample bags or the vent line. The vertical wind signal controlling the switching of the valves is high-pass filtered in real time to remove any potential bias in the vertical wind measurement. The signal is also adjusted to correct for any time delay in the sampling assembly. The use of a dead band helps to increase the valve lifetime and also enhances the concentration difference between the upward-moving and downward-moving air samples. The parameter A in (48.2) has been shown to be dependent on the magnitude of the dead band, and has been determined by simultaneous in-situ EC measurements for water vapor [48.44, 45].

48.4.7 Data Acquisition

Much progress has been achieved in the area of data acquisition. Great strides in computer speed, storage capacity, and ruggedness have made data collection much more reliable in the demanding environment of an aircraft, and have allowed the computation and display of an ever-increasing list of variables, including real-time flux estimates [48.70]. Signals that must be recorded in flight originate in a host of analog and digital devices. In the Twin Otter, for example, the input/output (I/O) boards that interface to the input and output devices include RS232 serial boards, analog to digital, digital to analog, and digital I/O boards, small computer systems interfaces, along with a video graphics array. The analog signals are conditioned with a two-phase filtering process. The signals first pass through hardware and signal conditioning, where each signal is low-pass filtered at 100 Hz, amplified, and biased. These signals are then digitally sampled at a rate of 256 Hz. A digital 47-point 10-Hz low-pass filter is applied and the data are then recorded at 32 Hz on various types of recording media. It is important that all data sets for calculating the various fluxes are treated the same way in order to avoid phase shifts in the various signals, as these would lead to errors in the flux density calculations. The use of a 10 Hz low-pass filter implies that, at a true airspeed of 60 m s^{-1} , a full data record is collected every 6 m traveled.

48.5 Specifications of Sensors for Flux Density Measurements

Many different sensors have been used for aircraft-based flux measurements. A list of the variables measured on the NRC Twin Otter aircraft is given in Table 48.5, as are details regarding accuracy and frequency response. For flux density measurements realized using the EC and wavelet covariance tech-

niques, sensors with a fast frequency response are required, especially for measurements at low altitudes. High-resolution measurements are essential, while the reliability of the absolute values is not as critical. A flight evaluation of two vertical wind-measuring systems [48.71] showed that the sensible heat flux

Table 48.5 Specifications of the sensors used on the Canadian Twin Otter flux aircraft

Variable	Reliability of absolute value	Resolution	Frequency response	Instrument type
Vertical wind velocity	0.1 m s ⁻¹	0.01 m s ⁻¹	16 Hz	Gust probe; IMU ¹ /GNSS ²
Horizontal wind velocity components	0.5 m s ⁻¹	0.01 m s ⁻¹	16 Hz	Gust probe; IMU/GNNS
Humidity	0.5 × 10 ⁻³ kg m ⁻³	10 ⁻⁴ kg m ⁻³	2 K s ⁻¹	Dewpoint hygrometer
Humidity fluctuations	10 ⁻³ kg m ⁻³	0.005 × 10 ⁻³ kg m ⁻³	10 Hz	Infrared gas analyzer
Air temperature	0.5 K	0.05 K	10 Hz	Platinum resistance
Carbon dioxide	0.5 ppmv	0.05 ppmv	10 Hz	Infrared gas analyzer
Pressure	40 Pa	5 Pa	10 Hz	Quartz crystal transducer
Absolute altitude	2–3 m	0.2 m	16 Hz	Radar altimeter
Heading	1°	0.001°	100 Hz	IMU/GNSS
Attitude	0.25°	0.0001°	100 Hz	IMU/GNSS
Position	2 m	0.01 m	10 Hz	IMU/GNSS
Surface temperature	1.0 K	0.02 K	10 Hz	Infrared radiometer
Solar radiation (upward and downward)	20 W m ⁻²	2 W m ⁻²	0.2 Hz	Thermopile
Ozone	1 ppbv	0.1 ppbv	10 Hz	Chemiluminescence-based
Methane	50 ppbv	3 ppbv	5 Hz	Cavity ring-down spectroscopy

² Global Navigation Satellite System

agreed within 1 W m⁻². For trace gases that lack fast-response analyzers, slow-response gas analyzers have been used with the REA and mass balance techniques. In these cases, the resolution requirements are greater than those with EC. For example, with the available slow-response gas analyzers, the resolutions for N₂O

(10 pptv) and CH₄ (90 pptv) are adequate to measure agricultural emissions using aircraft-based technology [48.27, 29]. Slow-response sensors are sufficient for determining parameters such as the location and the atmospheric and surface conditions during the measurements.

48.6 Quality Control

Aircraft-based flux measurements involve the collection of large quantities of data. Many factors can affect the accuracy of flux measurements. It is therefore important to minimize the collection of poor data by assessing data quality during and after data collection. For further information, refer to Chap. 3.

48.6.1 Quality Assessment

Assessing the quality of the data helps to minimize the amount of poor data collected. This can best be done by performing preliminary flux calculations in real time during the flight and displaying the resulting estimated flux values to the flight engineer. During a typical month-long field campaign during BOREAS, approximately 100 variables were recorded by the Twin Otter data acquisition system 32 times per second for about 100 h. This represents about a billion data points. Quality control of the data should also be carried out after each flight prior to calculating the flux; for instance, the data should

be despiked to remove outliers [48.72] and it should be synchronized to maximize the correlation between the vertical wind and the scalar of interest [48.73]. This corrects for the spacing between various sensors. Several software packages such as EddyPro and TK3 have been developed to standardize and automate EC data preparation, flux computation, and quality assessment [48.74], and these can be applied to aircraft-based data. An open-source and extensible EC data processing software package that can be applied to aircraft-based data is also available [48.75]. Errors can also occur because the flux sampling criteria are not met due to a poor sample size resulting from either a run that was too short or an insufficient number of repeated passes. For trace gas flux measurements such as CH₄, it has been found to be extremely useful to perform a flight with a constant gas concentration flowing through the analyzer in order to evaluate the accuracy of the flux measurements and develop techniques for minimizing errors caused by the sensitivity of the analyzer to pressure fluctuations [48.29].

48.6.2 Spectral Response

An inappropriate frequency response of a sensor can be detected by inspecting the shape of the spectra. All variables used for flux density calculations should show a well-behaved spectral shape with a $-5/3$ slope down to a wavelength of 10 m (5 Hz). Examining the

cospectra can also help identify potential problems. For example, as reported in [48.40], plots of the normalized cospectra for various heights indicated that the $\text{CO}_2/\text{H}_2\text{O}$ analyzer response was not adequate to measure the high-frequency contribution to the flux density for runs at a height of 10 m, but it was adequate for runs at 25 and 50 m.

48.7 Maintenance

Sensor calibration is important for ensuring the quality of the measurements. However, a wide range of sensors are used on flux aircraft, and calibration requirements tend to vary among sensors (Table 48.6). Several procedures are used to routinely check the accuracy of measured variables. After each flight, the data from each sensor are examined; if anomalies are detected in one of the measurements, a partial calibration check of the sensor is carried out. The three-dimensional wind measurements that are integral to flux measurements, pressure sensors, and radiation sensors are calibrated before each measuring campaign. Atmospheric variables such as pressure, temperature, humidity, and wind are compared with measurements from towers during low-level passes and with data from other aircraft during formation flights [48.20]. Gas sensors such as

those for O_3 , CO_2 , and CH_4 all have different calibration requirements depending on the type of sensor used at the time. The original fast-response $\text{CO}_2/\text{H}_2\text{O}$ analyzer used on the Twin Otter had to be cleaned after each flight, as it tended to drift due to dirt on the mirrors. It was eventually replaced with a LiCor $\text{CO}_2/\text{H}_2\text{O}$ analyzer, which is much more stable. Ozone analyzers are probably the sensors that require the most frequent calibration. Some of the calibration details for the NRC Twin Otter aircraft are given in [48.76], while [48.77] describes the performance and calibration information for a newer instrument. An infrared surface temperature sensor needs to be calibrated on occasion using a black metal cone immersed in a well-mixed water bath mounted under the temperature sensor.

Table 48.6 Maintenance of aircraft-based sensors for flux measurement campaigns

Maximum interval	Pressure sensors	Gas sensors	Air-temperature sensors	Radiation sensors	Dewpoint sensors	Surface temperature

48.8 Applications

Over time, aircraft have consistently demonstrated their relevance to the study of mass and energy exchange over a wide range of ecosystems. Their versatility and their ability to be deployed in remote locations and to sample large surface areas make them an excellent complement to tower-based measurement systems. Examples of aircraft-based flux density measurements for several applications will now be presented. Although aircraft-based flux density measurements are available from many research groups, as a matter of convenience, the examples presented in this review are mainly taken from the authors' research. Many patterns have been flown to attempt to evaluate the accuracy of aircraft-based flux measurements and improve our

understanding of biosphere-atmosphere exchange. Flying by a tower has been a common flight pattern to perform in order to check the representativeness of tower-based flux measurements. Flight patterns consisting of L and T shapes (i.e., with an intersection at the endpoint or midpoint of perpendicular flight passes) at multiple altitudes provided the data required to calculate the flux divergence with height as well as to compare aircraft-based and tower-based flux measurements. A *reciprocal grid* pattern at a constant altitude provided spatial coverage of fluxes at a particular instant in time; these fluxes could then be compared to surface features [48.78]. Over hilly terrain such as the FIFE site, data from long transects, double stacks, and

Fig. 48.3 Comparison of sensible (H) and latent heat (LE) fluxes measured using aircraft and tower-based systems over grassland on 2 July 1997 (CDT: central daylight time). Flux measurements are presented for two aircraft platforms (the Twin Otter and Long EZ) and one tower-based platform (after [48.79])

grid flights were used to show that flux measurements over a 15 km distance were sometimes substantially underestimated [48.80]. A double-stack pattern of sixteen 15 km runs along two tracks 11 km apart—which consisted of four runs at approximately 75, 220, 500, and 740 m AGL followed by eight runs on the other track at 740, 500, 220, 75, 75, 220, 500, and 740 m and then four more runs on the first track at 740, 500, 220, and 75 m—provided the data needed to estimate all the terms in the budget equation for a conserved scalar [48.14, 15]. Data obtained over different types of surfaces were used [48.81] to examine the vertical depth of the influence of surface heterogeneity on blending height theory, convective boundary layer scaling, and internal boundary layer theory.

48.8.1 Comparison of Aircraft-Based and Ground-Based Flux Density Measurements

Many studies have focused on comparing aircraft-based and tower-based flux measurements [48.82]. However, several studies [48.78, 83] have shown that large differences in footprint size (Chap. 1) between those two platforms make it impossible to sample the same area. Even when flying a circle around a tower, it is highly unlikely that the flux measurements will be the same unless the area is homogeneous [48.21]. Nevertheless, comparable flux measurements are frequently obtained for relatively homogeneous areas. Figure 48.3 shows

the half-hourly sensible (H) and latent heat (LE) fluxes measured over grassland using a 1.5 m tower-based system. The corresponding fluxes measured using the NRC Twin Otter and the Long EZ aircraft funded by NOAA are also shown for individual runs of 3.7 km measured at an altitude of 30 m [48.79]. The time series for the flux calculations for the Twin Otter were linearly detrended, whereas the Long EZ data were high-pass filtered with a 3 km cutoff. In this case, the detrending and high-pass filtering of the data had little impact, and the agreement between tower-based and aircraft-based flux measurements was quite good. This meant that the surface conditions along the flight track were similar to those within the tower-based flux footprint, and the long-wavelength contribution to the flux measurements was small.

Aircraft-based flux density measurements have aided the interpretation of surface flux measurements. A comparison of midday and nighttime flux measurements obtained over the FIFE site using the Twin Otter aircraft and two tower-based systems is presented in Table 48.7. The aircraft-based fluxes at night are the average of five passes over a distance of 15 km and the tower-based flux values are the half-hourly averages obtained during the period the aircraft made the measurements. The tower-based fluxes of CO_2 were about -0.2 to $-0.6 \text{ mg m}^{-2} \text{ s}^{-1}$ at midday and 0.1 – $0.2 \text{ mg m}^{-2} \text{ s}^{-1}$ at night, while the aircraft flux measurements made at an altitude of about 100 m along the 15 km tracks were about -0.4 to $-0.6 \text{ mg m}^{-2} \text{ s}^{-1}$ around midday and

Table 48.7 Daytime and nighttime fluxes measured over the Konza Prairie on 10 August 1989

	Time of day ^a (CDT)	Distance ^b (km)	Altitude (m)	Radiation (W m ⁻²)	Latent heat (W m ⁻²)	Sensible heat (W m ⁻²)	CO ₂ flux (mg m ⁻² s ⁻¹)

^b Distance refers to the average length of the aircraft flight track

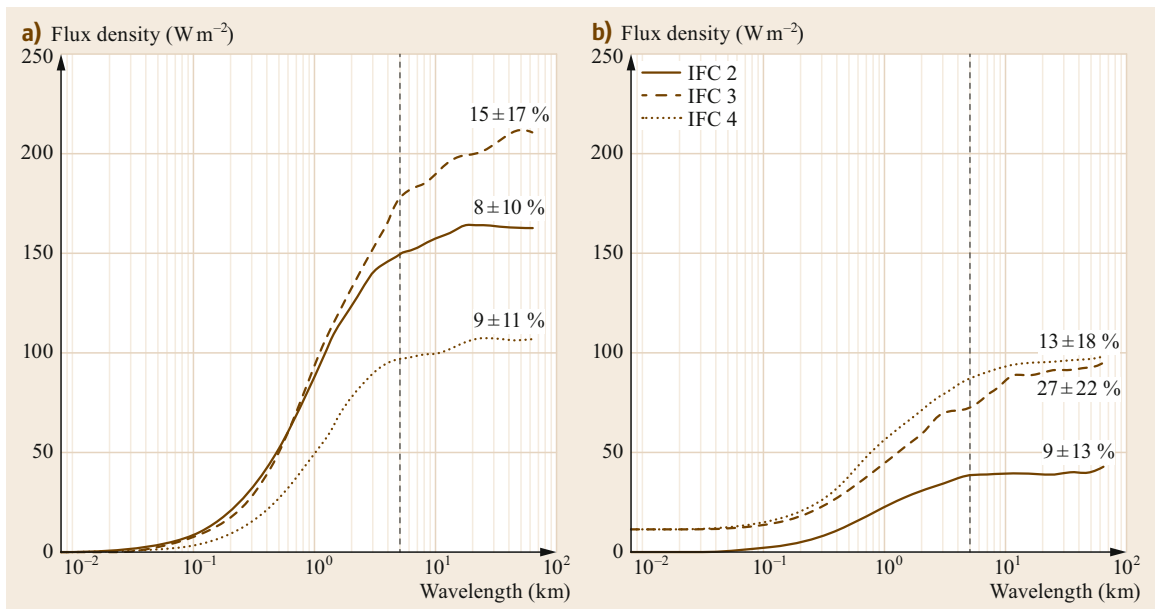

Fig. 48.4a,b Cumulative contributions to the latent (a) and sensible (b) heat fluxes for a 75 km flight track at an altitude of 150 m during three intensive field campaigns (IFCs). The vertical lines show a turbulent wavelength cutoff threshold of 5 km. The percent contributions above this cutoff are also given, along with the percent standard deviations

zero at night. The measured flux magnitudes at the top of the nocturnal boundary layer (100 m) were all found to be negligible at night, which is what is what would be expected from estimating the flux at night by measuring the change in concentration in the nocturnal boundary layer [48.84].

A second example is provided by measurements of the change in the CO₂ concentration over Candle Lake during BOREAS [48.85, 86], which showed that the large temperature differences between the forest and the lake surface during the night resulted in a nocturnal land/lake breeze. This led to substantial transport of CO₂ from the forest to the lake, which was vented over the lake in the morning. Under these conditions, some

of the CO₂ respired by the forest would go undetected by a tower-based flux system located over a forest close to a lake.

Figure 48.4 shows the contributions of various scales to the sensible and latent heat fluxes at an altitude of 150 m along a 75 km transect. These data were collected as part of three intensive field campaigns (IFCs) during FIFE. The flight track passed over part of the Konza Prairie at one end and flatter terrain with mixed agriculture at the other end. The percent contributions (and their standard deviations) to the sensible and latent heat fluxes for wavelengths longer than 5 km are shown for about ten runs per IFC. The 5 km cutoff was chosen based on the height of the measurements.

These results show that the flux density contributions at wavelengths greater than 5 km were substantial and that they were slightly larger during the late growing season (IFC 3). For latent and sensible heat, the mean long-wavelength flux contributions during IFC 3 were 15 and 27%, respectively. The long-wavelength contributions were also very variable from day to day, as can be seen by the standard deviations.

48.8.2 Quantifying Flux Density Over Complex Ecosystems

The versatility of an aircraft-based flux system for different situations is now demonstrated with a couple of examples. During the CODE project [48.30], there was concern that nitric oxide emissions from vehicle exhausts might impact O₃ fluxes at sites near to a major interstate highway. The hypothesis was that nitric oxide emitted by vehicles would destructively react with and thereby increase the downward flux of O₃. Aircraft-based flux measurements proved to be a suitable way to address this concern. By conducting flux measurements upwind and downwind of the interstate, it was shown that regions downwind to a distance of 1 km were impoverished in O₃ and featured larger downward O₃ fluxes [48.65]. However, at a flight altitude of 60 m, measurements conducted 1.5 km downwind of the interstate showed O₃ concentrations and fluxes that were comparable to those observed upwind of the interstate.

Flux measurements over the city of Fresno in California provide another example of the versatility of aircraft-based flux systems. Figure 48.5 shows the average fluxes of sensible and latent heat as well as CO₂ and O₃ measured along a 45 km transect that crossed over the city of Fresno during a clear sunny day on the afternoon of 29 July, based on one pass flown at an altitude of 150 m. The track extended from about 10 km northwest of the city to approximately 15 km southeast of the city. The wind was from the west at 4 m s⁻¹. The flux density estimates were calculated using wavelet analysis. The large contribution from wavelengths greater than 5 km for latent heat as compared to the other fluxes implies that long-wave transfer of water vapor was much greater than for the other scalars. This means that if these fluxes had been measured at the same level using a tower-based system, there would have been considerably more underestimation of the latent heat flux than the other scalars. It also means that, in this case, if the fluxes had been adjusted for energy budget closure using the Bowen ratio technique, there would have been considerable errors in the flux estimates of CO₂ and O₃.

48.8.3 Evaluation of GHG Emission Inventories

Aircraft-based flux-measuring techniques have frequently been used to obtain the regional flux of CO₂ over a wide range of ecosystems [48.9, 13, 21, 30–32, 35, 67]. However, until the last decade, there had not been any independent estimates of agricultural GHG emission inventories of N₂O and CH₄. Such independent estimates are important considering that bottom-up inventories of N₂O and CH₄ fluxes from agricultural sources have been reported to be highly uncertain [48.87, 88] and account for 52% and 84% of the global anthropogenic CH₄ and N₂O emissions, respectively [48.89]. Aircraft-based flux measurements of N₂O were compared with model estimates for an agricultural region [48.27]. Since process-based models only estimate direct emissions whereas an aircraft-based system measures the total N₂O emissions, it was then possible to estimate the contribution from indirect emissions and to show that the 20% value associated with the Intergovernmental Panel on Climate Change (IPCC) methodology was a reasonable estimate for the region studied.

Methane emissions from flux measurements and inventory estimates are compared in [48.66] for the agriculturally dominated Reuss Valley. The measured flux densities were found to be larger than the expected CH₄ emissions. This implied that the Swiss agricultural CH₄ inventory estimates were likely to be too low. Similarly, data from the Scanning Imaging Absorption Spectrometer for Atmospheric Cartography (SCIAMACHY) satellite [48.90] indicated that there was a 40% underestimation of the CH₄ emissions from US livestock. In contrast, it was concluded that the Canadian agricultural CH₄ emission inventory for a region that was 90% agriculture agreed reasonably well with aircraft flux measurements [48.29]. However, the authors of that work emphasized that validating agricultural CH₄ emissions inventories using top-down measurements is challenging because of the presence of other CH₄ sources such as wetlands as well as anthropogenic sources such as waste treatment plants, biodigesters, etc. Figure 48.6 shows the bottom-up agricultural CH₄ emissions and the top-down CH₄ emissions obtained by flying at an altitude of 150 m along two 20 km transects [48.29]. For the flight track dominated by agricultural land use (Fig. 48.6a), the agreement is good but not perfect (Fig. 48.6c). The most likely reasons for the small disagreement are that it was impossible to replicate the mixing that takes place in the boundary layer in the calculation of the bottom-up es-

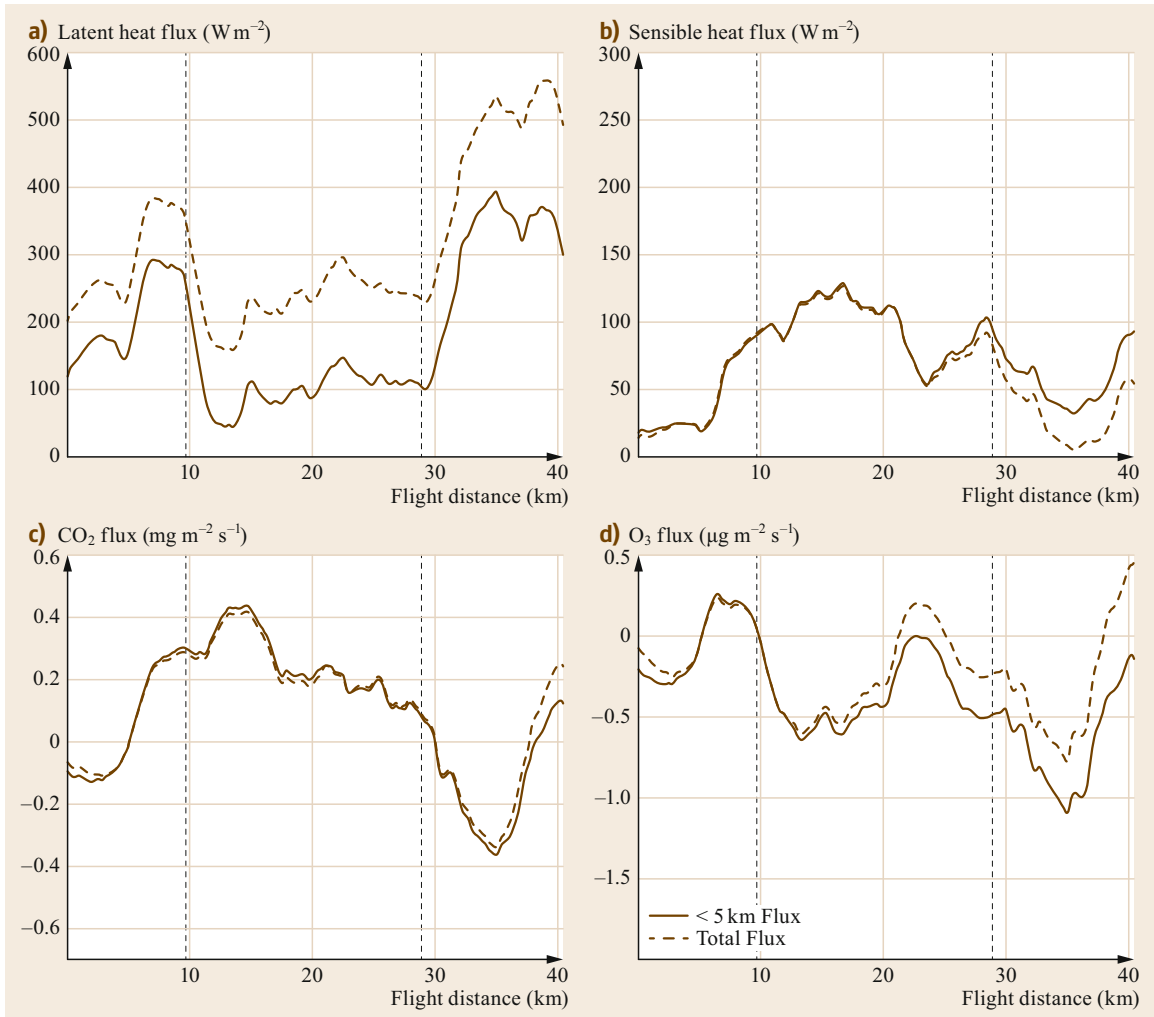

Fig. 48.5 Spatially resolved fluxes of sensible and latent heat and of CO_2 and O_3 measured at 150 m over the city of Fresno in California between 13:56 and 14:10 PDT (Pacific Daylight Time) on 29 July 1991. The city limits along the flight track are indicated by vertical lines

timates based on the data available, and that there were also small patches of wetlands that were emitting CH_4 . In contrast, when much of the aircraft footprint corresponded to wetlands (Fig. 48.6b), the substantial CH_4 emissions from the wetlands in relatively warm conditions led to very poor agreement between the top-down and bottom-up agricultural CH_4 emissions estimates (Fig. 48.6d).

Aircraft-based measurement platforms have also demonstrated their value for monitoring emissions from the oil and gas sector, enabling comparisons with inventory estimates. For example, the CH_4 emissions from an oil- and gas-producing region in Utah (USA) were

estimated from aircraft-based measurements using the mass balance approach [48.91], and top-down emissions were found to be a factor of 1.8 greater than bottom-up inventory estimates. Similarly, a recent study of aircraft estimates of CH_4 emissions from the oil and gas infrastructure in two regions of Alberta (Canada) reported that CH_4 emissions were four times greater than the region-specific bottom-up inventory-based estimate [48.92]. The authors of that study hypothesized that underreporting of the venting gas associated with cold heavy oil production in this region was the most likely source of the discrepancy between bottom-up and top-down estimates.

Fig. 48.6a–d Major land-use types and their distribution within the aircraft flux footprint (**a,b**) and 1 km spatially resolved CH_4 fluxes based on bottom-up agricultural CH_4 inventory estimates and top-down aircraft flux measurements (**c,d**). The plots highlight the difference between a flight track dominated by agricultural land use (**a,c**) and a flight track with substantial wetland areas (**b,d**). The shaded gray area represents ± 1 SE

48.9 Future Developments

Many aircraft-based flux density measurements have already been collected during large field campaigns such as HAPEX, ABLE, FIFE, BOREAS, SGP, and LBA. These measurements have the potential to provide valuable information on biosphere–atmosphere exchange. To facilitate the development of new applications, the data collected between 1987 and 2011 using the NRC Twin Otter atmospheric research aircraft are available for anyone interested [48.93]. These are high-quality data from over 4000 flux runs flown over a variety of

ecosystems. A wide range of spectral data using various types of satellite simulators have been collected simultaneously with flux measurements of $\text{CO}_2/\text{H}_2\text{O}$, and only very limited use has been made of these data. The development of environmental response functions to increase the value of satellite information is a very promising area of research [48.50]. More efforts should be made to identify the various ecosystems over which flux measurements have been taken, as this may yield flux data for ecosystems that are currently short of such

data [48.17]. Aircraft flux measurements also have the potential to help quantify mesoscale transfer, which is the cause of the lack of energy budget closure with many tower-based flux measurements [48.94]. The data already collected from the many aircraft flux campaigns probably include the information needed to improve our understanding of mesoscale transfer.

New developments such as small aircraft [48.56], the miniaturization of gas sensors, and the potential to deploy gas sensor packages on UASs (Chap. 49) all point to the increased use of aircraft-based flux density measurements in the coming years. Further, given the ongoing development of gas-detecting satellites [48.95], combining the data from them with aircraft-based flux density measurements [48.29] is an

area of research that has the potential for a major research breakthrough in the coming years. These technologies have the potential to greatly reduce the cost of flux measurements and help improve and validate GHG emission inventories, which is essential if the changes are to be included in the inventories [48.96, 97]. Data from satellites that are now being proposed should provide better geographical coverage coupled with higher temporal resolution [48.97]. However, before this information can be effectively used to estimate GHG emissions and verify the impacts of mitigation practices, it will be essential to calibrate the satellites. This will probably be best achieved using aircraft-based flux measurements owing to the comparable spatial and temporal scales of the measurements.

48.A Appendix

48.A.1 True Airspeed by the Flight Mechanical Angles α and β

To obtain a proper solution of (48.7), we start in the aerodynamic coordinate system ADONS (index a) of the flight. The ADONS is defined as the system in which the airspeed vector has the components

$$\mathbf{v}_{\text{tas},a} = (-|\mathbf{v}_{\text{tas}}|, 0, 0),$$

and is therefore called the airspeed-fixed coordinate system. A rotation of the ADONS about the vertical (lift) axis z_a by the angle $-\beta$

$$\mathbf{T}_{\text{ea}}(-\beta) = \begin{pmatrix} \cos \beta & -\sin \beta & 0 \\ \sin \beta & \cos \beta & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (48.9)$$

and then about the transverse axis (cross-force) axis y_a by the angle α

$$\mathbf{T}_{\text{fe}}(\alpha) = \begin{pmatrix} \cos \alpha & 0 & -\sin \alpha \\ 0 & 1 & 0 \\ \sin \alpha & 0 & \cos \alpha \end{pmatrix} \quad (48.10)$$

yields the description of the airspeed vector in the ACONS [48.98],

$$\begin{aligned} \mathbf{v}_{\text{tas}} &= \begin{pmatrix} u_{\text{tas}} \\ v_{\text{tas}} \\ w_{\text{tas}} \end{pmatrix} = \mathbf{T}_{\text{fe}}(\alpha) \mathbf{T}_{\text{ea}}(-\beta) \mathbf{v}_{\text{tas},a} \\ &= -|\mathbf{v}_{\text{tas}}| \begin{pmatrix} \cos \alpha \cos \beta \\ \sin \beta \\ \sin \alpha \cos \beta \end{pmatrix}. \end{aligned} \quad (48.11)$$

The angle α is positive for nose-lifting rotations, while β is positive for rotations to the port side. Both

the angles and the order of rotation have their origins in wind-tunnel experiments. The first rotation \mathbf{T}_{ea} leads to the experimental coordinate system (index e) that is cross-axis fixed. The components of the true airspeed vector \mathbf{v}_{tas} in the ACONS are:

- u_{tas} , which is oriented along the roll axis of the aircraft and positive in the flight direction
- v_{tas} , which is oriented along the pitch axis of the aircraft and positive in the starboard direction
- w_{tas} , which is oriented along the normal (or yaw) axis and positive downwards.

True Airspeed by the FHP Angles $\tilde{\alpha}$ and $\tilde{\beta}$

The outputs of the FHP (Fig. 48.2) are pressure differences that are used to calculate \mathbf{v}_{tas} in spherical coordinates in the ACONS:

- $\tilde{\alpha}$ (air flow from below gives a positive $\tilde{\alpha}$)
- $\tilde{\beta}$ (air flow from starboard gives a positive $\tilde{\beta}$)
- $|\mathbf{v}_{tas}|$ (the norm of the true airspeed vector).

The flow angles $\tilde{\alpha}$ and $\tilde{\beta}$ should not be confused with the rotation angles α and β that are commonly used in flight mechanics and wind-tunnel experiments [48.98].

There is a well-defined relationship between the two sets of angles,

$$\cos \tilde{\alpha} = \frac{u_{tas}}{\sqrt{u_{tas}^2 + w_{tas}^2}} = \cos \alpha \quad (48.12)$$

and [48.61]

$$\tan \tilde{\beta} = \frac{v_{tas}}{u_{tas}} = \frac{\tan \beta}{\cos \alpha}. \quad (48.13)$$

Using only the measurable angles $\tilde{\alpha}$ and $\tilde{\beta}$ (where $\tilde{\alpha} \equiv \alpha$), the expression for the true airspeed vector equals the well-known definition in [48.99],

$$\mathbf{v}_{tas} = -\frac{|\mathbf{v}_{tas}|}{D} \begin{pmatrix} 1 \\ \tan \tilde{\beta} \\ \tan \alpha \end{pmatrix}, \quad (48.14)$$

where the normalization factor

$$D = \sqrt{1 + \tan^2 \alpha + \tan^2 \tilde{\beta}} \quad (48.15)$$

(see also [48.59, 61, 100]).

Rotation into the MONS

The attitude of the aircraft can be described by the Eulerian angles Θ (pitch), Φ (bank or roll), and Ψ (yaw,

heading, or azimuth; see Fig. 48.7). Transformation from the ACONS to the MONS is performed via three sequential rotations [48.98, 100],

$$\mathbf{T}_1(\Phi) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \Phi & -\sin \Phi \\ 0 & \sin \Phi & \cos \Phi \end{pmatrix} \quad (48.16)$$

(i.e., about the x_f axis),

$$\mathbf{T}_2(\Theta) = \begin{pmatrix} \cos \Theta & 0 & \sin \Theta \\ 0 & 1 & 0 \\ -\sin \Theta & 0 & \cos \Theta \end{pmatrix} \quad (48.17)$$

(pitching about the y_f axis), and

$$\mathbf{T}_3(\Psi) = \begin{pmatrix} \cos \Psi & -\sin \Psi & 0 \\ \sin \Psi & \cos \Psi & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (48.18)$$

(yawing about the z_f axis). The permutation

$$\mathbf{T}_4 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix} \quad (48.19)$$

is necessary to transform into the MONS, which is defined by the following meteorological wind vector components:

- u , which is positive eastwards
- v , which is positive northwards
- w , which is positive upwards.

Finally, $\mathbf{M}_{mf} = \mathbf{T}_4 \cdot \mathbf{T}_3 \cdot \mathbf{T}_2 \cdot \mathbf{T}_1$ is inserted into (48.7), and the components of the meteorological wind \mathbf{v} can then be calculated.

48.A.2 True Airspeed, Temperature, and Pressure

The true airspeed $|\mathbf{v}_{tas}|$ of the aircraft in relation to the stagnant air causes a significant discrepancy between the total temperature T_{tot} and the total air pressure p_{tot} (both located at the tip of the FHP) on the one hand and the intrinsic properties T and p (the static temperature and pressure) of the undisturbed atmosphere on the other. The total pressure at the tip of the FHP is

$$p_{tot} = p + \Delta p_q, \quad (48.20)$$

where Δp_q is the dynamic pressure increment due to the airspeed. This can be determined from (48.20) by measuring p in a hole in the aircraft fuselage at a location

Fig. 48.7 (a) Aircraft attitude angles Θ and Ψ in the MONS and air-flow angles α , β in the ACONS: (b) top view, (c) side view, (d) front view (after [48.99] © American Meteorological Society, used with permission)

where the flow is parallel to the aircraft skin, similar to a Prandtl (Pitot static) tube.

Energy conservation in a compressible flow,

$$\frac{u_1^2}{2} + c_p T_1 = \frac{u_2^2}{2} + c_p T_2 \quad (48.21)$$

(where c_p is the specific heat capacity of air, $u_1 = |\mathbf{v}_{\text{tas}}|$, $u_2 = 0$, $T_1 = T$, and $T_2 = T_{\text{tot}}$), leads to the true airspeed as a function of the temperature difference,

$$|\mathbf{v}_{\text{tas}}|^2 = 2c_p (T_{\text{tot}} - T) \quad (48.22)$$

(see also [48.100]). Since the intrinsic air temperature T is not measured, T is replaced using the equation for an ideal fluid undergoing an adiabatic process,

$$\frac{T}{T_{\text{tot}}} = \left(\frac{p}{p_{\text{tot}}} \right)^\kappa, \quad (48.23)$$

where the Poisson number

$$\kappa = \frac{R_L}{c_p} = \frac{\gamma - 1}{\gamma}. \quad (48.24)$$

Here, $R_L = c_p - c_V = 287 \text{ J (kg K)}^{-1}$ and $\gamma = c_p/c_V$, where $c_V = 718 \text{ J (kg K)}^{-1}$ is the specific heat at constant volume. Finally, the true airspeed can be obtained

without the intrinsic temperature via

$$|\mathbf{v}_{\text{tas}}|^2 = 2c_p T_{\text{tot}} \left[1 - \left(\frac{p}{p_{\text{tot}}} \right)^\kappa \right]. \quad (48.25)$$

Remaining measurement uncertainties are treated by including calibration and installation coefficients that can only be determined through comparison with a pressure sensor that is not influenced by the flow field around the aircraft, for instance with a trailing cone on a calibration flight [48.101].

Using the Mach Number

Applying the definition of the Mach number (the ratio of the true airspeed to the speed of sound) [48.102, 103],

$$\text{Ma}^2 = \frac{2}{\gamma - 1} \left[\left(\frac{p_{\text{tot}}}{p} \right)^\kappa - 1 \right], \quad (48.26)$$

to (48.25) transforms it into

$$|\mathbf{v}_{\text{tas}}|^2 = \gamma R_L T \text{Ma}^2, \quad (48.27)$$

and applying (48.26) to (48.23) transforms it into

$$\frac{T_{\text{tot}}}{T} = 1 + \frac{\gamma - 1}{2} \text{Ma}^2. \quad (48.28)$$

Recovery Factor

In practice, the temperature cannot be measured at the same location as the true airspeed vector v_{tas} (located at the stagnation point at the tip of the FHP). Also, the heat produced by the dynamic pressure increment immediately starts to diffuse into the surrounding air. The temperature T_m measured somewhere in the vicinity of the FHP is smaller than T_{tot} but still larger than the intrinsic temperature T . The ratio [48.99, 103, 104]

$$r_c = \frac{T_m - T}{T_{\text{tot}} - T} \leq 1 \quad (48.29)$$

is referred to as the recovery factor. It depends on the sensor and is usually a function of the true airspeed (but not the air moisture). Inserting (48.29) into (48.23) gives the static (intrinsic) temperature of the air,

$$T = \frac{T_m}{r_c \left[\left(\frac{p_{\text{tot}}}{p_s} \right)^\kappa - 1 \right] + 1} \quad (48.30)$$

(in contrast to [48.99, equation 15]). It is also advisable to apply the recovery factor to the true airspeed calculation in (48.27), yielding

$$|v_{\text{tas}}|^2 = \frac{2c_p T_m}{r_c + \frac{2}{\text{Ma}^2(\gamma-1)}} \quad (48.31)$$

(unlike [48.99, equation 16]).

If the recovery factor r_c is not known (i.e., not provided by the manufacturer of the sensor), the pressure p_T at the location of the temperature probe has to be measured using an additional pressure probe. The static temperature is then calculated using (48.23)

$$T = T_m \left(\frac{p_s}{p_T} \right)^\kappa. \quad (48.32)$$

This method was applied in the fast temperature probe of the Helipod [48.105]. The true airspeed is then calculated by inserting (48.32) into (48.27).

48.A.3 Flow Angles

The following description addresses the application of typical FHPs, which (in addition to the static pressure) only measure differential pressures [48.106]. Air flow systems involving more or less than five holes [48.104, 107, 108] or a single turning sensor [48.109] for differential pressure measurement are treated in a very similar way. In larger probes (e.g., pressure holes in the aircraft fuselage, as used in the Space Shuttle and the F-18 High Angle of Attack Research Vehicle), it is possible to measure individual absolute pressures and determine flow angles even more accurately [48.110]. The

description of outdated systems such as vanes [48.2, 102, 103, 111] exceeds the limits of this analysis.

The local wind vector in the ACONS is determined from the dynamic pressure increment Δp_q and the pressure differences between opposite pressure holes in the FHP (i.e., the pressure differences in the horizontal plane $\Delta p_\beta = P2 - P4$ and the vertical plane $\Delta p_\alpha = P1 - P3$, where p_j denotes the individual holes of the FHP and the central hole is denoted P0; see Fig. 48.2). The pressure differences Δp_α and Δp_β increase as the flow angles α and β increase, but they also depend on the airspeed (and therefore on the dynamic pressure increment Δp_q and the Mach number) and the air density ρ (and therefore the altitude z). In general, this can be expressed via

$$\varphi = F(\Delta p_\varphi, \Delta p_q, z) \quad \text{where } \varphi = \alpha, \beta. \quad (48.33)$$

Here, F denotes a functional relationship.

Usually, the influences of the airspeed and the altitude can be considered by weighting the pressure difference by the dynamic pressure increment. The simplest assumption is therefore

$$\varphi = \frac{1}{K_{\text{FHP}}} \frac{\Delta p_\varphi}{\Delta p_q}, \quad (48.34)$$

where the calibration coefficient K_{FHP} considers any disturbance of the airstream by the FHP (and also by the entire aircraft fuselage) and local stream effects directly at the pressure hole.

It is difficult to determine the dynamic pressure increment Δp_φ and the total pressure p_{tot} (48.20) since the stagnation point is usually located somewhere between the holes of the FHP, so it cannot be measured directly. Approximating the total pressure by the pressure p_5 measured at the central hole of the FHP would lead to a wind vector measurement that is very sensitive to the aircraft attitude, wind speed, and wind direction (see also [48.109]).

It is understood that any offset angles α_0 or β_0 due to either bias in the pressure transducers or asymmetry of the FHP must be quantified in a laboratory, a wind tunnel, or in flight tests beforehand. Calibration routines for both wind-tunnel experiments and flight maneuvers can be found in the literature [48.59, 60, 101–103, 110, 112–114].

The well-known FHP made by Goodrich Sensor Systems (formerly Rosemount) provides an additional pressure difference

$$\Delta p_{\text{ref}} = P0 - P2 \quad (48.35)$$

between one of the horizontal holes and the central hole. The dynamic pressure increment is then estimated using

$$\Delta p_q \approx \Delta p_{\text{ref}} + \frac{1}{2} \Delta p_\beta, \quad (48.36)$$

and the flow angles are determined via (48.34) with K_{FHP} set to 0.088 for airspeeds below 0.6 Ma [48.115].

It should be noted that Δp_{ref} refers only to the horizontal plane (i.e., the stagnation point is assumed to be located somewhere along the line connecting the two opposite holes #2 and #4).

An improvement on the Rosemount method requires an additional differential pressure measurement between the central hole and one of the holes in the vertical plane (#1 or #3), resulting in two disjunct equa-

tions of the same type as (48.34),

$$\alpha = \frac{1}{K_{\text{FHP},\alpha}} \frac{\Delta p_\alpha}{\Delta p_{\text{ref},\alpha} + \frac{1}{2} \Delta p_\alpha} \quad (48.37)$$

$$\tilde{\beta} = \frac{1}{K_{\text{FHP},\beta}} \frac{\Delta p_\beta}{\Delta p_{\text{ref},\beta} + \frac{1}{2} \Delta p_\beta}. \quad (48.38)$$

It is obvious that this method represents only a slight rather than a fundamental improvement on the usual Rosemount method, since no consistent dynamic pressure increment can be determined. This is mainly due to the general strategy of using a Cartesian approach to solve a rotationally symmetric problem. More sophisticated and complex methods have also been published [48.60–62].

Raymond Desjardins

Science and Technology Branch
Agriculture and Agri-Food Canada
Ottawa, Canada
ray.desjardins@canada.ca

Raymond Desjardins is an Emeritus Scientist at the Ottawa Research and Development Centre, Central Experimental Farm, Science and Technology Branch, Agriculture and Agri-Food Canada. He received a PhD in Micrometeorology from Cornell University in 1972. He is a Member of the Order of Canada, Member of the Order of Ontario, and a Fellow of the Royal Society of Canada. He develops techniques to quantify mass and energy exchange over a wide range of ecosystems using tower and aircraft-based systems. Some of his recent research is focused on improving estimates of the carbon footprint of agricultural products and helping Canadian farmers compete on the international markets.

Devon Worth

Science and Technology Branch
Agriculture and Agri-Food Canada
Ottawa, Canada
devon.worth@canada.ca

Devon Worth is a physical scientist at the Science and Technology Branch of Agriculture and Agri-Food Canada at the Ottawa Research and Development Centre in Canada. He obtained an MSc from McMaster University in micrometeorology in 2002. His work focusses on mass and energy exchange using aircraft-based measurement techniques.

John Ian MacPherson

National Research Council of Canada
Ottawa, Canada
ian.macpherson@rogers.com

John Ian MacPherson is a retired Principal Research Officer from the Flight Research Laboratory, Institute of Aerospace Research, National Research Council of Canada. He received a Master of Applied Science in Aerospace Engineering from the University of Toronto in 1966. He was the principal scientist in charge of the NRC Twin Otter Atmospheric Research Aircraft and conducted national and international experiments in cloud physics, remote sensing, atmospheric turbulence, and the airborne measure of trace gas fluxes.

Matthias Mauder

Institute of Hydrology and Meteorology
Technische Universität Dresden
Dresden, Germany
matthias.mauder@tu-dresden.de

Matthias Mauder is a Professor in meteorology at the Technical University Dresden, Germany. Up to September 2021 he was the head of the group "Transport Processes in the Atmospheric Boundary Layer" at Karlsruhe Institute of Technology. He received his Doctorate in Micrometeorology from the University of Bayreuth (2006). As a postdoc, he developed new methods for the analysis of airborne eddy-covariance measurements and multitower measurements. His research aims to combine different observational techniques with numerical modeling to improve our understanding of turbulent transport processes and boundary-layer dynamics.

Jens Bange

Centre for Applied Geo-Science
University of Tübingen
Tübingen, Germany
jens.bange@uni-tuebingen.de

Jens Bange is a Professor for Environmental Physics at the University of Tübingen since 2010. He received a PhD in meteorology in 1998 and a diploma in physics in 1992 at the University of Hannover. His research interests include atmospheric turbulence, boundary-layer meteorology, wind-energy research, airborne meteorology, and environmental measurement technology. He is a founding member of the research networks ISARRA and WindForS.

Unmanned Aircraft

49. Unmanned Aircraft Systems

Jens Bange , Joachim Reuder , Andreas Platis 

UAS (unmanned aircraft systems) for atmospheric research are able to fulfill scientific tasks comparable to manned research aircraft and carry similar instruments. On the one hand, the payload aboard small UAS is much smaller and lighter and the endurance is shorter. On the other hand, the logistic efforts are more manageable, and disturbance of the turbulent atmospheric flow by UAS is also much weaker. In this chapter, we focus on the measurement of temperature, water vapor, aerosol, and the three-dimensional (3-D) wind vector measured aboard UAS, also considering the statistical uncertainty of turbulence measurements. We also discuss rotary-wing and fixed-wing UAS, weight classes, engines, autopilots, legal limits, and flight strategies. Finally, some exemplary field campaigns of the past are introduced.

Research aircraft, in general, close the spatial gap between ground stations (including meteorological masts and towers) and ground-based or satellite-based remote sensing. Like micrometeorological stations, aircraft can be equipped with fast and accurate sensors in order to measure atmospheric turbulence. Modern unmanned research aircraft (UAS) can be equipped with similar measurement systems to manned aircraft, limited of course by the size of the UAS (Sect. 49.8.1). There are many other names in use for UAS, like drones, UAV (unmanned aerial vehicle) or RPA (remotely piloted aircraft). However, in this text, UAS is used for unmanned instrumented aircraft.

Since UAS are commonly controlled by autopilot systems, flight path and altitude can be maintained with a higher accuracy compared to many manned systems. This can be very helpful for various meteorological missions. Small UAS can carry less scientific payload

and have less endurance compared to large and manned aircraft, on the one hand. On the other hand, their disturbance to the atmospheric flow is much smaller, as are the logistic efforts necessary to operate small UAS (smaller crew, very mobile, almost no ground facilities required). Moreover, if they are propelled by an electric engine, also the environmental impact is minimized (e.g., less noise in bird protection areas, no exhaust fumes during air chemistry and aerosol experiments). UAS can be operated in areas that are too dangerous for manned flight (e.g., active volcanoes) or too remote (e.g., polar regions). Last but not least, the purchase and especially the operation and maintenance of UAS is much less costly compared to manned research aircraft.

In this chapter, we can give only examples and an incomplete overview on the meteorological UAS applications, since a vast number of research groups are working with these new instruments, and every month

new publications occur in various journals. In addition, we will focus on smaller and medium-sized airframes, because the really big ones (e.g., the Global Hawk or

the Ikhana), are both under the aspects of instrumentation and operation very similar to manned research aircraft.

49.1 Measurement Principles and Parameters

Essentially, UAS are sensor carriers. That is, the user of UAS can mount any sensor described in this book that is light and small enough to be carried by the chosen aircraft. In order to inform on measurement principles and parameters, we refer to the corresponding chapters in this handbook, but especially to the chapter on research aircraft. In Tables 49.1 and 49.2, the most common parameters measured by UAS are listed. Further variables used there are:

- Air density ρ
- Specific heat at constant pressure c_p
- Heat of evaporation for water λ
- Turbulent fluctuations of wind vector components (u' , v' , w')
- Turbulent fluctuations of potential temperature θ'
- Turbulent fluctuations of specific humidity q' .

49.2 History

Atmospheric research can claim the privilege of having been the main driver for the adaptation and application of UAS technology in the field of nonmilitary science. Other research fields with extended spatial and temporal sampling requirements, e.g., forestry [49.1], biology [49.2], or archeology [49.3], have followed during the past years and profited from those developments. A comprehensive overview on small UAS for atmospheric research is given by [49.4].

The first documented application of unmanned, remotely controlled aircraft for atmospheric research dates back to 1970 [49.5]. The authors of that work used a commercially available hobby model airplane with a wingspan of ≈ 2.5 m and a combustion engine to measure profiles of temperature and humidity up to 3 km above ground. Systematic attempts to use UAS on a larger scale for meteorological research started in the 1990s, mainly based on rather large airframes of military origin that had been modified and adapted for scientific use [49.6, 7].

A first step towards smaller and more cost-effective systems was the development of the Aerosonde [49.8], with a wingspan of 2.9 m, an overall takeoff weight of 15 kg, and a scientific payload of around 5 kg [49.8]. The Aerosonde was developed as medium to long en-

Table 49.1 The most common meteorological parameters measured by UAS

Parameter	Description	Unit	Symbol
Height above ground	Altitude with respect to the underlying surface	m	z_{agl}
Height above sea level	Altitude with respect to the sea level	m	z_{asl}
Pressure	Air pressure	hPa	p
Wind vector	(Turbulent) meteorological wind speed and direction	m s^{-1}	$\mathbf{v} = (u, v, w)$
Temperature	(Turbulent) air temperature	K	T
Humidity	(Turbulent) water vapor mixing ratio	g kg^{-1}	m

duration UAS with a range exceeding 4000 km and was the first small UAS to cross the Atlantic and penetrate into the eye of tropical cyclones [49.9].

The rapid progress in microelectronics and component miniaturization made in the beginning of the millennium paved the way for a soaring development of airframes, autopilots, and meteorological sensors for meteorological research. One of the first low-cost attempts was the remotely controlled, but not autopiloted, system

Table 49.2 Other relevant parameters measured by UAS

Parameter	Description	Unit	Symbol
Vertical sensible heat flux	$Q_H = \rho c_p \overline{w'\theta'}$	W m^{-2}	Q_H
Vertical latent heat flux	$Q_E = \rho \lambda \overline{w'q'}$	W m^{-2}	Q_E
Vertical flux of horizontal momentum in direction of x	$\tau_{zx} = \rho \overline{w'u'}$	N m^{-2}	τ_{zx}
Vertical flux of horizontal momentum in direction of y	$\tau_{zy} = \rho \overline{w'v'}$	N m^{-2}	τ_{zy}
Turbulent kinetic energy	$\text{TKE} = \rho/2(u'^2 + v'^2 + w'^2)$	J m^{-3}	TKE

Kali, which performed more than 150 flights in Nepal and Bolivia to investigate thermally driven flows modified by orography in high alpine regions [49.10, 11]. The following years saw rapidly increasing activities by various research groups making their sensors and instrumentation airborne within a reasonable budget. Most of those early systems were based on fixed-wing airframes, such as e.g., SUMO (Small Unmanned Meteorological Observer) [49.12], M2AV (Meteorological Mini Aerial Vehicle) [49.13], MASC (Multi-purpose Airborne Sensor Carrier) [49.14], Smartsonde [49.15, 16], ALADINA (Application of Light-Weight Aircraft for Detecting In Situ Aerosol) [49.17], and Pilatus [49.18], to name a few. From around 2010, the use of rotary-wing multicopter systems (Fig. 49.1) for atmospheric research began to increase [49.19–21]. With their ability to hover and to slowly ascend and descend vertically, they are now the preferred choice for many measurement tasks related to boundary and surface layer profiling.

During the past decade, a series of community activities were initiated to foster the international col-

laboration in development and application of UAS in atmospheric research. These started in Europe with the successful Cooperation in Science and Technology (COST) Action ES0802 *Unmanned Aerial Systems for Atmospheric Research* [49.22] that resulted after its finalization in 2013 in the Foundation of ISARRA (International Society for Atmospheric Research with Remotely Piloted Aircraft Systems, www.isarra.org). ISARRA aims to provide a discussion and knowledge exchange platform for all aspects of the development and application of UAS in atmospheric research, including relevant airframe and sensor development, and also in the field of regulatory issues for UAS operations. Another recent activity to be mentioned was the *National Center for Atmospheric Research/Earth Observing Laboratory (NCAR/EOL) Community Workshop on Unmanned Aircraft Systems for Atmospheric Research* in February 2017, which resulted in an interesting overview report of all aspects related to UAS in atmospheric research [49.23].

49.3 Theory

UAS technology is a very fast-growing market with numerous daily new inventions and developments, therefore several names are currently used to designate these unmanned aircraft systems.

49.3.1 Terminology

The term *unmanned aircraft system* (UAS) refers to the unmanned aircraft and all of its components, including ground control stations and software, remote control transmitters, telemetry and payloads. This term has prevailed in international authorities such as American and British organizations. The United Kingdom's Civil Aviation Authority (CAA) provides a complete definition and explanation of this choice:

The terms Unmanned Aircraft (UA) or Remotely Piloted Aircraft (RPA) are used to describe the aircraft itself, whereas the term Unmanned Aircraft System (UAS) is generally used to describe the entire operating equipment including the aircraft, the control station from where the aircraft is operated and the wireless data link.

This UAS terminology is also exploited by the Federal Aviation Administration (FAA—United States), the European Aviation Safety Agency (EASA), and the Unmanned Aerial Vehicle Systems Association (UAVSA).

Formerly, the EASA (European Union Aviation Safety Agency), EUROCONTROL (European Organisation for the Safety of Air Navigation), and other civil aviation authorities used the term RPAS (remotely piloted aircraft), its associated remote pilot station(s), the required command and control links, and any other components as specified in the type design. However, this term was recently replaced by UAS. The catch-all term *drone* is the broadest terminology and is very common on the Internet but is not officially used by authorities.

A general weight-naming classification also exists for UAS. According to their mass, different names are used:

- MAV (micro air vehicle): for unmanned aircraft with a mass of < 1 kg
- sUAS (small unmanned aircraft system): for unmanned aircraft < 25 kg
- UAS: for unmanned aircraft with a weight of > 25 kg.

In this text, we use the term UAS to describe the unmanned airborne platform for meteorological measurements regardless of their takeoff weight.

Currently, UAS cannot perform all of their functions without the supervision or intervention of an operator, e.g., sense and avoid other aircraft or unexpected envi-

ronmental obstacles. These UAS still require a human action, such as preprogramming of their flight paths with Global Navigation Satellite System (GNSS) waypoints. Therefore, UAS are not fully autonomous but automated as in automated systems, an operator decides the course of its action. Describing a system as *autonomous* entails the absence of an operator that is responsible for that system.

49.3.2 UAS for Atmospheric Research

One of the most interesting applications of UAS in meteorology is the in-situ measurement of atmospheric turbulence. Small UAS cause little disturbance to the atmospheric flow due to their small size, especially when the propulsion is mounted on the rear of the aircraft (pusher configuration), while the measurement instrumentation is mounted at the nose, in sufficient distance to the front of the fuselage and the wings, see e.g., Figs. 49.2 and 49.3. Thus, small UAS are possibly the most suited (and less costly) instrument filling the gap between micrometeorological ground stations and remote sensing. Applications extend from fundamental science in remote areas [49.24–26] to wind-energy research [49.27], also in complex terrain [49.28].

Turbulent datasets should be sampled on straight and level flight sections (legs) in order to avoid any disturbing aerodynamic effects while turning. During measurement flight, track and altitude should be kept as constant as possible. This gives a distinguished orientation in space, e.g., x (which later helps with the data analysis). Also, most turbulent quantities are scaled with altitude z , especially in the atmospheric boundary layer (ABL).

49.4 Devices and Systems

In the following, UAS types are classified e.g., by weight, and the measurement systems most common aboard UAS are presented.

49.4.1 Airborne Carrier

There are several different types of UAS with specific limitations, benefits, and drawbacks. The main classification by the legal authorities is primarily by the takeoff weight of the UAS. The weight category is the crucial factor for the CAA rules in many countries and the handling abilities, see Table 49.3. Further, depending on the flight mission, a variety of different aircraft designs are available. The main airframe types are the fixed-wing aircraft and the multicopter (also often called multirotor, copter, quadcopter, etc.).

Since turbulent motion causes air parcels to change altitude z within a flow, only adiabatically invariant quantities should be used in turbulence analyses, e.g., the potential temperature θ and the water-vapor mixing ratio m , or their specific humidity q .

A very important criteria to fulfill for any research aircraft is the Taylor hypothesis of frozen turbulence in order to transform measured time series based on time t to spatial series based on coordinate

$$x = tU_x, \tag{49.1}$$

with airspeed U_x of the aircraft along x with respect to resting (stationary) air. Unfortunately, there is no absolute quantitative criteria that states when Taylor’s hypothesis is fulfilled, i.e., when (49.1) is applicable. Willis and Deardorff suggest that Taylor’s hypothesis is valid for moderately turbulent conditions and gives the empirical threshold of $\sigma_U/U < 0.5$ [49.29, 30]. In order to sample a significant number of large turbulent eddies (to keep the statistical error of a turbulent dataset small) the integral length scale I_θ of a turbulent quantity θ (potential temperature in this example) should be covered many times by one leg (ideally 100 times, which is often not achievable on one leg due to the changing characteristics of the Earth’s surface, for instance). The integral length scale is defined via the integral time scale [49.31]

$$I_\theta = U_x \int_0^{\tau_1} \text{Cor}_\theta(\tau) d\tau, \tag{49.2}$$

with autocorrelation function $\text{Cor}_\theta(\tau)$, time lag τ , and the first zero of $\text{Cor}_\theta(\tau)$ at τ_1 [49.32].

Multicopter

Multicopters (Fig. 49.1) are the most common used UAS on the global market. They consist of a central body and multiple rotors that power rotor blades to maneuver the UAS. These usually have four rotors (quadcopter) but can have as many six or eight (hexacopter and octocopter) and are always powered by electrical engines. Once in the air, a multicopter

Table 49.3 Weight classes of UAS

Type	Class	Weight (kg)	Example
sUAS	Very light	< 5	SUMO [49.12]
sUAS	Light	< 10	MASC [49.14]
sUAS	Medium	< 25	ALADINA [49.17]
UAS	Heavy	> 25	Aerosonde

Fig. 49.1 Example of a multicopter research UAS. This system is equipped with a particle and pollen trap (photo © Jens Bange, University of Tübingen)

controls its attitude and vehicle motion by varying the revolution speed of each rotor to change the thrust and torque produced, allowing movement in each direction and hovering on a fixed position.

The *advantages* of a multicopter are the following.

- Unlike fixed-wings aircraft, multicopters can perform vertical takeoffs and landings. They also require less space to take flight, can hover mid-flight, and maneuver in any required direction, see also Sect. 49.8.2.
- Multicopters do not require the surface area or wingspan that fixed-wing aircraft need.
- Multicopters are easier to fly for both humans and autopilots.

The *disadvantages* of a multicopter are the following.

- The main limitation is the flight range on a single battery, as they have a high demand for power consumption during flight. Most multicopters can fly for about 10–30 min before returning home for battery replacement; thus the flight range is limited.
- They have a high impact on the atmospheric small-scale flow due to the strong production of swirls by the rotor blades during flight. Therefore, accurate turbulence measurements with a multicopter are not possible.

Fixed-Wing Aircraft

Fixed-wing UAS are designed like traditional model aircraft, which look similar to an aeroplane. They are made of a central fuselage that has two attached wings

Fig. 49.2 Example of a very light class UAS: the SUMO, designed and operated by the University of Bergen Norway (after [49.12] photo is not included in [49.12])

Fig. 49.3 Example of a light class UAS: the Multipurpose Airborne Sensor Carrier MASC-3, designed and operated by the University of Tübingen, Germany (photo © B. Altstädter)

and usually a single engine. Once in the air, the two wings generate lift that compensates for its weight, allowing the aircraft to remain in flight. Nowadays, most fixed-wing aircraft come with an electrical impulsion, as it makes the aircraft easier to handle and simplifies maintenance. However, for long-distance UAS flights, aircraft with combustion engines are in use, as they have a better fuel-weight to range ratio compared to a battery-powered aircraft. Depending on the weight and the design of the aircraft, different take-off strategies are available. The most common in use are catapult, hand start, bungee start, takeoff on a winch or self launch.

The *advantages* of a fixed-wing aircraft are.

- Fixed-wing aircraft have a significant range as they can fly longer than multicopters on a single battery cycle.

Fig. 49.4 Example of a medium class UAS: ALADINA, designed and operated by the TU Braunschweig, Germany (photo after [49.17], © B.Altstädter et al. 2015, Creative Commons Attribution 3.0 License)

- The air-frame design of fixed-wing aircraft gives most designs greater stability in high winds over multicopters. This is important for flying in environments where higher winds are expected or frequent. Further, turbulence measurements are very accurate, as the flow sensor can be attached in a nose boom in front of the fuselage, where the influence by the aircraft on the flow during the flight is marginal.
- Safer recovery from motor power loss: if a fixed-wing aircraft loses motor power, it is able to glide down. A multicopter will always crash.

The *disadvantages* of a fixed-wing aircraft are.

- Fixed-wing aircraft require a larger takeoff and landing zone, which can make them unsuitable for special missions.
- They are less compact, meaning that they are harder to pack away and often require assembly before flights.
- For most types of fixed-wing aircraft the requirements on the operators are higher, especially the flying skills of the pilot.

A very new category is vertical takeoff and landing (VTOL) UAS. These systems combine the benefits of vertical takeoff and landing with a fixed-wing cruising flight mode.

Autopilots

UAS are controlled by an airborne autopilot as well as by a ground station encompassing a mission planning and monitoring software utilizing a bidirectional data

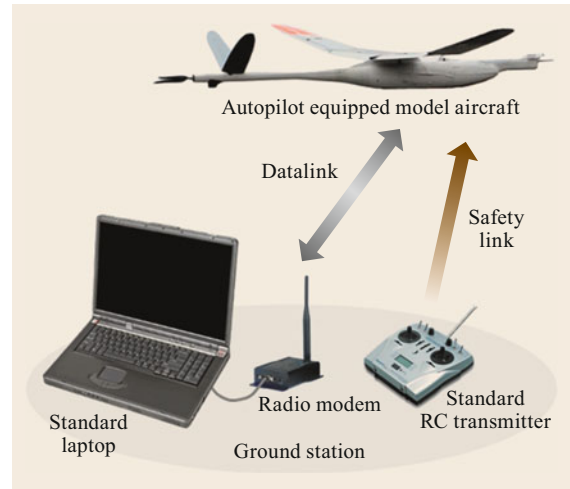

Fig. 49.5 Sketch of all the relevant components of a UAS (image © Andreas Platis, University of Tübingen)

link for telemetry and control as displayed in Fig. 49.5. There are several commercial and noncommercial systems on the market. Two very commonly used systems for research UAS are the Paparazzi [49.33] and the Pixhawk autopilot and ground-station software.

The key components of flight control on airframe systems are:

- Main autopilot board
- Autopilot sensors including:
 - attitude sensors, such as an inertial measurement unit (IMU) or IR sensors
 - GPS receiver
 - Pressure sensors
- Datalink radio modem
- Actuators (servos)
- Propulsion system, usually with an electric motor(s) with motor-controller and speed-controller
- Radio control receiver (safety link)
- Batteries.

The ground-control station is where an operator interacts with an unmanned aircraft. It generally consists of several parts, usually providing feedback about UAS activity, allowing command and control of the aircraft, and providing a method of override control for the system. The key components of the flight control on the airframe systems are:

- Ground computer
- Ground software
- Groundside datalink
- Radio control transmitter (safety link).

The ground station provides the interface between the UAS and the human for configuration, monitoring, and control of the UAS.

The basic component of the flight-control system on the airframe is the inertial navigation system (INS), which estimates the exact position, speed, and attitude. The INS consists of the GPS and an inertial measurement unit (IMU). Theoretically, an IMU alone is sufficient to obtain the position and attitude of an aircraft, by integrating linear accelerations caused by the motion and the rotation of the aircraft, with the gravity as a reference. However, due to the mathematical integration, small errors cumulate over time to an increasing position error. Therefore, a correction must be applied by using a long-term accurate system (like a satellite measurement) as a reference and a mathematical algorithm. This algorithm, a Kalman filter, merges the IMU and GPS signal to estimate the state the UAS, which is more accurate than an estimate based on the individual measurements alone.

49.4.2 Temperature Sensors for UAS

Principles for temperature measurements aboard UAS are very similar or identical to those on manned research aircraft (Chap. 48). Since at least fixed-wing UAS are move quickly through the air volume, the sensors must have a short response time (small sensor inertia), especially if turbulence has to be resolved. For operation on small UAS (Table 49.3: medium weight and lighter), the sensor has to be small, light, and robust with low power consumption (heavy UAS can use the same technology as manned aircraft; Chap. 48). For thermometer principles, see Chapt. 7. Two principles became common on UAS with respect to turbulence measurements [49.34]: the thermocouple and the thin-wire resistance thermometer (Fig. 49.6). Aboard a slow-moving multicopter (which is not well suited for turbulence measurements anyway), simple resistance thermometers (e.g., Pt-100) are sufficient (Chap. 7).

Fig. 49.6 Fine-wire fast-response thermometer aboard MASC. The entire instrument is about 4 cm in length and is attached to a measuring bridge (after [49.34] © N. Wildmann et al. 2013, Creative Commons Attribution 3.0 License)

Fig. 49.7 Capacitive hygrometer of about 10 mm × 70 mm in size (adapted from © Norman Wildmann, University of Tübingen, Creative Commons Attribution 3.0 License)

49.4.3 Humidity Sensors for UAS

Similar to temperature measurements, hygrometers aboard small UAS (Table 49.3: medium weight and lighter) should be small, light, and robust with low power consumption. Among those hygrometers mentioned in (Chap. 8, only capacitive and resistance hygrometers (Fig. 49.7) fulfill these requirements today. However, aboard small UAS such hygrometers are usually too slow to resolve atmospheric turbulence, especially aboard fast moving UAS. Coupled with a numerical sensor model, temporal resolution up to 3 Hz has been achieved [49.35]. Dewpoint mirrors, similar to those attached to radiosondes, might be an alternative in future developments. Medium-sized and heavy UAS might use infrared absorption hygrometers (IRGA) like the well-known LiCor 7500 or similar [49.36].

49.4.4 Wind Sensors for UAS

Any precise 3-D wind-vector measurement aboard research aircraft of any size, manned or unmanned, is based on a multihole flow probe (MFP) that measures the angle of attack α , side slip β , and the dynamic pressure enhancement p_{stag} in the coordinate system of the aircraft. These flow variables are then combined with the Eulerian angles of the aircraft attitude (pitch, roll and yaw, or heading), the ground speed of the aircraft, and its position; all of these variables are measured in Earth's coordinates. Fast attitude changes are usually measured using an inertia measurement platform (IMU), while the slow changes are very precisely measured using a Global Navigation Satellite System (GNSS, e.g., GPS, GLONASS, Galileo). Both slow and fast navigation data are usually combined using a Kalman filter. Together they form an INS (inertial navigation system). For details, see Chap. 36.

The approach above applies to small UAS as well. Due to its size, the MFP aboard a small UAS can even be calibrated in a wind tunnel while attached to the carrying aircraft. This is a big advantage compared to larger UAS or manned aircraft, since systematic measurement errors due to mounting imprecision can be minimized [49.37]. Besides the proper measurement

Fig. 49.8 Five-hole flow probe used aboard MASC. This probe is somewhat thinner than a pencil. Five pressure ports (P0 to P4) are used to measure the pressure differences caused by the angle of attack α , side slip β , and dynamic pressure enhancement p_{stag} . The holes denoted by Ps give the static pressure (photo after [49.37] © American Meteorological Society, used with permission)

and calculation of all the above quantities, a significant challenge is to achieve high (several 10 Hz) temporal resolution and an optimum in the signal-to-noise ratio (SNR). In addition to suitable pressure transducers based on MEMS (microelectromechanical systems) technology, the tubing strategy for connecting the MFP to the pressure transducers is of crucial importance [49.14]. In the end, the wind measurement unit aboard a UAS must also be calibrated in flight. However, this can be carried out much more easily compared to a manned research aircraft [49.37].

If turbulence is not of main concern, mean wind velocity components can be measured using simple Prandtl tubes or even no flow sensor at all [49.38]. In the latter approach, the wind shift of the aircraft is measured in order to calculate the mean horizontal wind [49.39]. Aboard multicopters, the wind measurement is even more difficult, since the downwash of the rotor blades distorts any flow measurement. An interesting approach, using the airframe itself as wind sensor, was published recently, e.g., [49.21, 40].

49.4.5 Aerosol and Particle Sensors for UAS

Atmospheric aerosols play an important role in our climate system [49.41] and in human health [49.42, 43]. Nowadays, UAS are a helpful tool to investigate small-scale vertical and horizontal variability of aerosol particles in the atmosphere by airborne in-situ measurements, mainly due to the improvement and the miniaturization of electronic components [49.17, 44, 45].

Two common instruments are used for in-situ particle investigation on UAS. For particles in the accumulation mode (diameter 0.1–1 μm) and the coarse mode (diameter > 1 μm), an optical particle counter (OPC) is used. A condensation particle counter (CPC) is used for *ultrafine particles* in the lower Aitken mode (diameter 10–30 nm), Aitken mode (diameter 30–100 nm) and nucleation mode (diameter 5–10 nm).

In the ALADINA UAS (Fig. 49.4), the OPC (model GT-526, Met One Instruments Inc., Washington, USA) and two CPCs (model 3007, TSI Inc., St Paul, USA) were miniaturized and implemented as displayed in Fig. 49.9 [49.17]. By using two airborne CPCs systems

Fig. 49.9 The aerosol payload installed in the UAS ALADINA in the front compartment of the air plane. The payload consists of two condensation particle counters and one optical particle counter that is mounted underneath (view from the rear). The first CPC (left) detects particle number concentrations in a particle diameter range of 5 nm to 2 μm . The second CPC (right) measures the particle number concentrations between 10 nm and 2 μm [49.25] (photo after [49.17] © B.Altstädter et al. 2015, Creative Commons Attribution 3.0 License)

simultaneously with different lower threshold diameters e.g., 10 nm and 5 nm, the difference between the number concentrations of the two CPCs can be used as an indicator of freshly formed particles (nucleation mode) [49.25]. When performing measurements with an OPC, special attention has to be paid to the

aerosol inlet, which should be isokinetic. If the sampling is nonisokinetic, the air measured will not be representative of the actual air, leading to particles of certain diameters being undersampled or oversampled, ultimately causing errors in the calculated concentrations.

49.5 Specifications

Table 49.4 give an overview on the technical properties of UAS sensors.

Table 49.4 Technical properties of sensors suited for small UAS, including relative (rel.) and absolute (abs.) accuracy, temporal resolution (maximum response frequency freq.), and references (ref.)

Quantity	Sensor	Range	Abs.	Rel.	Freq.	Ref.
Temperature	Fine-wire thermometer	−10 to 50 °C	0.2 K	0.01 K	10 Hz	[49.34]
Temperature	Thermocouple	−10 to 50 °C	0.2 K	0.01 K	10 Hz	[49.34]
Humidity	Capacitive hygrometer	15–85%	1%	0.1%	3 Hz	[49.27]
Wind speed	MFP incl. INS	$\alpha < 20^\circ$	0.5 m s^{-1}	0.05 m s^{-1}	20 Hz	[49.27, 37]
Wind direction	MFP incl. INS	$\alpha < 20^\circ$	1°	0.1°	20 Hz	[49.27, 37]

49.6 Quality Control

Since UAS are able to carry all kinds of sensors, the quality control of certain measurands is discussed in the corresponding chapters. However, some quality-control tools that are especially important in airborne turbulence measurements are discussed in the following. Also see Chap. 48.

49.6.1 Statistical Tools

The most important statistical tools for airborne in-situ turbulence measurements are the power spectrum $PS_\theta(f)$ and the structure function

$$D_\theta(\tau) = \frac{1}{t_{\text{tot}} - \tau} \int_0^{t_{\text{tot}} - \tau} [\theta(t + \tau) - \theta(t)]^2 dt \quad (49.3)$$

of measured quantity θ (the potential temperature in this example) during measurement period t_{tot} . The structure function (49.3) (Fig. 49.10) is well suited to assess the overall quality of the turbulence measurement. Due to less variation compared to the power spectrum, the identification of the Kolmogorov subscale of quasi isotropic turbulence (the famous $\tau^{2/3}$ -law) is easy and straightforward. A sudden deviation from this law at small time lags τ usually marks the inertia timescale of the sensor regarded.

The power spectrum

$$PS_\theta(f) = \frac{1}{t_{\text{tot}}} |\tilde{\theta}(f)|^2 \quad (49.4)$$

(with Fourier-transformed data series $\tilde{\theta}$) is very suited to identify systematic errors in the data, like noise, vibrancy, hum, crosstalk, and interspersions (Fig. 49.11).

Fig. 49.10 Structure functions of two thermometers aboard a MASC UAS: a thermocouple and a fine-wire sensor (after [49.34]). The Kolmogorov distribution is marked by a dashed line

Fig. 49.11 Power spectra of two thermometers aboard a MASC UAS: a thermocouple and a fine-wire sensor (after [49.34]). The Kolomogorov distribution is marked by a dashed line

Noise usually marks the physical limit of the measuring amplifier and the resolution of the sensor. On small UAS, this is an important issue, since electronics and sensor have to be small and light and are, thus, less perfectly built compared to heavy instruments for ground stations, for instance. Vibrancy can be caused by engine vibration. Hum can be an issue due to missing electrical grounding and shielding (many UAS are built of glass fiber). Crosstalk can happen within small and light ADC (analog digital converters). Moreover, interspersion is often caused by the remote-control systems and data telemetry to a ground station. Thin-wire thermometers are often prone to electro-magnetic fields in the environment, for instance.

49.6.2 Statistical Uncertainty of Turbulence Quantities

Flight legs of a UAS measurement flight are usually limited in space. If legs do not exceed the largest

eddies in size, the corresponding turbulent quantities will be sampled insufficiently. This causes a systematic statistical error by systematically underestimating or overestimating the turbulent quantity and its statistical properties. For more details, see [49.32, 46–48].

For the example, the vertical turbulent flux of sensible heat

$$H = \rho c_p \langle w' \theta' \rangle \tag{49.5}$$

(with leg average $\langle \dots \rangle$, air density ρ , specific heat at constant pressure c_p , and the turbulent fluctuations of the vertical wind w') is afflicted by a systematic statistical error

$$\Delta H \leq 2 \rho c_p \sigma_w \sigma_\theta \frac{\sqrt{I_w I_\theta}}{x_{\text{leg}}}, \tag{49.6}$$

with leg length x_{leg} and integral length scales I (49.2). The standard deviations σ also have a systematic statistical error given by

$$\Delta \sigma_\theta = 2 \frac{I_\theta}{x_{\text{leg}}} \sigma_\theta. \tag{49.7}$$

Even when $x_{\text{leg}} > I_\theta, I_w$ (the leg length exceeds the integral scales), different measurements under identical boundary conditions lead to different fluxes H due to its random statistical error σ_H , which can be calculated by [49.48]

$$\sigma_H = \rho c_p \sqrt{2 \frac{I_H}{x_{\text{leg}}} (\langle w'^2 \theta'^2 \rangle - \langle w' \theta' \rangle^2)}. \tag{49.8}$$

Of course, the ratio of systematic to random statistical error decreases with increasing leg length

$$\frac{\Delta H}{\sigma_H} \propto \frac{1}{\sqrt{x_{\text{leg}}}}. \tag{49.9}$$

49.7 Maintenance

In aviation, be it manned or unmanned, *safety is paramount*. Therefore, according to CAA rules in most countries unmanned aircraft systems (similar to manned aircraft) must be subjected to regular maintenance intervals. These intervals depend on the aircraft type and are usually documented in the operating man-

ual of the manufacturer. Scheduled inspections and maintenance that follow the manufacturer’s recommendations form the foundation on which a good safety record is built. An exemplary section of a maintenance table for a fixed wing UAS is shown in Table 49.5.

Table 49.5 Exemplary section of a maintenance table for a fixed wing UAS. All time intervals are usually subject to the manufactures maintenance and operating manual and only exemplified here

Time interval	Fuselage	Control surface	Engine	Batteries	Telemetry	Sensors
Before each flight	Visible check	Operational check	Test run	Capacity check	Status	Status
Before each flight day	Visible outside and inside check	Operational check	Test run visible rotor blade check	Capacity check voltage check of each battery cell	Status and range test	Calibration status check
Flight time 10 h	Visible outside and inside check	Operational check servo check	Grease rotor blade replacement	Complete charge and discharge capacity check	Status and range test	Calibration status check
Flight time 100 h	Overhauling visible outside and inside check	Servo replacement	Grease visible rotor blade check	Replacement	Overhauling	Calibration status check according to sensor type

49.8 Applications

Overall, UAS have become a well-established tool and sensor carrier for a wide range of measurement applications in atmospheric sciences and are used for a wide range of applications, and in particular in boundary-layer meteorology. This includes, among other fields, the investigations of the convective boundary layer (CBL) [49.49–51] and boundary-layer transitions [49.16, 52, 53], fine scale in-situ measurements of turbulence parameters [49.16, 24, 54–58], wind-power meteorology [49.27, 28, 59–61], hurricane [49.9, 62] and severe-storm research [49.63], aerosol and air-pollution measurements [49.25, 64, 65], data assimilation for the improvement of model simulations for weather forecast [49.66, 67], or the validation of atmospheric models [49.68–71] and remote sensing [49.15, 72–74]. One favored area of applications is stably stratified boundary layer (SBL) research in polar regions, where smaller to medium sized UAS can operate with limited infrastructural support [49.26, 56, 69, 75–77].

49.8.1 Civil Aviation Authority Rules and Regulations

Currently, there are no international agreements on UAS flight rules and classifications, since UAS lighter than 150 kg fall under the jurisdiction of national authorities and, therefore, manufacturers and operators are subject to different safety requirements and legal restrictions. National legislation and case laws differ in

each country. In some countries, legislation even only exists in the development process.

A useful practical guide based on hands-on experience is given by [49.78], who explains general airspace regulations and how UAS operations fit into the legal structure.

National and international aviation authorities started to collaborate in the framework of the *Joint Authorities for Rulemaking on Unmanned Systems* (JARUS) in recent years. JARUS is a group of experts from the national aviation authorities and regional aviation safety organizations including over 50 countries, as well as the EASA and EUROCONTROL. They give recommendation to national authorities and regional safety organizations to introduce a risk assessment methodology. This risk assessment allows for the establishment of a sufficient level of confidence that specific UAS operation can be conducted safely and how UAS can be integrated into airspace and at aerodromes.

On 31 July 2017, JARUS announced the publication of the *Specific Operations Risk Assessment* (SORA) of UAS. It allows the evaluation of the intended concept of operation and a categorization into six different specific assurance and integrity levels and is now being applied in many countries, e.g., in Germany and Norway as a basic tool for their legislation. Therefore, some basic regulations can be found in most of JARUS countries. Some of the most important regulations will be briefly listed using Germany, as an example.

The necessity and scope of a permit for UAS operation depends primarily on the weight, the kinetic energy of the UAS (speed and weight), the flight altitude, and the flight area (urban or rural, sight conditions, etc.). As an example according to the EU drone regulation, UAS below 25 kg do not need any specific approval by the authorities for the operation, if the UAS is not operated over uninformed persons, crowds of people and buildings. For the operation of UAS above 250 g, the pilot must always hold a drone license. For UAS heavier than 25 kg, an airworthiness certification of the aircraft has to be applied. The flight altitude for UAS is limited to a maximum of 120 m above ground level, and the flight always has to be in the visual line of sight (VLOS) of a safety pilot. In Germany, VLOS is 500 m. If the operation requires higher flight altitudes or is outside the line of sight, the drone license and the approval by national aviation authorities are again mandatory. Further, the operation of UAS is not permitted over sensitive areas, such as residential areas, aerodromes and their vicinity, controlled airspace, public facility, crowds, nature reserves, industrial plants, federal roads, etc.; exceptions can also be approved here.

Approval assessment and evaluation of the authorities is regulated mainly by SORA (Specific Operations Risk Assessment). Depending on the potential risks of a flight mission, UAS users may have to establish operational concepts for their mission and an assessment by expert inspectors.

For example, if you plan the operation with a 1 kg-light UAS over uninhabited area the risk category is very low. If the operation, however, is over a densely populated area or a crowd of people, and the UAS also weighs more than 25 kg, a complex approval process is to be expected, as this kind of mission is a very high risk class. For such a special permission, among other things, proof is required that certain flight procedures are applied, which are generally classified as safe and that safety-relevant systems on board the UAS system are redundant.

The ICAO works on a fundamental international regulatory framework for UAS operation [49.79]. However, at the time of writing, there were no international agreements on UAS flight rules and classifications. According to the UK Civil Aviation Authority [49.80], for instance, UAS can be classified by weight (Table 49.3).

49.8.2 Flight Strategies

Flight strategies for UAS have to take into account several boundary conditions. In addition to CAA rules (Sect. 49.8.1) and minimized statistical errors (Sect. 49.6.2), a limited flight endurance usually has to be considered. However, in comparison to most manned research aircraft, UAS autopilots are able to maintain

Fig. 49.12 Repeated legs for maximum significance or temporal development (after [49.38] © A. Rautenberg et al. 2018, Creative Common Attribution 4.0 License)

track and altitude with very high precision with only a few meters of deviation.

Repeated legs at identical height and location increase the statistical significance of turbulent statistics or describe, in highly non-stationary conditions, the temporal development in a fixed air volume (Fig. 49.12).

Vertical profiles of atmospheric quantities can be achieved by slant ascending and descending flights or by following a helical flight pattern. Typical vertical velocities are in the order of several meters per second, and UAS are able to perform such profiles up to several 1000 m.

A combination of horizontal straight and level sections (legs) with slant flights gives a spatial dataset of atmospheric quantities, and when repeated within the same volume, even its temporal development (Fig. 49.13).

Fig. 49.13 A combination of legs with slant flights gives a spatial data set of atmospheric quantities (after [49.38] © A. Rautenberg et al. 2018, Creative Common Attribution 4.0 License)

Fig. 49.14 Stacked race-track patterns are well suited for wind-energy research (after [49.38] © A. Rautenberg et al. 2018, Creative Common Attribution 4.0 License)

Stacked race-track patterns (Fig. 49.14) consist of pairs of legs at various altitudes with only slight height difference. This flight strategy gives a maximum spatial resolution of a relatively small air volume and is well suited for wind-energy research upstream or downstream of wind turbines, both for the initialization and validation of numerical flow simulations.

With multicopter UAS, vertical profiles and fixed-position measurements are feasible. The advantages of a fixed-point measurements is a longer sampling time at a certain location. This enables better statistics if the time resolution of the sensor is low, which is often the case for airborne aerosol particle and gas instruments onboard small UAS. The drawback is the limited spatial resolution of the fixed-point observation.

Many other flight strategies have been described and published, for instance with respect to ABL transitions [49.52], entrainment on top of the convec-

tive ABL [49.24], or for monitoring surface temperatures [49.51].

49.8.3 Important UAS Campaigns

A selection of important and ground-breaking campaigns with the participation of small to medium-sized UAS is presented in Table 49.6. This overview does not—by far—cover all UAS activities in atmospheric science during the most recent years, as the development and application of UAS systems seems to increase exponentially. In addition, some interesting and successful activities and campaigns (e.g., the *Characterization of Arctic Sea Ice Experiment* (CASIE)) are often not adequately covered by peer-review scientific publications.

It is worth to present one very recent and ground-breaking activity in more detail. In August 2018, the University of Colorado, Boulder, initiated and led the international LAPSE-RATE (Lower Atmospheric Process Studies at Elevation—a Remotely Piloted Team Experiment) field campaign. This field experiment [49.90], held in connection with the 6th ISARRA Conference, took place in the San Luis Valley, a large valley in the Colorado Rocky Mountains. More than 100 scientists from 18 universities, research institutions, and companies gathered for 1 week to investigate various relevant BL phenomena. Specifically, this included the role of BL structure and development for the convective initialization of thunderstorms, the importance of thermally driven circulations for the valley wind climate, the morning boundary layer transition in complex terrain, and the aerosol properties of a high-altitude valley. With more than 50 different UAS systems performing nearly 1300 scientific flight missions over 6 days, this campaign marks the beginning of a new era in the application of UAS in BL research.

Table 49.6 Selection of important UAS campaigns

Campaign	Location	# UAS flights	Reference
LHOMAR II 2001	Nepal, Kali Gandaki valley	108	[49.10]
JUIPIT'AYA 2003	Bolivian Altiplano	85	[49.11]
Typhoon eye-wall penetration 2005	Taiwan	1	[49.9]
MAC 2006	Maldives	45	[49.81–83]
FLOHOF 2007	Hofsjokull, Central Iceland	112	[49.68, 84]
CoCoNUE 2009	Pawnee, Colorado	5	[49.85]
LITFASS 2009	Lindenberg, Germany	ca. 50	[49.24, 54, 86]
BLLAST 2011	Lannemezan, France	ca. 350	[49.49, 51]
MISOPEX 2013	Oliktok Point, Alaska	24	[49.87]
CLOUD-MAP (since 2015)	Oklahoma, US	ca. 750	[49.88]
ISOBAR I 2017	Hailuoto, Finland	127	[49.26, 89]
ISOBAR II 2018	Hailuoto, Finland	387	[49.26, 89]
WINSSENT (since 2017)	Swabian Alp, Germany	ca. 50	[49.70, 71]
NPF (DFG) 2014, 2018	Germany and Svalbard	ca. 100	[49.25]
LAPSE-RATE 2018	San Luis Valley, Colorado	ca. 1200	[49.90]

49.9 Future Developments

There is no reason to assume that the rapid development in a number of relevant fields, such as material science (for lighter and more robust airframes), battery technology (for increased endurance and payload capacities), or microelectronics (for even smaller, lighter, faster, and less energy-consuming sensors and instruments) will slow down in the future. Experience from the past has shown that relevant innovations will be adapted and utilized on a rather short time horizon. The capabilities and level of application of UAS for scientific purposes will be increased in general and atmospheric research in particular.

With respect to sensors and instrumentation, there is an increasing demand for a fast, stable, and accurate humidity sensor that can be used on UAS of all sizes. Additional active development areas of high scientific interest are the further miniaturization of sensor systems for air chemistry and aerosols and the reliable measurement of wind and turbulence from multicopter systems, e.g., by a sonic anemometer mounted on a horizontal boom outside the flow distortion and downwash area of the rotors. The atmospheric measurement community would also highly benefit from the development of a standardized and exchangeable sensor suite for the basic meteorological parameters, at least temperature, humidity, and pressure (Chaps. 7, 8, 10) and a corresponding affordable and mobile calibration unit.

New airframe design and production methods (such as 3-D-printing) will be able to produce very specific and targeted UAS systems, with an increasing tendency to fuse airframe and sensors, in particular for the most lightweight classes. The ongoing development of hybrid systems, enabling vertical takeoff and landing, and normal fixed-wing operation during the scientific mission, will further ease and increase the applicability of UAS systems, e.g., for ship-based operation.

The development of new flight strategies, based on progress in communication and machine learning, will in the near future allow for the operation of multiple UAS in swarms and flocks [49.91–93]. Guided by artificial intelligence, such systems will be able to optimize flight strategies and data coverage for a given measurement task, without or only with very limited interaction by the UAS pilot and, thus, further paving the road from automated to autonomous operations.

The big open question remains of how these scenarios can be realized within the existing regulatory framework. The application of UAS in atmospheric science, both for increased experimental activities and envisaged operational application, will strongly depend on a transparent, reliable and, it is hoped, an internationally homogenized set of rules and regulations provided by the aviation authorities.

Jens Bange

Centre for Applied Geo-Science
University of Tübingen
Tübingen, Germany
jens.bange@uni-tuebingen.de

Jens Bange is a Professor for Environmental Physics at the University of Tübingen since 2010. He received a PhD in meteorology in 1998 and a diploma in physics in 1992 at the University of Hannover. His research interests include atmospheric turbulence, boundary-layer meteorology, wind-energy research, airborne meteorology, and environmental measurement technology. He is a founding member of the research networks ISARRA and WindForS.

Joachim Reuder

Geophysical Institute, and Bjerknes
Centre for Climate Research
University of Bergen
Bergen, Norway
joachim.reuder@gfi.uib.no

Joachim Reuder is Professor in Experimental Meteorology at the Geophysical Institute at the University of Bergen, Norway. He has more than 25 years of experience in boundary layer meteorology and has been involved in the development and application of small unmanned aircraft systems for boundary layer research for nearly 20 years. He is a founding member of the International Society Atmospheric Research using Remotely piloted Aircraft (ISARRA).

Andreas Platis

Centre for Applied Geo-Science
University of Tübingen
Tübingen, Germany
andreas.platis@uni-tuebingen.de

Andreas Platis studied Meteorology in Munich and did his PhD at the Environmental Physics Group at the University of Tübingen in the field of aerosol particles and turbulence measurements with unmanned research aircraft. Currently, he is working as a post-doc in the group. His research interests are atmospheric turbulence, boundary-layer meteorology, wind-energy research, airborne meteorology, and environmental measurement technology.

50. Ground-based Mobile Measurement Systems

Eberhard Parlow , Thomas Foken 

While stationary measurements can be performed relatively frequently, they do not permit detailed spatial analyses of meteorological variables, particularly air temperature. This problem can be resolved by making the sensor mobile and then taking measurements at a variety of locations within the area of interest. Mobile measurements have therefore been used in climatological research since the early twentieth century. Due to improvements in and the miniaturization of the relevant measurement technologies, mobile measurements have undergone a renaissance since the 1970s. Urban climatology has become an important field of great scientific interest. The realization that the measurements of just one urban weather station—generally located (in line with the recommendations of the World Meteorological Organization) on short-cut lawn—is not sufficient to represent all of the climates present in an urban area has led to the acceptance of and even the need for mobile measurements taken on cars, bikes, or buses. New methodologies have been implemented, and advances in digital measurement and storage on data loggers have made mobile measurements an important tool for spatially distributed studies of air temperature, air humidity, and air pollution.

Three important aspects must be considered when mobile measurements are analyzed:

- (1) A complete mobile measurement covers a time interval for the measurement, within which the meteorological variable changes its value. This change has to be corrected for to obtain quasi-synchronous data.
- (2) Since the instrumentation changes location, accurate geolocation of the measured data must be guaranteed. This can be achieved by operating a global navigation satellite system (GNSS) in parallel with the measurements.
- (3) Due to the spatial dimension of the measured data, it is convenient to perform some of the data analysis and visualization using modern geographic information system (GIS) technologies.

Mobile measurements are performed to circumvent a major problem with fixed stations. While these stations can provide data with high temporal resolution, the spatial aspects of meteorological fields are difficult to investigate in detail using fixed stations. Even when several fixed stations are maintained and the measurements from those stations are interpolated, the resulting data are often not sufficient to be able to probe the high spatial variability of meteorological fields in an urban, rural, or agricultural environment, such as frost risk for a hilly terrain. This issue can be resolved by making the sensor

mobile, meaning that measurements can be performed at a variety of locations within the area of interest. When the methodology of mobile measurements was devised approximately a century ago, automatic data recording was not possible, so measurements were carried out manually at given points in an effort to obtain a dense two-dimensional field of meteorological variables.

It should also be noted that there is a disadvantage of the mobile measurement method: it often does not yield a time series of measurements for a particular location.

50.1 Measurement Principles and Parameters

Mobile measurement methods can be classified into horizontal and vertical mobile measurement systems. The range of heights available with a vertical system is limited to just a few meters or decameters above the ground. Measurements at greater heights can be achieved with either aerological measurements (see Chap. 46) or by combining different systems (see Chap. 47). Horizontal mobile systems can be classified according to the horizontal distance covered by the measurements.

Mobile systems of both types can perform measurements along a traverse using either *continuous data sampling* or by implementing a *stop-and-go strategy* (e.g., moving the platform and sampling the data at the new location, and then relocating the platform and re-sampling). The strategy employed depends very much

on the meteorological element to be sampled. Because unmanned aircraft systems (UASs, see Chap. 49) fly at low altitudes, they can complement ground-based mobile systems or can be used instead of them.

An overview of mobile measurement systems is given in Table 50.1. The synchronization of measurement data with geographical coordinates to enable subsequent analysis of the two-dimensional data field is crucial for mobile measurement techniques.

Most meteorological variables are scalars, but a few variables (e.g., wind speed and direction) are vectors. It is quite tricky to separate wind speed and direction during data sampling when the measuring instrument is moved. Table 50.2 lists the most important parameters measured by mobile systems, together with possible sampling strategies for each.

Table 50.1 Classification of mobile measurement systems

Direction of sampling	Scale (m)	Typical systems	Remarks
Vertical mobile systems	1–100	Lifts on towers, balloons, unmanned aircraft systems (UASs)	See also Chaps. 46 and 49
Horizontal mobile systems	10–100	Fixed systems on rails or cables	See also Chap. 49
	100–10 000 (or larger)	Cars, trams, bicycles, etc. UASs	

Table 50.2 Parameters measured by mobile systems

Parameter	Sampling strategy		Remark
	Continuously	Stop and go	
Air temperature	×	×	Requires a radiation-shielded and ventilated detector, see Chaps. 7 and 8
Relative humidity	×	×	
Absolute humidity	×	×	
Wind speed		×	See Chap. 10
Wind direction		×	
Radiation (mainly global radiation)	×	×	See Chap. 11
Trace gas concentration (with a fast-response analyzer)	×	×	See Chaps. 8, 16, and 18
Trace gas concentration (with a slow-response analyzer)		×	

50.2 History

It had become apparent by the beginning of the twentieth century that the true spatial variability of the air temperature could not be determined with just a few fixed stations. To overcome this issue with fixed-point measurements, continuous mobile measurements were implemented. The first mobile systems performed long horizontal traverses. Fixed horizontal and vertical measurement systems that are capable of moving short distances have been available since the 1930s. Most meteorological variables can generally be sampled by mobile units. The main driving force for developing these systems was the desire to measure the air temperature fields in urban and rural environments in order to study heat stress in cities or frost risk in agricultural areas.

50.2.1 The First Systems in the Early Twentieth Century

The first publication on mobile measurements in climatology was written by *Wilhelm Schmidt* (1883–1936) [50.1]. He mounted a mercury thermometer on a car such that it was 20 cm away from the exterior and 1.2 m above the ground, and then performed temperature measurements within the city of Vienna (Austria) during three frosty nights in May 1927. Since automatic data recording systems were yet to be invented, he mounted a magnifying glass on the thermometer and noted the measurement time and location (e.g., house numbers) in order to make it easier to take accurate readings during his car trips. Soon after, and probably stimulated by Schmidt's work, *Albert Peppler* (1882–1942) also used this new mobile measurement method to determine the air temperature on the move [50.2]. In 1929, he measured air temperatures along several profiles across the city of Karlsruhe (Germany) using a car equipped with ventilated Assmann psychrometers (see Chap. 8). Since cars were not readily available in the 1920s, the car and driver used by each author were provided by local public services. The first measurements made using a bicycle-mounted instrument were conducted in 1933 [50.3] in the city of Munich. The unique advantage of this technique over other measurement techniques—that it can sample large areas in a very short time—was mentioned in [50.1, 2].

50.2.2 The Renaissance in Mobile Measurements Since the 1970s

While important urban climatology studies were carried out during the 1950s and 1960s, they were mostly based on data from fixed stations [50.4, 5]. Only a few papers that utilized data from mobile platforms were

published during this period [50.6, 7]. However, in the 1970s, mobile meteorological measurements underwent a renaissance. Micrometeorological research developed rapidly. One of the first mobile measurement systems developed in the 1970s was used to analyze the urban heat island of Freiburg (Germany) [50.8], the urban climate of Uppsala (Sweden) [50.9], and minimum temperatures and the frost risk in the wine-growing area of the Kaiserstuhl (SW Germany) [50.10]. Field measurements from mobile units that used special computer programs to study not only the air temperature distribution but also the humidity of the air, the vertical gradients of these parameters, and bioclimatological fields of equivalent temperature were published in [50.11]. Urban climatology became an increasingly important driver of climatological research. More and more urban climate studies were conducted, very often using a combination of mobile field measurements and up-and-coming remote-sensing technologies that used thermal infrared sensors aboard aircraft, which offered the ability to measure relevant meteorological variables to a resolution that was previously unobtainable. The spatial distributions of urban air and surface temperatures became important information for urban planning agencies. During that time, the methodologies used steadily improved. Initially, Pt100 resistance thermometers and thermocouples (see Chap. 7) were connected to a heavy registration unit driven by 220 V; this unit printed the recordings on a paper spool. In the 1980s, the first computer-based data-recording units and data loggers entered service, improving data analysis. During this period, measurement geolocation remained a major problem, as modern global navigation satellite systems (GNSS) were not yet available. In recent years, many works in which the spatial distribution of temperature within an urban area was measured using bicycles or public buses have been published [50.12]. Horizontal mobile system technology has become an important tool in local climatological studies and urban planning issues and has therefore been partly standardized [50.13]. It has also been used in combination with imaging techniques such as infrared imaging from aircraft (see Chaps. 42 and [50.14]).

50.2.3 Systems with Horizontal Mobility over Short Distances

Measuring systems with mobility over short horizontal distances have mainly been applied to study the heterogeneity of ecosystems. Investigations of this type started in the middle of the last century (see the review in [50.15]). These mobile systems were used when the heterogeneity was too large to be adequately captured

by fixed sensors, e.g., in woodlands. In the first studies, the mobile measuring systems mostly carried radiometers above and below forest canopies to measure the areal distribution of upwelling and/or downwelling radiation within forests [50.16–22] and grasslands [50.23, 24].

The *Asa Shuttle*, described in [50.25, 26], was a mobile system that measured the radiation and the air temperature along a horizontal transect of decreasing shelterwood density of Norway spruce. The TRAM (Transect Measurement) system [50.27] travels a loop through a forest ecosystem and over a creek (the Ameri-Flux site at Niwot Ridge, see Sect. 50.4.2). A similar system, but based on a small train [50.15], was built to measure radiation components, the air temperature and humidity, and the CO₂ and O₃ concentrations on both sides of a forest edge (see Sects. 50.4.2 and 50.8.3).

50.2.4 Vertical Mobile Systems

The first vertical temperature profile measurements achieved with lifts were obtained in the 1930s–1940s

over water bodies, such as off the island of Greifswalder Oie in the Baltic Sea [50.28] and above a freshwater pond [50.29, 30]. In the 1960s, an initiative by *Hans Hinzpeter* (1921–1999) led to the construction of highly sensitive temperature lifts [50.31, 32] that utilized 1–2 μm thick platinum wire. These had a lifting speed of $\approx 1 \text{ m s}^{-1}$, a vertical resolution of $< 1 \text{ mm}$, and were used to study the molecular layer above the surface of the water in the Baltic Sea and Caspian Sea.

A lift was also installed in the 80 m high tower of the Aerological Observatory Lindenberg (Germany) in the 1950s to study the air temperature and air humidity structure in the lowest part of the atmospheric boundary layer [50.33].

Vertical mobile systems are still of interest for air chemistry studies. They allow profiles to be measured using only one gas analyzer providing the response time is sufficiently fast that the transport and reaction timescales are larger than the duration of a measurement performed with the lift [50.34, 35].

50.3 Theory

Mobile measuring systems are highly dynamic systems, and most can be assumed to be first-order dynamic systems (see Chap. 2). Therefore, the response time of the sensor and the velocity of the system determine the dynamic error and the time shift (related to the change in the distance) of the signal. Furthermore, the sampling theorem together with the horizontal or vertical structures of the distributions of the meteorological parameters in the field (see Chap. 1) determine the time constant and sampling rate.

50.3.1 Technical Requirements

The itinerary for mobile measurements is dictated by the technical requirements of the measurements. The measurements should ideally follow the rules given below (which are valid for all types of mobile systems), otherwise the quality of the data may be affected [50.13]:

- Cover all relevant regions in which the meteorological variable of interest is expected to vary over space and time.
- For nonfixed systems, the itinerary must ensure that the system has the right of way at traffic crossings in order to avoid excessively long stops and any influence of heat or exhaust emissions from the mobile unit on the measurements.

- The movement of the mobile unit should be relatively slow compared to the instrument response time to circumvent issues due to a relatively long response time. However, the time needed to carry out the whole itinerary should not be too long, and a reasonable area should be sampled. Chemical sensors may require special attention.
- Measurements for the area investigated should be available from at least one fixed station as a means to validate and potentially calibrate the mobile measurements.
- The longer the time taken to cover the itinerary, the more that the variable(s) of interest (e.g., the air temperature) will change over that period, and these changes will need to be corrected for.
- In the presence of low wind speeds and the nocturnal cooling effect, warm exhaust gases must not be allowed to contaminate the temperature probes during measurements.
- In any case, a proper radiation shield is needed. The speed of the mobile unit normally results in enough ventilation of the sensor when the speed is $> 3 \text{ m s}^{-1}$; below this, separate ventilation is required.
- It is recommended that a modern GNSS system should be used during the itinerary to synchronize the measurements with spatial information. Data can also be stored for further analysis in an attribute

Table 50.3 Typical moving speeds and response times of various mobile systems. Note that smaller-scale rather than larger-scale systems are used to investigate smaller structures (see Table 50.3)

Direction of sampling	Typical systems	Moving speed (m s ⁻¹)	Time constant (s)	Duration of one measurement cycle (min)
Vertical mobile systems	Lifts on towers or balloons	0.1–1	0.5–30	2–15
Horizontal mobile systems	Fixed systems on trails or cables	0.1–1	0.5–30	2–15
	Cars, trams, bicycles, etc.	3–5	10–60	60–90
	Unmanned aircraft systems (UASs)	10–30	0.05–1	10–60

databank linked to the appropriate geographic coordinates within a geographic information system (GIS).

Table 50.3 lists typical characteristics of the mobile systems classified in Table 50.1. Sensors must be chosen according to the time constant and stability required during the measurements.

50.3.2 Response Time and Dynamic Error

It is very important to consider the sensor response time in mobile systems. The output signal from a sensor with a substantial response time will suffer from two distortions: a delay (a lag time) before a change in the measured variable is registered by the system, and signal damping caused by the finite response time of the sensor to the registered change in the variable. The damping will depend on not only the sensor response time but also the frequencies of the temporal and spatial variations in the measured quantity (i.e., the dynamics), and can cause substantial spatial errors in the measurements obtained from the sensor [50.15, 34, 36], as illustrated in Fig. 50.1.

One special type of transfer function (i.e., the relationship between the input and output of a sensor) is that in which the signal changes sharply from $X = X_0$ when $t \leq t_0$ to $X = X_\infty$ when $t > t_0$. A first-order measurement system such as a system for evaluating the temperature can be described by the differential equation

[50.37] (see also Fig. 50.1b and Chap. 2)

$$X_s(t) = X_i(t) + \tau \frac{dX_i}{dt}. \quad (50.1)$$

Thus, the relationship between the input X_i and output X_s signals depends on the time constant τ . The time constant describes the dynamic error of a measurement system. In meteorology, a dynamic error typically arises due to a near-linear change in the value of the meteorological parameter over a given time span. However, for mobile measurement systems, a change in location is also possible. The solution of the above equation for the time-dependent variable after the value of the variable has changed markedly is

$$X(t) = a t - a \tau \left(1 - e^{-\frac{t}{\tau}}\right), \quad (50.2)$$

where the second term on the right-hand side in (50.2),

$$\Delta X_d(t) = a \tau \left(1 - e^{-\frac{t}{\tau}}\right), \quad (50.3)$$

is responsible for the time lag in the measured signal relative to the input signal, and is called the dynamic error.

If the input signal varies linearly over time, the output signal is shifted in relation to the input signal by the time difference $\Delta t = \tau$. Dynamic errors often lead to hysteresis. When the input signal function is known, the

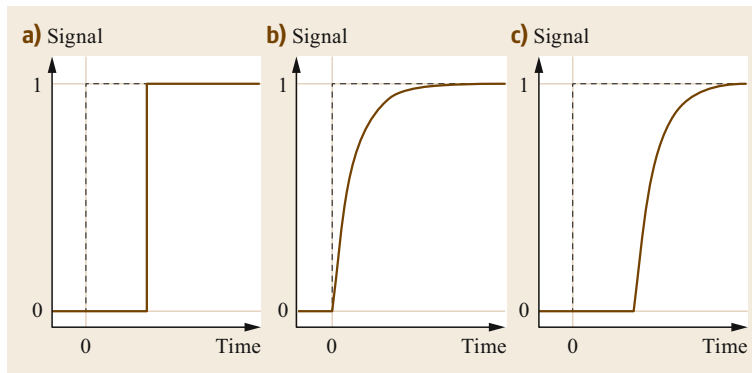

Fig. 50.1a–c Schematic showing the response of a measurement system (black line) to a prescribed step change in the measured variable at time $t = 0$ (gray line) under the influence of (a) the sensor lag time only, (b) the sensor response time only (i.e., dynamic error), and (c) both the lag time and the response time (after [50.34] with permission from Borntraeger, Stuttgart, Germany)

Fig. 50.2 Itinerary and locations of fixed weather screens (A–F) used in an urban climate study performed in the city of Freiburg. Measurements were initially taken at point A; all measurements were corrected for the base temperature at point E (after [50.8] with the permission of the Department of Physical Geography, University of Freiburg, Germany)

dynamic error can easily be corrected for either mathematically or using a correction network. This may be important when precisely determining the temperature gradient of a vertically thin inversion layer. For measurements near the Earth’s surface, the dynamic error correction was also demonstrated for vertically and horizontally mobile measurement systems [50.15, 34].

50.3.3 Measurement Strategies: Designing Itineraries Involving Large Distances

Generally, a zigzag pattern is the best itinerary design if it is necessary to perform detailed mobile measurements across a large area. This design offers several options for data correction and is therefore useful when the itinerary will overlap at several points. If the itinerary and the time needed for one course is short, we can assume, as a first guess, that the meteorological variables change linearly over time in the area of interest. The gradient of the variable over time can then easily be computed from the measurements taken at the overlapping points along the itinerary. On

the other hand, if the itinerary is long, and the measurements take some time, nonlinear behavior of the variable over time can be assumed during data correction [50.13]. When the start and end points of the itinerary coincide, a further control is available. The difference between the temperatures measured at the start and the end of the itinerary tends to reflect the general trend in the measured variable during the sampling time. Finally, data from a fixed station within the study area can be studied to determine whether the variable has decreased or increased, and to what extent. This makes data correction much easier. Since the intervals between mobile measurements tend to be longer than those between fixed-position measurements, and mobile measurements are normally not performed continuously, a fixed station can be used to link the mobile measurements to a longer time series, which makes the mobile measurements more representative. Figure 50.2 shows the itinerary from an urban climate study performed in the city of Freiburg, which used a microbus with sensors for dry and web bulb temperature, both at 2 and 0.6 m AGL.

Fig. 50.3 Variation of air temperature and deviation of dry and wet bulb temperature from linear temperature trend during mobile measurements taken at 12 points (locations) in Basel before sunrise (cloud coverage 1/8, cloud type As)

A further aspect to consider is that the absolute value of the meteorological variable studied tends to be of much less interest than the variation in the variable along the itinerary (it is not much of a scientific challenge to investigate whether it is warmer in summer than in winter!). Therefore, measurement data should be stored as the deviations from the mean trend in the variable. The linear trend during the time of the measurement can be computed as

$$\text{Trend } (T) = \frac{T(\text{end}) - T(\text{start})}{\Delta t}, \quad (50.4)$$

where T is the air temperature and Δt is the duration of the itinerary.

Since the deviation of the variable is quite often similar at various multiple measurements along the same itinerary, a more representative mean deviation accounting for all itineraries can be calculated and mapped with a GIS system. The technique of splitting the measurements into a basic temperature trend and the deviation from the trend at each point along the itinerary allows the measured temperature (dry and wet bulb)

and all relevant air variables like mixing ratio and dew-point to be calculated in an appropriate manner. An example is shown in Fig. 50.3.

Ideally, mobile data sampling would be performed across a large area in a very short time, resulting in quasi-simultaneously measured data. However, in reality, it takes a significant amount of time to carry out the itinerary, and most of the meteorological variables change in value to some extent during that time. Depending on the time of day that the itinerary is traveled, these changes may be very large (e.g., during the warming phase of the day) or very small (e.g., shortly before sunrise in the early morning). In any case, the temperature changes must be accounted for to obtain accurate data. Therefore, mobile data sampling requires weather patterns with low pressure gradients (very low wind speeds).

As already mentioned, if the itinerary is relatively short and does not take much time, the measured quantity can generally be assumed to present a linear trend over time, which can easily be computed. For longer itineraries, the trend can be estimated from measurements obtained at intersections in the itinerary. In any

case, it is advisable to run a permanent station or to utilize the data from an official station in the area to correct for meteorological peculiarities (changes in air mass, passages of fronts, etc.). A permanent station is also useful when attempting to determine how representative the mobile measurements are of the local environment [50.13]. Other influencing factors on mobile measurements are:

- The tail wind, as this can transport gases from the exhaust pipe to the sensors. The itinerary should therefore be selected so as to prevent sensor contamination from exhaust gases. Note that this problem is negligible with electric cars.
- Traffic jams or stop-and-go traffic, because there is no or very little sensor ventilation when the vehicle is not moving.

50.4 Devices and Systems

Since they were first performed in the early twentieth century, mobile measurements have been synchronized with geographical coordinate data to enable analysis of the two-dimensional data field for the variable of interest. With the advent of technology that allowed the automated recording of mobile measurements at predefined intervals on an electric or electronic device, it became important to be able to determine the position of a mobile unit at a particular time during a field campaign, as this makes it much easier to subsequently associate each measurement with the location at which it was performed. Today, modern GNSS systems that automatically coregister geolocation and measurement data very precisely have become standard. Also, the size of the instrument setup used to take mobile measurements has decreased in recent decades to such an extent that it can be installed on bicycles or even on UASs (see Chap. 49).

50.4.1 Large-Scale Horizontal Measurement Systems

Most recent studies that have utilized mobile measurements have investigated spatial variations in air temperature and humidity. There are now many ways

for mobile units to investigate two-dimensional variations in air temperature and humidity as well as bioclimatological variables. Mobile measurements have been performed for a variety of meteorological elements due to the development of more sophisticated electronic measurement and data storage methods, instrument miniaturization, and easier access to mobile platforms [50.38]. Besides mobile air temperature and humidity sampling, mobile measurements have also been used to study air pollution [50.40], nitrogen dioxide (NO_2) and ozone levels (O_3) [50.41], ultrafine particles ($\text{PM}_{0.1}$) [50.42, 43], carbon dioxide levels [50.44, 45], particulate matter ($\text{PM}_{2.5}$, i.e., particles $< 2.5 \mu\text{m}$

in diameter) and black carbon concentrations [50.46, 47], and radiation in urban street canyons [50.48], for example.

Using a car makes it possible to investigate a large area within a reasonably short time frame. This method has the advantage that a construction can be attached to the front of the car which can measure vertical temperature or humidity profiles of the atmospheric boundary layer up to a height of 2 m (Fig. 50.4).

Another useful and comfortable way to measure these variables is to attach the sensor to a public bus

or tram [50.12], Fig. 50.5). The advantage of this approach is that it is easy to obtain a large number of meteorological profiles (normally more than could be measured in an individual campaign) of a sizable area in a relatively short space of time. A disadvantage of it is that the route is fixed and does not necessarily represent the optimal itinerary for a micrometeorological study. A further disadvantage is that these vehicles stop frequently, potentially leading to the sensor ventilation and contamination issues mentioned earlier, which can significantly affect the quality of the mea-

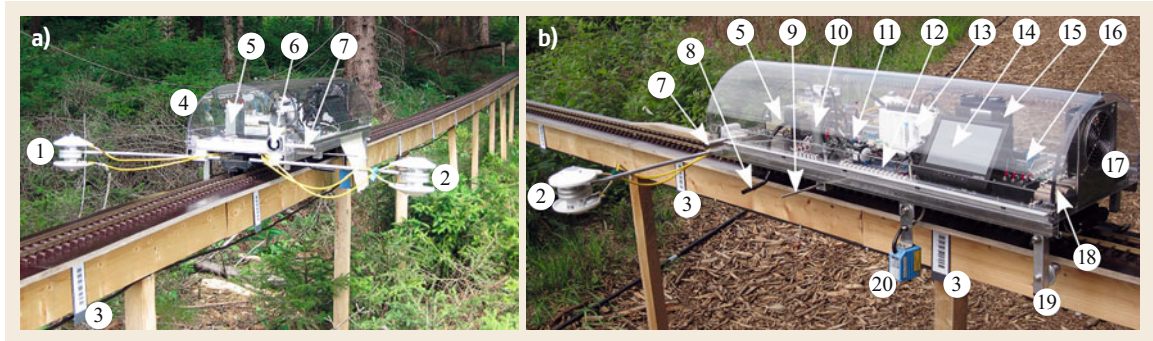

Fig. 50.8 (a) Front and (b) lateral views of the Horizontal Mobile Measuring System (HMMS). 1 Shortwave radiation sensors on a 0.4 m long boom, 2 longwave radiation sensors on a 0.4 m long boom, 3 barcode, 4 Makrolon® cover to protect the HMMS from rain and dirt, 5 Enviroscope O₃ analyzer, 6 fan to ventilate the HMP 155 temperature and humidity sensor, 7 double-shielded inlet for the HMP 155, 8 PTFE (polytetrafluoroethylene) inlet for the O₃ analyzer, 9 aluminum inlet for the CO₂ analyzer, 10 pump for the O₃ analyzer, 11 pump for the CO₂ analyzer, 12 Edinburgh Instruments Ltd. Gascard® NG CO₂ analyzer, 13 National Instruments data acquisition device, 14 7" TFT (thin-film transistor) monitor, 15 micro PC, 16 LGB (Lehmann-Groß-Bahn – Lehmann-big-train) analog throttle with potentiometer, 17 fan to cool the entire system, 18 onboard storage battery, 19 lateral holder to protect the HMMS against falls, 20 Sick CLV412-1010 barcode scanner (after [50.15]) © the authors, CC Attribution 3.0 License)

measurements. It is then necessary to correct or remove the corresponding problematic data from the overall dataset.

In recent years, some studies have used bicycles to transport the instrumentation employed for mobile measurements. An advantage of this is that it is possible to traverse areas in which cars are prohibited, such as urban green areas and parks. Figure 50.6 shows a bicycle with a thermistor mounted on the handlebar and appropriate data logger infrastructure on the luggage rack.

50.4.2 Small-Scale Horizontal Measurement Systems

The mobile systems that are used for short itineraries tend to be miniaturized systems with many integrated sensors. Such systems are applied to study small-scale heterogeneities at the micro- β and micro- γ meteorological scales (10–100 m, see Chap. 1). These heterogeneities are caused by vegetation (forest) and urban areas. In the following, two systems that were recently developed for mobile studies in heterogeneous forests are discussed.

Table 50.4 Comparison of various mobile systems with various fixed multisensor systems

	Mobile systems	Fixed multisensor systems
General remarks	Can only be used for short measurement periods Often use simple or miniaturized sensors, a high level of quality control is required Possibility of time shifts between measurement points and dynamic error	Useful for short- and long-term measurements Application of recommended sensors [50.49] is possible
Large-scale horizontal measurement systems	Larger areas are covered, high flexibility in terms of area studied (dependent on weather conditions)	Only a few measuring points, no flexibility in terms of area studied
Small-scale horizontal measurement systems	High spatial resolution, dynamic error is possible	Only a few points can be observed
Vertical measurement systems	Use expensive instruments with a small offset and time shift	Highly accurate systems are necessary

The TRAM (Transect Measurement) system [50.27] runs in a loop while measuring the wind speed (using an ultrasonic anemometer), CO₂ concentration, air temperature, and humidity. Its developers were able to create a measurement track through a forest ecosystem and over a creek through the use of steel cables and masts, allowing mobile measurements to be obtained across long horizontal distances and at different heights (Fig. 50.7).

The HMMS (Horizontal Mobile Measurement System) is a small train on rails [50.15] that measures short- and longwave radiation components, the air temperature, the air humidity, and the CO₂ and O₃ concentrations 150 m from both sides of the edge of a forest at a height of ≈ 1 m above the forest floor (see Fig. 50.8; for results, see Sect. 50.8.3).

50.4.3 Vertical Measurement Systems

The system presented in this section was constructed to measure the vertical mixing ratio profile of nitrous acid

(HONO) near a forest floor [50.35] using a long-path absorption photometer (LOPAP; QUMA, Wuppertal, Germany) with a time resolution of 3 min. Because this photometer has low time resolution, the vertical lift (Fig. 50.9) was used in a stop-and-go mode, remaining at each of the three levels for 7–9 min. Therefore, it was possible to measure a vertical profile every 30 min. A benefit of this construction was that it required only one expensive analyzer. The need for just one analyzer was also advantageous because there were small gradients of the mixing ratio in the region studied, meaning that small offsets between multiple instruments would have caused problems with the measurements.

50.4.4 Comparison of Different Methods

Table 50.4 provides a comparison of various mobile systems with various fixed multisensor systems to aid the selection of the most appropriate type of measuring system for a particular application.

50.5 Specifications

The sensor specifications largely depend on the sensor quality. Table 43.10 lists the specifications of highly accurate single sensors [50.49], compact or multiparameter

sensors (see Chap. 43), and simple sensors (crowdsourcing, see Chap. 44). The relevant variables should be measured with a mobile system of the same quality class.

50.6 Quality Control

Quality control is a very important issue for mobile systems due to the high mechanical stress of such systems and the often low accuracy in relation to effects such as delay time and dynamic error. It is therefore very important to obtain reference measurements for two main reasons:

- To correct for changes in the values of the measured meteorological variables during the time taken to perform the itinerary. The system should pass the reference measurement station as often as possible.
- To recalibrate simple sensors or sensors where there is time drift. Therefore, the frequency with which

Table 50.5 Recommended maintenance activities for mobile systems

Maintenance interval	Sensors without drift	Sensors with drift
Before each measurement cycle or daily	Visual check	Comparison with the reference instrument
Before each batch of measurement cycles or weekly	Comparison with a reference instrument	Sensor recalibration
Before using the system after a long period of disuse, or annually	Recalibration or comparison with the reference instrument for very stable sensors	Sensor recalibration

the mobile system should stop at the reference station depends on the response time of the sensor.

Reference measurements should be made with high-quality sensors, and the siting conditions should be of the highest class [50.49] (for more details, see the relevant parameter-specific chapters).

Mobile systems encounter windy and calm areas, sunny and shaded areas, and so on during their itineraries. Therefore, the effects of environmental parameters such as the wind speed, wind direction, solar radiation, and humidity on the measurement system should be investigated before the measurements are first performed. If necessary, temperature screens, ventilation, inlets that are not wind-direction sensitive, etc. should be applied. The influence of the vehicle (e.g., the car) used to transport the measurement system on

the measurements should also be investigated. Uncorrectable influences on the measured data should be at least one order of magnitude lower than the effects that are being investigated.

Quality control should also be carried out in accordance with the meteorological situation. Because vertical gradients may be very large during stable stratification (see Chap. 1), small changes in the sensor height or the surrounding canopy height may generate changes in the measured variables.

All relevant sensor-specific quality control procedures (e.g., those for temperature, see Chap. 7; humidity, see Chap. 8; wind, see Chap. 9; or radiation, see Chap. 11) should be applied. Because the quality control process may differ markedly between mobile systems, the procedure performed should be carefully documented and all relevant metadata should be recorded.

50.7 Maintenance

Maintenance should be carried out as recommended for the applied sensors or described in the relevant chapters of this Handbook. Because of the high mechanical stress on mobile systems, maintenance should not only

be performed at predefined time intervals (just as for fixed sensors), but should also be adjusted according to the frequency of use of the mobile system. Table 50.5 gives some maintenance recommendations.

50.8 Application

Applications of the three types of mobile systems defined above are richly diverse. The following examples show how powerful such systems can be at yielding information on meteorological field distributions that cannot be extracted using only fixed sensors or satellite images that have no dynamic component.

50.8.1 Urban Climate and the Urban Heat Island Effect

One of the major applications of mobile measurements has been to investigate the climate and air quality in urban regions. Initially, nearly all of the studies in this area investigated nocturnal air temperature fields—mainly frost risk and minimum temperature fields. In

recent decades, however, the urban heat island effect has become a major driver for these investigations, although the development of appropriate instruments has also led to studies of air chemistry and fine particles in urban areas.

Figure 50.10 shows the air temperature variations in the city of Basel (Switzerland) and the effect of urban parks on afternoon and nocturnal air temperatures measured during three bicycle campaigns during summer 2005 (on 5 August 2005 at 18:50 CET (Central European Time), 11 August 2005 at 00:05 CET, and 30 August 2005 at 01:15 CET). Note that the nocturnal air temperature is significantly lower (by several degrees) in the two urban parks with different quantities of vegetation than in other areas traversed during the bicycle campaigns.

Fig. 50.10 Nocturnal bicycle-based measurements taken in urban parkland in the city of Basel (Switzerland). The red lines indicate the entry and exit points for two urban parks (Margarethen Park and Schützenmatt Park). The temperature from measurement at 05.08.2005 is shown on the left axis and the temperatures from measurements at 11.08.2005 and at 30.08.2005 are shown on the right axis

50.8.2 Ventilation and Mountain Breezes

An important issue in urban planning is the existence and distribution of cold air drainage systems or mountain breezes. One of the most well-known mountain breeze systems, and one of the first to be reported, is the *Höllentäler* wind system in the city of Freiburg (Black Forest, Germany). The effects of this wind system on the urban climate of Freiburg were first published in 1840 [50.50]; since then, numerous studies have investigated the wind system in more detail [50.51]. Figure 50.11 shows the variation in the air temperature during mobile measurements in Freiburg.

50.8.3 Forest Climate at an Edge

Various meteorological parameters were observed at the edge of a 25 m high spruce forest next to a clearing by the Horizontal Mobile Measurement System (HMMS) described in Sect. 50.4.2 [50.15]. Because the response

time of the sensors was relatively slow compared to the speed of travel of the system, the resulting dynamic error was accounted for using (50.2). Figure 50.12 shows the shortwave downwelling radiation before and after the correction. It is easy to discern when the system was moving from the forest to the clearing or in the opposite direction in the uncorrected data, but not in the corrected data. A linear radiation gradient at the edge was assumed for the purposes of correction as a first approximation.

Figure 50.13 presents the daily cycles of the four radiation components based on corrected data obtained at a height of ≈ 1 m above the forest floor. The shortwave radiation plot shows sunny spots in the forest and, in the morning, a shadow effect at the forest edge. The downwelling longwave radiation is strongest in the forest during daytime due to the warm crown area of the trees, while the upwelling longwave radiation is strongest above the clearing during daytime. Similar plots were generated for temperature, humidity, and carbon dioxide, and ozone.

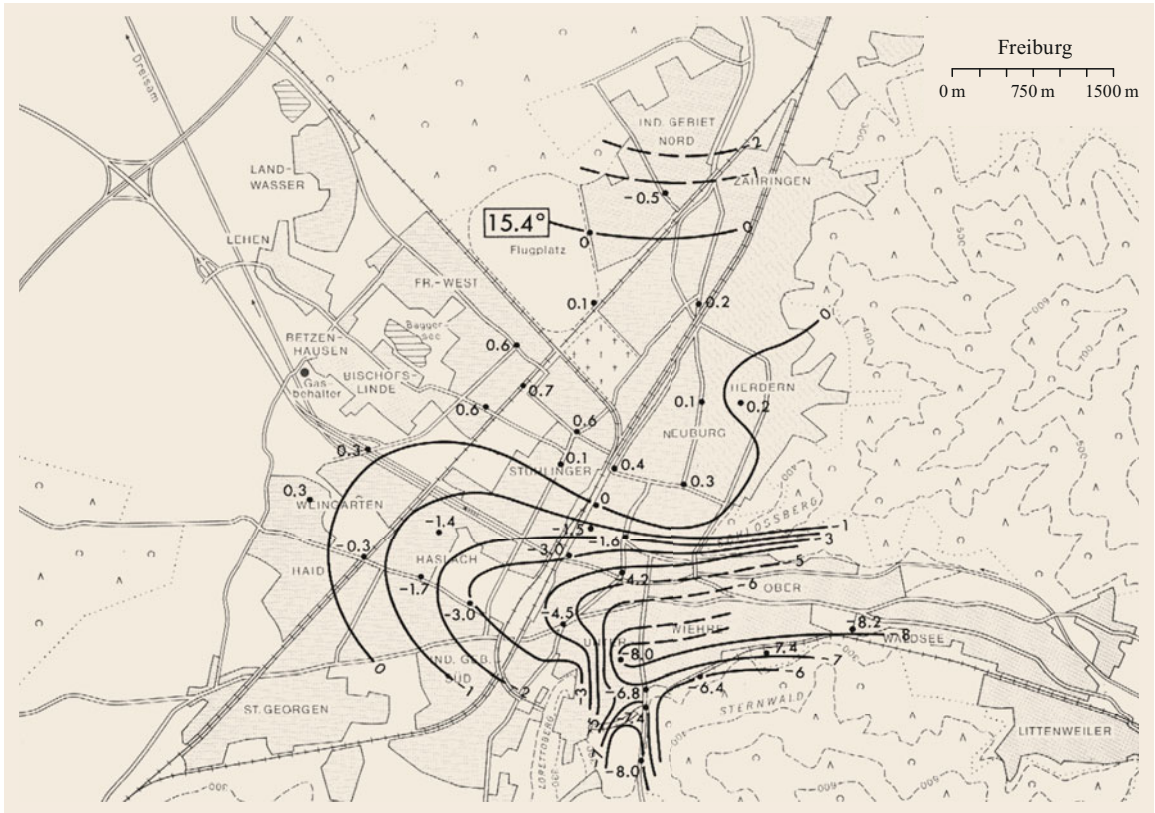

Fig. 50.11 The nocturnal mountain breeze in Freiburg at 19:00 CET on 5 October 1972 decreased the air temperature by up to 8 K in the valley outlet as compared with the base temperature of 15.4 °C measured at a fixed station in the western part of the city (after [50.8] with the permission of the Department of Physical Geography, University of Freiburg, Germany)

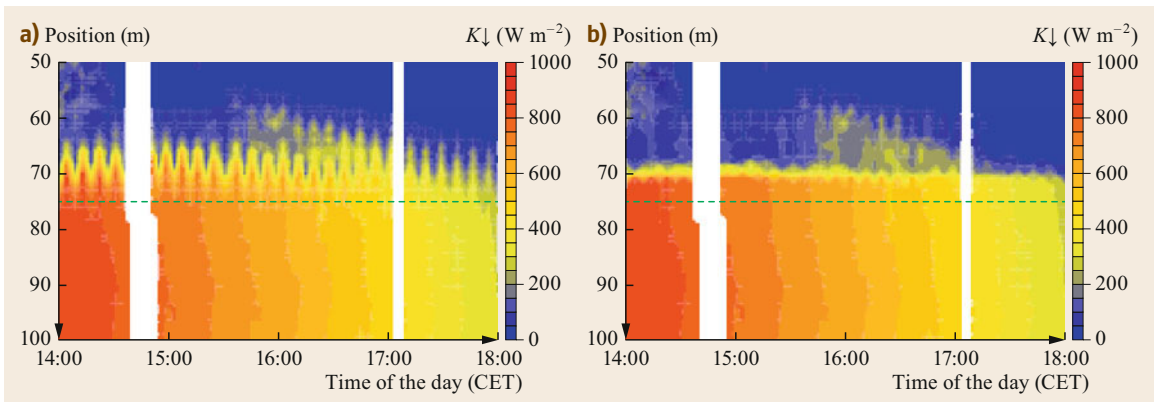

Fig. 50.12a,b Horizontal profile of the downwelling shortwave radiation ($K \downarrow$) 1 m above the forest floor at the forest edge (dashed line) on 28 June 2011, 14:00–18:00 CET (a) without and (b) with dynamic error correction. Position corresponds to the distance from the starting point in the forest; the forest edge was 75 m from the starting point (horizontal green dotted line) and the far side of the clearing was 150 m from the starting point (after [50.15] © the authors 2014. CC Attribution 3.0 License)

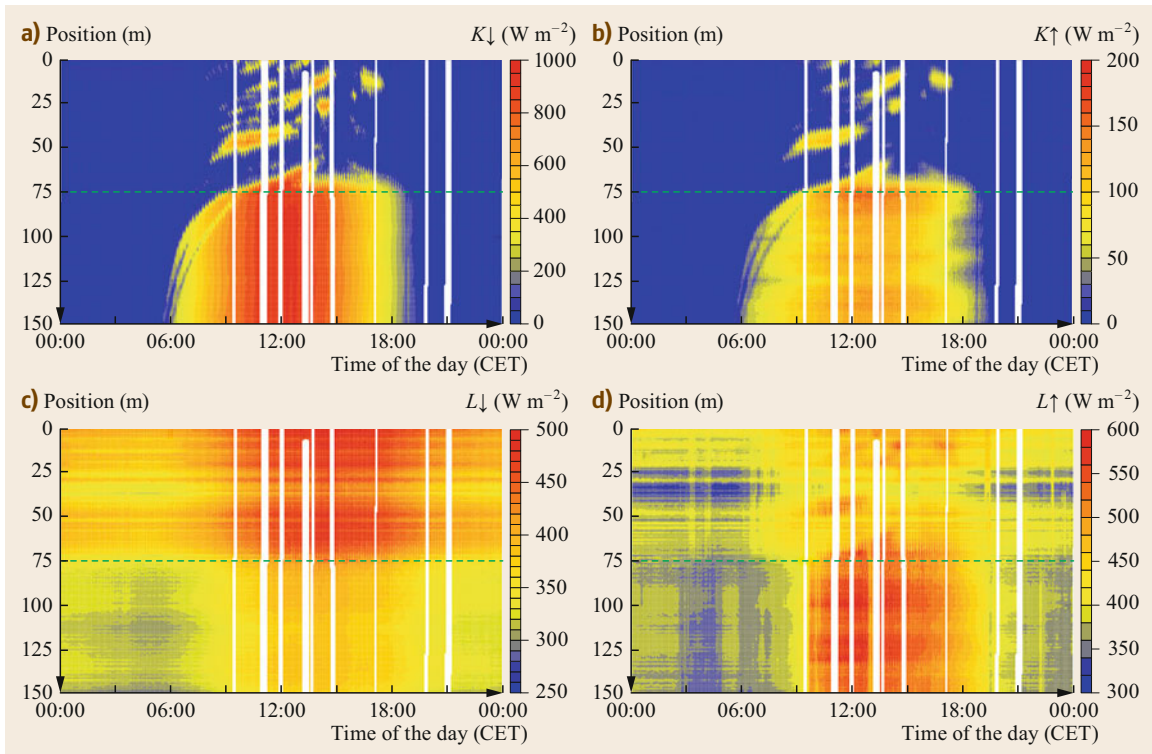

Fig. 50.13a–d Horizontal profiles of the four radiation components 1 m above the forest floor at a forest edge (*dashed line*) on 28 June 2011 (Waldstein-Weidenbrunnen site, Fichtelgebirge mountains, Germany): (a) downwelling shortwave radiation ($K \downarrow$), (b) upwelling shortwave radiation ($K \uparrow$), (c) downwelling longwave radiation ($L \downarrow$), and (d) upwelling longwave radiation ($L \uparrow$). Note that the four plots have different irradiance scales. *Position* corresponds to the distance from the starting point in the forest; the forest edge was 75 m from the starting point (*horizontal green dotted line*) and the far side of the clearing was 150 m from the starting point (after [50.15] © the authors 2014. CC Attribution 3.0 License)

50.9 Future Developments

Mobile systems that cover short distances are currently used mainly for specific research questions, and horizontal mobile systems that travel large distances are mainly used for urban measurements (see Chap. 52). However, other systems have become increasingly popular in recent years, such as UASs (see Chap. 49), crowdsourcing (see Chap. 44), and satellite imaging (see Chap. 42), all of which are used in combination

with GNSS and geoinformation systems [50.14]. It is a major methodological challenge to combine all of these systems in order to obtain comprehensive three-dimensional pictures at various time steps in areas of interest. Thus, in the near future, mobile systems will generally be used in conjunction with other systems rather than on their own. This approach will influence measuring strategies and sensor selection.

Eberhard Parlow

Department of Environmental Sciences
Atmospheric Sciences
University Basel
Basel, Switzerland
eberhard.parlow@unibas.ch

Eberhard Parlow is Professor Emeritus at the Department of Environmental Sciences and was previously Full Professor and Director of the Meteorology, Climatology, and Remote Sensing Lab at the University of Basel. He was President of the Commission for Remote Sensing at the Swiss Academy of Natural Sciences and President of the European Association of Remote Sensing Laboratories. His research combines micrometeorological flux measurements with remote-sensing techniques, especially in urban climatology.

Thomas Foken

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

51. Measurement Systems for Wind, Solar and Hydro Power Applications

Stefan Emeis , Stefan Wilbert 

Wind, solar, and hydropower are major forms of the so-called renewable energies. Effective application of renewable energies to supply heat and electricity is weather dependent and needs short-term weather forecasts, as well as historical and climatological information. All relevant measurement sensors were introduced in previous chapters. Here, the special requirements of wind, radiation, and precipitation measurements for planning and operating renewable energy power plants are addressed. The cooling of conventional thermal power plants, the transmission of electricity in cables above ground, and the overall energy demand are weather dependent as well, and thus need atmospheric measurements.

Meteorological competence directed to a meaningful and smooth application of devices that supply electricity and heat from fossil and renewable energy sources is summarized in the subdiscipline “energy meteorology” today. Energy meteorology comprises theoretical considerations, data capture, data analysis, and weather forecasts relevant to power generation, distribution, and consumption. Energy meteorology for wind energy is covered in [51.1]. For solar energy applications, more detailed information is provided, e.g., in [51.2]. For hy-

dropower applications, the reader can refer to [51.3] for more details. A short review on the present status of the whole subject is found in [51.4].

Although fossil and renewable energy supply devices have been operated for a long time, energy meteorology mainly developed during the last three decades due to the growth of the renewable energy capacity and its much larger need for meteorological information compared to fossil power plants. With a few exceptions the main difference in the required meteorological

knowledge for power generation purposes is that for fully fossil power plants, meteorological information is mainly needed in order to assess the load (e.g., high

loads during cold spells). For renewable energy, meteorological information is also needed to estimate the energy production.

51.1 Measured Parameters

Table 51.1 gives an overview on the meteorological parameters needed for the planning and operation of renewable energy sources and an electricity grid with fossil and renewable energy sources. The parameters are listed next to the form in which the parameter is required, its application, unit, and symbol.

The deployment of measurement instruments for site assessment or performance monitoring of renewable energy power plants will be very much determined

by the intended use of the generated power (e.g., the instantaneous generation of electricity or the accumulative storage of heat). The main requirement is that the measurements are representative for an area or an air volume covered by the foreseen devices for power generation. For instance, wind measurements often have to be performed at exposed sites, such as hilltops. In this case, attention has to be paid to the problem of curved streamlines, as described in Sect. 23.6.3 of this

Table 51.1 Measured parameters used in renewable energy applications

Parameter	Form	Relevance	Unit	Symbol
Wind speed	Time series, statistics, extreme values, vertical profiles	Wind energy, power lines, solar energy	m s^{-1}	u
Wind direction	Time series, statistics, vertical profiles	Wind energy, solar energy	$^{\circ}$	
Air temperature	Instantaneous values (wind energy, power lines, cooling towers), weekly or monthly average (cooling water for hydropower)	Wind energy (air density, risk of icing), power lines, solar energy, hydropower (evaporation, warming of cooling water), operation of cooling towers, load estimations	K	T
Pressure	Time series, statistics	Wind energy (air density), power lines, cooling towers	hPa	p
Humidity	Instantaneous values, weekly or monthly averages	Wind energy (air density, risk of icing), hydropower (evaporation), operation of cooling towers, power lines	% (relative humidity), $10^{-3} \text{ kg kg}^{-1}$ (absolute humidity)	RH, q
Global horizontal irradiance	Time series, statistics, extreme values	Solar energy, hydropower (evaporation), power lines	W m^{-2}	G (according to [51.5]), often GHI, atmospheric sciences use K_{\downarrow}
Direct normal irradiance	Time series, statistics, extreme values	Concentrating solar technologies	W m^{-2}	G_b , according to [51.5], also DNI
Global tilted irradiance	Time series, statistics, extreme values	Non or low concentrating photovoltaic plants, flat plate collectors	W m^{-2}	G_t , also GTI
Beam attenuation	Time series, statistics	Solar tower plants	–	A
Solar and circum-solar radiance profile	Time series, statistics	Concentrating solar technologies	$\text{W m}^{-2} \text{ sr}^{-1}$	S
Circumsolar contribution	Time series, statistics	Concentrating solar technologies	–	CSC
Soiling rate	Time series, statistics, extreme values	Solar energy	s^{-1}	$\hat{\xi}$
Solar spectral irradiance	Time series, statistics	Photovoltaic plants	$\text{W m}^{-2} \mu\text{m}^{-1}$	E_{λ}
Precipitation	Amount and intensity (spatial averages), time series, statistics, extreme values, form (snow, hail)	Hydropower, solar energy	L, mm	P
Snow cover	Amount	Solar energy	cm	

book, which is relevant for remote sensing of wind profiles in complex terrain. Normal representativeness considerations, which are relevant for climatological and meteorological studies, and which have been listed

in the respective sections of this handbook, cannot be fulfilled in every case. Therefore, further hints and details for power-related measurements can be found in Sect. 51.4.

51.2 History

The usage of renewable energies and the operation of classical fossil energy infrastructures (power plants and power lines) are based on existing meteorological expertise and data and site-specific measurements (see the sections below). By around the turn of the millennium the paramount importance of meteorological data for the operation of renewable energies became clearer, and the subdiscipline energy meteorology started to emerge. The first German specialty conference on energy meteorology took place 2009. The inaugural International Conference on Energy & Meteorology was convened in Australia in 2011. The development of renewable energies is very much driven by private companies. Thus, additional site-specific measurements up to now have very often been planned and executed by these private companies. This data is usually not publicly available.

51.2.1 History of Measurements for Wind Energy

Wind measurements have accompanied the usage of the kinetic energy contained in winds through all times. Traditional windmills have been built for centuries in Europe, and the growing political and economic importance of sailing ships in the eighteenth and nineteenth centuries led, e.g., to the development of the Beaufort wind scale. Compared to this the construction and deployment of wind turbines for the generation of electricity was a rather new development that emerged in the twentieth century. In the beginning until the 1980s, 10 m wind data were extrapolated to the then hub heights of the first wind turbines of less than 50 m. Later, the erection of meteorological masts became the most accepted wind assessment technology, when hub heights were about 50 m and above. In the 1990s, the interest in surface-based acoustic remote sensing (Chap. 23) grew, since the deployment of taller masts in the order of 100 m height became more expensive than ground-based acoustic remote sensing, although the trust in remote-sensing data remained less than the trust in in-situ cup anemometer measurements. A major reason for the persisting trust in cup anemometer data was that these instruments could be easily calibrated in wind tunnels.

In the 2000s, optical remote sensing (Chap. 27 on wind lidars) took over from sodars, because wind lidars

became commercially available, and the data availability of wind lidars is considerably better than that from sodars. After 2015, wind energy guidelines [51.6] started to accept optical remote sensing as an independent source for reliable wind data.

Specific data capture for the development of offshore wind farms started with large masts as well. Near-coastal masts were, e.g., erected close to the Danish west coast at a wind turbine test site at Høvsøre in 2002 [51.7]. In the German part of the North Sea, the first real offshore meteorological mast about 45 km off the coast was erected (the 100 m-high mast FINO 1 [51.8]) in 2003. Two more similarly instrumented masts (FINO 2 in the Baltic Sea and FINO 3 in the northern part of the North Sea) followed a few years later. Remote sensing was no option for these offshore measurement platforms, because acoustic remote sensing due to unavoidable fixed echoes (Chap. 23 on sodars and RASS) was not possible close to the mandatory masts on these platforms, and optical remote sensing was not commercially available at the time of planning the first of these measurement platforms. Even today, wind lidars are not part of the standard instrumentation on these three platforms. Such devices were only brought to the platforms during limited measurement campaigns.

Specific data for winds in complex terrain are available from a 200 m-mast erected on the Rödeser Berg near Kassel, Germany, at the end of 2011 [51.9]. A test site for wind turbines in complex terrain exists south of Boulder, Colorado, close to the foothills of the Rocky Mountains [51.10]. A further wind turbine test site with meteorological masts close to an about 200 m-high escarpment is presently being designed and erected east of Stuttgart, Germany.

Temperature profile measurements to assess the thermal stratification of the atmospheric boundary layer for the purpose of generating energy from the wind are rarely executed. For a long time, the impact of thermal stratification on wind energy generation was considered to be negligible with higher wind speeds. Today, for issues such as low-level jets and wake propagation, these measurements appear to be more and more necessary for a proper assessment of wind energy.

51.2.2 History of Measurements for Solar Energy

Solar energy applications have a long history, starting centuries before the first solar radiation measurements became possible (Chap. 11 for the history of radiation measurements). The first simple solar heating and lighting applications did not require the measurement of solar radiation or other meteorological parameters. By the end of the nineteenth century *Augustin Mouchot* (1825–1911) developed the first solar powered engine [51.11], which was demonstrated at the Universal Exhibition in Paris in 1878. At the latest then atmospheric data were required for solar energy in order to decide whether or not this new technology was a competitive alternative to other power sources, such as coal. Apparently, decision-makers estimated that this was not the case, as more intense research on solar energy started only after World War II. By then, pyrheliometers and pyranometers were already available, as well as measurement systems for most of the other relevant atmospheric parameters. These instruments could be used for performance testing and system characterization, two main applications of meteorological measurements for solar energy. With the growing interest in solar energy in the 1970s due to the oil crisis, it became increasingly clear that the already available meteorological data were not enough to provide a good estimate of the solar resource available at a given site and, hence, the corresponding expected power plant yield. Due to the spatial variability of meteorological conditions and, in particular, solar irradiance it was found that the resource data must be collected for a site close to the envisioned power plant site. Even today data from ground-based measurements are not available close to most potential power plant sites. Therefore, existing measurement networks were enhanced and model approaches were investigated.

As interesting power plant sites are often remote, it is often not feasible to maintain pyranometers and pyrheliometers good enough to achieve the desired accuracy. Therefore, and to reduce the costs of the instrumentation, less maintenance intense instruments, such as the rotating shadowband irradiometer (RSI) were developed [51.12]. Such instruments were continuously improved and are widely used for solar energy applications, especially for the planning of solar power plants.

Even if a measurement station is deployed for the resource assessment at a site, the dataset is typically too short to analyze the interannual variability of the irradiance well enough for the determination of the expected solar plant yield. Therefore, methods to derive long-term datasets were developed. Long-term datasets are mostly derived from related measurements. His-

torically, modeling efforts included the determination of global horizontal and direct normal irradiance from sunshine duration measurements [51.13], as these were much more frequent than pyranometric or pyrheliometric measurements. Today, irradiance models based on sunshine duration are only of historic interest and are no longer recommended according to best practices [51.2]. Modeling efforts also included the creation of irradiance maps, for example based on interpolation techniques between the stations. Such spatial interpolations are still used today in some cases, but the application of satellite derived long-term datasets is much more common. Satellite-based measurements of the radiation reflected from the ground or clouds to the satellite have been used to derive irradiance since the 1980s (Chap. 40) and have become a standard data source for the planning of solar power plants.

Today, combinations of satellite and ground-based measurements are used for the planning of large solar power plants with several MW output power, as will be explained in more detail in Sect. 51.4.5. Due to the growing grid penetration of solar energy irradiance forecasting systems were developed in the last two decades. These systems also rely on ground measurements of irradiance, ground-based all-sky imagers and/or satellite data.

51.2.3 History of Measurements for Hydropower

Since there has not been much development in the usage of hydropower in the last decades, the means of measurements have not changed either. Hydropower relied and still relies on monitoring the discharge of rivers for hydropower plants at rivers and the water level in natural and artificial reservoirs for hydropower plants operating below such reservoirs.

51.2.4 History of Measurements for Conventional Power Plants, Grid Operation, and Electricity Transmission

Engineering sciences have dealt with the weather impact on conventional power plants, electricity transmission structures, and grid operations. Meteorological data was required for these assessments, but no special measurement techniques have been developed for this purpose.

Measures such as heating degree days (HDD) [51.14] and cooling degree days (CDD) [51.15] have been developed for the assessment of the energy demand. However, these measures were computed from the available classical weather and climate data.

51.3 Theory

This section summarizes the relevance of the different atmospheric parameters for the different forms of power generation (see the respective column in Table 51.1). A proper operation of power grids (and less strictly, also heating/cooling systems) requires a nearly perfect balance of generation and consumption at any moment. Therefore, atmospheric parameters are necessary to assess the production potential, as well as the expected consumption. These estimates have to be supplied at least 1 day ahead and then have to be refined in several steps until 15 min before the very moment. For example, the regulation of the electricity grid in Germany is performed by trade at the energy stock exchange in Leipzig. Expectations computed from atmospheric data are the basis for this trade. The generation of electrical energy from wind power depends on meteorological parameters in several respects, which are addressed in the following.

51.3.1 Dependence of Wind Energy on Meteorological Parameters

The harvest of electrical energy from the wind principally depends on the third power of the wind speed [51.1], as long as the rated power of the used wind turbines is not reached. Between the rated power of the turbines and the cut-off wind speed (see below) the harvested electrical energy is maximum and independent on wind speed. Additionally, the energy harvest below the rated power of the turbines depends on air density. Cooler and dryer air is denser than warmer and more humid air. The energy harvest is linearly proportional to the density of the air.

The power available from the wind energy, P_{wind} in atmospheric flow, i.e., the kinetic energy of the air, $0.5\rho u^2$ advected with the wind, u is quantified by the following relation

$$P_{\text{wind}} = 0.5\rho A_r u^2 u = 0.5\rho A_r u^3, \quad (51.1)$$

where ρ is the air density, A_r is the rotor area of the turbine, and u is the average wind speed over the rotor area. Equation (51.1) gives the available wind power over the rotor disk in Watt when the air density is given in kg m^{-3} , the rotor area in m^2 , and the wind speed in m s^{-1} . Theoretically, turbines can extract up to 16/27 of this power [51.16, 17]. This limit is known as Betz limit today.

Assessments of annual energy harvest potentials not only depend on the mean annual wind speed but also on the distribution of the wind speed due to the non-linear dependence of the energy harvest on the wind

speed. Weibull (Swedish engineer, scientist, and mathematician *Ernst Hjalmar Waloddi Weibull*, 1887–1979) statistics [51.18] are usually computed for the annual distribution of 10 min mean wind speeds. Additionally, Gumbel (German mathematician *Emil Julius Gumbel*, 1891–1966) statistics [51.19] are used to estimate extreme 10 min mean wind and gust speeds that are load relevant. The probability $F(u)$ of the occurrence of a wind speed smaller or equal to a given speed u is expressed in terms of the Weibull distribution by

$$F(u) = 1 - \exp\left(-\left(\frac{u}{A}\right)^k\right), \quad (51.2)$$

where A is the scale factor of this distribution in m/s, and k is the shape factor. Once the two factors A and k are known, the available annual wind power resource can be computed by replacing u^3 in (51.1) by the third central moment of the Weibull distribution

$$E_{\text{wind}} = 0.5\rho A_r A^3 \Gamma\left(1 + \frac{3}{k}\right), \quad (51.3)$$

where Γ is the Gamma function.

The Gumbel distribution gives the probability $F(u)$ of the occurrence of a wind speed smaller than or equal to a given speed u by

$$F(u) = e^{-e^{-(u-a)/b}}, \quad (51.4)$$

with the scale factor a and the shape factor b (both in m/s). An extreme value is then computed from known factors a and b by

$$u_{\text{max}} = a(-\ln(-\ln(p))) + b, \quad (51.5)$$

where the probability p depends on the number of available data within the addressed return period. The probability of a, e.g., 50-year extreme from such a time series with 10 min-intervals (52 560 data points a year) is given by $p = 1 - 1/(50 \times 52 560)$, giving $-\ln(-\ln(p)) = 14.78$. For a time series with hourly values, the threshold value would be 12.99.

Wind turbines only run when the 10 min mean wind speed is in a certain range of wind speeds. They start to operate at the cut-in wind speed of 4–5 m/s. They usually stop operating at the cut-off wind speed of 25 m/s. The cut-off at higher wind speeds is necessary in order to avoid too large loads on the wind turbines.

The vertical profile of wind speed is of paramount importance for wind energy. For the assessment of energy yields and mean loads on today's large rotors

with diameters of much more than 100 m, the rotor-equivalent wind speed (REWS) is computed from an (rough) integration of the wind speed distribution across the rotor plane. The provision of wind speed profiles with a vertical resolution of about 20–30 m is necessary for the computation of rotor-equivalent wind speeds. The 2017 version of the IEC standard 61400-12-1 [51.6] now refers to the REWS, which is defined by a weighted sum of the cubes of simultaneous wind speed measurements at a number of heights spanning the complete rotor diameter between lower tip and upper tip [51.20]

$$v_{\text{eq}} = \left(\sum_{i=1}^n v_i^3 \frac{A_i}{A} \right)^{1/3} \quad \text{with} \quad \sum_{i=1}^n A_i = A, \quad (51.6)$$

where n is the number of measurements across the rotor area, v_i is the 10 min mean wind speed at height $z = z_i$, A_i is the area of the i -th rotor segment, and A is the total rotor area. The segment areas are computed between two lines z_j and z_{j+1} , which are positioned exactly halfway between two measurements

$$A_i = \int_{z_j}^{z_{j+1}} c(z) dz, \quad (51.7)$$

where $c(z)$ is the area of a segment of a circle

$$c(z) = 2\sqrt{R^2 - (z - H)^2}, \quad (51.8)$$

where R is the rotor radius, and H is the hub height.

Loads on wind turbines increase with increasing vertical shear and increasing turbulence intensity. The turbulence intensity is given by

$$I_u(z) = \left(\ln\left(\frac{z}{z_0}\right) - \Psi_m\left(\frac{z}{L_*}\right) \right)^{-1}. \quad (51.9)$$

This means that turbulence intensity increases with shear (the left-hand term of (51.9)) and with decreasing stability (the right-hand term of (51.9)); Ψ is the integral correction function for atmospheric thermal stability [51.21–25]. See Chap. 1 for a basic treatment of this parameter. Several extreme atmospheric phenomena such as gusts, thunderstorms, lightning, and icing have an impact on the operation of wind turbines.

51.3.2 Dependence of Solar Energy on Meteorological Parameters

Here, we have to differentiate between different available solar energy technologies (Fig. 51.1). Common photovoltaic (PV) plants and nonconcentrating solar heating and cooling collectors use the global tilted irradiance (G_{tilt}) incident on the collector plane. Bifacial

PV modules also use the in-plane rear-side irradiance. PV modules can also be tracked in one or two axes to increase G_{tilt} ; PV cells can also be mounted behind a focusing lens or in the focal point of mirrors that are tracked to the sun. In this case, direct normal irradiance (G_b) is used. This is also the case for concentrating solar power (CSP) plants that use mirrors to focus the direct radiation on an absorber to create heat. This heat can be used for industrial processes, heating, cooling, or to generate electricity using a thermodynamic cycle. Depending on the plant type, actually not G_b , but its projection on the collectors' aperture is used. This projection is calculated in plant models, and G_b is provided as a result of the meteorological measurements. Low concentrating PV collectors are tracked to the sun and only have a small ratio of the aperture to the PV cell surface. In this case, G_b and another diffuse fraction of G_{tilt} is used. The fact that different technologies use different components of solar radiation greatly affects their production. Clouds and fog diminish the yield of all solar collectors, but concentrating collectors are much more sensitive to clouds and fog than flat-plate collectors and nonconcentrating PV, as they only use direct radiation.

The specification of direct normal irradiance (G_b) is actually not a complete description of the resource used for concentrating collectors. Depending on the concentrator and the receiving surface, radiation from a different angular region around the sun is used by solar collectors. While pyrheliometers measure the irradiance coming from an approximately 2.5°-wide circular region around the sun (half-angle), most concentrating solar plants for solar thermal electricity generation and high concentrating PV systems accept only a narrower region (e.g., 1.5°). For concentrating PV systems and process heat collectors, also wider acceptance angles can be found. This effect is accounted for in state-of-the-art plant models, but this requires another input parameter – the sunshape. The sunshape is the radiance of the sun and the circumsolar region closely around the sun as a function of the angular distance from the center of the sun, normalized to 1 in the center of the sun. The description of the radiance distribution with a sunshape corresponds to the assumption that it is radially symmetric. The sunshape can be characterized by the circumsolar contribution: the ratio of the circumsolar normal irradiance coming from a given angular region between an inner and an outer boundary angle close to the sun and the direct normal irradiance including radiation from the solar disk and the circumsolar radiation up to the outer boundary angle.

For flat plate collectors and nonconcentrating PV, also the angular distribution of the irradiance is of interest, as the efficiency of the collectors depends on the incidence angle. The specification of the contribution

Fig. 51.1a–d Solar collectors at CIEMAT’s Plataforma Solar de Almería. **(a)** Tower plant CESA-1, **(b)** parabolic trough collector, **(c)** solar thermal collector, and **(d)** photovoltaic plant **(a)** photo © Christoph Prah, DLR, **(b–d)** photos © Stefan Wilbert, DLR

of direct and diffuse irradiance to G_{tilt} is nearly always sufficient for such models.

In the case of PV, also the spectral distribution of the irradiance is of importance, as PV cells only use

a certain part of the solar spectrum. Furthermore, the efficiency of PV cells varies strongly on the incoming wavelength, even within the accepted wavelength interval.

Besides radiation several other parameters affect the solar plant yield. PV cells operate most efficiently at low module temperatures. Thus, air temperature and wind speed are relevant as well. Thermal collectors operate more efficiently in warm conditions with low wind speeds, as heat losses are lower in such cases. However, the cooling for the thermodynamic cycle of CSP plants is less efficient for high temperatures and low wind speed. Also the pressure and humidity affect cooling.

Wind speed, direction, and wind gust also pay another important role in solar power generation, as wind can damage the plant components. This is of high importance for tracking collectors that do not withstand strong winds in operation, but only in a security position (stow position). This leads to production losses, as the collectors might not be able to collect energy (CSP, high concentrating PV), or as they will only collect significantly less radiation (tracked PV systems, low concentrating PV).

The effects of precipitation are descriptive. Snow cover on the collectors stops their operation while snow in front of a snow free PV module or flat plate collector increases the ground reflected radiation on the collector. Very large hail stones are a threat to the integrity of solar collectors. Rain accumulating on the collector surface reduces its transmittance or reflectance, but it can also have positive effects. One positive effect is the cooling of the PV module. Another positive and more relevant effect is the potential cleaning of the collectors. Atmospheric dust can settle on the collectors and greatly reduce the transmittance or reflectance. This effect is described by the cleanliness, which is the ratio of the efficiency in the current potentially soiled status of the device and the efficiency of a clean device under otherwise unchanged conditions. Soiling is described by the soiling rate, the change of the cleanliness with time. Note that at times, rain actually does not clean the collectors but on the contrary decreases the cleanliness by wet deposition of particles.

For solar tower plants, another parameter is of high relevance: the atmospheric extinction between the mirrors (heliostats) and the receiver. The path between the heliostats and the receiver can be greater than 1 km. Even for a clean, dry atmosphere with a high visibility of about 75 km, about 5% of the reflected radiation is lost on a 1 km light path to the receiver. For hazy conditions, this loss can be 100%, and high losses of about 50% can occur even at high direct irradiance levels.

51.3.3 Dependence of Hydropower on Meteorological Parameters

Assessment of hydropower potentials requires the capture of areal instantaneous and seasonal averaged precipitation amounts in the catchment areas of rivers and

reservoirs. Evaporation processes are only relevant, if the water is to be stored over several months or even years. See Chap. 57 for evaporation measurements and calculations.

Peak river discharges depend on the precipitation amounts of the last hours and days in the catchment area of rivers. Soils saturated with moisture from preceding precipitation events enhance the river discharge, because most of the new rain water cannot infiltrate the wetted soil and runs off immediately. Thus, the soil's water content in the catchment area is to be monitored as well. In springtime, melting snow covers in the catchment area can contribute considerably to river discharges. Long frost periods, dry spells, and droughts can cause very low river discharges. The water levels in reservoirs depend on longer-term precipitation amounts over a few days to months. Again, melting snow and ice from the last winter can contribute considerably to the water level.

51.3.4 Dependence of Thermal (Conventional) Power Plants on Meteorological Parameters

Temperature and humidity influence the conditions for wet cooling towers and water cooling of thermal power plants. In a wet cooling tower (or open-circuit cooling tower), warm water can be cooled to a temperature lower than the ambient temperature. As ambient air is drawn past a flow of water, a small portion of the water evaporates, and the energy required to evaporate that portion of the water is taken from the remaining mass of water, thus reducing its temperature. This type of cooling is most effective when the saturation deficit of the air is large.

If sufficient water is available (at the banks of larger rivers) direct cooling using water from the river (once-through cooling) can be used. Here, the efficiency depends on the temperature of the water from the river. Often, the warming-up of the water from the river downstream of the power plant is limited by regulations to a given threshold temperature for ecological reasons. If the temperature of the water upstream of the power plant already exceeds this threshold temperature, once-through cooling is no longer permitted.

In longer drought situations, low water levels in rivers can cause problems in transporting the necessary coal to the power plants. In hard winters, the coal could also be frozen in goods waggons, which hampers the supply of power plants as well.

51.3.5 Dependence of Energy Transmission on Meteorological Parameters

Cables in overhead transmission lines warm up in operation proportionally to the electrical resistance of the

cable and the strength of the electrical current flowing through them. Warmer cables expand, and, thus, transmission cables hanging from masts sag more and come closer to the ground. In order to prevent excessive sagging, the temperature of these cables must be limited. Normal high-voltage transmission cables with steel cores are not allowed to warm up to more than 80 °C during normal operation and 100 °C at peak operation. Special ACCC (aluminum conductor composite core) cables have a smaller thermal expansion coefficient and can be operated up to a temperature of 175 °C.

On the other hand, the temperature of transmission cables is influenced by the environmental atmospheric conditions [51.26]. The cables are cooled by heat conduction to the air flowing past them, and they are warmed up by absorbing incoming short-wave radiation. The cooling depends on wind speed, air density, and the heat conductivity of the air. Air density and heat conductivity depend on air pressure, temperature, and humidity. Without any temperature monitoring transmission cables must be operated according to the worst-case scenarios given in standards and guidelines (e.g., [51.27]) assuming 35 °C air temperature, 0.6 m s⁻¹ wind speed, and 900 W/m² global radiation. Monitoring the cable temperature and/or near-cable atmospheric data can help with a much more efficient use of the transmission cables.

The accretion of ice at transmission cables could become a problem in wintry weather situations, when rain falls from warmer layers above into colder near-surface

air layers with temperatures below the freezing point. This may sometimes happen in the case of approaching warm fronts. The weight of the accreted ice can lead to extreme sagging of cables. In some cases, even the breaking of cables and entire electricity pylons has been observed. Excessive ricing in the case of advection of very humid air masses and fog to power cables at temperatures below the freezing point can lead to similar effects.

Extreme winds may be a hazard for above-surface power lines and electric pylons as well. This could be the direct impact of the wind on the power lines, as well as the impact of falling trees and other structures on these lines.

51.3.6 Dependence of Energy Demand on Meteorological Parameters

Electric energy demand for heating and cooling, as well as lighting of living places and work spaces depends on the ambient air temperature, wind speed, incoming daytime short-wave radiation (especially direct normal irradiation), and nocturnal long-wave radiation. Very often, heating-degree days [51.14] and cooling-degree days [51.15] are used as an approximate measure to assess the demand for heating and cooling. It is anticipated that the future energy demand for individual electric mobility is temperature-dependent as well, because the performance of batteries is strongly temperature dependent.

51.4 Devices and Systems

Many of the devices and systems described in detail earlier in this handbook and briefly in [51.28] are used to capture the necessary data for running energy systems. This section summarizes specific comments on some of these devices. Precipitation gauges are described in Chap. 12.

51.4.1 Cup and Sonic Anemometers

Near-surface wind speed is very often measured by cup anemometers (Chap. 9) that have been calibrated in wind tunnels. Site-specific wind speed measurements up to heights in the order of 50–100 m are quite often made from masts erected for this purpose. See Chap. 9 on anemometry and [51.29] for details. Measurements of turbulence are described in [51.30]. Cup and sonic anemometers deliver scalar means of wind speed representative for small measurement volumes (in-situ measurements). Sonic anemometers are also

able to deliver turbulence measurements. Because they are much more expensive than cup anemometers, sonic anemometers have not found widespread usage in wind energy so far, but their usage is increasing. For instance, they have now found a role in wind turbine nacelles for wind speed and yaw control purposes. Appropriate calibration standards comparable to those for cup anemometers have not yet been developed [51.31].

51.4.2 Surface-Based Remote Sensing of Wind and Temperature

Today's wind energy applications require knowledge of vertical wind distributions above those heights that can meaningfully be reached by mast measurements. Surface-based remote sensing has been used for this purpose for about 20 years [51.32]. The first sodars were deployed at potential wind energy sites, and now Doppler wind lidars are operated, because they promise

better data availability, a higher vertical range, and less environmental interference. See Chap. 23 and [51.33] for details on sodars and Chap. 27 and [51.34] for details on wind lidars. Wind profile measurements together with temperature profile measurements are available from radio-acoustic sounding systems (RASS) as well. RASS are described in Chap. 23 and [51.35]. Remote sensing of wind profiles would also be feasible with wind profilers (Chap. 31 and [51.36, 37]), but these instruments are not movable, and they do not have sufficient vertical resolution in the height range of wind turbines. Remote sensing delivers vector means of wind speed for larger measurement volumes determined by the pulse length and the opening angle between the beams originating from the instrument.

Passive radiometers (Chap. 29) are also designed to measure vertical temperature (and humidity) profiles. However, their vertical resolution is in the order of 50 and 100 m, which is not sufficient for wind energy purposes. Scanning at very low elevation angles in order to obtain a better vertical resolution would result, in turn, in more extended horizontal averaging, which in most cases is unwanted in energy site assessments.

51.4.3 Satellite Wind Observations

A meaningful option to capture areal distributions of offshore near-surface winds is the analysis of synthetic aperture radar (SAR) images from satellites. SAR data allow for a determination of the near surface wind speed and the detection of spatial gradients in these near-surface wind fields from the observation of capillary waves on the ocean's surface [51.38]. Capillary waves are supposed to change nearly immediately with the near-surface wind speed. These small-scale waves cause scattering of the radar waves emitted from the satellite, and less radiation is scattered directly backwards towards the satellite during the presence of these waves.

Principally, the evaluation of these images gives near-surface winds only. It is only the application of vertical extrapolations based on wind profile laws (i.e., the logarithmic law with possible corrections for atmospheric thermal stability or the power law with a suitable exponent) that allows the estimation and assessment of the hub height wind speed for wind energy applications. However, these extrapolations need additional input data, especially the vertical temperature profile. Nevertheless, the usability of SAR images to detect offshore wind-farm wakes was proven for the first time in [51.39]. First comparisons between SAR images and mesoscale wind simulations using the weather research and forecasting WRF model have been shown in [51.40]. The results from model simula-

tions and SAR images were proved for the first time by aircraft measurements behind North Sea wind farms in 2016 [51.41]. See Chap. 41 on microwave radiometers as well.

51.4.4 Measurement Stations for Solar Energy

During the planning, commissioning, and operation of large solar power plants with a capacity of about 1 MW or more on-site measured meteorological data are required. Meteorological measurements are also necessary for the testing of solar plant technologies.

Radiometers are the core of measurement stations for solar energy. Radiation measurements are described in Chap. 11. Also the other relevant and typically measured parameters have been discussed in previous chapters (wind speed and direction in Chap. 9, air temperature in Chap. 7, humidity in Chap. 8, pressure in Chap. 10, and precipitation in Chap. 12).

The instruments, their application and maintenance for solar energy applications are basically the same as for other atmospheric measurements. However, there are some differences. Specific recommendations for solar energy related measurements can be found in [51.2, 42]. The mentioned differences are caused basically by two reasons. First of all the measurements must characterize the conditions at the power plant site or in the plant. Therefore, stations must at times be positioned such that they do not fulfil fundamental requirements of measurements carried out for other purposes. For example, in the case of climate research, a free horizon is recommended for the site with no obstructions above 5° elevation [51.43]. For climate research, the baseline surface radiation network (BSRN) recommends that stations should not be close to major roadways or airports [51.44]. For the maintenance of the station during the solar resource assessment and for the costs of the power plant construction such infrastructure can be of great advantage, so that such recommendations do not apply to solar energy-specific measurements. Obviously, such differences also exist for other meteorological applications, such as transport meteorology, where measurements must be carried out close to airports and roads. The second reason why solar energy specific measurements might deviate from other atmospheric measurement stations is that different applications also bring along different optimal cost/benefit ratios. The most important example for this is that it is often not feasible to set up a high accuracy measurement station with a solar tracker and thermopile sensors (Fig. 51.2a) at the envisioned plant site for the resource assessment if this site is remote. For such sites, it is often impossible or at least too costly to assure

**Fig. 51.2**

(a) Measurement station for solar resource assessment in Tataouine, Tunisia, equipped with thermopile radiometers, cup anemometer, wind vane, pressure, temperature, and relative humidity sensors. (b) Rotating shadowband irradiometer as part of a solar resource assessment station close to Erfoud, Morocco (photos © Birk Kraas, CSP-Services)

the required daily maintenance by sufficiently qualified personnel. Reduced cleaning frequency and the corresponding soiling of the entrance windows is especially relevant for pyrheliometers, but also pyranometers with clear entrance windows suffer from soiling. Therefore, less maintenance intense sensors, such as rotating shadowband irradiometers (RSI, at times also called RSP or RSR, with P for pyranometer and R for radiometer) are often used at remote sites (Fig. 51.2b). They achieve lower accuracy in well-maintained stations with daily cleaning of the instruments' entrance windows, but if specific correction functions are applied, a better accuracy is reached for less frequent maintenance [51.45], for example only once every week or every 2 weeks. Correction functions are needed, as simple silicon pyranometers with higher incidence angle, temperature, and spectral errors are used in most cases. The lower maintenance requirement is due to the fact that RSIs apply pyranometers with diffusors in front of the detector, without an additional clear entrance window. Furthermore, RSIs are cheaper than thermopile sensors with solar trackers and are more robust and simpler, which leads to less frequent malfunctions, user mistakes, and data loss [51.46]. Another option to reduce the cost and maintenance requirements compared to pyrheliometers are instruments with sensor arrays and specific shading structures that avoid the requirement

of any moving part for direct irradiance measurements. However, unlike RSIs, such instruments still require the same cleaning frequency as thermopile pyranometers. An example of such a sensor is the SPN1 radiometer [51.47].

A significant cost reduction of a meteorological station can be achieved if direct normal irradiance (G_b) is not measured. For concentrating solar power plants (CSP and concentrating PV), G_b is required, and for tracked PV plants and large power plants it is desirable. For concentrating technologies, this is obvious. For the other plants mentioned, in principle, only global tilted irradiance G_{tilt} must be known. However, for more accurate plant yield calculations, the direct component in G_{tilt} is of interest, as mentioned in Sect. 51.3.2. In the case of tracked PV collectors, G_{tilt} measurements would also require a tracker for the pyranometer, so that no significant cost advantage remains. Furthermore, measuring the three radiation components (direct, global, and diffuse) allows for a better quality control of the data, which is of high value. For fixed collectors, G_{tilt} can be measured with an adequately mounted pyranometer without a solar tracker. Typically, for solar resource assessments for fixed PV and flat plate collectors, common global horizontal irradiance measurements are used combined with conversion models to derive G_{tilt} .

The sunshape and circumsolar contribution can be measured with special cameras [51.48, 49]: pyrheliometers with different fields of view [51.50] or RSIs [51.51]. For remote sites, RSI is the only commercially available measurement option. Camera-based instruments for circumsolar radiation measurements are only used at research stations, as they are highly maintenance intense and expensive.

Solar spectral irradiance measurements have so far been limited mainly to research sites. To change this, radiative transfer calculations can be used based on simpler measurements, such as the multifilter rotating shadowband radiometer [51.52], sun photometers, or multifilter radiometers [51.53].

In recent years, measurement stations for solar tower plants have also started including meteorological optical-range (MOR) measurements to obtain information on the beam attenuation between the mirrors and the receiver on the tower. Chapter 13 introduced visibility sensors. It is important to mention that the conversion from the MOR [51.54] to the required broadband beam attenuation is not a simple task (broadband refers to the wavelength range from about 280 to 4000 nm), as the instruments and the definition of MOR do not refer to broadband radiation. Therefore, correction functions are required [51.55].

Also, soiling rate measurements have been included in meteorological stations for solar energy applications in the last decade. For PV, such measurements can be obtained by comparing the short-circuit current or power output of cleaned and uncleaned PV reference cells or modules [51.56]. For concentrating collectors with mirrors, the reflected direct normal irradiance is compared to G_b [51.57], or reflectance measurements are carried out on exposed mirror samples.

Solar radiation measurements are important input for the accurate forecasting of solar radiation. Additional ground measurements are provided in the form of all-sky images mainly relating to forecasting for the next 15 min. Such images of the complete upper hemi-

sphere are taken with fisheye lenses or curved mirrors. The images can be used to detect clouds and to track and forecast their position. Finally, with additional assumptions on the clear-sky atmosphere, this allows the prediction of the solar irradiance in a power plant or in an area with several power plants (e.g., a city with many PV rooftop systems). For these irradiance forecasts, the cloud height is required if spatially resolved irradiance maps are to be forecasted. Cloud height measurements can come from different sources, such as ceilometers or multiple all-sky imagers. Current research indicates that all-sky imagers are the preferable option [51.58]. All-sky imagers have also been used to measure the current downwelling shortwave irradiance (G , G_b). However, such methods do not reach the accuracy required for solar energy applications so far.

At times, PV reference cells are also applied in solar resource assessment to obtain data that are more comparable to the expected production of PV collectors. While thermopile pyranometers are designed to measure broadband irradiance with low errors introduced by the incidence angle, temperature, and spectral effects, such effects occur in PV modules and reference cells. If the applied reference cells are similar to the PV module of interest, the data collected with the reference cell can be used more easily to calculate the expected PV production, as the mentioned errors do not have to be modeled in the PV plant yield model. However, most PV models include the modeling of these errors, so that PV reference cell data must be used with great care. Furthermore, PV reference cell measurements are difficult to compare with other existing datasets from pyranometers and satellites, which further complicate their application. Therefore, measurements with reference cells are rather carried out as additional measurements next to other radiometers. A dataset that only contains PV reference cell data must currently be considered of lower quality. Advantages and disadvantages of the measurement options mentioned for solar energy applications are included in Table 51.2.

Table 51.2 Advantages and disadvantages of selected measurement devices with respect to energy meteorology

Device	Advantages	Disadvantages
Cup anemometer	Can be calibrated in wind tunnel, calibration standards exist	Needs masts for locating at height of rotor plane, extrapolation to greater heights necessary, limited turbulence measurements, horizontal wind speed only
Sonic anemometer	High-frequency wind measurements, turbulence measurements, all three wind components available	Rain droplets or ice at the sound transducers can disturb the measurements, appropriate calibration standards have not been developed
Wind lidar	Does not need calibration, direct profile measurements	Measurement obstructed by fog, clouds, and precipitation
SAR on satellites	Not obstructed by clouds, operates day and night, large areas are covered simultaneously	Several days between satellite overpasses, offshore application only, near-surface winds only

Table 51.2 (Continued)

Device	Advantages	Disadvantages
Thermopile pyranometer	Achieves the highest available accuracy for tilted irradiance measurements under well-maintained conditions in high frequency	Require frequent cleaning and other maintenance (daily). Available stations are rare, especially for long-term data sets (> 10 years). Costs
Thermopile pyrheliometer	Achieves the highest available accuracy for direct irradiance measurements under well-maintained conditions in high frequency	Requires frequent cleaning and other maintenance (daily) and expensive and error-prone solar trackers. Available stations are rare, especially for long-term datasets (> 10 years). Costs
Rotating shadowband irradiometer	Simple, robust, frequent, and cheap option for determination of global horizontal, direct normal and global tilted irradiance. Only less frequent cleaning required compared to instruments with clear optics (e.g., every week)	Achieves a lower accuracy compared to thermopile sensors even if correction functions for systematic errors are applied. Available stations are rare, especially for long-term datasets (> 10 years)
PV reference cell	Measures an output signal close to that of specific corresponding PV modules in high frequency	Difficult to compare with more frequently available broadband irradiance data and incompatible with many PV plant models. Available stations are rare, especially for long-term datasets (> 10 years)
Ground-based spectroradiometer	Accurate and frequent measurements of solar spectra can be obtained	Difficult to maintain, too expensive for most stations
Satellite-based imager for irradiance measurements	Long-term datasets (> 10 years) available for the whole planet, even spectrally resolved. No data gaps, maintenance issues. Relatively low costs, as satellites are paid by somebody else	Lower accuracy compared to ground-based methods, lower temporal frequency (15 min compared to 1 min or higher)
Camera-based circumsolar radiation measurement	Some systems can reach high accuracy. Complete information for plant models measured, including sunshape	High costs and maintenance requirements
Pyrheliometer pairs with different field of views for circumsolar radiation measurements	High accuracy for the circumsolar contribution and integrated irradiance for one angular interval	No angular resolved radiance, only integrated irradiance for one angular interval. Modeling needed for determination of sunshapes. Daily maintenance required, error-prone to soiling
Rotating shadowband irradiometers for circumsolar radiation measurements	Low maintenance effort, simple data evaluation	No angular resolved radiance, only integrated irradiance for one angular interval. Modeling needed for determination of sunshapes. Lower accuracy compared to camera and pyrheliometer-based methods
Beam attenuation measurement based on MOR measurements	Simple measurement method	Requires correction for spectral and broadband effect
Satellite-based imager for circumsolar irradiance measurements and beam attenuation measurements	Long-term datasets (> 10 years) can be determined for the whole planet. No data gaps, maintenance issues. Relatively low costs, as satellites are paid by somebody else	Still in development phase, low accuracy compared to ground measurements
Soiling-rate measurement with test mirrors or test PV cells/modules	Frequent measurements of cleanliness and soiling rate	Maintenance intense
Ground-based all-sky imager for forecasting	Highly temporally and spatially resolved irradiance data can be determined	Costs, maintenance. Forecasts confined to the next approximately 15 min
Satellite-based imager for forecasting of irradiance	Forecasts can be determined for the whole planet. No data gaps, maintenance issues. Relatively low costs, as satellites are paid by somebody else. Forecast horizon up to approximately 6 h	Lower accuracy, temporal and spatial resolution than all-sky imagers

51.4.5 Satellite-Based Radiation Measurements

As explained in Sect. 51.3.2, satellite-based surface radiation measurements are a standard data source for solar energy applications to create the required long-term datasets (≈ 10 years or more). The applied methods and technology are explained in Chap. 40 on airborne radiation sensors and in Sect. 22.4.3 on cloud observations that are an important intermediate result. For solar energy applications the postprocessing of these data is of high importance.

As the accuracy of satellite-derived data is significantly lower than that of well-maintained ground measurements, the latter are frequently merged with the satellite data to create bankable solar resource data during the planning phase of the power plant. This is especially relevant for the planning of solar plants with several MW power output, as financing costs depend on the risk of the project and, hence, on the uncertainty of the resource data. The final long-term dataset is created by merging the at least 1 year-long dataset from ground measurements and the satellite-derived data [51.59]. Plant yield calculations for the feasibility study and plant layout are carried out with these long-term datasets. For the detailed design of the plant, also measurement data are used due to the higher temporal resolution and accuracy.

51.5 Specifications

Users of wind speed measurement data for the assessment of available wind energy often request a rather high accuracy in the order of 1%, because wind energy depends on the third power of the wind speed (51.1). A 1%-error in wind speed thus means up to 3% error in wind energy. Therefore, most guidelines [51.6] favor cup anemometers as in-situ devices for wind energy purposes, because they can be carefully calibrated in wind tunnels to achieve the requested accuracy. Remote-sensing instruments cannot be calibrated in the same way as cup anemometers in wind tunnels. Actually, they do not even need to be calibrated, because they are based on fundamental physical principles. Please note, that wind

Satellite-derived irradiance data are also applied at times for the power plant monitoring of some medium-sized facilities. Furthermore, the data are key for radiation forecasts with a horizon of up to 6 h. Cloud-motion vectors are determined from series of satellite images, and the detected cloud positions are then extrapolated to the future. These predicted cloud positions are then used to calculate the solar irradiance.

Apart from broadband direct normal, global horizontal, and global tilted irradiance, satellite data may also be used to derive further parameters, such as circumsolar radiation, beam attenuation in tower plants, and spectral irradiance. For circumsolar radiation, such efforts [51.60] are still in the development phase and are not used commercially. The same holds for beam attenuation studies. Spectral irradiance can be derived from satellite data [51.61], and such datasets have already been integrated in selected PV yield analysis tools [51.62].

51.4.6 Comparison of Methods

The advantages and disadvantages of some of the mentioned measurement methods for wind (first four lines) and solar (rest of the table) energy applications are compared in Table 51.2.

data from remote sensing and in-situ measurements are not fully comparable due to the different measurement principles (cup anemometers are in-situ instruments; sodars and wind lidars are volume-averaging instruments).

Specifications of solar energy related instruments are also included in Table 51.3.

While cup anemometer data is nearly always available, wind lidar data is not available during fog and precipitation events. The vertical range of optical remote sensing can also be limited by the aerosol content of the atmosphere. Very low aerosol concentrations may lead to insufficient signal-to-noise ratios of the backscattered signal.

Table 51.3 Specifications of selected measurement methods for the application in the field of generation of renewable energies

Method	Typical total uncertainty	Temperature range (°C)	Humidity range (%)
Cup anemometer	±1% [51.6]	−10 to 50	0–100
Wind lidar	±0.1 m s ^{−1} (Class A), ±0.5 m s ^{−1} (Class B), ±1.0 m s ^{−1} (Class C) [51.34]	−20 to 40	0–100
Thermopile pyrheliometer	0.7% (1 min resolution)	−40 to 80	0–100
Thermopile pyranometer	1.2% (1 min resolution)	−40 to 80	0–100
Silicon pyranometer with correction functions for global horizontal measurements	3.5% (1 min resolution)	−40 to 65	0–100
Twin RSI	3.5% (global horizontal and direct normal irradiance in 10 min resolution)	−40 to 65	0–100
Satellite-derived irradiance data after site adaptation with ground measurements	Annual average: 4% for global horizontal irradiance, (for complex areas higher) Hourly: 7% to 35% for global irradiance (depending on cloud, aerosol and ground conditions) Direct irradiances errors are typically about twice the errors for global horizontal irradiance [51.2]	Does not apply	Does not apply
Beam attenuation measurements with MOR sensors	≈ 5% in terms of broad band transmittance over a path of 1 km [51.55]	−55 to 65	0–100
Camera-based circumsolar radiation measurements [51.49]	15% for circumsolar contribution, minimum 0.01	−10 to 45	0–100
Pyrheliometer-based circumsolar radiation measurements [51.50]	15% for circumsolar contribution, minimum 0.01	−40 to 65	0–100
RSI-based circumsolar radiation measurements	20% to 30% for circumsolar contribution, minimum 0.02 [51.51]	−40 to 65	0–100
Soiling rate measurement systems	≈ 0.2%/day [51.57]	−40 to 65	0–100
Ground-based spectroradiometers (350–1600 nm)	0.2 nm wavelength uncertainty below ≈ 1000 nm, 5% spectral irradiance	−10 to 40	0–100
Tipping bucket (Cs700) precipitation measurement	2%	0 to 70	0–100
Optical weather sensor (FD12P) with precipitation measurement	30%	−40 to 55	0–100

51.6 Quality Control

Planning, siting, and operation of renewable energy facilities need data of high accuracy and quality, because the financial success of these facilities often crucially depends on data quality. While companies and organizations working in planning and siting of energy converters have to fulfil the usual data quality demands for their measurement devices (mostly according to the instructions given by the manufacturers of these instruments),

instruments mounted at or near to operating energy facilities should be included in the data quality procedures of these installations. Please refer to the respective chapters on specific quality control procedures for the different instruments. For cup anemometers, see also [51.63], for sonic anemometers [51.64], and for wind lidars [51.34]. For solar energy applications, specific minor adaptations of the common quality checks exist; see, e.g., [51.65].

51.7 Maintenance

The demands and strategies for the maintenance of instruments delivering meteorological parameters for planning, siting, and operation of energy conversion facilities are very much similar to those given for data quality in Sect. 51.6 above. For the required maintenance procedures please refer to the respective chapters

on the specific instruments. It should be mentioned again that the feasible maintenance intensity for solar resource assessment stations might be more limited than recommendations for solar radiation measurements as already discussed in Sect. 51.4.4.

51.8 Application

This section gives two application examples of measurements. The first example refers to the wind and thermal stability conditions for the operation of offshore wind parks; the second example displays radiation measurements relevant for solar power plants.

Fig. 51.3 Stability wind rose indicating the frequency (number of 10-min intervals per 12° wind direction sector) of atmospheric stability. Lines are labeled in terms of the stability measure z/L , where z is the height above ground, and L is the Obukhov length. Blue and red shading indicate stable and unstable stratification, respectively. The higher the value of z/L , the stronger the stability. Data are from the FINO 1 offshore platform in the North Sea for the whole year of 2005 at a height of 60 m above the sea surface. Data is available from <http://fino.bsh.de/>. Only data with wind speeds between the cut-in (5 m s^{-1}) and cut-off (25 m s^{-1}) wind speed were considered (after [51.41]) ▶

Fig. 51.4 Irradiance measurements in 1 min-resolution from a meteorological station equipped with thermopile sensors close to Tabernas, Spain on 23.05.2018 (GHI: global horizontal irradiance, DNI: direct normal irradiance, DHI: diffuse horizontal irradiance)

51.8.1 Wind Energy Applications

It has been stated in this chapter that atmospheric turbulence (at the end of Sect. 51.3.1) and wakes behind wind turbines (at the end of Sect. 51.2.1) not only depend on wind speed but also on the atmospheric thermal stability. Therefore, for the assessment of wake interactions and fatigue issues of wind turbines, both parameters have to be assessed together. Figure 51.3 gives an example of an evaluation of 10 min-mean data obtained at 60 m above sea level at the FINO1 platform in the German Bight from a cup anemometer for wind speed and from a sonic anemometer for atmospheric stability. The FINO1 platform was erected for the investigation of the wind conditions in the marine atmospheric boundary layer in the German Bight. These data serve for the planning of the large offshore wind farms, which are presently being erected there. Figure 51.3 demonstrates that wind direction and thermal stability are correlated with each other offshore [51.41]. Stable atmospheric stability mainly occurs with southwesterly wind directions. Southwest is the prevailing wind direction in warm sectors of cy-

clones on the Northern Hemisphere, where warmer air is advected over colder waters. Likewise, we observe unstable conditions mainly occurring with northwesterly winds. This is the prevailing wind direction in the cold air masses behind the cold front of cyclones in the Northern Hemisphere. Such a correlation is not observed for onshore conditions, because here the diurnal day–night variation of the thermal stability dominates.

51.8.2 Solar Energy Applications

As was already briefly mentioned in Sects. 51.3.2, 51.4.3, and 51.4.4, different measurement techniques have different applications. As an example the results of typical measurement stations with thermopile pyranometers and pyrhemometers for 1 day are shown in Fig. 51.4. Such graphs are used for the daily quality control of the collected measurements. Figure 51.5 shows a histogram of the three irradiance components for a measurement station in India in April 2018. Such histograms are used as a tool to evaluate the variability of the solar irradiance.

Fig. 51.5 Histogram of irradiance measurements with thermopile sensors from a meteorological station close to Greater Noida India in April 2018 derived based on data in hourly resolution (GHI pyr: global horizontal irradiance measured by a pyranometer, DNI pyr: direct normal irradiance by a pyrhemometer, DHI pyr: diffuse horizontal irradiance by a shaded pyranometer). Irradiance is given in units of $W m^{-2}$ within a $\pm 25 W m^{-2}$ interval. Courtesy of Birk Kraas, CSPS Services, Stefan Wilbert, DLR

51.9 Future Developments

Measurement techniques for atmospheric parameters at hub height of wind turbines and over the area swept by their rotors have changed. In-situ measurements by cup and sonic anemometers are no longer fully sufficient. The growing hub heights and upper tip heights of the turbine rotors make it more and more impossible to perform in-situ measurements from masts specially erected for this purpose. Therefore, in many cases, ground-based remote sensing has replaced mast measurements in the last few years. Overviews of the basic abilities to probe the atmospheric boundary layer by ground-based remote sensing are given in [51.28, 32]; however, the development of some of the techniques has proceeded in the last 7 to 8 years since their publication. The substitution process from in-situ to remote-sensing measurements is to be accompanied by scientific investigations that compare the wind and turbulence data obtained from masts and remote-sensing techniques. Such investigations are continuing and have already led to rewritten standards for measurement procedures [51.6]. Given the present state of instrument development, optical techniques such as wind lidars will be the main measurement tools of the future [51.66]. SAR satellite image evaluation techniques are presently evaluated by data from in-situ aircraft data and may become an increasingly important tool for marine wind assessment [51.41].

However, not only wind conditions must be captured by ground-based remote sensing. It has become increasingly clear that atmospheric thermal stability is a really important parameter for the assessment of wind energy. Increasing stability (potential temperature increases with height above ground) reduces turbulence

intensity, increases vertical wind shear, and prolongs wakes of wind turbines and entire wind farms. Devices for ground-based remote sensing of temperature are still limited in their capabilities. Passive radiometers (Chap. 41) have a very coarse vertical resolution (50–100 m); active devices such as Raman lidars (Chap. 25) still require large technical efforts and have a low signal-to-noise ratio in the daytime due to disturbing sunlight. RASS (Chap. 23) is not a perfect alternative, as it cannot be operated in the vicinity of settlements because of its audible acoustic signals.

With respect to solar energy, future developments will surely be related to increase the accuracy of ground and satellite-based measurements of all relevant parameters. The respective guidelines are under revision or have been revised recently [51.67]. For ground-based sensors, this will, on the one hand, be achieved by increasing their accuracy under well-maintained conditions. However, improving their robustness and simplicity and their maintenance requirements – especially including the need for frequent cleaning – is another way to improve the accuracy. Future developments will also include alternatives to thermopile sensors and the required corrections for systematic errors. For satellite-derived irradiance, accuracy improvement will be developed by applying higher temporal, spectral, and spatial resolutions. The speed of this enhancement will depend on the deployment of the next generations of satellites. Some of the mentioned parameters related to solar energy are still in early development stages (e.g., satellite-derived attenuation and circum-solar radiation measurements). Such methods should be elaborated further in the future.

51.10 Further Readings

A thorough introduction into wind energy meteorology can presently be obtained from two books:

- S. Emeis: *Wind Energy Meteorology – Atmospheric Physics for Wind Power Generation*, 2nd edn. (Springer, Heidelberg 2018) XXVI + 255 pp.
- L. Landberg: *Meteorology for Wind Energy*. Wiley, XIX+204 pp. (2016)

Related to solar energy meteorology:

- M. Sengupta, A. Habte, C. Gueymard, S. Wilbert, D. Renné, P. Blanc, A. Dobos, E. Lorenz, R. Meyer, D. Myers, L. Ramírez, K.P. Nielsen, A. Lopez,

J. Kleissl, J. Remund, J.A. Ruiz-Arias, R. Perez, J. Polo, L.M. Pomares, M. Suri, T. Stoffel, F. Vignola, S. Wilcox, J. Wood, Y. Xie, L. Zarzalejo. *Best Practices Handbook for the Collection and Use of Solar Resource Data for Solar Energy Applications*. Second Edition, NREL Technical Report NREL/TP-5D00-68886, 238 pp. (2017)

A broad overview on all renewable energy techniques can be found in:

- M. Kaltschmitt, W. Streicher, A. Wiese: *Renewable Energy* (Springer, Heidelberg 2007), XXXII+564 pp. A revised 5th German edition of this book appeared in 2013.

Stefan Emeis

Institute of Meteorology and Climate Research
Karlsruhe Institute of Technology (KIT)
Garmisch-Partenkirchen, Germany
stefan.emeis@kit.edu

Stefan Emeis is an unsalaried Professor of Meteorology at the University of Cologne, group leader at KIT, and editor-in-chief of *Meteorologische Zeitschrift*. His research mainly involves ground-based remote sensing of the atmospheric boundary layer. He has written books on measurement techniques and wind energy, organized conferences (e.g., ISARS 13, METTOOLS VI), and was awarded the Honorary Medal of the VDI and the Reinhard Süring Medal from the German Meteorological Society.

Stefan Wilbert

Institut für Solarforschung
Deutsches Zentrum für Luft- und
Raumfahrt e. V. (DLR)
Almeria, Spain
stefan.wilbert@dlr.de

Stefan Wilbert works in the Institute of Solar Research at DLR in the permanent delegation at the Plataforma Solar de Almería, Spain since 2006. He is leader of the research group “Solar Energy Meteorology”. Both his Diploma thesis in physics at the University of Bonn and his PhD thesis at the University of Aachen were related to meteorological effects on solar power plants. His research interests are meteorological measurements for solar energy applications, radiative transfer modelling, nowcasting of solar radiation and solar power plant simulation.

52. Urban Measurements and Their Interpretation

Sue Grimmond , Helen C. Ward 

Urban environments create distinct challenges for successful atmospheric measurements primarily due to their complex surface structure (i.e., presence of buildings, a wide variety of construction materials, and heterogeneous land cover). In addition, human-generated emissions of heat, water, or pollutants may be considerable and can often vary dramatically in both space and time. Observational techniques have been adapted and theoretical frameworks developed to address some of these challenges of the urban environment. This chapter provides an overview of commonly used approaches to measure the urban atmosphere (including observations of temperature, humidity, wind, precipitation, radiation, the surface energy balance, and boundary layer height and dynamics), plus the key parameters used to quantify the urban environment (e.g., roughness length, surface cover fraction). Additional considerations that need to be made when measuring or interpreting urban measurements are discussed, alongside open issues that are the subject of ongoing research. Examples of various applications are given.

With the majority of the world's population now living in cities [52.1] understanding the urban atmosphere is critical for the short and long-term well-being of citizens. Accurate and reliable meteorological measurements are fundamental to improving our knowledge of this extremely complex environment. As urban areas are the major source of greenhouse gases and aerosols that impact the global atmosphere [52.2, 3], cities are also highly relevant to many global problems. For examples of needs and applications, see Sect. 52.8.

Compared to their rural surroundings, cities are known to modify the surface-atmosphere exchange of energy, water, and pollutants. Exactly how this exchange is modified depends on the surface properties, such as the density of buildings or the amount and type of vegetation present [52.4], as well as the human activities. Hence, surface-atmosphere exchanges typically have considerable variation both within and between urban areas [52.5]. Furthermore, urban areas affect the climate not only within the city itself but also at regional scales [52.6].

Urban observations are undergoing a massive transition because of a combination of factors occurring almost simultaneously. These include: technological changes (e.g., miniaturization of measurement devices, developments in ground and satellite-based remote sensing), communication improvements (e.g., WiFi networks via mobile phone), smart data (e.g., combining data from multiple sources), citizen science (e.g., using mobile phones or local citizens [52.7] to gather meteorological data), enhanced computer power (e.g., allowing higher-resolution weather forecasts), development of climate services (e.g., Global Framework for Climate

Services [52.8], integrated urban services [52.9]) that expect meteorological services to go the *last mile* to deliver the information actually needed, and urbanization itself causing numerous agencies to recognize that urban residents' needs have to be addressed because of their density of exposure (e.g., UN Habitat [52.10, 11], World Bank [52.12–14], and WMO [52.15]). This creates both opportunities and some potential pitfalls. In this chapter, we focus on identifying what needs to be considered in undertaking measurements in urban areas and provide examples of applications to help facilitate the design of appropriate systems.

52.1 Measurement Principles and Variables

Given the complexity of the urban environment and its rapid rate of change, undertaking measurements in urban areas requires a careful four-dimensional (4-D) characterization of the site and its surroundings throughout the period of interest.

52.1.1 Challenges of the Urban Environment to Standard Measurement Techniques

With respect to measurements, what makes urban areas distinct from most other landscapes is the large size of the roughness elements (e.g., buildings and trees) and the wide range of land cover types that are typically found in varying proportions across a city. A critical characteristic of almost all cities is that they vary horizontally and vertically, and, with buildings in cities becoming ever taller, the influence of the surface extends to ever greater heights.

One of the main challenges of undertaking measurements in urban environments is to ensure that the observations are representative of the area of interest. Great care needs to be taken in siting instruments to consider their measurement principles. For example, a downward-facing pyranometer will respond to the surface below the sensor that is within its field of view. When installed on a rooftop, the field of view (which depends on the height and location of the pyranometer) may encompass a single rooftop of uniform material or multiple roofs of varying materials, slopes, and aspects, plus perhaps some vegetation or road surface. In most neighborhoods there will be many different roof types with a wide range of properties. For a micro-scale study, it may be important that the radiometer measures only the rooftop of interest; for a local- or neighborhood-scale

study, the radiometer should provide a representative measurement for the neighborhood (Sect. 52.3.2). To ensure that this is the case requires careful siting of the sensors such that the area sampled is sufficiently large, which usually means measuring at greater height. If this is not possible, multiple sensors installed at different locations may be needed to provide a more accurate estimate of the neighborhood-scale value and its spatial variability [52.16].

Due to the heterogeneity of urban areas many instruments need to be installed at considerable height in order to obtain representative measurements for the area of interest. Moreover, the effective height of the surface is typically raised to a height of several meters above ground level because of the presence of buildings (and trees). These large bluff bodies present an obstacle to the flow and deflect the flow both around them and over the top, similar to flow over forests. This increase in the height of the effective surface is described by the displacement height. Locating measurements sufficiently above the displacement height can be challenging given the financial and safety considerations associated with installing a tall (e.g., 10–50 m) tower on a rooftop or within a street canyon (more on ground-based platforms can be found in Chap. 6). Moreover, for all urban measurements (not only those at height), obtaining site permissions can be problematic, and theft or vandalism may occur, as in nonurban locations. The practicalities of installing and maintaining the equipment in a populated area must be considered. Cranes and road closures may be required, which must cause minimal disruption to the daily life of the city. Non-eye-safe lasers or sodars, which emit audible sounds, are generally better suited to less populated areas.

52.1.2 Measured Variables

Almost all variables that are measured in other environments are also of interest in urban environments, along with some additional variables. The most commonly considered variable in urban areas is temperature. This is because of the well-known urban heat island (UHI) effect [52.17]. Different types of urban heat islands are defined, depending on what type of temperature is measured (e.g., air, surface, or soil temperature) and where it is measured (e.g., between the roughness elements or above the surface layer within the boundary layer).

In urban areas, air temperature measurements at standard screen height (Chap. 7) will lie within the urban canopy layer (Fig. 52.1), where the flow is highly heterogeneous and is affected by nearby roughness elements. The air in this layer may be separated from the inertial sublayer (or constant flux layer) above, particularly if buildings are close together, such that air skims across the top of the buildings rather than flowing into the urban canyon. As buildings become taller, the level of standard screen height may lie deep within a street canyon and be separated from the overlying air by several tens of meters. Careful interpretation is therefore required.

Other types of urban heat islands are based on the surface, soil or ground temperature, or the temperature measured higher in the boundary layer. These UHIs generally have different magnitudes and different diurnal patterns to each other. A critical aspect of the UHI intensity is the *rural* measurement, which also needs careful consideration with respect to sensor placement and fetch to ensure it provides a suitable and representative baseline with which to compare the urban temperature.

Beyond enhanced temperatures, urban areas have distinct humidity patterns, complex interactions with precipitation, a strong influence on wind due to the roughness introduced by buildings and trees, and impacts on boundary layer height, surface energy fluxes, and air quality [52.5]. As with temperature, any comparison with nonurban sites or other urban sites must also carefully consider the characteristics of the surroundings. As an illustration, whilst urban areas are typically associated with lower evaporation rates than outside the city because of reduced vegetation and increased impervious cover, the opposite result has been observed for some urban environments (e.g., in Sacramento [52.18], Phoenix [52.19], and Salt Lake City [52.20]), with higher evaporation rates observed in the city as many residents have irrigated gardens and the surroundings are semiarid.

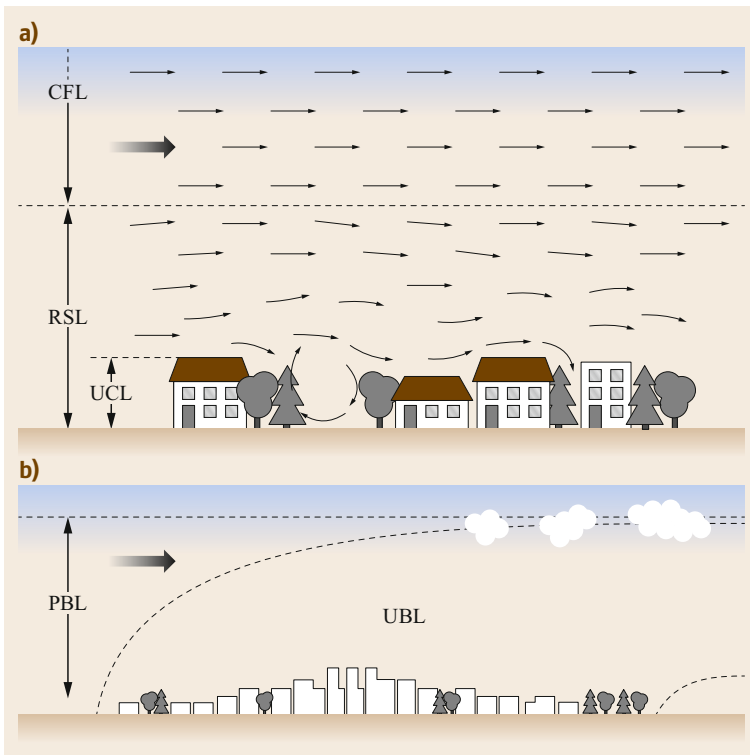

Fig. 52.1a,b Layers of the atmosphere including (a) the urban canopy layer (UCL), roughness sublayer (RSL), and constant flux layer (CFL) or inertial sublayer (ISL), and (b) the planetary boundary layer (PBL) and urban boundary layer (UBL). Winds are indicated by arrows with the prevailing wind from the left (*large arrow*)

To assist interpretation and analysis it is often essential to collect additional data about the study area. Such data fall into two categories: approximately static or slowly changing site characteristics (such as building height, building materials, or land cover type) and temporally varying information about processes that rarely need to be considered in nonurban environments but can have a significant impact in urban environments. Examples of the latter include vehicle counts (used to relate carbon dioxide emissions to traffic load [52.21] or to quantify sources of anthropogenic heat) and building energy use statistics (used to calculate the anthropogenic heat release [52.22, 23]). Ideally, high-resolution spatiotemporal datasets would be collected for the study site and study period to accompany the observed meteorological datasets, but this is rarely achievable in practice. Instead, models may be used to estimate the anthropogenic heat emissions or traffic load based on more readily available (often coarser resolution) data [52.24]. Such additional information can be extremely useful in quantitatively relating observed trends to human activities.

The urban surface energy balance is more complicated than that over many nonbuilt surfaces. Firstly, there is the additional anthropogenic heat flux term describing the additional energy supplied as a result of

human activities (including building heating, combustion associated with transport and human metabolism). Secondly, the storage heat flux is much greater than for many vegetated environments and often constitutes a large proportion of the available energy. This is because buildings receive intense radiation loads, and the building materials have large thermal capacity. The storage heat flux includes the energy stored and released in the urban fabric (e.g., buildings' roofs and walls, roads, pavements, vegetation, and the air) and, thus, varies considerably in space and time. There is no known way to measure the storage heat flux directly given the complexity of the urban surface [52.25, 26]; the most common approach is to approximate it from the residual of the energy balance, but this means all the errors associated with the other energy balance terms are combined in this term. As the observed surface energy balance rarely closes even in simple environments, there are always uncertainties with this approach. Thirdly, the advection term in the surface energy balance is usually assumed to be negligible, although this may not always be an appropriate assumption in the urban environment. Thus, in addition to the *measured variables*, there are also *nonmeasured variables* or *nonmeasurable variables* that may have to be estimated.

52.2 History

As cities or towns are places where people have lived for thousands of years, the earliest measurements (e.g., concerning air pollution [52.27]) were associated with urban locations. Similarly, the development of more formal instrumentation (e.g., European development of the temperature sensor, Chap. 7) also involved urban measurements. In neither case was the original intent to observe the urban environment per se but rather to measure the locale or region. However, once multiple sensors were installed across the region, urban–rural differences became evident.

The first to take measurements and to recognize through analysis of the data that there was an urban effect was *Luke Howard* (1772–1864) [52.28]. Through temperature observations sited in various places in London in the early part of the nineteenth century, he identified regions of the city with warmer temperatures and related these to a higher density of buildings and greater release of anthropogenic heat (Sect. 52.1.2) which, at the time, was predominately associated with

fires [52.29, 30]. As more sensors became available other urban areas and additional variables were measured.

Key historical measurement innovations in the urban environment have involved trying to measure the spatial variability. The first spatial measurements using a vehicle mounted sensor, by *Wilhelm Schmidt* (1883–1936) in Vienna, observed thermal minima [52.31]. Other notable developments included mobile traverses by car, bike, or on foot; identifying the effects of the urban environment by concurrent measurements at multiple sites within and around a city, and investigating vertical profiles of various quantities both in between and above the buildings. See Chap. 50 for an overview of mobile measuring systems.

The influence of urban areas on precipitation has been the subject of much debate and research over an extended period [52.32–36]. Much of the early debate comes about because of the difficulties of undertaking measurements in an urban environment and the

range of factors that may be influenced by the presence of a city. These include the urban heat island, larger roughness elements, and added aerosols. The METROMEX (Metropolitan Meteorological Experiment) studies were prompted by the so-called *La Porte anomaly* [52.32, 37], which was suggested to indicate a precipitation enhancement downwind of Chicago (and Gary, Indiana). Although METROMEX and companion studies did not answer the precipitation debate, they resulted in a number of important firsts in urban meteorological observations [52.38, 39]. Surface energy balance fluxes were measured using eddy-covariance techniques, and the challenges of storage heat flux and advection were addressed [52.40–43]. In addition, measurements that crossed a wide range of spatial scales (Sect. 52.3) were combined to give a 4-D view of the urban atmosphere, using (at the time) state-of-the-art instrumentation.

The use of eddy covariance to study the surface energy balance and turbulent exchange in urban areas has grown considerably in the last few decades. Urban flux towers are now found all over the world [52.5, 44], although there remain more in the northern mid-latitudes. Observations of turbulent fluxes from these towers have revealed a huge amount of information about energy partitioning and flow patterns in cities, in particular how surface cover and human activities strongly influence flux partitioning and turbulent exchange. As one example, the Institute of Atmospheric Physics' (IAP) 320-m-tall tower in Beijing has, since 1979, provided one of the tallest vertical profiles of meteorological variables in a city, but because of the immense changes in the city, these observations are also an amazing record of urbanization. Notably, the change in the wind regime as the city became taller, and the aerodynamic parameters became larger [52.45]. Scintillometry has also been used to determine sensible heat fluxes in cities [52.46–54]. Small-aperture scintillometers operating over paths of 50–250 m have been used to study the different fluxes from rooftops and canyons in Basel [52.55], whereas large aperture scintillometers provide fluxes representative of much larger areas ([52.56], Fig. 52.3).

Notable urban meteorological campaigns in the last two decades have combined physical and chemical measurements. Examples include dispersion-related studies in Hamburg [52.57], Salt Lake City (URBAN 2000 [52.58]), Oklahoma City (Joint Urban 2003 [52.59]), New York City (Madison Square Garden [52.60]), and London (DAPPLE: dispersion of air

pollution and its penetration into the local environment [52.61]), REPARTEE (Regents Park and Tower Environmental Experiment) [52.62], ClearfLo (Clean air for London) [52.63]), which consider the indoor and outdoor environments, from street canyon to neighborhood scale. Large campaigns, such as ECSOMPTE (French acronym for a field experiment to constrain the models of pollution emission transport) in Marseille [52.64, 65], crossed from the regional scale to the city scale, where poor air quality (from refineries) was an issue. Network designs for different purposes in cities have been a key focus [52.66, 67], for example air temperatures in Birmingham [52.68, 69], canopy layer variables in Oklahoma city [52.70], precipitation in Dallas-Fort Worth [52.71], and multivariable, multi-scale, and multipurpose studies in Shanghai [52.72] and Seoul [52.73].

With air quality, a critical public health issue in urban areas globally, the measurement of boundary layer depth has been an important and ongoing observational concern. COST (European Cooperation in Science and Technology) 710 [52.74, 75] provided a significant review of measurement approaches and a detailed comparison of the techniques and their relative strengths and weaknesses.

The AMDAR (Aircraft Meteorological Data Relay) data from onboard sensors mounted on commercial aircraft (Chap. 63) has provided cities with a new source of boundary layer data as planes take off and land [52.76, 77]. Cities with dense networks of airports have close to realtime data, which are delivered via the WMO Integrated Global Observing System and the Global Observing System (Chap. 63). These data are obviously limited to times when planes are flying (many cities have late night curfews because of noise, e.g., Sydney and London) and flight path locations. Although the three-dimensional (3-D) position of the data sample is provided, the time the plane spends within the boundary layer is very short. Also, as many airports may be some distance from the city, these data may not be directly relevant to the urban environment.

There have been reviews of the state of urban measurements that address full-scale [52.78–81] and physical (or hardware) models [52.82] plus numerous recommendations [52.83–86]. Consideration has also been given to network design in urban areas [52.66] and what metadata should be provided [52.67]. Other reviews have been more focused to include such topics as thermal remote sensing [52.87, 88] or the urban heat island [52.89].

52.3 Theory

An important consideration before undertaking measurements in the urban environment is the basic measurement principle. Although new technology is constantly being developed, even the *latest* sensor poorly sited will not overcome fundamental issues in understanding. Related to this, a critical requirement prior to undertaking observations is a clear understanding of what is of interest. For example, observational needs will be different if the interest is in the urban effect on a process relative to the surrounding area or the variability of a process within a city. This section provides an overview of some of the key concepts in urban micrometeorology that are used to understand and interpret measurements.

52.3.1 Idealized Layers of the Atmosphere

The urban atmosphere is normally characterized by a series of vertical layers (Fig. 52.1). Understanding their characteristics and where they are likely to be located is fundamental to correct instrument deployment and interpretation of measurements.

The four layers extending from ground level into the atmosphere are (Chap. 1):

- *Urban canopy layer.* The urban canopy layer is the region between the buildings, trees, and vehicles from the ground up to the top of the roughness elements. In nonurban areas, this is equivalent to the air between the grass blades in the prairie environment, between the crops and the soil in farmland, between vines in a vineyard, or between the trees in an orchard. The urban canopy layer is where humans spend their day-to-day life, and thus, for the provision of many climate services, this is the layer of interest. The vertical extent of the urban canopy layer is becoming ever larger as buildings become taller. Across a city there may be neighborhoods where trees are the tallest elements and other areas where trees are dwarfed by buildings. In this layer, conditions are very variable. For example, the sunlit or shaded side of the street; building density, shape, and orientation to the prevailing wind; vents of buildings; and traffic and people moving through the area all combine to mean that sensors located anywhere in this 3-D space can be measuring different microclimates. Moving the sensors from one area to another means that different radiation, temperature, wind, and humidity environments are to be expected. Thus, to sample appropriately at this scale to get some sort of representative measurement, or to document the spatial variability, usually requires extensive sampling. Challenges may also arise because access to many areas is restricted (e.g., walkways, traffic routes), although the use of sensors mounted on vehicles or people means that some variables can be measured in otherwise inaccessible areas (Chap. 50, Sect. 52.2).
- *Roughness sublayer (RSL).* The roughness sublayer extends from the surface to above the roughness elements. The vertical extent depends on the packing of the roughness elements and the variability of their height. Generally, more dense areas with consistent heights (low standard deviation) will have a shallower RSL (in proportion to the mean height of the roughness elements) than areas where their packing density is lower or the variability in building (and tree) height is larger. A rule of thumb to estimate the height of the RSL is about two to five times the mean height of the roughness elements [52.90, 91]. The roughness sublayer defines the region within which the flow is affected by individual objects. The flow patterns are, therefore, highly complex and spatially heterogeneous. Thus, measurements in this region are still considered to be at the micro-scale and moving sensors a small distance will result in potentially large variations, as in the urban canopy layer.
- *Inertial sublayer or constant flux layer.* Above the roughness sublayer lies the inertial sublayer or constant flux layer. Here, the effects of individual roughness elements are no longer evident; the individual disturbances are averaged out. In the constant flux layer, the fluxes are approximately constant with height and do not vary dramatically in space. Thus, observations conducted within this layer are representative of larger areas, referred to as a local or neighborhood scale. If instruments at these heights are moved small distances, only small differences in the measurements should result. This is referred to as having one-dimensional (1-D) scaling. In nonurban areas, the equivalent measurements would be a few meters above an extensive grass surface or cropland. In the urban environment, a key challenge is to ensure that the sensors are high enough and there is sufficient fetch; i.e., an upwind area with consistent characteristics. The constant flux layer is typically the lowest 10% of the boundary layer.
- *Boundary layer.* Between the surface and the free atmosphere there is the dynamic boundary that grows and collapses daily in response to surface heating and regional and synoptic scale conditions. The urban boundary layer (UBL), as with boundary layers over other surfaces, tends to have convective growth during the daytime. Stable boundary layers may be less common in urban areas because of the large storage heat flux

release at night, enhanced sensible heat and anthropogenic heat fluxes. This may result in deeper nocturnal and daytime boundary layers than for surrounding land surfaces. Moreover, this urban effect may extend downwind for some distance aloft (Fig. 52.1b).

As urban areas have extensive emissions of pollutants, air quality is of significant concern for public health. Therefore, the dynamic nature of the UBL is important. Often, major air quality episodes are related to changes in UBL depth rather than changes in emissions, which have regular weekly and annual cycles. Thus, understanding how synoptic conditions modify city scale UBL depth, and hence air quality, is very important for citizens' wellbeing. Concern for urban air quality has led to behavioral changes (e.g., reducing vehicle use to lower emissions – in Paris [52.92] and Beijing [52.93]).

52.3.2 Scales of Measurement

It is critical that the scale of interest for an application is understood and is appropriate before deciding upon a suitable measurement technique and sensor siting. The distinct microclimates found within a city may exhibit larger differences than those between neighborhoods of similar types in different cities. For example, the central business districts (CBDs) of two European cities may be more similar to each other than, say, the CBD compared to an adjacent neighborhood with large mature trees in one city. The scale of interest influences the measurement technique, sensor location, number of sensors, sample rate, and measurement time, and depends on the physical processes involved (Fig. 52.2, Chap. 1).

In urban areas, there are three general scales that may be of interest:

- *Microscale.* At the microscale (< 10 m), urban areas are made up of different facets (e.g., walls, roofs, ground). Examples of microscale observations include the temperature differences between the sunlit and shaded sides of the same street or the flow distortion around a building. Thus, sensors installed within a street canyon will measure very different microscale environments if moved even a short distance horizontally and/or vertically. In order to characterize the microscale environment, the radiative properties, flow patterns, and thermal behavior need to be considered. There are various strategies that can be used to achieve this:
 - Locate the sensors at one point and carefully describe the site including potential factors that could influence the measurement.
 - Deploy many sensors to capture the spatial variability.
 - Use numerical modeling (e.g., computational fluid dynamics (CFDs), such as Reynolds-averaged Navier–Stokes (RANS), large eddy simulation (LES), or direct numerical simulation (DNS)) to inform where sensors should be located to investigate the process of interest. Numerical models can also be used to indicate how measurements might vary across the microscale [52.94] and to understand potential bias due to the location of sensors.
 - Use hardware modeling (e.g., wind tunnels, water tanks) to understand microscale variability [52.82, 95, 96].
- *Local or neighborhood scale.* Cities consist of areas with similar *repeated* characteristics, which, typically, were built at about the same time, with similar form (driven by architectural design or planning regulations) and materials. These neighborhoods (10^2 – 10^4 m), if sufficiently large, can create their own local-scale climates. Several distinct neighborhood types can be found within a city (e.g., old residential, new residential, low-rise commercial, large parks, etc.). Within each neighborhood, the urban form and characteristics should be similar. That is, building height, height-to-width ratio of the street canyons, land-cover fractions, age of vegetation, etc., should not vary much across the neighborhood. Local-scale measurements aim to provide representative measurements for the neighborhood (i.e., to capture the influence of this composite surface). It is, thus, critical to mount instruments high enough above the roughness elements to get an integrated response: measurements should be within the constant flux layer (Sect. 52.3.1). Flux measurements using eddy covariance are usually local-scale observations.
- *City scale.* At the city scale (0.5×10^4 – 10^5 m), measurements need to describe the integrated effect of the city as a whole.

In both hardware and numerical modeling there are some critical challenges and benefits. Challenges come from models assuming neutral atmospheric stability, but in urban areas this is less frequent than in other environments. In addition, models are by definition simplifications of reality and influential details may be missed or too expensive to include. However, both hardware and numerical models provide the capability to assess observations already made and/or inform measurement strategies for future campaigns.

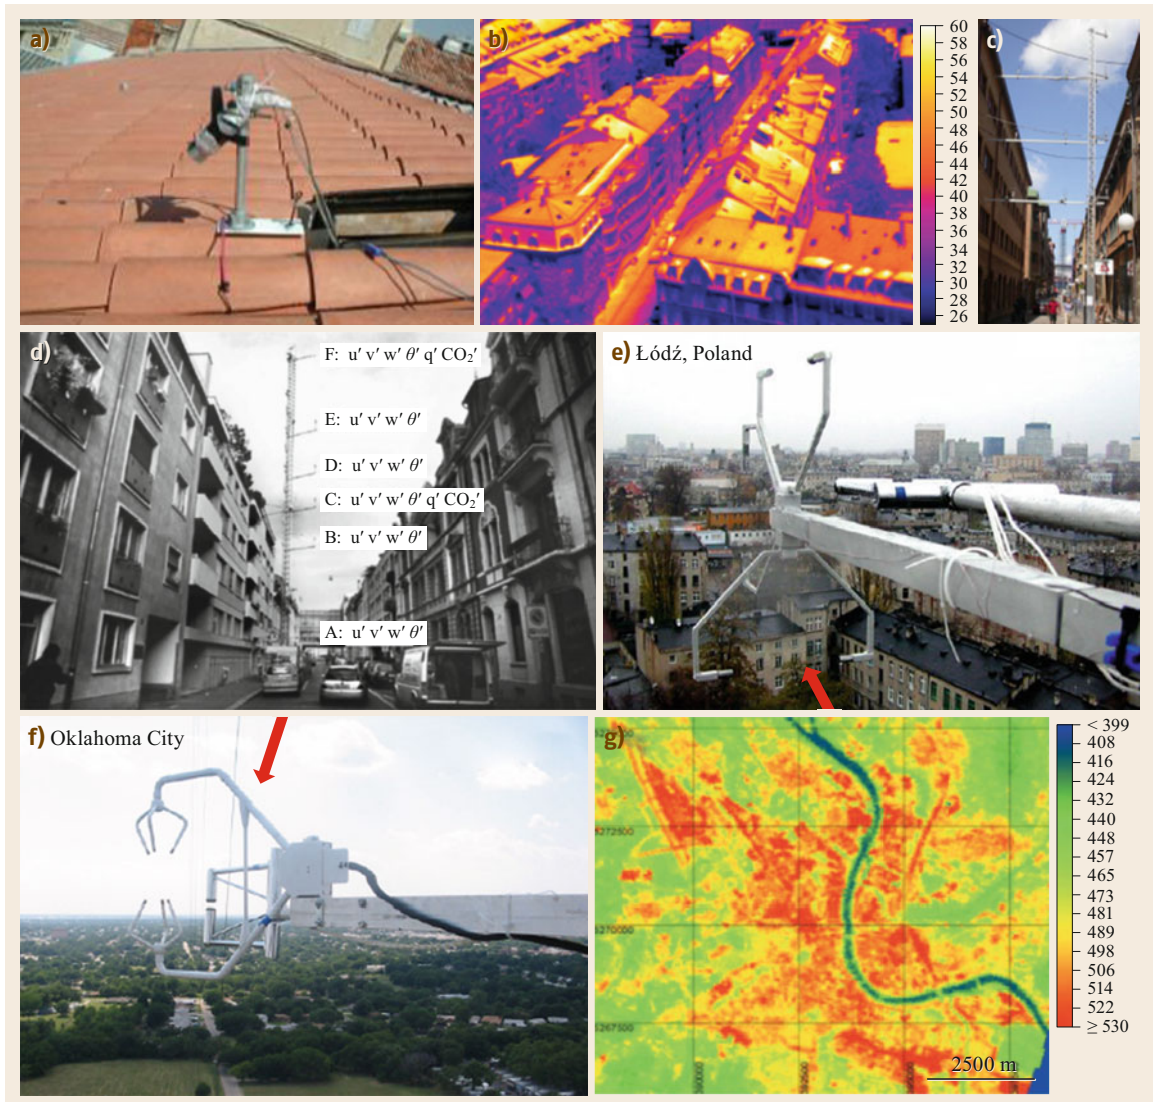

Fig. 52.2a–g Examples of urban measurements at various scales. (a) Microscale measurements of the temperature of a tiled roof surface in Marseilles. (b) Thermal image showing substantial microscale differences in surface temperature in an urban canyon and nearby courtyards in Basel (after [52.55] © American Meteorological Society, used with permission). The temperature variability reflects the variation in building materials, roof angle, and receipt of solar radiation. Eddy-covariance towers equipped with multiple measurement levels in (c) Gothenburg (after [52.97] with permission from Elsevier) and (d) Basel (after [52.98]) to study microscale flow patterns in street canyons and local-scale turbulence (top levels). Local-scale eddy-covariance measurements in (e) Łódź and (f) Oklahoma. (g) City-scale, longwave emissions from Basel (after [52.98]) derived from satellite data with calibration against surface measurements

52.3.3 Characterizing the Urban Environment

There are several parameters used to describe important characteristics of the urban environment (Table 52.1). There have been a number of efforts to provide basic parameters (e.g., [52.99]), to map areas with common

characteristics (e.g., [52.100]) and to provide tools to determine parameters (e.g., [52.24]).

- *Height*. The height of the roughness elements (i.e., buildings and trees) is a key parameter.
 - It is often used to estimate the depth of the roughness sublayer and, hence, to identify a suit-

- able height for neighborhood-scale measurements [52.90, 91], Sects. 52.3.1 and 52.3.2).
- It is one of the main controls on the aerodynamic roughness parameters.
- It is used to derive the *height-to-width* ratio of street canyons. This is related to the sky view factor and affects the radiation balance. In canyons with a large height-to-width ratio (H:W), radiation trapping can occur, reducing the outgoing longwave radiation and nocturnal cooling [52.101, 102]. The ratio is also used to classify flow at the microscale between skimming, wake, and isolated flow [52.90, 103]. These distinguish flow that skims across the tops of the buildings, penetrates the canyons generating turbulent wakes, or is affected by isolated buildings.
- *Aerodynamic roughness parameters.* There are many different methods to estimate roughness length (z_0) and zero plane displacement height (z_d) from information about the surface roughness elements [52.90, 104]; the simplest require only the mean height of the roughness elements, whilst others also take into account the height variability through the standard deviation of building height and maximum building height or consider the density of buildings through the plan area index or the frontal area index [52.104]. As well as these morphometric methods to estimate z_d and z_0 , there are anemometric methods that use wind speed data to

calculate z_d and z_0 from in-situ measurements. Unfortunately, there is considerable variation between the methods and no clear way to identify the *true* values [52.104]. Recent research appears to suggest that accounting for the variability in building height is important, with the consequence that the displacement height could be much higher than traditionally thought [52.104–106]. An accurate displacement height is important for applications that employ similarity scaling (e.g., comparison of results between sites, calculation of heat fluxes from scintillometry).

- *Plan area index.* The plan area index is the ground area of buildings relative to the total ground area of interest. This two-dimensional (2-D) description, along with other *surface cover fractions*, provides a way to broadly classify the surface composition. The fraction of vegetated area is an important control on energy partitioning and carbon dioxide fluxes and, therefore, can often explain differences in observed fluxes between neighborhoods [52.48, 107–109]. Surface cover fractions are a helpful metric for assessing how similar or different neighborhoods are, and, therefore, are useful for planning network sampling density across a city. Furthermore, surface cover fractions are extremely useful for making comparisons between studies and can even be used to predict typical fluxes for areas where measurements are not available [52.107, 110].

Table 52.1 Parameters used to describe the urban environment

Parameter	Description	Applications
Mean height of roughness elements	Mean building height Mean tree height	Wind profile Radiation modeling
Variability in height of roughness elements	Standard deviation of building/tree height	Wind profile
Maximum height of roughness elements	Maximum building/tree height	Wind profile
Aerodynamic roughness length	The height above the zero-plane displacement height that the mean wind speed becomes 0 m s^{-1} . This is based on extrapolation of the logarithmic wind speed profile towards the surface into the roughness sublayer	Wind profile Similarity scaling Dispersion Scintillometry Model input
Zero-plane displacement height	With tall roughness elements, the logarithmic wind profile is displaced vertically upwards. The displacement height is the mean height of the momentum sink	Wind profile Model input
H:W	Height to width ratio of street canyon	Sky view factor Flow regime
Surface cover fraction	Proportion of buildings, paved surfaces, grass, trees, water, and soil in the study area	Bowen ratio estimation Energy balance studies
LCZ	Local climate zones – neighborhoods with particular characteristics	Thermal regime UHI (urban heat island) studies Provides typical values for parameters, e.g., for model input

- *Frontal area index.* The frontal area index is the total surface area presented to the oncoming flow (i.e., walls) relative to the total ground area. The frontal area index varies with wind direction.

To describe, compare, and parameterize urban areas, the features of an urban canyon are often used. The urban canyon space can be complex, as it comprises a range of urban forms, from widely-spaced single-storey buildings, to row houses with long canyons and intersections, to tall building clusters. However,

the parameters in Table 52.1 provide a way to classify the urban environment in terms of a few key quantities. The benefits of such a classification are illustrated by the widespread usage of the local climate zones (LCZ); these describe typical regions of an urban area (e.g., compact mid-rise, sparsely built, heavy industry) and suggest reasonable ranges for these parameters [52.111]. The intent of the LCZ are to allow international comparison of observational sites so that a city and the rural area are better understood and measurements can be put into context.

52.4 Devices and Systems

There is nothing particularly distinct about measurement systems in urban areas per se. Rather, the critical needs are related to siting. Sampling frequencies used during deployments are dependent on sensor design and spatial scales of interest (Chap. 2). In general, new sensors are capable of increasingly rapid sampling, allowing, for example, vertical lidar (light detection and ranging, Chaps. 25 and 27) profiles with shorter gates and more rapid profile repetition. Data acquisition systems will determine how much raw data can be saved or realtime processing can occur (Chap. 2).

52.4.1 Temperature

Whilst it is relatively easy to measure air temperature (Chap. 7), obtaining a representative measurement for an urban area is much more challenging. Numerous studies have investigated the spatial variability in air temperature across a city using a variety of techniques; for example, installing a temperature sensor on a bike or car and traversing (Chap. 50) selected routes through the city [52.112]. The disadvantages of this approach are that it is noncontinuous and labor intensive (data are only generated when and where the traverses are made), and the measurements are not synchronized in time, so the traverses have to be short enough that any change in atmospheric conditions during the traverse is small compared to changes due to spatial variation. For such studies, it is important that the response time of the sensor is fast enough that the measurements correspond to the vehicle location at the specified time and not to the region through which the vehicle was passing several minutes previously.

Recently, crowdsourced data from amateur weather stations [52.7, 113] or mobile telephones [52.114] have been used to demonstrate spatial patterns in temperature. These sources offer a large amount of data but with many quality control issues, such as improper siting

or incorrect metadata. Nevertheless, efforts are being made to make this growing pool of data more useful to atmospheric scientists, for example the development of algorithms to exclude data from amateur weather stations that have likely been installed inside rather than outside buildings [52.115].

In some studies, however, it is the temperature of an internal building that is of interest. An example could be how the temperature inside a building (which is important for the thermal comfort of residents) responds to factors such as height above ground or window aspect in an apartment block [52.116]. Radiation shielding may be necessary, but otherwise small sensors strategically located allow spatial variations to be assessed. With increasing numbers of smart sensors, the sensor itself may play a key role in regulating the thermal environment (e.g., heating on/off, opening windows for natural ventilation).

Vertical profiles of temperature can provide very important data across a range of spatial scales, if there is sufficient resolution. The release of radiosondes is often restricted because of air traffic. Arranging permission for specified flight lines over a city for observations can be extremely difficult and subject to last minute changes. Sensors that are audible at frequencies that humans can hear (e.g., RASS: radio acoustic sounding system, sodar: sonic detection and ranging; Chap. 23) are not usable (i.e., there are too many complaints). Drones or unmanned aircraft systems (UAS) (Chap. 49) provide a platform to mount sensors that allows the 3-D characteristics of the air to be sampled. However, in many urban areas there are very stringent height restrictions because of aviation and privacy concerns. The limitations posed from other mobile traverse systems also apply. Sensors mounted on towers or other infrastructure provide a way to obtain vertical information but are obviously constrained by the height of the structure, and mounting possibilities for towers may be very lim-

ited. Furthermore, the structure itself will modify the flow, which may mean that booms need to be used to minimize the effect on the measurements. Microwave radiometer (Chap. 41) techniques have the potential to provide useful information at greater heights but may be of quite coarse resolution close to the surface. Thus, combining techniques for long-term sampling may be essential. Mobile platforms may provide a useful way to get detailed information close to the surface for short-term studies or intensive observations periods, providing that security permissions allow their use.

Surface temperatures of the urban facets (e.g., walls, roofs, roads) may be measured using noncontact thermal infrared (IRT) sensors (e.g., cameras, pyrgeometers, etc. [52.117–120]) or with fine wire thermocouples attached to a surface with a thin veneer on the surface material covering the sensors ([52.121], Chap. 11). The challenge with IRT sensors or longwave radiometers is that an emissivity is needed to convert the brightness temperature. Measuring emissivity is challenging, and there are only a few spectral libraries with values for urban materials [52.122]. Given the increasing potential of using satellite thermal remote sensing or earth observation [52.123, 124] the need to properly understand the surface heterogeneity (materials and morphology) and the thermal anisotropy requires more detailed observations [52.87, 120, 125, 126].

52.4.2 Humidity

Many studies of temperature also include humidity, and, therefore, the previous comments are also applicable. As errors in humidity measurements are larger at the extremes (Chap. 8), it is important to consider which conditions are of interest and what are acceptable measurement errors.

As the surface-based emissions of water vapor can be immense and variable, the variations in humidity in urban areas can be large. Natural controls include the amount of vegetation, which may be very spatially variable (e.g., very little in the central business district compared to highly vegetated parks), and the density of people and animals [52.127, 128]. In addition, urban infrastructure releases large amounts of moisture, including transport (from fuel combustion), building ventilation (e.g., mechanical vents, windows) and industry (from chimneys releasing water vapor as a byproduct). The implications are that there may be some locations where there are very high humidities for long periods of time. These locations need to be considered when siting instruments. These sources of humidity may be of interest, as they may be the cause of ice fog in high-latitude winters, where the air is regionally extremely dry because of the cold temper-

atures (Chap. 8) and, therefore, be important for road safety. Or they may represent microscale anomalies in a local-scale measurement (e.g., building vents on roofs or mechanical floors in high-rise buildings, Fig. 52.3), which, ideally, would be avoided [52.129].

In hot, humid environments under heat-wave conditions, life-threatening humidity levels may be reached (e.g., Chicago 1995 [52.131–133] and Indian cities [52.134]; Sect. 52.8.1), which require that sensors perform very well under challenging observational conditions (Chap. 8). As airports are highly impacted by fog, and small changes in topography and moisture sources can influence the location and density of fog, a dense network of sensors that perform well at high humidity may be warranted in addition to visibility sensors.

52.4.3 Wind

The type and location of wind sensors depends on the application (Chap. 9). Is it the mean wind speed and direction that are of interest, or rather the variability of the flow and intensity of turbulence? For microscale studies, such as the flow around a building, measurements are made close to the building and within the roughness sublayer. For local-scale studies, the measurements should be above the roughness sublayer, such that the wind field is not distorted by individual roughness elements but rather responds to the properties of the neighborhood. For measurements much higher than the roof level or over long distances, wind profiles can be derived from lidar measurements [52.135] (Chap. 27); a variety of outputs are available depending on the scan strategy and number of lidars available.

Extreme spatial variability and the impact of individual buildings and streets on the flow have been demonstrated in the few studies which deployed a vertical profile of sonic anemometers from within the street canyon to above the roughness sublayer (Fig. 52.4). For the lowest measurement levels, the observations suggest vortices within the street canyon; near the rooftops turbulence is greatest, and wakes may be induced by the edges of buildings; at a greater height above the rooftops the flow is less turbulent and less spatially variable. Given the financial and logistical challenges of making such observations, models have been used to extend such analyses, for example to analyze the role of height-to-width ratio, roof shape, or canyon orientation on the flow patterns [52.136]. Wind tunnel studies, either using idealized arrays [52.137] or replicas of real cities [52.138] have also proven to be very useful in probing spatial variability [52.82]. It has also been shown that vehicles can influence the flow, both due to their presence (i.e., their roughness) and motion (i.e.,

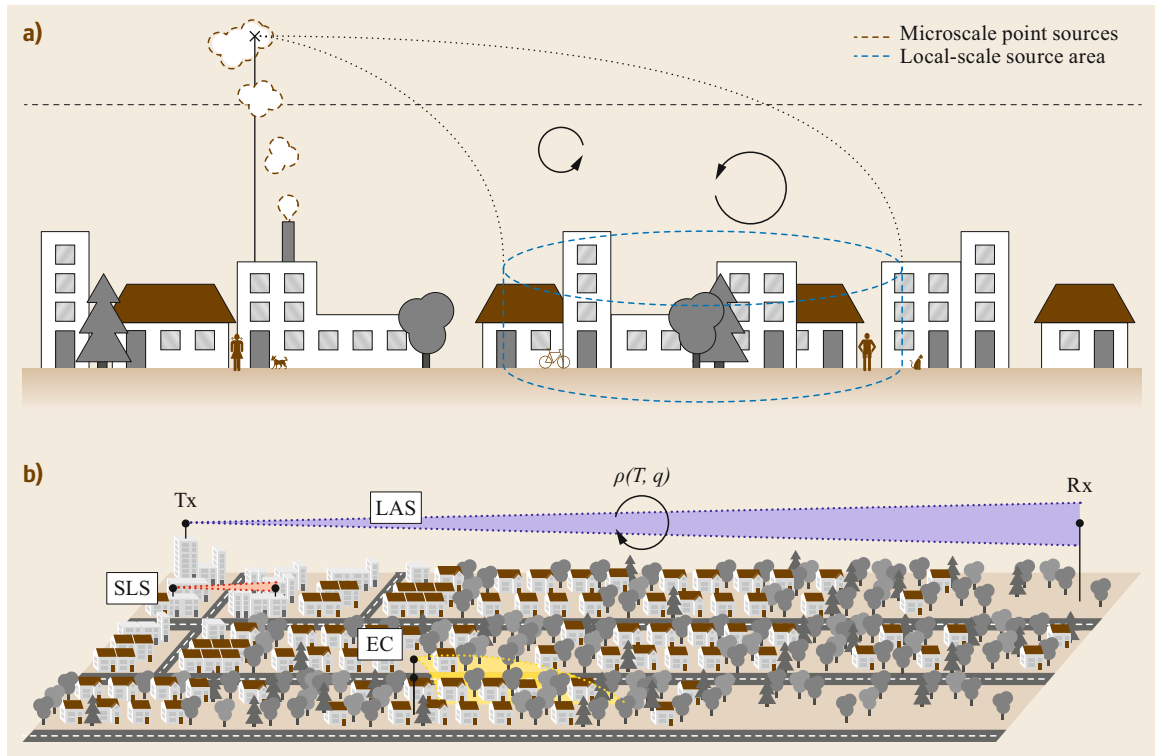

Fig. 52.3 (a) Eddy-covariance measurements (cross) of the local-scale source area influenced by a microscale point source. The *black dashed line* indicates the blending height or top of the roughness sublayer or the bottom of the constant flux (or inertial sub)layer (Chap. 1) (after [52.129] with permission from Elsevier). (b) Difference of source area extent (not to scale) between a large-aperture scintillometer (LAS, *blue violet*), a surface-layer scintillometer (SLS, *red*), and an eddy-covariance station (EC, *yellow*). For the scintillometer a beam is sent from the transmitter (Tx) to a receiver (Rx). The beam is scattered by turbulent eddies that have a density ρ at temperature T and humidity q (after [52.130] © IOP Publishing, reproduced with permission)

generation of wakes [52.57], which affects the transport and dispersion of pollutants in the street canyon.

52.4.4 Precipitation

Intense precipitation can have rapid and severe consequences for areas of cities or across the whole city. Intense rainstorms combined with large fractions of impervious surfaces (e.g., buildings, pavement) enhance runoff rates (in terms of both volume and timing) potentially causing flooding. Snow, hail, and freezing rain can make transport networks unusable or dangerous. Intense hailstorms can cause a lot of damage to infrastructure and vehicles. Intense convective precipitation, if associated with thunderstorms, also has the potential of electrical activity creating another hazard to both citizens and infrastructure.

As noted (Sect. 52.2), the measurement of precipitation processes in urban areas is notoriously difficult. The measurement of rain even in the most ideal setting (i.e.,

without large rough elements) is challenging (Chap. 12), and the problem is further complicated in the city. The sheltering effects of buildings, the impact of enhanced wind speed at roof level, and drip effects from vegetation all need to be considered. For example, driving rain causes the windward wall of buildings to be much wetter than the leeward wall. This may be of significant interest at the building scale but prevents meaningful measurements when detecting city-wide movement of a storm. Often, an extensive roof top (i.e., to minimize edge effects) with appropriate surroundings may be the best site for precipitation measurements in dense urban areas.

Radar data with increasing spatial resolution and the ability to dynamically change scan patterns with meteorological conditions (Chap. 32) likely provide the best neighborhood-scale information on precipitation events. The calibration in urban areas may be challenging, and the noise from tall buildings may require additional processing of data. However, with these systems, storm paths can be tracked across cities, allowing

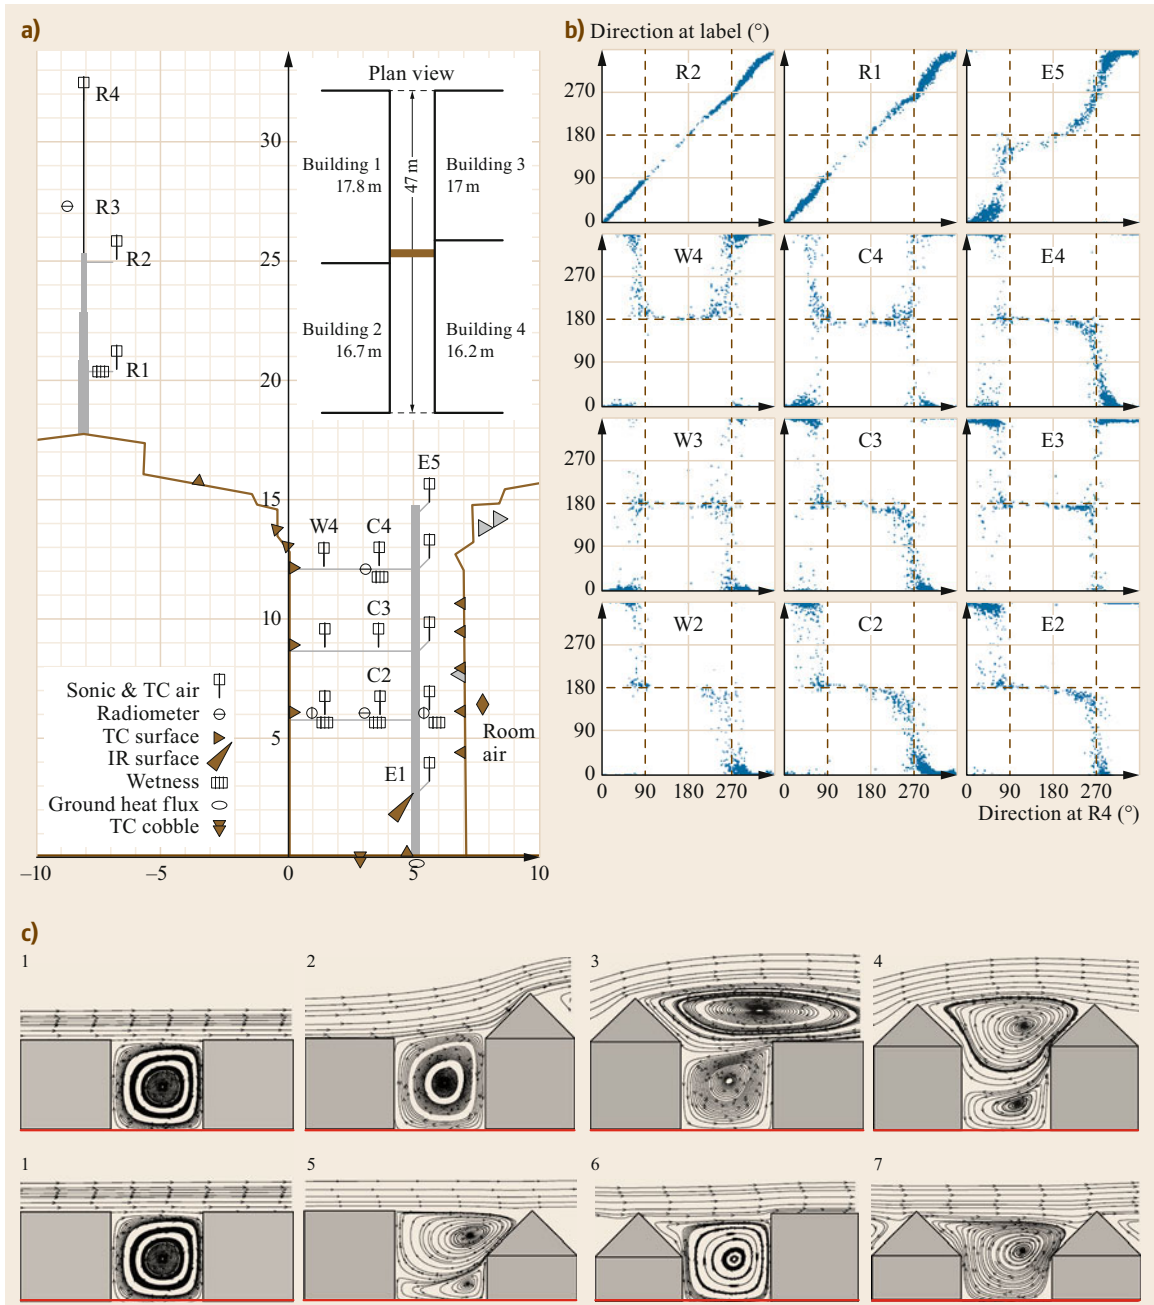

Fig. 52.4a-c Observations of wind direction with sonic anemometers (number and letter) in and above an urban canyon at 13 positions **(a)** shown relative to the highest sensor (R4). Conditions are when R4 has wind speeds $> 2 \text{ m s}^{-1}$ **(b)** (after [52.97] with permission from Elsevier). The influence of the surroundings becomes greater as the sensors move away from the highest sensor. Numerical simulations **(c)** show how roof shape and building height influence flow in the street canyon and the formation of vortices (after [52.136] with permission from Elsevier)

forecasts to be made of where the highest intensity precipitation is expected (Sect. 52.8.3).

There are various attributes of hydrometeors beyond ground-based rainfall that may be of interest. The drop-size distribution can be measured using a disdrom-

eter; a present weather detector (PWD) allows type and visibility to be observed, and automatic lidar and ceilometers (ALC) can detect the presence of raindrop size aerosols from large attenuated backscatter. The performance of different sensors has been compared generally (e.g., [52.139]). As the impact of hydrometers may be significant to transport operations and safety (e.g., fog to airports, intense precipitation to roads) these sensors are often located in the vicinity of this infrastructure.

52.4.5 Radiation

All four components of radiation (i.e., incoming and outgoing shortwave and longwave radiation) are affected by the urban environment. Incoming shortwave radiation can be reduced by polluted urban areas [52.140]. Outgoing shortwave radiation depends on the albedo of the surface, which is usually lower in urban areas than over vegetated surfaces (Chap. 11), but it of course depends on the urban materials used and thus varies between regions [52.122, 141, 142]. Incoming longwave radiation is affected by cloud cover and atmospheric transmissivity. Outgoing longwave radiation is generally larger in urban areas, because the surface temperatures tend to be higher than for vegetated areas, although radiation trapping can occur in street canyons, which restricts the outgoing flux. As always, the application determines the variables of interest and, hence, the type of sensor (pyranometer, pyrgeometer, four-component radiometer, or net radiometer), and how it should be deployed.

There are numerous applications related to radiation. These include determining the optimum position for solar panels to maximize solar energy receipt [52.143–145] or estimating the radiation load on pedestrians [52.146–148]. For the latter, a specialized setup may be used that involves mounting three four-component radiometers perpendicular to each other at 1.1 m above ground level to determine the 3-D radiation field [52.149].

Scale models (e.g., [52.82, 150–152]) have been built to allow for facet-scale radiative exchange processes to be measured. The models can be large (e.g., 1 : 4) if realistic variability of the facets is to be captured. For local-scale energy balance studies, the source area needs to be large enough to include a representative range of surfaces. The simple radiative footprint can be approximated using the height above the surface as 50% of the radius of the field of view [52.153], although large roughness elements and the presence of vertical surfaces make the calculation of the probable area more challenging.

A typical urban canyon will have multiple materials that are part of the walls (e.g., glass windows, painted wooden doors, brick and mortar walls), the road (e.g., concrete side walk, asphalt road with painted lines, vegetated median), and the roof (e.g., pitched with terracotta tiles). These facets are at a range of pitch angles and orientations, and their detailed arrangements all modify the radiative exchange. The impact of microscale variability on local-scale radiation measurements can be large in some situations [52.154]. By plotting outgoing shortwave radiation as a function of the azimuth angle, it is also possible to identify reflections from roof windows (Fig. 52.5).

To get a detailed understanding of which surfaces are being measured or to calculate representative surface temperatures, models such as DART (discrete anisotropic radiative transfer) [52.156] or TUF3-D (temperatures of facets in 3-D) [52.157] are very useful. Given the complexity of urban surfaces and the coarseness of thermal remote sensing these models provide a way to interpret the details of ground-based observations [52.126, 158] and consider how satellite-based sensors are biased (e.g., towards the surfaces seen, [52.87, 125]).

Spectral measurements of radiation (Chap. 11) are extremely useful for architects and others in construction industries interested in material characteristics and their interaction with both shortwave and longwave radiation at the microscale. Measurements in the shortwave region are reasonably straightforward and can be easily be conducted outdoors, as the sample sizes are large and, therefore, easily representative of the material (although measurements of glass and highly reflective coatings are more difficult). Measurements in the longwave region are more challenging, because it is necessary to account for longwave emission from all objects (Chap. 11; [52.122]).

52.4.6 Surface Energy Fluxes

The most widely used and most direct method to study the surface energy balance in urban (and nonurban) areas is eddy covariance (Chap. 55). Particular challenges in the urban environment are mostly related to siting (i.e., achieving sufficient measurement height in the constant flux layer and a reasonably homogeneous source area), although the size of fluxes (very low water vapor fluxes in city centers have large uncertainties) and appropriate quality control measures (Sect. 52.6) are also important considerations.

A sonic anemometer provides the momentum flux and the turbulent sensible heat flux. With a gas analyzer, latent heat fluxes and carbon dioxide fluxes can

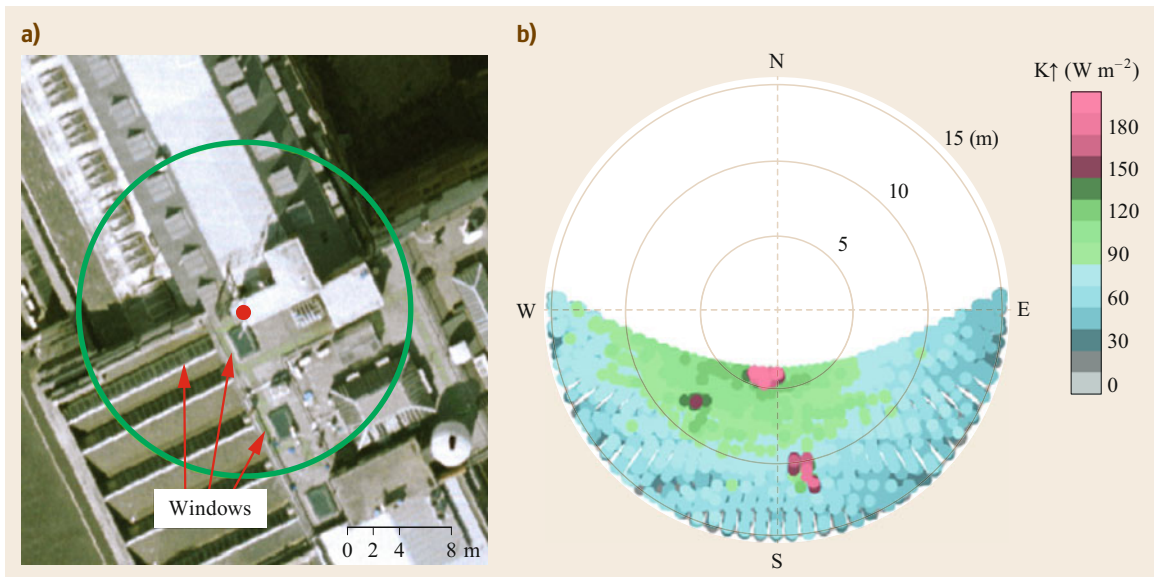

Fig. 52.5 (a) Aerial photo (NERC ARSF 2008) of the field of view of a downwards facing radiometer installed at King's College London (the *green line* indicates 80% of the source area) and (b) the observed median reflected shortwave radiation arranged by solar azimuth angle and distance of maximum specular reflection. Three windows clearly show up as peaks in the outgoing shortwave radiation (after [52.155])

be obtained (and more exotic species with more expensive equipment). For energy balance studies, a key issue is the compatibility of the turbulent flux footprint, which influences the sensible and latent heat flux measurements, and the radiometer footprint, which influences the net radiation measurements. Due to the very different measurement principles, these two footprints are not the same. Whilst the radiometer footprint is fixed in time (although influenced by diurnal and seasonal shadow patterns), the turbulent flux footprint varies with atmospheric conditions including wind direction, friction velocity, and stability (Chaps. 1 and 55). Differences in footprint (Chap. 1) composition can be estimated using footprint models [52.159–164] and minimized by siting the instruments such that the composition of their source areas is similar. Note, however, that footprint models were developed for much simpler environments, although they are widely used in urban areas to provide an indication of the region influencing the measurements.

Scintillometry (Chap. 34) can provide observations of sensible and latent heat flux [52.48, 49, 56, 130]. Scintillometry offers several advantages: a much larger source area than eddy covariance, meaning that the fluxes are representative of a larger area and, thus, often vary less with atmospheric conditions; robust statistics at shorter timescales allowing for shorter averaging times than are recommended for eddy covari-

ance; and minimal influence of turbulence distortion around the mounting structures at the ends of the path, which means that it can be easier to find suitable sites. However, there are also disadvantages: fluxes must be derived from structure parameters via similarity theory and so have large uncertainties due to the potentially questionable applicability of similarity theory and uncertainties in the input data (particularly z_0 and z_d) [52.52]; and sites must be obtained for both the transmitter and receiver with clear line-of-sight between.

It is worth considering what is expected from the observations given the site characteristics (e.g., land cover, climate), so that resources can be directed to where they are most useful. For example, a city-center site with very little vegetation or available water would be expected to partition very little energy into evaporation, and it may not be worth the effort to try to measure such small water vapor fluxes. On the other hand, if the study is specifically interested in the water balance, additional steps may need to be taken to try to improve the reliability of the water-vapor flux measurements.

In addition to net radiation, the sensible heat flux, and latent heat flux, the energy balance can include considerable contributions from the anthropogenic heat flux and storage heat flux, which cannot be directly measured (Sect. 52.1.2). Storage heat flux has been estimated by surface energy balance residuals or by

combining numerous sensors (e.g., surface infrared thermometers (Chap. 11), internal air temperature sensors, and soil heat flux plates (Chap. 49) etc. [52.25, 165]), but there are large uncertainties associated with these approaches. The anthropogenic heat flux has been estimated by the energy balance residual [52.166, 167] or by using eddy-covariance sensors to estimate releases from individual buildings [52.129]. Since the anthropogenic heat flux is associated with human activities, it is extremely variable in space and time. It is always an extra source of energy and impacts heat fluxes and the surface temperature [52.22, 23]. As well as an anthropogenic heat flux, there is also an anthropogenic moisture flux [52.168]. The importance of the anthropogenic heat flux, relative to other fluxes, varies by season and location. For example, in cold (high-latitude) climates, the flux can be much larger than the wintertime net all-wave radiation contributing to both the sensible heat flux but also to the latent heat flux. The anthropogenic heat flux is typically much larger in the central business district than in residential areas (e.g., almost three orders of magnitude [52.169]) because of the much higher population density, larger building volume, and associated energy demand. In hot climates, air conditioning becomes a more important source but constitutes a smaller percentage of the net all-wave radiation, as the shortwave radiation receipt is higher [52.23].

These considerations mainly concern the local-scale energy balance. At the microscale, the transport of air into and out of buildings is of interest, as processes within buildings influence the external environment. Concerning the construction industry, a critical issue in building design is ventilation. This can be natural (e.g., opening windows, cracks around doors) or mechanical (e.g., air conditioning, forced ventilation systems). The chosen location of ventilation inlets needs to consider air quality (e.g., proximity to vehicles or other building exhausts [52.170, 171]) and meteorological conditions (pressure, wind speed, and wind direction). Forced ventilation systems modify microscale conditions significantly (e.g., [52.129]) and can impact temperature, humidity, and air quality in the street canyon.

52.4.7 Boundary Layer Height

As noted (Sects. 52.1 and 52.3), the boundary layer height is of critical interest in urban areas because of air quality concerns. The air plume that extends downwind

of a city is also potentially of ecological interest or concern, as it is likely to carry warmer polluted air, which influences the surroundings (e.g., [52.172]), is entrained into the developing boundary layer associated with the new nonurban area, or is transported regionally or globally. Downwind urban effects are starting to be detected by satellite remote sensing, which needs to be calibrated by aircraft mounted and other sensors [52.173] (Chaps. 16–18, 25, 26, and 55).

A variety of different types of lidars (Chaps. 25–27, and 38) and aircraft sensors (e.g., AMDAR data; Sect. 52.1) can be used to infer properties of the urban boundary layer (e.g., mixing height (MH), mixed layer height (MLH)). However, the measurement technique is critical, depending on the boundary layer variable obtained (e.g., the height of the temperature inversion, MH with a threshold in vertical velocity variance measured with doppler lidar [52.79, 174], or MLH from aerosol concentrations from attenuated aerosol backscatter as measured by a lidar or ceilometer [52.75, 175]). Lidars allow continuous measurements with high temporal resolution, but few cities have this as an ongoing capability. Comparisons between lidar techniques also highlight the critical need to stratify conditions by cloud cover, as averaging across all conditions can apparently give contradictory results biased by synoptic frequency relative to sensor behavior [52.175]. Additional uncertainty between lidar sensor types arises from differences in gate size and range (Chaps. 25–27, and 38), where the first measurement is usable above ground level. For all techniques, analysis of the raw sensor data needs to be done with care. There is still minimal knowledge about the horizontal variability of MLH (or MH) with land cover beyond short-term campaigns, and appreciable measurement uncertainties require involved data processing.

Automatic lidar and ceilometer (ALC) measurement of cloud height and cover, and more recently, volcanic ash [52.176], can also be used to determine MLH characteristics [52.177–182]. A range of software is available for analysis of ALC data [52.183–188]. The ceilometer attenuated backscatter signal can provide high resolution (5 or 10 m vertically, 15 or 30 s samples) information on aerosols [52.189, 189, 190], and their use is being explored for data assimilation (Sect. 52.8.3). Doppler lidars [52.175, 191–193] and other research lidars and profilers have provided an extensive amount of knowledge from short campaigns (e.g., [52.194–199]).

52.5 Specifications

For sensors and their expected specifications, see the appropriate chapters throughout this volume (Chap. 1). Decisions about the appropriate or required instrument specifications are dependent on having a good understanding of the objective of the measurements, the acceptable measurement errors, and the expected spatial and temporal variability of processes or phenomena to be measured at the scale of interest. Other issues that must be factored in are the likelihood of theft or vandalism (i.e., cost versus benefit), and where the sensors can practically be installed. With current technologies, there is often a tradeoff between quality and quantity of instruments. Again, the appropriate choice is obviously dependent on the goal of the measurements. If quantity seems helpful, then it is always essential to incorporate some higher specification instruments to provide ongoing interinstrument performance assessments on a routine basis (e.g., by bringing sensors into a lab for

calibration, locating sensors near each other in the field, or using mobile transects).

When designing a network, it is important to consider which factors to keep constant between sites and which factors to vary. For example, a network of temperature sensors spread over a city with the aim of measuring the spatial variability between neighborhoods requires individual sensors to be installed in as similar a location as possible. If some sensors are in sunlit locations, and others in shaded ones, it is likely that direct insolation will largely determine the measurements, probably concealing any spatial variation due to neighborhood characteristics. It is useful to build in some redundancy to network design so that initial hypotheses based on a few sensors can be supported or rejected by additional measurements.

In almost all applications, there is an essential need for those designing meteorological sensor networks to

Fig. 52.6 Location of a weather station in St James' Park (red circle) London, which has much lower sky-view factor (SVF) (white) than the surrounding built-up areas. The streets are black (lower SVF) and the roofs white (higher SVF). SVF at 4 m-resolution modified (after [52.146])

work closely with the end users of the data to ensure that the most appropriate instrumentation and network design (e.g., spacing, configuration) are selected. For almost all urban measurements, standard WMO surface station design [52.200] is very likely to result in a station being located in an anomalous location rather than a typical urban setting (e.g., in London, St James’

Park location versus the surrounding urban landscape – Fig. 52.6). Therefore, careful consideration of the process and the scales of interest (Sect. 52.3) should guide the network or instrument deployment. Guidelines exist for urban surface stations [52.201] (Chap. 63), but these should be used as guidance and not as regulations in light of the need for the measurements.

52.6 Quality Control

When quality controlling data from urban environments, it is important to remember that methods designed for rural environments may not be applicable in urban areas. The simplest example is threshold checking, whereby data exceeding a specified threshold value are excluded on the basis that they are not physically reasonable. For vegetated mid-latitude environments, an upper threshold for the sensible heat flux of, say, 400 W m^{-2} may be appropriate, whereas this value may often be exceeded in an urban area subject to the same synoptic conditions. Thus, threshold values may need adjusting so that they are better suited to the urban area, in the same way as adjustments may be required for a site in a different climate zone. Given the strong influence of surface cover within a city and the resulting variability in meteorological conditions (Sect. 52.3.3), general values for a city are likely to be inappropriate and need to be developed with an understanding of the local and microscale conditions and the goal of measurements themselves.

For eddy covariance, several of the quality-control tests given in the literature are not particularly useful in urban areas. The low friction velocity screening to reject nighttime periods with low turbulence is not always applicable, since the rough urban surface tends to generate high friction velocities, and the urban atmosphere often remains unstable through the night [52.202]. Integral turbulence tests may also not be appropriate, since urban measurements may not follow ideal surface-layer scaling [52.203, 204]; even for nonurban locations, there is variation between the similarity relations identified at different sites. Energy balance closure is often used as an indicator of the reliability of the measurements (Chaps. 11 and 55). However, this cannot really be used in the urban environment, since the storage heat flux and the anthropogenic heat flux can be significant yet cannot be accurately directly determined. In most cases, the storage flux must be estimated as the residual of the energy balance (Sect. 52.1.2) and a degree of closure assumed.

Due to the heterogeneity of urban areas, measurements generally have greater variability (i.e., from one

measurement to the next) compared to more micro-meteorologically *ideal* sites. Some urban studies use longer averaging periods to produce more stable results, but there is always a compromise to be made with stationarity.

Depending on the site, additional quality control measures may be necessary. These can include removing spikes or troughs in radiation data caused by an isolated reflection or shadow, excluding data from certain wind sectors that may be unduly influenced by nearby structures, or minimizing the impact of microscale anthropogenic heat emissions on local-scale flux measurements. Procedures are available to filter out nearby microscale sources of waste heat, water, and carbon dioxide emissions from eddy-covariance measurements; when applied to the roof of a university building in London, this approach made it possible to simultaneously provide an estimate of the building-scale anthropogenic heat flux, as well as the local-scale fluxes [52.129].

Other methods to quantify the anthropogenic contribution to the observed dataset include comparing different time periods. Comparison of weekdays and weekends frequently reveals differences that can be related to patterns of human behavior (e.g., in the diurnal pattern of carbon dioxide fluxes related to traffic patterns and commuting to and from work [52.52, 205]). Similarly, the larger anthropogenic heat flux in winter resulting from increased building heating demand is often identifiable in comparisons of summer and winter data. For these methods to work successfully, it is important that datasets are long enough that there are no significant differences in weather patterns between weekdays and weekends that could explain the observed differences.

More focused studies have investigated the impact of a particular event, such as an irrigation ban [52.18, 206], driving restrictions [52.207], the Olympic Games [52.208], or the Burning-Man ephemeral city [52.209]. For these comparisons, it is crucial to consider any changes in background conditions (e.g., synoptic meteorology), as well as the change in human behavior.

Data collated from citizen weather stations require additional quality control, since there is limited knowledge of the station available (compared to stations installed and maintained by research groups), and

some stations may be inappropriately sited for the research question. These issues were briefly discussed in Sect. 52.4, and further details can be found elsewhere (e.g., [52.115])

52.7 Maintenance

Maintenance details for any specific instrument will be found in the relevant chapters elsewhere in this volume. Urban specific maintenance issues are most likely related to air pollution, which means that sensors become covered in aerosols (large and small) more rapidly than in more pristine environments and may require more frequent cleaning. Given the wide range of vegetation normally present in cities, biological contamination (e.g., leaves in rain gauges, pollen on radiation shields) may extend over longer time periods than in areas with less diversity in species where phenology changes occur over a short period.

In urban areas, sensors must often be mounted higher, either to make it difficult for the public to interfere with them or to be at sufficient height to make representative measurements. Hence, the equipment may be difficult to access, which complicates maintenance. For example, if cherry pickers are needed to access towers, this usually results in additional cost and/or the restriction of limited periods when such vehicles can park on roadways, therefore requiring out-of-hours maintenance. Maintenance of sensors mounted high above the ground may require people qualified to climb towers or access rooftops. Health, safety, and liability issues may mean the owners (or managers) of the infrastructure specify who can work on the infrastructure. This can necessitate both payment (or negotiated in-kind support) to access the installation and also the training of those who have access (e.g., riggers) to undertake the work that needs to be done.

Having instruments accessible over the internet, which is normally achievable in urban areas (due to

good mobile network coverage), allows for a large amount of diagnosis and repair to be undertaken without necessarily needing direct access to the instruments. Through careful setup, data can be delivered for routine systematic processing and errors that require attention flagged (e.g., automatic email messages sent to appropriate groups) and responded to rapidly. Preliminarily, data analysis can also be undertaken (e.g., fluxes calculated) for review on a regular basis.

During maintenance visits it is extremely helpful to always take photographs of sites. As urban areas change rapidly, knowing the time window when changes occur that might impact measurements is extremely helpful. Given that such changes occur at many times scales (e.g., reroofing, roadworks, new buildings), it is almost impossible to capture all of these. If understanding the chronology of such changes is important, then webcams can provide valuable data that also include information on other relevant human activities (e.g., traffic patterns, snow clearing).

Regularly noting relevant activities (e.g., outdoor irrigation, outdoor lighting) in a digitally searchable record can also help with data interpretation. Such records can help determine if a *real* phenomenon is being measured and the data should be kept, or if there is some sort of interference or contamination that justifies data removal, instrument maintenance, or resiting. With mobile phones it is possible for these data to be captured and emailed to team members or uploaded to a database in realtime to allow feedback or suggested remedies to be made while people are in the field.

52.8 Applications

As integrated urban weather, water, environment, and climate services are developed [52.9,210], the need for observations will become increasingly more clearly specified (Fig. 52.7). Today there is a wide range of reasons for needing observations in urban areas. This section provides examples of applications that require meteorological measurements in urban environments.

It is critical that the meteorological observation networks are designed in conjunction with an interdisciplinary team so that the meteorologist is aware of the critical thresholds that need to be measured well (e.g., absolute humidity thresholds), and so that those using the data are aware of how they may differ from previously used data (e.g., Sect. 52.8.2) for design and decision-making. For example, air-quality related ob-

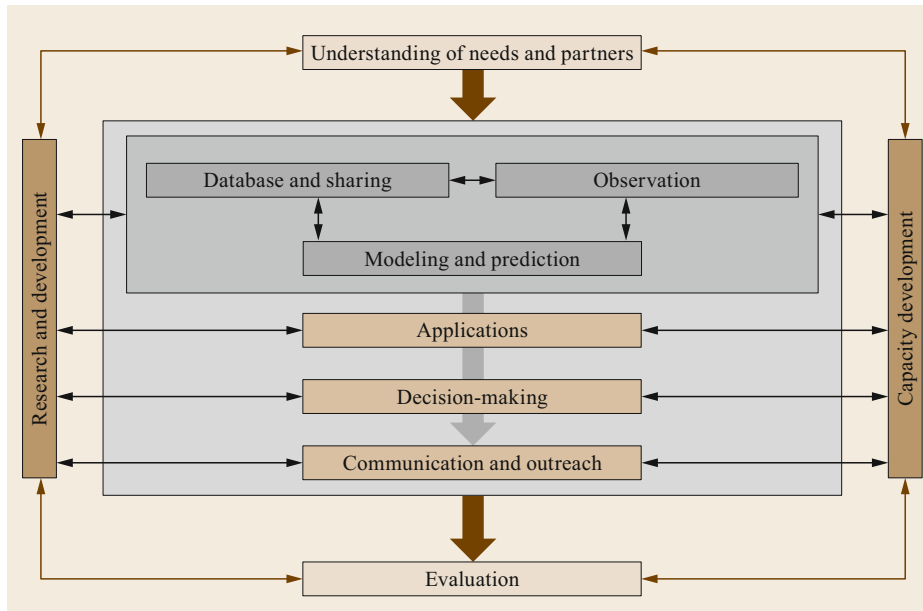

Fig. 52.7 Components of an urban integrated Hydro-Meteorological, Climate, and Environmental Service. Central to this are observations, closely linked to modeling and the communication in an appropriate manner to a wide range of end users who need information in an appropriate form for their decision-making processes (after [52.9, 210])

servations need collaboration between practitioners in a range of fields (e.g., transport planning, environmental meteorologists (i.e., measuring air-quality concentrations and fluxes), atmospheric chemistry researchers (e.g., trying to understand new chemical species and their reactions within the urban environments), public health planners, and physical meteorologists).

52.8.1 Human Comfort and Health

As extreme heat and cold cause premature deaths and hospital admissions of vulnerable people [52.148, 211], increasing efforts are being directed to the development of models to predict the areas within cities most at risk and to identify preventative measures. The evaluation of these models requires observations at ever higher spatial resolution. The conditions (e.g., temperature, humidity, radiation) in the areas where people are exposed (e.g., bedroom, workspace, metro, parks, courtyards) need to be known. As people adapt over time to their regional climate, it is insufficient to have an absolute value of, say, temperature. Rather, knowledge of the temperature distribution is needed so that a percentile-related metric [52.143] can be used. This requires long-term measurements to provide the city context.

Outdoors, people are exposed to a wide range of conditions that need to be forecast (with well-verified models) throughout the year: heat, humidity, ultraviolet radiation, wind chill, pollutants, etc. That is, the need for information about microscale variations in conditions is extensive. Critical limits vary with the

people exposed: school children, outdoor workers, elderly walkers, marathon runners, etc. In addition to forecasting the expected conditions, it is also critical for agencies to recommend mitigation strategies. These also need to be evaluated through a combination of careful measurements and modeling to ensure that interventions have the intended consequences. It should be remembered that resources may be limited for those at risk. Through careful design of observation campaigns to look at the local-scale and microscale variability of the pertinent meteorological variables *in conjunction with* socioeconomic data, public health experts and building designers can ensure that the available resources are most appropriately used, and support is directed to the most appropriate areas when an extreme condition is forecast.

Under conditions of high humidity combined with high temperatures [52.148, 212, 213], the body becomes unable to cool itself, which can be fatal. Thus, cities located in hot, humid climates need to ensure that the human comfort metrics also take humidity into account.

However, in many cities winter conditions can put increased stress on health services [52.214] with reduction in absolute humidity thought to be critical to allowing the influenza virus to spread more easily [52.215, 216]. Thus, awareness of spatial variability of hygrothermal conditions provides useful data for public health planning. With COVID-19, the importance of observations of ventilation patterns both indoors and outdoors, has become very apparent to help understand aerosol transport in urban areas.

As modeling becomes more sophisticated, identifying where people may be exposed to critical thresholds (both indoors and outdoors) allows for mitigation strategies to be developed. A comprehensive view of this hygrothermal environment is needed, which covers indoors (e.g., schools, hospitals, theaters), microscale (e.g., streets), local scale (e.g., across city neighborhood variability), and public transport (e.g., vehicles, stations). This requires standardized instrument siting, instrument calibration, sensor sampling and postprocessing, and rapid data transmission. These data also have important value for postevent evaluation of whole-system services.

In many cities, the residents are exposed to harmful air-quality concentrations [52.217]. With changing vehicle fleet characteristics, building materials and interiors fabrics, travel to work patterns (e.g., increasing number of cars in China [52.218], increasing number of bicycles in London [52.219]), the chemical nature of emissions is always changing. The need to measure these well for high spatial resolution emissions inventories (< 1 km) is critical for chemical transport modeling (CTM). With numerous new low-cost atmospheric chemistry sensors being developed ensuring that the data are appropriate still requires significant efforts [52.220, 221] and consideration of deployment strategies [52.222].

Chemical emissions tend to have regular patterns based on human activities (e.g., weekday, weekend travel patterns, daily cooking patterns [52.223]). However, with changing meteorology, the chemical reactions change (e.g., temperature, ultraviolet (UV), humidity) [52.224, 225], and with changing boundary layer depth the volume of air that they are being mixed in, and, therefore, the concentrations, change. Air-quality measurements are often microscale measurements (e.g., curb side) and, therefore, should be expected to vary significantly if sensors are moved (Sect. 52.3). As the emissions vary with socioeconomic context (e.g., where cooking occurs, what fuels are used [52.226, 227]), governance or regulatory environments (e.g., permitted concentrations, enforcement policies), and climatic settings, the critical meteorological thresholds may vary. With time, acceptable air-quality limits also change (e.g., London in the 1950s compared to now).

52.8.2 Building Design, Construction, Management, and Planning

The time scales that need to be considered for buildings and planning are long (from decades to centuries), which means structures and cities will experience meteorological extremes and should be built

to withstand these. On the other hand, the presence of new buildings or a development will impact its surroundings (e.g., wind flow, shadows, thermal environment), and this must be considered at the planning stage.

Although datasets exist to provide likely climate conditions (e.g., building design, typical meteorological year (TMY), design summer year (DSY), test reference year (TRY)), these are often regional (e.g., 14 for the UK CISBE (Chartered Institution of Building Services Engineers) [52.228]; ASHRAE (American Society of Heating, Refrigerating, and Air-Conditioning Engineers) for 8118 places globally [52.229]) and, therefore, extremely coarse relative to any building or subdivision development. During building design, decisions are made about lighting, ventilation, heating, cooling, etc. using these data. A growing awareness of building energy use and its consequences (e.g., greenhouse gas emissions) has encouraged low-energy alternative design-rating systems (e.g., BREEAM (building research establishment environmental assessment method) [52.230], LEED (leadership in energy and environmental design) [52.231]). Many local planning authorities use these as part of their decision process. As natural heating, ventilation, and cooling are encouraged, the local climatological conditions become increasingly important to ensure that these buildings work as intended.

The canopy layer (2 m air temperature) urban heat island under extreme conditions can be > 10°C warmer in the center of a city [52.5], but parks of varying size can significantly modify these temperatures. Thus, the design of buildings needs to consider the neighborhood and the microscale siting effects, otherwise the building (e.g., ventilation) will not operate as intended once built. This can lead to costly renovations (e.g., [52.232, 233]) and/or operating costs [52.234]. For example, if the buildings are too hot in summer, then the need for air conditioning in the future may result in additional energy use and have feedback on outdoor temperatures, making it necessary for others to also install air conditioning. Not taking the wind environment into account can be deadly and/or require expensive retrofitting [52.235]. If the building surroundings are not pleasant (e.g., too little or too much shading) then it may not be a desirable location (e.g., in terms of office rentals).

Thus, a good understanding of the microclimate setting is critical for design. Clearly, the constraint in real-world measurements is that the new structure does not exist, and once it does, it will modify the microscale climate (or a larger region). Models to *urbanize* meteorological data are being developed [52.143]. It is important that these be well evaluated with a wide range

of meteorological observations (including mean variables and their extremes).

Monitoring of postoccupancy buildings (both indoors and outdoors) provides more robust data for model verification. Understanding critical thresholds in building operations (e.g., what should trigger ventilation changes), how people are using the building (e.g., is this as designers intended or not), and how the building managers maintain and operate the building systems is important. There is an increasing tendency for building designers to be required to operate the building for some time after completion to ensure the stated efficiencies are achieved. With careful network design, indoor and outdoor building operations can be automated and allow for dynamic response to people's behavior and meteorological conditions. This can improve the efficiency of buildings from assuming fixed seasonal heating (e.g., on and off by date in a year) independent of users' needs (e.g., unseasonably hot or cold), which may also save money.

Green and blue infrastructure (e.g., trees, green roofs, water features) are generally encouraged [52.236, 237], but their success is dependent on having enough water for them to provide the intended benefits (e.g., cooling, water retention, flood prevention). Careful monitoring of the soil moisture status can help ensure that the irrigation (if needed) is sufficient to maintain vegetation without excess use (or wastage) of this resource. Irrigation (or hosepipe) bans are a common local policy to save water (e.g., [52.238–240]), which have other local climate impacts. To prevent peri-urban wildfires, there are occasions where intense irrigation is being considered (e.g., Melbourne). Thus, there is an increasing need to have a good network of soil moisture,

temperature, and wind sensors to assess how to provide benefits at the microscale and manage city-scale threats (e.g., water shortages, wildfires, heat waves, flooding).

52.8.3 Data Assimilation

Data assimilation to improve forecasting in urban areas is starting to be explored. Increasing locally generated energy (e.g., from solar (PV, photovoltaic) panels, wind turbines) requires high-resolution meteorological data (e.g., 1 min cloud cover or solar radiation data) for real-time energy forecasting and power grid management. Dense networks of solar panels can provide useful data as clouds pass over a large city (e.g., 50 km wide) – the early observations from the direction of the synoptic flow provides information that can be used to improve nowcasting (< 6 h) [52.145, 190].

Similarly, rain gauge networks and radar data can be important for providing improved realtime forecasting of flood hazards [52.241]. As the city topography and drainage network are constant over the lifetime of a storm (except in the most damaging of events), once the rainstorm track and intensity are known precalculated flood forecasts can be used to improve the spatial resolution of warnings and reduce the emergency response needs. Sensitivity testing with hydrological models can inform rain gauge network design and radar scanning patterns [52.242].

Ceilometer networks are also being explored to provide a source of data for data assimilation into numerical weather prediction [52.225, 226]. Vertical profiles of attenuated backscatter (Sect. 52.4.7) or other variables are likely to be useful, as they provide an integration across spatial scales (Sect. 52.3; [52.243]).

52.9 Future Developments

Urban areas are extremely complex and, despite progress made in recent years, major challenges remain. There is huge uncertainty in roughness length and displacement height values; the storage heat flux is a significant term in the energy balance but remains extremely difficult to quantify; and models and observations reveal that the flow below the constant flux layer is extremely difficult to characterize. Progress in other areas may be more easily achievable, such as better estimates of anthropogenic heat flux via more detailed information on building energy use and traffic volume. In this respect, greater availability of high-resolution data from energy companies and city authorities would be extremely beneficial. The issues of privacy and commercial sensitivities remain, but as smart cities bring

more and more data together, these difficulties may be overcome more effectively.

Use of big data is likely to develop further as an affordable method to capture spatial variability, particularly if data quality can be improved and uncertainties reduced. The demand for mapped data of various quantities (e.g., temperature, rainfall, air quality) over large areas suggests a greater focus on combining ground-based sensors with satellite-based remote-sensing instruments with numerical models. Unfortunately, satellite-retrieved datasets have been largely developed for nonurban regions and often struggle to give reasonable values in cities [52.87, 125]. Nevertheless, recent efforts to improve understanding [52.119] and accuracy in urban areas could lead to substantial

Table 52.2 Examples of applications of urban measurements

Application	Of interest to	Relevant scale	Relevant variables
Impact assessment for new buildings/roads/parks	Architects, construction industry, town planners	Micro – local	Wind, radiation
Wind load on buildings	Architects, construction industry	Micro	Wind
Optimal location for wind-energy generation	Energy companies, homeowners	Micro	Wind, turbulence
Optimal location for solar panel installation	Energy companies, homeowners	Micro	Radiation
Pedestrian thermal comfort	Town planners	Micro	Temperature, humidity, radiation, wind
Air quality alerts	Health agencies	Local – city	Wind, energy fluxes, boundary layer height

advances in the future [52.123]. Ground-based remote-sensing instrumentation, such as lidars, offer a wealth of information about the flow and turbulence above the city [52.135, 244–246]. Newly developed scan strategies or configurations with multiple lidars [52.247] are also promising in terms of increasing measurement capability.

With taller and taller buildings, established theory breaks down [52.248]. What happens when the roughness sublayer becomes so deep that there is no constant flux layer? Understanding the impacts of tall buildings (i.e., considering vertical as well as horizontal homo-

geneity) is logistically challenging but necessary for understanding the cities of today and correctly representing their effects in mesoscale models.

Over the last 30–40 years, the field of urban meteorology has grown considerably [52.249]. Today, we have a vast amount of data available to us and increasingly closer links with numerous applications (Table 52.2), which means science is being used more and more to influence planning and policy decisions. It is crucial, now more than ever, that urban measurements are conducted and interpreted correctly.

Sue Grimmond

Department of Meteorology
University of Reading
Reading, UK
c.s.grimmond@reading.ac.uk

Sue Grimmond, Professor of Urban Meteorology and Met Office Joint Chair, Department of Meteorology, University of Reading, UK, received her BSc(Hons) from the University of Otago (NZ), her MSc and PhD from the University of British Columbia (Canada). She was Assistant/Associate/Full Professor at Indiana University and Chair of Physical Geography at King's College London. Her research group undertakes measurement and modeling of urban–atmosphere exchanges across a wide range of scales.

Helen Ward

Department of Atmospheric and
Cryospheric Sciences
University of Innsbruck
Innsbruck, Austria
helen.ward@uibk.ac.at

Helen Ward studied physics at Oxford University and received her PhD in urban micrometeorology from King's College London (2013). She carried out postdoctoral research at the Centre for Ecology and Hydrology, Reading University and Yonsei University and is currently based at Innsbruck University, Austria. Her research focuses on improving understanding of turbulent exchange, particularly in complex environments (e.g., urban areas and mountainous terrain), through measurements (eddy covariance, scintillometry) and modeling.

Fog Deposition

53. Fog Deposition

Shih-Chieh Chang , Robert S. Schemenauer

Atmospheric water, in its liquid form, is deposited on surfaces mainly through wet deposition processes driven by gravity (rain, snow, or hail). However, at some locations, or during specific time periods, the dominant wet deposition process is the deposition of fog droplets.

Unlike the relatively simple methodology for quantifying precipitation deposition, the deposition rate of fog droplets depends on the properties of the surface as well as the micrometeorological conditions present, such as the wind speed, fog liquid–water content, and droplet size distribution. Therefore, there is no standard method or simple equipment that is universally applicable for measuring fog deposition rates under all conditions. The methodology for quantifying fog deposition in diverse ecosystems has been developed over many decades. One straightforward method is the direct quantification of the water mass that is captured by plant surfaces under foggy conditions. When rainfall, canopy interception, throughfall, and stemflow are measured simultaneously, the amount of fog water deposited can be quantified by simple algebraic calculations. The downward flux of fog water from the atmosphere to the canopy can be determined via the eddy–covariance method using 3–D sonic anemometers and fog droplet spectrometers. Under some atmospheric conditions, the deposition of fog droplets is predominantly driven by gravitation, so the deposition of fog water can be calculated using droplet size classes and the respective deposition velocities. In this chapter, these methods are reviewed and the operational processes are summarized.

Fog droplet diameters range from 1 to 40 μm , with the droplet size distribution varying considerably depending on the type of fog and meteorological conditions present. A typical mean volume diameter would be 10 μm . A droplet of this size has a terminal velocity of $\approx 0.3 \text{ cm s}^{-1}$. This is much smaller than typical windspeeds near the

surface, so the resulting fog flux is nearly horizontal and parallel to the surface. For this reason, fog flux measurements and fog water collectors are often made with specially constructed vertical surfaces. These and additional measurement techniques and instrumentation will be discussed in this chapter.

The atmosphere is a source of important nutrients (e.g., nitrogen) as well as fresh water for terrestrial ecosystems. Therefore, atmospheric deposition processes determine the form and viability of life on land. For most of the land area on Earth, a good understanding of the atmospheric water input can be gained by determining the level of precipitation (rain and snow) deposition. However, fog deposition plays an important or even a key

role in the atmospheric water input at some locations on Earth. Atmospheric water deposition also includes the condensation of water vapor on surfaces (i.e., the formation of dew, and the conversion of water vapor into frost when the temperature is below freezing). Although all of these deposition pathways can contribute significantly to the total atmospheric water deposition, we only consider fog deposition in this chapter.

53.1 Measurement Principles and Parameters

Fog droplets are much smaller than raindrops. This makes the fog deposition process different from rainfall. In this section, the properties of fog droplets will be highlighted, and the major principles and parameters for quantifying fog deposition will be introduced.

53.1.1 Basic Physical and Chemical Properties of Fog

Fog is composed of liquid water droplets (although fog also exists as ice particles in some extremely cold environments) with diameters ranging from 1 to 40 μm . The fog droplet size range varies with the type of fog considered. Radiation fog typically has droplets that are < 10 μm in diameter. Many advection fogs have droplets that are up to 25 μm in diameter and have a mean volume diameter of $\approx 10 \mu\text{m}$. The largest droplet sizes are obtained when convective clouds move over the terrain or when the terrain is immersed in deep stratus clouds. Except for the larger particles in the droplet size spectrum, most droplets are too light to have significant settling velocities. Fog droplets therefore move with horizontal, vertical, and turbulent air movements. When the windblown fog droplets collide with an obstacle, they are removed from the air. Unlike the precipitation deposition process, which is driven by gravity, the rate of fog deposition is dependent on droplet size, the characteristics of the collecting surface, and the wind speed. The fog deposition rate is significantly affected by the arrangement and surface properties of obstacles. About 200 years ago, during hydrologic studies performed in Britain, it was observed that more water came from hilly areas than could be accounted for by precipitation alone. This led to speculation that there was another water deposition process in play, which was sometimes called *occult* deposition [53.1]. Also, because fog droplets generally move horizontally with the wind and may, for example, be collected by the line of trees at the edge of a forest, fog deposition is sometimes called *horizontal deposition*.

Depending on its relative contribution to the total atmospheric water deposition, fog deposition can be negligible for ecosystems that receive ample precipitation or can be the most important water source for entire ecosystems in dry regions. A famous example of a fog-water-fed ecosystem is Fray Jorge, a coastal forest ecosystem in north-central Chile, where the annual precipitation is only $\approx 150 \text{ mm}$. The windward edges of the forest patches receive extra water from fog, which is sufficient to support the growth of trees in this semi-arid region [53.2, 3]. In general, it is not just the fog deposition itself that increases the water available to ecosystems in foggy conditions. Fog-induced reductions in solar radiation, air temperature, and vapor pressure deficit all weaken the driving force for evapotranspiration and thus indirectly increase the available water in the soil. A comprehensive review of the contribution of fog deposition to ecosystem water budgets has been written by *Bruijnzeel et al.* [53.4].

As with precipitation, fog deposits chemical components onto the recipient surfaces. The relative importance of precipitation compared to fog deposition at a particular site depends on the amount of water received by each mechanism, the chemical compositions of the rain, snow, and fog, and the vulnerabilities of the recipient surfaces to vertical and horizontal water inputs. Using size-fractionating fog water collectors, it has been shown that the chemical concentrations in smaller fog droplets are higher than those in larger ones, which are also higher than those in rainwater [53.5]. While the nutrients in fog water may have a positive effect on the recipient ecosystems, the H^+ ions and other pollutants in the fog water may be harmful [53.6]. Acidic fog has received considerable attention since the 1960s as air pollution has become increasingly problematic in heavily industrialized regions. In the 1980s, forest dieback on hills and mountains in Europe and in eastern North America that are frequently covered in fog generated considerable concern [53.7, 8].

Table 53.1 Measured and calculated fog deposition parameters

Parameter	Unit	Description
Fog deposition rate	mm yr ⁻¹	Annual fog water input from the atmosphere to the ground surface Any other unit of time may also be employed
Nutrient/pollutant deposition due to fog	kg ha ⁻¹ yr ⁻¹	Atmospheric deposition of nutrients, pollutants, or other materials in fog water Any other units of time and area may also be employed
Fog interception rate	g H ₂ O m ⁻² h ⁻¹ or L m ⁻² d ⁻¹	Amount of fog intercepted per unit surface area of the intercepting objects and unit time

Table 53.2 Other relevant parameters for fog deposition measurements

Parameter	Unit	Description
Surface area	m ²	The cross-sectional surface area of the fog-intercepting object
Surface area index (SAI)	m ² m ⁻²	The total surface area per unit ground surface
Visibility	m	Horizontal visibility measured by optical sensors
Liquid water content	g m ⁻³	Mass of fog liquid water in a specified volume of air
Fog droplet distribution	–	Size spectrum of fog droplets
Wind speed	m s ⁻¹	Horizontal wind speed measured on top of the canopy and where the fog flux (interception) measurements are made
Wind direction	°	Horizontal wind direction measured on top of the canopy

53.1.2 Measured Parameters

Fog deposition is a form of atmospheric water deposition, so it is generally expressed as a water depth (in mm) on the ground surface per unit time—the same unit used for precipitation measurements (Table 53.1). Fog deposition expressed in this way allows direct assessment of the contribution of fog deposition to the total atmospheric water deposition. The contribution of fog deposition can be ignored for most lowland areas, where fog occurrence is a rare event or the fog occurs as radiation fog with little or no wind present. However, substantial fog deposition rates are observed in elevated areas covered with orographic fog or fog produced by the advection of clouds over the terrain. It can also be substantial in coastal regions, where the advection of low stratus cloud forms fog when it touches the ground on coastal hills and mountains. For example, the annual fog deposition measured in a high-elevation *Erica arborea* forest in Portugal [53.9] was stated to be 4170 mm yr⁻¹, or ≈ 160% of the annual precipitation.

Airborne fog droplets must first be intercepted by obstacles, such as vegetation components (leaves and twigs), before they have the chance to reach the ground surface. Therefore, the fog interception rate, often expressed as the amount of fog water captured by a unit surface area of the obstacle during a certain period of time (e.g., g H₂O m⁻² h⁻¹), is the parameter that can be experimentally quantified. This parameter is also used for some artificial materials of interest, for example to understand the fog collection efficiency of mesh (Sect. 53.8; [53.10]). The determination of the fog de-

position rate requires knowledge of three parameters: the free stream fog flux, the fog droplet collection efficiency of the vegetation or material, and the surface area index (SAI), which is the total surface area of a fog-capturing obstacle that will produce water for one square meter of ground surface (Table 53.2). Although large uncertainties arise from the heterogeneous distribution pattern of the canopy components and the variations in wind speed and fog droplet distribution in the 3-D canopy space, an approximate value for the fog deposition rate can be obtained via

$$\begin{aligned} \text{Fog deposition rate} \\ &= \text{free stream fog flux} \\ &\quad \times \text{efficiency of collecting surface} \times \text{SAI}, \quad (53.1) \end{aligned}$$

where the fog deposition rate is the fog water input on the ground (g H₂O m⁻² h⁻¹) under specific atmospheric conditions, as calculated from the fog interception rate (g H₂O m⁻² h⁻¹) of the obstacle, which is the product of the measured free-stream fog flux and the measured or estimated efficiency of the collecting surface under the specific atmospheric conditions present. This is multiplied in turn by the SAI, which is the surface area index (m² m⁻²) of a collecting object such as a tree. Here, the relevant atmospheric conditions are mainly the wind speed, the fog liquid-water content, and the fog droplet size distribution. However, it is important to note that there are considerable uncertainties associated with translating the collection of a horizontal flux of fog water on a vertical 3-D surface into a depth of water on a horizontal 2-D ground surface.

When the chemical composition of fog water has been determined, the atmospheric deposition of the chemical compounds in fog can be calculated by simply multiplying the fog deposition rate by the concentration of the specific chemical compound.

53.1.3 Measurement Principles

Unlike most atmospheric parameters for which measurement principles and techniques have been studied extensively and equipment has been developed and commercialized, there is currently no standard method for the quantification of fog deposition. For the fog droplets in the airstream to be effectively intercepted, the surface of the ground requires some vertical components such as aboveground stems, twigs, and leaves. These parts are referred to below as the *intercepting surfaces*. Table 53.3 provides a summary of the measurement principles of fog deposition for different types of ground cover.

- *Direct measurement of the deposited water mass or volume.* The direct quantification of water deposited on an intercepting surface is the most straightforward method of ascertaining the amount of fog water that has been deposited. A report of measurements of the fog water collected by a bundle of reeds placed over the top of a rain gauge on Table Mountain in Cape Town, South Africa was published as far back as 1905 [53.17]. The uncomplicated theoretical basis for this method means that the fog deposition rate is determined by simply measuring the volume of water collected or the weight gain of the object during a certain time interval under foggy conditions. The calculated intercepting-surface-based deposition rate must then be converted to the ground-surface-based deposition rate using a carefully derived scaling factor, such as that derived from measurements of dew on vegetation [53.18]. The cross-sectional area of the tree or other natural obstacle is important when determining the amount of fog water that will be collected. *Schemenauer* and *Cereceda* [53.19] reviewed the literature and found that the vertical cross-section of a tree collects fog water at a rate of $\approx 10 \text{ L m}^{-2} \text{ d}^{-1}$ during fog events. This led to a depth of water on the ground under the trees of $1\text{--}5 \text{ cm d}^{-1}$. If the weight changes of the ground surface and the intercepting surface or the volumes of water received by those surfaces can both be measured, additional information on the fog deposition rate for a specific time interval can be extracted. Complicating factors include the retention of water in the structure of the vegetation and the possibility of fog deposition from both wind-driven impaction on the surface and the sedimentation of fog droplets directly on the surface of the ground. Care must also be taken to account for any wind-driven drizzle or raindrops that may form part of the collected water [53.20].
- *Surrogate method.* To understand the potential for fog deposition at a certain location, an artificial object mimicking the surface properties of vegetation can be placed in the field. The volume of water collected or the weight gain of the object under foggy conditions can be recorded, and a deposition rate can then be calculated. This method allows a comparison of the fog deposition potentials at different locations. However, it is not realistic to build different fog collectors for every type of vegetation to be investigated, for fogs with different droplet sizes, or for different wind speed ranges. To overcome this problem, the Standard Fog Collector (SFC) was developed [53.13]. This is an easy-to-replicate 1 m^2 fog collector made of an inexpensive Raschel mesh that is effective at collecting wind-blown fog droplets [53.21]. It collects 50–60% of the free-stream fog water arriving at the surface of the mesh, and has been used in over 40 countries to date. However, the construction and utilization of many different types of fog collectors by different investigators led to an inability to quantitatively compare different sets of measurements. This issue remains a challenge to this day. A range of different types of fog-collecting materials and structures are reviewed in [53.13]. Any fog collector will collect only a fraction of the fog water arriving at its surface. This is because the wind that brings the fog droplets must pass through the collector, taking some of the fog droplets with it. Field measurements of the collection efficiency at the surface of the Raschel mesh have been performed [53.21]. A cylindrical fog collector that uses teflon strings was developed [53.22] and has been used in various slightly modified forms to sample fog water for chemical analysis. Its collection efficiency has been directly compared to the SFC under limited conditions [53.13]. In the 1950s and 1960s, a fog collector consisting of a small vertical cylinder made of metal mesh was in use [53.23]. Another cylindrical fog collector utilized a louvered metal screen [53.24]. It was developed in Hawaii and is still used in some locations today. These are all examples of *passive fog collectors*, where the wind provides the energy to impact the fog droplets on the collection surface. A variety of *active fog collectors* (e.g., that of *Daube* et al. [53.25]) that utilize a fan powered by electricity to draw in outside air

Table 53.3 Summary of fog deposition measurement principles for different land cover types and different site conditions

Method	Land cover type	Intercepting surface	Parameters	Conversion factor	Device	Procedure in brief	Limitations	References
Direct measurement of collected water mass or volume	Short vegetation	Whole vegetation including soil surface	Fog deposition, both wind-driven and through sedimentation	–	Precision balance, instruments to measure meteorological and soil conditions	Monitoring the mass and seepage of water from an isolated soil pit, including vegetation	Weight loss due to evaporation and transpiration may bias the estimation; formation of dew needs to be monitored	[53.11]
Direct measurement of collected water mass or volume	Forest	Canopy components, e.g., needles, leaves	Fog interception rate, fog droplet sizes, fog flux	SAI (m ² m ⁻²)	Precision balance/lysimeter, rain gauges for fog drip, material for stemflow, device to determine SAI	Measure the weight increase of samples when fog is present, measure all water removed and stored by vegetation	Large uncertainty in upscaling, representativeness of canopy components sampled	[53.12]
Surrogate method	Open area	Artificial fog-collecting material, e.g., mesh, 3-D rigid mesh, filaments	Fog collection efficiency; horizontal fog flux	SAI (m ² m ⁻²)	Rain gauge at ground level; fog collector with recording device	Record fog flux in L m ⁻² d ⁻¹ ; verify the presence or absence of rain and drizzle using the rain gauge	The measurement represents only the potential deposition rate depending on the similarity of the artificial material and the vegetation	[53.13, 14]
Water budget method	Forest	Whole canopy or canopy top	Throughfall (fog drip), stemflow, fog flux at canopy top, precipitation	Cross-sectional area of exposed trees at canopy top	Gauges for rain, throughfall (fog drip), and stemflow; fog collectors at canopy top	Monitoring the components of the canopy water budget allows the fog water input to be calculated	Water storage in canopy is subject to estimation errors; forest may be nonuniform in nature; complex terrain affects wind flow	[53.15]
Eddy-covariance method	Any homogeneous and low-slope surface	–	Vertical flux of fog droplets	–	3-D sonic anemometer, fog droplet spectrometer	Instruments installed on a flux tower continuously measure the vertical transport of fog droplets due to turbulence in the air above the canopy top	Generally limited by the terrain conditions for the eddy-covariance method; demanding in terms of power and maintenance; not well suited to radiation fog due to low turbulence	[53.16]

and move it past the collection fibers or mesh have also been developed. These designs typically have a downward-facing opening and minimize the entry of drizzle or raindrops. The amount of sample collected is normally fairly small but sufficient for chemical analysis. When designing the collector, it is important to consider whether the fog droplets collected will be representative of those present under free-stream conditions.

- **Water budget method.** If the surface of interest is tall vegetation, the principle of water balance can be applied to derive the fog deposition component. The vegetation canopy exposed to the wind flow (canopy top) is the main area of fog deposition. The atmospheric water deposition—the sum of the precipitation and fog deposition—will equal the liquid water outflow due to throughfall and stemflow and the temporary storage in the canopy (53.4) [53.4]. Therefore, to calculate the input fog deposition, it is necessary to quantify the other four water budget terms in the equation. *Schemenauer* and *Cereceda* [53.26] gave an example of two intertwined olive trees in southern Oman that dripped an average of 860 L d⁻¹ into a 5 m diameter cement reservoir during one 79 d fog season and 580 L d⁻¹ in a second 83 d fog season. In this case, all of the throughfall derived from the fog deposition, which represented an average of 4 and 3 cm H₂O d⁻¹ on the reservoir base during the fog seasons at that location.
- **Eddy-covariance method.** The turbulent transport of fog droplets can be quantified by applying the eddy-

covariance method, which has been widely used to measure CO₂/H₂O fluxes between ecosystems and the atmosphere. The instruments needed for this purpose are a fast-response fog droplet spectrometer and a 3-D sonic anemometer mounted on a measurement tower downwind of the targeted surface. A detailed description of the theory and application of the eddy-covariance method can be found in Chap. 55. For more on the specific application of the eddy-covariance method to fog deposition estimation, readers may refer to [53.16, 27, 28].

- **Isotope method.** Stable isotopes of H and O have been used to infer the contributions of fog water to soil water, stream water, and plant water use. The analytic techniques employed are beyond the scope of this chapter. The basic concept is that fog has been found to have higher concentrations of the heavier isotopes ²H and ¹⁸O than rain due to differences in formation temperature and air mass history. Isotopic signatures in soil and surface water, as well as in tree sap, can be compared to standard values, and the differences can be used to estimate the relative proportions of fog water and rainwater sources. Readers interested in this method can refer to [53.16, 29–31]. This methodology has been used for decades [53.32] but is not in widespread use. Sampling protocols need to be well defined and carefully followed. This method is especially useful in locations where other information indicates that fog may contribute substantially to the groundwater.

53.2 History

A number of extensive reviews of the collection and use of fog have been written [53.1, 33, 34]. Comments on fog go back to biblical and Roman times. *Gilbert White* (1720–1793), a naturalist in England, observed that vegetation collected substantial amounts of fog water [53.35]. Records of fog deposition in the early literature were mostly limited to qualitative descriptions, rather than quantitative measurements. For example, in 1917, *William S. Cooper* (1884–1978) published his observations regarding the distribution of redwood (*Sequoia sempervirens*) in a coastal area of California (USA), and noted that there was a higher soil water content under the redwood canopy, possibly due to the contribution of fog water that had dripped from the canopy to the soil [53.36]. He also noticed that the redwood only occurred in locations where fog was a frequent occurrence. The shape of redwood needles may help them to intercept fog droplets in the airstream [53.37]. In

1905, *Rudolf Marloth* (1855–1931) published possibly one of the first scientific articles on fog deposition rate estimation [53.17]. During some dry summer months (December 1902 to February 1903) in South Africa, he installed two rain gauges on top of Table Mountain, where the vegetation is much more abundant than the short bushes seen in the lowland and hill areas. As noted earlier, the top of one of the gauges was fitted with a bunch of reeds to intercept fog water. The difference in deposition between the modified and unmodified gauges was very large—it corresponded to the deposition of an extra 190 mm of water within 56 days. However, this difference is not an accurate reflection of the additional contribution of fog water, since the reeds would also have collected wind-blown drizzle and rain, so there would have been a far higher input of drizzle and rain into the gauge with the reeds than into the unmodified rain gauge [53.20]. This is a common mea-

surement error in many measurements of fog collection rates.

Ever since it was first applied at the beginning of the twentieth century, this two rain-gauge system has been widely used to evaluate the amount of fog deposition. Therefore, in locations where fog, drizzle, and rain are all present during the measurement period, the utilization of this gauge system has resulted in significant errors in reported values of the ratio of fog deposition to precipitation deposition due to factors such as ignoring the contribution of wind-blown precipitation and the placement of the unmodified rain gauge above ground level, where the catch may be influenced (reduced) by strong winds. In addition, the conversion of the amount of fog water collected by the modified rain gauge to a depth of water on the ground is often problematic; indeed, the process used to perform this conversion is frequently not explained. These factors make it difficult to draw quantitative conclusions from many of the studies that have used this two rain-gauge system. That said, the importance of fog deposition, especially in upland areas, has been clearly demonstrated. In 1968, *Hubert W. Vogelmann* (1928–2013) and coworkers installed this system along an elevation gradient that increased from 540 to 1080 m ASL in Vermont (USA), and demonstrated a clear corresponding elevation gradient in fog deposition rate [53.38]. The same measurement technique was used on the Hoher Sonnblick, a mountain in Austria, and the fog deposition rate was found to decrease with distance from the ocean [53.39]. Similar observations of the variation in fog deposition along a slope were made along an elevation gradient from 16 to 2425 m in Mexico [53.40] and another gradient from 300 to 900 m in Chile (where measurements were also taken at several points along the crest of a ridge line) [53.41]. Both the altitude and the characteristics of the terrain were found to be important influences on the fog deposition rate. As the altitude increased, the soil became more acidic due to increasing fog interception by the forest canopy [53.42].

Fog may be seen on hills in arid coastal locations due to the onshore advection of marine cloud decks that are too thin to form precipitation. Such conditions occur on the coasts of Chile, Peru, California, the Sultanate of Oman, and Namibia, for example. In these arid regions, or during a dry season when rainfall is minimal, normal rain gauges positioned below vegetation have been used to estimate the deposition of fog water on the ground. For example, a study of normal rain gauges installed beneath different tree species in coastal Californian hills during dry summer months showed that the water collected was only fog water that dripped from the tree crown [53.43]. The tree species, the exposure of the individual tree, as well as the topography of the

site determined the amount of fog intercepted and thus the fog deposition rate.

Starting in the 1960s, when it became apparent that the atmospheric deposition of pollutants/nutrients was a serious problem in industrialized countries, ecosystem nutrient cycling has been monitored using the vegetation canopy as the domain for budget calculations. The nutrient input to the canopy via wet (precipitation and fog) and dry (particulates and gases) deposition is balanced by the output: throughfall, stemflow, and the canopy interaction. The term *occult deposition*—a deposition process other than precipitation and dry deposition—has been used to denote water and chemical deposition by fog/cloud droplets onto canopy surfaces. The fog deposition can be estimated when other terms of the budget equation are known or negligible [53.15]. The water budget principle has proven useful at the watershed scale. During a period without rainfall, the streamflow may peak sometime after the occurrence of fog. The water depth on the ground contributed by fog can be inferred [53.44].

Instead of placing fog-collecting materials on top of rain gauges, an artificial tree has been used to intercept fog water, and the collection efficiency of this artificial tree has been compared with those of a real tree and a passive string fog collector [53.14]. The collection efficiencies of these three collectors, while different, were highly correlated. This confirmed the applicability of artificial fog collectors to the estimation of fog deposition; however, the coefficient for the conversion from the collector to the fog deposition rate on vegetation needs to be carefully deduced.

In a recent study, a water budget method for determining fog deposition in a blanket bog ecosystem was developed [53.45]. An undisturbed peat monolith was isolated, and its change in weight due to the difference between the precipitation and fog deposition (input) and the evaporation (output) was measured regularly. The precipitation was recorded using a normal rain gauge, and the evaporation was calculated using the Bowen ratio/energy balance method. Unlike the other methods mentioned previously, this calculated fog deposition rate represented the *real* net fog deposition rate, especially when there was no rain during the measurement period (≈ 12 h in this case).

In remote mountainous regions where conventional water resources are limited, techniques for the collection of fog water for domestic use have been developed [53.26, 33, 34]. Evaluating the horizontal fog flux using small portable instruments permits the selection of appropriate locations for large fog collectors and allows the amount of water that might be collected to be predicted [53.13]. The largest fog collection project ever undertaken was on a coastal mountain in Chile, El

Fig. 53.1 A portion of the array of large fog collectors used in the El Tofo project in Chile during the late 1980s and 1990s (photo © Robert S. Schemenauer 2020; all rights reserved)

Tofo, where water from 100 large fog collectors, each with a surface area of 48 m^2 , was taken through a 7 km pipeline to the coastal village of Chungungo [53.26] (Fig. 53.1). The average daily water production was $3 \text{ L m}^{-2} \text{ d}^{-1}$, giving a total average production of almost 15000 L d^{-1} when the water generated by the project was at its maximum. The project ran for 10 years. The peak daily production from fog water collection exceeded 100000 L on some days. Websites main-

tained by nonprofit organizations provide descriptions of many past fog collection projects as well as access to proceedings from a series of eight conferences on Fog, Fog Collection, and Dew that began in 1998 [53.46, 47].

With the development of fog deposition models, a new gateway for studying fog deposition has been opened [53.48]. The application of simulation models has become popular, and the on-site measurement of dripping fog water by gauges can be used to verify these models, enabling them to be improved so that they are more accurate when applied at larger spatial and temporal scales [53.49]. At the watershed scale, where fog frequently occurs, the incorporation of fog deposition into a hydrological model has greatly improved the simulation of streamflow [53.50]. For sites where direct measurements are not feasible, models can be a useful alternative way to estimate fog deposition, although some basic meteorological parameter values and surface measurements are still needed before the models can be applied and verified.

The application of fog deposition models to areas beyond small forest plots remains a major challenge, particularly when moving away from flat domains to complex mountainous terrain [53.51]. A detailed discussion of the methodology and limitations of fog deposition models is beyond the scope of this chapter but can be found in the literature [53.52].

53.3 Theory

In this section, the theories behind the fog deposition measurement methods discussed in Sect. 53.1.3 are explained in detail. Except for the eddy-covariance method and the isotope method, the methods of quantifying fog deposition are based simply on the law of mass conservation.

53.3.1 Direct Quantification of the Deposited Water Mass

The most straightforward way of determining how much fog water is deposited onto a specific surface may be to directly measure the weight change of the object. There are two kinds of natural intercepting surfaces for which different direct measurement approaches can be used. The first kind of intercepting surface is the forest canopy. A direct measurement taken on the canopy must then be converted to the ground-surface-based fog water flux. The second kind of intercepting surface is short vegetation, for which there are fewer technical difficulties when performing a *real* direct measurement of the fog deposition rate. A measurable subset of the

ground surface (soil and vegetation) can be separated from its surroundings, and its change in total weight due to fog deposition can be measured.

In both cases, a precision balance is needed to weigh the intercepting surface plus the deposited fog water. The maximal load of the balance and the required balance precision (usually 0.1 g) should be determined in advance according to the object to be measured. If continuous recording is preferred, the balance should have a serial output port that allows values to be sent to a storage device (either a datalogger or a computer).

To mimic the real fog deposition process, the measurement system should be placed at the location within the original vegetation from which the leaves/small vegetation were taken.

For forested ecosystems, the canopy is the main place to receive atmospheric deposition, including wet, dry, and fog deposition. The leaves/needles in the forest canopy have a much larger total surface area overall than the twigs and branches, which partly explains why they are the main intercepting surface for fog droplets. Another reason is that the leaves or needles make up the

outer layer of a tree, and it is this layer that is primarily exposed to the wind carrying the fog droplets. The air that penetrates beyond the outer structure of the tree will have been stripped of many of the fog droplets, and the wind speed will have been reduced. Both of these factors will result in lower fog deposition in the internal structure of a tree or other vegetation.

To conduct the measurement, sample leaves are taken from the canopy and placed at the same position to intercept fog droplets under foggy conditions. The weight of the leaves, including any water dripping from the leaves, can be repeatedly determined by a precision balance. The fog interception rate (FIR) of the intercepting surface, in units of $\text{g H}_2\text{O m}^{-2} \text{h}^{-1}$, can be calculated when the surface area of the sample leaves is determined afterwards. The FIR applies to the leaves at that specific location. Factors such as wind speed and fog liquid water content that determine the FIR normally decrease downwards from the canopy top. The FIR might need to be determined at different depths from the top of the canopy.

Subsequently, the FIR is converted to the fog water deposition rate at the ground surface using the leaf area index (LAI) via

$$\begin{aligned} \text{Fog deposition rate (mm h}^{-1}\text{)} \\ &= \text{FIR (g m}^{-2} \text{h}^{-1}\text{)} \times \text{LAI (m}^2 \text{m}^{-2}\text{)} \\ &\quad \times 10^{-3} \text{ (mm m}^2 \text{g}^{-1}\text{)}, \end{aligned} \quad (53.2)$$

where $10^{-3} \text{ (mm m}^2 \text{g}^{-1}\text{)}$ is the factor needed to convert the water flux from mass units to length units. If the vertical gradient of the FIR is considered, the vertical distribution of the leaf area index must be determined accordingly. From a practical perspective, the canopy can be divided into n layers, and the overall fog deposition rate can then be determined using

$$\text{Fog deposition rate} = \sum_{i=1}^n \text{FIR}_i \times \text{LAI}_i \times 10^{-3}. \quad (53.3)$$

Chang et al. [53.12] estimated the fog deposited in a *Chamaecyparis obtusa* var. *formosana* forest by this method. The fog deposition rate calculated from a single measurement event indicated that the FIR was higher at higher positions in the canopy, indicating that a multilayer approach is necessary for forest canopies. However, this one-time in situ exposure experiment only provided the fog deposition rate under the specific micrometeorological conditions of the experiment. Chang et al. also performed the experiments under a range of visibility conditions and used the results to

build an empirical model of fog deposition in which the fog deposition rate was a function of visibility. Using that model and the visibility monitoring data obtained at that site, the annual fog deposition rate was estimated to be 328 mm yr^{-1} .

53.3.2 Estimation Using Surrogates

Microscale, mesoscale, and macroscale factors influence real-world fog deposition rates. The fog deposition rate is greatly influenced by the arrangement, density, and surface characteristics of the intercepting surface. Short of bringing the actual vegetation into a wind tunnel, a surrogate fog-collecting material will never be identical to real vegetation. Whether a wind tunnel is employed with droplet spray devices or computer models are used to simulate the wind flow around surrogate structures, there will always be compromises that have to be made. Despite these difficulties, artificial intercepting surfaces have been shown to have comparable collecting efficiencies to real vegetation in some conditions [53.13]. For instance, Joslin, Mueller, and Wolfe [53.14] used a passive fog collector, an artificial tree, and a live spruce tree to collect fog and observed good correlations between the collection efficiencies of these intercepting surfaces.

An alternative approach is to directly measure the free-stream flux of fog water and then use this flux as an input to estimate fog water deposition on various surfaces, including natural vegetation and artificial fog collectors. The fog water flux can be determined from measurements of wind speed and fog liquid-water content (LWC) in open terrain or at the canopy top. In practice, this is only viable for experiments where personnel are available at the site and the research has considerable funding. An alternative is to use a passive (no energy required) fog collector made of a material that is effective at collecting fog droplets. This provides a direct measurement of the fog flux at the location of the collector.

In recent years, there have been claims in the literature that the *collection efficiency* can be improved by changing the surface characteristics of the fibers in fog collectors; in some cases, the claims are that the efficiency can be greatly enhanced. The collection efficiency of a fiber increases with decreasing fiber width, increasing droplet velocity, and increasing droplet size. It is the aerodynamics that determines whether a fog droplet with a typical diameter of $1\text{--}20 \mu\text{m}$ will be collected by a fiber $\approx 1 \text{ mm}$ wide. The droplet has no knowledge of what the surface characteristics of the fiber are until after it is collected. This means that nanoscale changes to the hydrophobic or hydrophilic characteristics of the fiber or other minute modifica-

tions to the fiber surface will not change the collection efficiency. The collection efficiency is the fraction of the fog droplets that approach the surface that actually strike it. The second important consideration is whether they stay attached to the surface. This factor is termed the coalescence efficiency (coalescence is discussed in cloud physics textbooks [53.53]). It is effectively 1 (100%) for these conditions, i.e., 10 μm diameter fog droplets that strike a 1 mm wide fiber will remain attached. This means that changing the surface characteristics can at best change the drainage of water in a fog collector; however, in practical terms, this is not an issue, as was shown in field studies that used artificial fog collectors in Chile [53.54]. A large fog collector with a mesh panel that is 4 m high and 10 m long will begin to drain water within $\approx 30\text{--}45$ min and then continue to drain water from the mesh as long as fog and wind are present.

53.3.3 Inference from a Canopy Water Budget

The fog deposition rate on the surface of the ground is most often inferred from the canopy water budget of a forest ecosystem [53.55]. The spatial scale at which this method is applied is a forest stand. Assuming that the forest canopy is the system of interest, precipitation (P) is the main input flux of water for most forest ecosystems. For forests with frequent fog immersion, fog deposition (FG) is another input pathway for water into the canopy. Water leaves the canopy by dripping to the forest floor as throughfall (TF), by flowing downwards along the surfaces of branches and stems as stemflow (SF) (Fig. 53.2), or by interception and subsequent evaporation. The water budget of the canopy is a simple mass balance equation,

$$P + FG = TF + SF + IL, \quad (53.4)$$

where IL is the interception loss, representing the amount of water that has been stored on the surfaces of leaves and twigs that later evaporates and exits the system (i.e., the canopy). Absorption of water by plant tissue may also occur in some plant species, but this is typically a small component of the IL. Due to the time lags associated with the movements of deposited water in the canopy space, a practical temporal scale for mass balance measurements would be no shorter than a whole day. Thus, the deposition rates for these water balance terms can be given in mm d^{-1} or mm yr^{-1} .

A detailed description of precipitation measurement can be found in Chap. 12. Here, we present the general principles of precipitation measurement. Precipitation can be measured using a simple funnel and bottle system for manual measurement (Fig. 53.2), or automatic rain gauges that record the rain intensity with high temporal resolution. A typical automatic instrument is the tipping bucket rain gauge, with a resolution of 0.1–0.5 mm, depending on the collecting area and the capacity of the tipping bucket. To estimate the precipitation input to the forest canopy, the rain gauges are usually installed in a nearby clearing. The installation of the gauges must follow defined guidelines, mainly to prevent the distortion of air flow by obstacles near the gauges.

In mountainous regions, it is very difficult to determine the amount of rainfall that would reach the ground surface using only standard rain gauges mounted 1 or 1.5 m AGL. This has long been recognized [53.56], and specialized conferences on hydrology in mountainous regions have addressed this problem. The terrain plays a large role in influencing the amount of rainfall reaching the ground surface, and there are significant differences between windward and leeward slopes. One modification to rainfall measurements is to place the rain gauge below ground level, with the opening of the rain gauge angled to be parallel to the surface of the

Fig. 53.2 Fog deposition rate quantification via the canopy water balance; note that FG can be calculated once IL has been estimated

ground [53.57]. There is also the possibility of using remote-sensing technologies such as radar to measure precipitation above the forest canopy and then use this as an input to large sites or regions.

Throughfall (water dripping from the vegetation to the forest floor) in forest ecosystems can be monitored with the same type of rain gauge as used to monitor precipitation. These throughfall gauges are placed beneath the canopy on the forest floor (Fig. 53.2). The distribution of leaves and twigs (and thus the gaps) in a forest canopy will influence the throughfall distribution at a small scale. The distribution pattern at a larger scale depends on the spatial distribution of individual trees and the wind both above and within the canopy. Therefore, the amount of throughfall may have large spatial variations. To get a reliable mean value for the throughfall beneath a heterogeneous canopy structure, throughfall gauges with a sufficient number of replicates are needed. An alternative way of collecting throughfall is to increase the collecting surface area of the gauge [53.58]. Trough-type gauges with long troughs and large-capacity tipping bucket gauges are flexible in terms of construction and setup, making them ideal for use in cloud forests [53.59]. In all cases, a protocol must be established to assess whether there are enough throughfall gauges to be able to estimate the errors and uncertainties in the measurements [53.60].

The estimation of stemflow (water flowing down the trunk of a tree) demands more effort than measurements of precipitation and throughfall. A detailed review of stemflow has been given by *Levia and Germer* [53.61]. The stem of a tree is referred to as a trunk. The water flowing down the trunk needs to be conducted to a large gauge. A spiral conduit fixed around the trunk can serve this function [53.62] (Fig. 53.2). To convert the water volumes collected by single trees to the stand-scale water flux, a certain number of sample trees must be selected for stemflow collection. For a natural forest composed of many different tree species, a quadrat of certain size will be selected and all trees within that quadrat will be used for stemflow collection. The total water volume (in L) divided by the ground area of the quadrat (in m²) will give the stemflow as a depth of water expressed in mm. On the contrary, if a plantation with a single dominant tree species is studied, a couple of sample trees with different diameters at breast height (DBHs) can be selected from the stand and used to collect the stemflow. A correlation equation predicting the stemflow volume as a function of DBH can then be created, which in turn allows the stemflow volumes generated by all of the trees within the stand to be calculated from the DBH values of the trees. Finally, the stand-scale stemflow can be calculated using the same

procedure as that used for the natural forest. There are, however, complicating factors. For instance, the relationship may well vary depending on the precipitation rate, fog deposition rate, and ratio of the rainfall input to the fog input. A range of input intensities must be examined. Light precipitation or fog events, which can reduce incoming radiation, evaporation, and evapotranspiration, may result in little or no stemflow.

When the three components P, TF, and SF have been quantified, an estimate for IL is needed to solve for FG using (53.4). To get this, the general form of canopy water balance (53.4) is modified such that the interception loss IL is replaced by the interception capacity (IC), yielding

$$P + FG = TF + SF + IC \quad (53.5)$$

Here, IC represents the maximum amount of water stored on the surface of the canopy; i.e., IC is a constant that is specific to each forest canopy. It is assumed that TF and SF only occur when the canopy storage is saturated and any further input of water from the atmosphere starts to produce detectable TF and SF. The constant IC can be derived from (53.5) by selecting some sampling periods during which there is no fog but sufficient P, TF, and SF. Finally, the FG can then be calculated for any sampling period with fog.

It will be apparent that there are large uncertainties in the measurements and in the models used to apply the measurements to the entire forest plot under consideration. The resulting expected error in the final results will also be large and should always be kept in mind. This means that if the goal is to use the water fluxes P, TF, and SF to calculate FG by (53.5), then the calculated FG value will necessarily have considerable uncertainty. When the values are reported, the number of significant figures should reflect the expected error in the measurements.

53.3.4 Eddy-Covariance Method

A detailed description of the eddy-covariance methodology is given in Chap. 55. The part of this method that is specific to the measurement of fog deposition is given in this section.

The eddy-covariance method can be used to determine the vertical turbulent transport of any scalar (e.g., momentum, gases, particles) that can be measured very frequently, typically at a rate of 10 Hz. To measure the vertical turbulent fog droplet flux, a 3-D sonic anemometer and a fog droplet spectrometer are needed to measure the vertical wind speed (w) and the fog droplet concentrations (C) for various droplet size

Fig. 53.3 Eddy-covariance system for measuring the fog deposition rate at the Chi-Lan Mountain site in northern Taiwan (photo © Shih-Chieh Chang 2020; all rights reserved)

classes [53.28] (Fig. 53.3). Due to the cubic relationship between droplet diameter and droplet volume, smaller size classes are better for quantifying the LWCs of the respective size classes. The flux of droplets within a specific size class can be calculated as

$$F_{\text{drop}} = \overline{w' C'}$$

Here, w' and C' are the turbulent fluctuations of the vertical wind speed and the fog droplet concentration for a specific size class, respectively. The turbulent fluctuations are calculated by subtracting the mean w and C during the averaging period (typically 30 min) from the time series of w and C . The overbar denotes the mean of the averaging period for which the turbulent flux is calculated. The droplet flux in each size class is converted to the LWC flux and then integrated across all droplet sizes to yield the total water volume flux.

53.4 Devices and Systems

Table 53.3 gives a summary of the devices and systems that are used for the different methods of quantifying fog deposition. In this section, common laboratory devices such as the balance used in weighing procedures are not discussed. Some sensors that are needed to derive the parameters in Table 53.2 (e.g., the anemometer for measuring the wind and the droplet spectrometer for determining the fog droplet size distribution and liquid water content) are discussed in the relevant chapters of this Handbook.

53.4.1 Canopy Water Balance Monitoring System

To employ the water budget method (Sect. 53.1.3) of deriving the fog deposition rate, a monitoring system for the canopy water budget is needed. Such a system includes collectors for precipitation, throughfall, and stemflow (along with suitable replicates) installed in the forest/shrub land. Since the 1980s, long-term ecosystem research sites around the world have used this monitoring system to study the atmospheric deposition of water, nutrients, and pollutants. Collectors for evaluating nutrient/pollutant deposition must be made of an inert material such as high-density polyethylene (HDPE) or even HDPE with teflon coatings. The sampling frequency has to be high enough to enable temporal changes in the chemical composition of the collected water samples to be discerned. Figure 53.2 shows the most commonly used system. When fog occurs frequently, FG contributes to the canopy water balance and must be calculated (Sect. 53.3.3).

53.4.2 Eddy-Covariance Method

A flux tower must be erected at a location sufficiently downwind of the fog-intercepting surfaces. This area surrounding the tower that influences the flux measurements is called the flux footprint. The eddy-covariance method provides an opportunity for continuous observations of vertical droplet fluxes to study the characteristics and temporal variability of processes. On the other hand, the actual fog deposition values obtained using this method are not very comparable with other methods of estimating fog deposition.

The constraints of the eddy-covariance method, which commonly arise during gas flux measurements (e.g., the less-developed turbulence during the night), must also be dealt with. This is especially important when quantifying fog deposition in radiation fog, which only develops under stable boundary layer conditions with nearly no turbulence. Moreover, the application of the eddy-covariance method under foggy conditions is problematic as fog droplets interfere with the operation of sonic anemometers. The accuracy of the measurements are strongly influenced by droplets deposited on transducer surfaces and those that are floating in the air [53.63]. The data acquisition rate and/or data quality are therefore not always satisfactory.

In addition, the eddy-covariance method demands a continuous supply of alternating current (AC) power to drive the air pump for the droplet spectrometer. This, as well as the considerable expense of the instruments used, has prevented the wide application of the eddy-covariance method in the measurement of fog deposition.

53.4.3 Fog Collectors for Chemical Analysis

Wet deposition [53.64] and dry deposition from the atmosphere are important pathways into vegetation and the ground surface for both pollutants and nutrients. In locations where fog is frequent, it has the potential to dominate the wet deposition process. This has been shown to be the case in mountain locations. While the amount of water deposited as rain and snow at higher elevations may be greater than the amount of water deposited from fog, the concentrations of major ions, heavy metals, and some organic compounds may be 3–5 times higher in fog water than in rainwater or snow [53.5, 65].

Although the additional input of plant nutrients provided by fog water can be beneficial to plant growth, any harmful chemicals present in the fog water could damage the ecosystem. In some cases, such as nitrate deposition, it can be both the amount and the timing of the deposition during the year that determines whether the nitrate input is beneficial or harmful to the forest. The chemical fluxes can be calculated by multiplying the concentrations of the chemicals in fog water by the fog deposition rate. To sample fog water for chemical analysis, specialized fog collectors are needed.

There are two main categories of fog collectors: passive collectors and active collectors. The most widely used passive fog collector uses vertically strung teflon strings as the intercepting surface (Fig. 53.4). It was designed by *Falconer and Falconer* in 1980 [53.22] and subsequently modified by *Mohnen and Kadlec* in 1989 [53.66] and termed the Atmospheric Sciences Research Center (ASRC) collector. This collector has been widely used in projects such as those noted above. The strings are normally arranged cylindrically to reduce the influence of the wind direction. It is not possible to avoid drizzle, rain, and snow collection when sampling under windy conditions. Additionally, dry deposition in the form of both gases and particulates will impact on the collecting strings. Therefore, the chemical concentrations obtained from passive fog collectors have to be interpreted with care. Baseline values can be obtained by exposure under no-fog conditions and through comparison with the concentrations in samples obtained from bulk collectors installed in parallel.

The usual approach is to have parallel measurements of rainfall and snowfall intensity to define periods when precipitation is known to have occurred. This can help to identify periods when there is only fog deposition. It is not possible to eliminate the dry deposition component, but it is typically much smaller than the wet deposition component. The dry deposition component can be estimated by exposing the passive fog collector under conditions when there is no fog or precipitation to determine the possible contamination from

Fig. 53.4 The 1 m² SFC (*on the left*) and the Environment Canada version of the ASRC collector (after [53.66]) (*on the right*). The photo was taken during the Chemistry of High Elevation Fog project in southern Québec, Canada (photo © Robert S. Schemenauer 2020; all rights reserved)

this source [53.5]. A further possibility is to break up the periods when water is collected by the passive fog collector into three parts: fog only, precipitation only, and a mixture of both fog and precipitation [53.5]. This effectively defines the range of wet deposition events to which forests and mountain vegetation are regularly exposed. Sampling and analytical protocols relating to the use of the ASRC collector have been discussed in the literature [53.5, 54].

When sufficient power is available, active fog collectors can be used to address some of the problems mentioned above. An active fog collector has its intercepting surface inside the equipment. The air containing fog droplets is sucked into the equipment by fans located downstream of the intercepting surface. Many active fog collectors are based on the designs of *Daube et al.* [53.25]. The fans can be activated by a relay system triggered by a datalogger that receives signals from a visibility sensor. The active fog collectors can be set to work only when the visibility is < 1000 m (the standard meteorological definition of fog), meaning that particulates and gases in the air will not contaminate the intercepting surface when there is no fog. Problems may occur when visibility is reduced by smoke or heavy precipitation if the sensor cannot distinguish the source of the visibility reduction. The main difficulty with active collectors is attempting to suck in an air sample that contains a free stream concentration of fog droplets. The sampling process in which droplets are brought into the collector can be size selective, which in turn can bias the chemistry of the bulk fog water sample obtained. This needs to be considered during the design of the active collector.

The fog droplet collection efficiency depends on the wind speed, the fog droplet size, and the size and arrangement of the collecting strings in the active fog collector [53.67]. When the chemical concentrations in

Table 53.4 Advantages and disadvantages of the different methods of calculating fog water deposition in a forest

Method	Advantages	Disadvantages
Direct measurement of collected water mass or volume	Relatively simple	Weight loss due to evaporation and transpiration may bias the estimation A conversion factor is needed to convert to ground-based deposition rate Difficult to sample all representative vegetation and locations
Surrogate method	Useful for understanding the potential fog deposition rate	Weight loss due to evaporation and transpiration may bias the estimation A conversion factor is needed to convert to ground-based deposition rate It is difficult to create surrogates of all exposed vegetation types
Water budget method	Low maintenance costs Applicable to diverse forest/shrub land-cover types	Cannot detect small/short fog events Large errors when calculating the parameters in the water budget equation
Eddy-covariance method	Provides undisturbed, continuous (usually 30 min) vertical fog water flux data	Only feasible under suitable micrometeorological conditions Instruments and maintenance are expensive AC power is required Does not directly measure fog deposition
Free-stream fog flux	Fog water flux above or approaching the forest is measured using passive fog collectors	Measured fog fluxes are used as input for a computer model of the forest that calculates the deposition parameters Complex terrain and complex forest canopies are difficult to model

droplets belonging to different size classes are of interest, the active fog collector can be designed accordingly.

Another factor to keep in mind is sample volume. Different analytical procedures may require different fog water sample sizes. A longer sampling time will clearly lead to a larger sample with less time resolution. A 1 m² SFC that is used to measure fog fluxes will typically collect about five times as much water as the ASRC teflon string fog collector [53.13]. The ASRC collector will in turn normally collect more water per unit time than an active fog collector, but this depends on a variety of factors, including wind speed and the design of the active fog collector.

When the goal is to understand the chemistry of fog water collected for human consumption, there are several different issues. First, the collection surfaces on large fog collectors or the interiors of the water storage tanks are typically not cleaned prior to sampling. Second, the chemistry of the fog water is compared to the World Health Organization drinking water standards, and so certain levels of major ions or heavy metals are deemed acceptable [53.68]. Third, careful storage and transport protocols need to be put in place when moving samples from remote locations to laboratories.

In all chemical analyses of fog water, the instrumentation used for analysis must have suitable detection

limits. These should be in the range of 0.01 ppm for major ions and 0.5–10 ppb for trace elements, depending on the element.

53.4.4 Visibility Sensor

According to the World Meteorological Organization, fog is present when the horizontal visibility is < 1000 m [53.69]. Having a visibility sensor installed on site leads to a better understanding of fog climatology. It provides information about the pattern of fog occurrence and thus a presumption of the significance of FG at the site. Visibility is expressed in meters, and its magnitude is a nonlinear function of the size spectrum of water droplets in the air. The sensor typically uses infrared forward-scatter technology to detect the optical properties of the suspended particles between the light source and the detector arms, which are usually less than a meter apart.

53.4.5 Comparison of the Methods

An outline of the different methods for quantifying fog deposition is given in Table 53.3. A brief description of the advantages and disadvantages of each method is given in Table 53.4.

53.5 Specifications

As described in Sect. 53.1, there is no standard method of fog deposition quantification. Researchers design the measurement system according to their site characteristics. The uncertainty in the final fog deposition rate comes from the instruments employed, the system de-

sign, the operation of the system, and the difficulty involved in calculating fog deposition in a complex natural ecosystem that may be hectares or square kilometers in extent. Table 53.5 lists the uncertainties, measurement ranges, and resolutions of the basic instru-

Table 53.5 Typical characteristics of instruments used for fog deposition measurements

Instrument	Typical total uncertainty	Range	Resolution
Balance	Variable	0.01 g–5 kg	0.01 g
Rain gauges or other collecting systems for fog water	–15% to +20%	Minimum: 0.1 mm–0.2 mm	Typically 0.1 mm, can be lower or higher depending on instrument
Visibility sensor	±10%	10 m–20 km	1 m
Fog droplet spectrometer	< ±10% (small droplets) to ±90% (larger droplets)	Droplet diameter 2–50 μm	Individual droplet in each size bin
Standard fog collector (SFC)	±5% to 10%	All droplet sizes	Depends on rain gauge used to measure the collected fog water

ments. The uncertainty and specifications associated with a general instrument such as a datalogger are given in Chap. 2. An eddy-covariance system used for fog deposition measurement contains a 3-D sonic anemometer and a fog droplet spectrometer. The uncertainty and specifications associated with the former are given in Chap. 55 on eddy covariance.

Because most fog deposition processes result in whole or in part from the horizontal movement of wind-driven fog, the conversion of the interception of fog by vertical surfaces, such as the cross-sectional area of a tree, to a depth on the ground is not straightforward, and calculations are often problematic. The uncertainties introduced by these extrapolations are typically greater than the expected errors in the instrument measurements.

The accuracy and precision of an electrical balance are important when it is employed to weigh the deposited fog water. Windy conditions in the field may cause continuous and irregular changes in balance readings [53.11]. Nevertheless, this is one of the more precise measurements used to estimate fog deposition rates.

Strictly speaking, the method used to quantify the canopy water balance shown in Fig. 53.2 is only applicable in situations where there is no wind, when the input is from rainfall, and when the fog deposition component is zero. When there is no wind above the canopy, the raindrops will fall vertically. When wind is present, the raindrops will fall at an angle determined by the wind speed and the droplet fall velocity, which is in turn directly related to the droplet diameter [53.20]. When wind is present, exposed treetops play the primary role in collecting both raindrops and

fog droplets [53.51]. Emergent treetops will collect proportionally more windblown rain, and the amount collected will be related to the rain shadow area downwind of the treetop. Emergent treetops will also be prime collectors of fog droplets. The uniformity, or lack thereof, of the canopy top will significantly impact the uniformity of water delivered to the surface of the ground. The cross-sectional area of the emergent treetops is an important factor in calculations of water input from windblown precipitation and fog. In the case of precipitation in the form of snowfall, the interception loss component can be much higher than for an equivalent water input in the form of rainfall.

One can assume that the precipitation input to a forest plot is, to a first approximation, independent of the leaf or needle shape and the density of foliage coverage. This is not the case for the fog water input component. The shape and dimension of a leaf or needle are critical influences on its efficiency at collecting microscopic fog droplets. The collection efficiency of a pine needle, for example, will increase as the wind speed increases, the droplet size increases, and the needle diameter decreases. These issues are discussed in the literature [53.21] and are important factors when choosing or designing materials for artificial fog collectors. The porosity of the treetop when viewed from the side is another important determinant of the fog collection/deposition rate. If the tree is very dense, the streamlines of the wind flow will pass around the tree and carry most of the fog droplets past the object. A treetop with an open structure composed of fine pine needles will be a much better collector of fog droplets than a treetop with large leaves and a dense structure.

53.6 Quality Control

To ensure the precision and accuracy of the estimated fog deposition rate, the instruments must be regularly calibrated and the measurement procedures standardized. Table 53.6 lists the general guidelines for quality control. If fog water is to be collected for chemical analysis, all of the steps—from cleaning the collectors

to collecting, storing, and shipping the sample as well as analysis in the laboratory—are critical. These procedures have been discussed in detail in works cited earlier [53.5]. Eddy-covariance instruments must be calibrated according to the instructions of the company prior to the field trip and repeated in the field as required.

Table 53.6 Quality control for various methods of estimating the fog deposition rate

Method	Instrument/procedure	Quality control
Direct measurement of collected water mass or volume	Balance	Use on level base and prevent vibration caused by wind Calibration with standard weights
Water budget method	Water collectors	Precipitation collectors must be located where the wind is not disturbed by surrounding obstacles Sufficient throughfall and stemflow collectors are required to determine the spatial heterogeneity
Eddy-covariance method	Instruments	The guidelines for the installation of the eddy-covariance instruments must be strictly followed since any deviations from the correct installation can strongly influence the data acquisition and the interpretation of the flux data Flagging systems must be used for data quality control
Fog flux	SFC	Check that the mesh is undamaged and that there are no leaks from the trough or pipe Calibrate rain gauges with a measured amount of water

53.7 Maintenance

Table 53.7 gives an overview of the maintenance requirements of the systems used for fog deposition measurements. General rules for maintenance apply; e.g., the cleanliness of the equipment must be routinely checked. When rain gauges are used to record water fluxes in the water budget method, the gauges should be inspected and detritus from the forest and soil must be removed from them. The dataloggers that are used to record sensor readings must also be checked, especially for power supply outages at remote sites.

Eddy-covariance systems and visibility sensors can produce erroneous readings if the sensor heads are contaminated (e.g., by bird droppings or spider webs). Also, optical surfaces must be regularly cleaned to remove dust and chemicals deposited by rain and fog droplets. Infrared gas analyzers must

be calibrated regularly using zero and span gases. Both infrared gas analyzers and fog droplet spectrometers have to be factory calibrated at least every 2 years.

Specialized protocols must be implemented when the instrumentation is operated in difficult weather conditions. Many mountain locations at temperate latitudes experience severe winter weather, including temperatures that can drop to -30°C , which will affect many instruments, power supplies, etc. Snow will need to be regularly cleared from instrumentation. Hoar frost may form on instruments; if present on optical surfaces, this frost will prevent proper operation. Fog droplets are present in the liquid form down to perhaps -20°C , or sometimes even lower temperatures under certain conditions when there is no wind. When these fog droplets strike a cold surface they freeze, forming rime ice. This

Table 53.7 Maintenance of instruments used for fog deposition measurements

Maximum interval	Balance	Rain gauges	Water collectors for chemical analysis	Standard fog collector	Visibility sensor	Eddy-covariance system	Data logging system
Each time before use	Calibration		Spray with deionized water and save sample	Check for any visible evidence of damage	Check for obstructions and dirt		
2 weeks		Clean, check for mechanical function	Thoroughly wash and clean with deionized water	Clean tipping bucket and trough	Clean sensor heads	Clean sensor heads	Inspect data collected for possible instrument malfunctions
3 months				Calibrate tipping bucket; check all water seals; check that frame is vertical		Calibration of gas analyzer	
2 years		Calibration	Re-string the collectors with new teflon fibers	Retighten the mesh on the SFC frame	Factory calibration	Factory calibration of fog droplet spectrometer	Factory calibration

is an opaque white build-up that is familiar to skiers and can result in large ice deposits on surfaces. Freezing rain occurs when liquid raindrops fall onto surfaces with temperatures $< 0^{\circ}\text{C}$. The raindrops spread over the surface, forming a hard layer of clear ice. All of these conditions must be effectively dealt with when measuring fog water in winter conditions. Some instruments have heated inlets or optics, and they should be checked daily or at least during every visit by the site operator.

53.8 Applications

There are two practical applications of fog deposition. They both involve the collection of microscopic fog droplets in enormous numbers. It takes about 10 million fog droplets to make a water drop the size of a match head. Fortunately, wind-blown fluxes of fog contain huge numbers of droplets, typically $\approx 300\text{ cm}^{-3}$ or 300 million m^{-3} . The first practical application involves planting tree species in open areas where fog is frequent in order to reforest clearcut areas or introduce native species into areas that have long been free of trees. The second application involves installing man-made fog collectors to collect fog water for human consumption or for use in agriculture. A blended application is to use fog collectors to generate water that irrigates tree seedlings until they are large enough to collect sufficient irrigation water themselves. A major project to investigate the utilization of fog deposition in this manner took place along the southern coast of Peru for 5 years in the late 1990s [53.33].

Fog collection has been shown to be a useful option for providing domestic water in some remote regions

where normal water resources such as rain, surface water, and groundwater are scarce. The history of this work was discussed above [53.26]. To collect the tiny fog droplets from the air in a cost-efficient way, an enlarged version of the passive SFC with a collection surface of up to 40 m^2 is constructed. In a typical construction process, the fog collectors utilize commercial shade nets to ensure that construction costs are low enough for sustainable operation. There are also projects or experiments that use mesh with a plastic backing, rigid fabrics, and 3-D rigid fabrics. Worldwide, there are numerous systems that successfully collect fog water for use by villages and remote farms. Such systems, which collect fog water at an annual average rate of $3\text{--}10\text{ L m}^{-2}\text{ d}^{-1}$, have greatly improved the quality of life in many areas by supporting small-scale agriculture and providing drinking water for people and animals [53.34]. A detailed manual that describes the scientific background for fog collection and provides the technical construction information needed to select sites and build large fog collectors is available [53.70].

53.9 Further Developments

Quantifying the interception of fog water in situ at different locations in the canopy may lead to a greater understanding of the fog deposition process in forest ecosystems. A useful methodology to achieve this could be to install strain gauges on branches, although the sensitivity of the gauges would need to be increased and it would be necessary to filter out wind-induced vibrations. Additionally, the application of low-cost open-source electronics platforms (e.g., Arduino, <https://www.arduino.cc/>, Accessed 21 July 2021) to data acquisition could increase the spatial sampling framework.

A number of research efforts are underway to determine if adjusting the fiber dimensions or weave of

the collecting material can improve fog collection rates, and whether changing the physical structure could be advantageous for fog collection. There is also considerable interest in using nanotech coatings on plastic or metal meshes in fog collectors. All of these developments require rigorous field testing in a variety of actual fog conditions before they may be adopted. The increased cost of these materials and structures must be balanced against the potential for a significant increase in water production compared to the inexpensive double layer of Raschel mesh that has been used effectively for 40 years.

53.10 Further Reading

Tropical montane cloud forests are research hotspots for fog, fog deposition, and the influences of fog on ecosystems. A collection of synthesized findings and individual research at diverse tropical locations can be found in:

- L.A. Bruijnzeel, F.N. Scatena, L.S. Hamilton (Eds.): Tropical Montane Cloud Forests: Science for Conservation and Management, International Hydrology Series (Cambridge University Press, 2010)

In 1998, an international conference series was initiated that aimed to provide a forum where scientists working in the many areas relating to fog and dew could interact with scientists and development specialists working in applications of fog collection. Its goals were to improve fog and dew science and to directly benefit people in need of alternative water supplies. To date, there have been eight conferences in the series, with the most recent taking place in 2019 in Taipei, Taiwan. Information on this conference series and proceedings from it can be found at www.fogquest.org, Accessed 21 July 2021 and www.fogdew.org, Accessed 21 July 2021.

fogquest@shaw.ca

Robert S. Schemenauer is a retired research scientist living in Canada. He had a lengthy career with Environment Canada and was the first emeritus research scientist in the Atmospheric Environment Service. He also held an adjunct professorship, founded the charity FogQuest: sustainable water solutions, and initiated the international conference series on Fog, Fog Collection and Dew. He has published extensively on fog and cloud microphysics and fog collection.

Immission and Dry Deposition

Ivonne Trebs , Christof Ammann , Jürgen Junk 

The Earth's surface is both an important source and sink for atmospheric trace compounds (gases and aerosols). This chapter provides a detailed overview of methods to determine immission, dry deposition fluxes, and deposition velocities of trace substances to the biosphere. In particular, relevant measurement techniques are described, and their requirements and limitations for determining accurate fluxes are analyzed. Furthermore, several quality control procedures are outlined. Typical applications are explained in detail, taking into account current and future challenges and developments.

The dry deposition of trace compounds to terrestrial ecosystems plays key roles in atmospheric chemistry, air quality, and the climate, as it constitutes a major sink for trace gases and aerosols in the troposphere. Furthermore, it influences the biogeochemical cycles of carbon and nitrogen and is a direct source of pollutants and/or nutrients for the biosphere, potentially causing eutrophication and acidification of ecosystems. Dry deposition occurs through passive turbulent transport (mixing) of the air constituents towards the surface, where they are absorbed due to various biological and physicochemical processes. Hence, the rate of dry deposition of an atmospheric compound is closely related to the concentration of the compound near the surface (i.e., the respective *immission*). The accurate quantification of dry deposition fluxes is crucial for our understanding

of and ability to predict the atmospheric composition, the chemical processes in the atmosphere (e.g., ozone production or the formation of aerosol particles), the atmospheric inputs to ecosystems, and the effects on the ecosystem. Dry deposition represents only part (on average about half) of the total deposition of many trace compounds to the surface. Locally, the contribution of dry deposition depends mainly on the frequency of rain events (climate zone) and the characteristics of the underlying surface [54.1–4]. Further deposition pathways are wet deposition, sedimentation, and fog deposition (Chap. 53). Moreover, some compounds may be both deposited to and emitted from surfaces, depending on their physiological/chemical production and consumption at the surface as well as the prevailing ambient concentration [54.5, 6].

54.1 Measurement Principles and Parameters

The measurement of dry deposition generally includes concentration measurements of the atmospheric trace compounds of interest near the surface (immission measurements). This approach is most relevant for the following inorganic trace gases and related aerosol compounds: sulfur dioxide (SO_2)/aerosol sulfate (SO_4^{2-}), ammonia (NH_3)/aerosol ammonium (NH_4^+), nitric acid (HNO_3)/aerosol nitrate (NO_3^-), nitrous acid (HNO_2), nitrogen dioxide (NO_2), peroxyacetyl nitrate (PAN), and ozone (O_3). Moreover, the deposition of metal ions in aerosols and of elemental mercury is of importance for terrestrial ecosystems. Since the transport of gases and particles from the surface layer to the Earth's surface is controlled by turbulent diffusion, dry deposition methods usually combine concentration measurements with a quantification of the vertical turbulent transport (micrometeorological methods). Generally, the eddy-covariance (EC) technique (Chap. 55) is considered to be the most direct and sophisticated micrometeorological flux method. It is often used as a reference for the measurement of surface–atmosphere exchange fluxes. The

relaxed eddy accumulation (REA) method can be a suitable alternative (Chap. 56). However, due to administrative, logistical, or financial restrictions, fast-response analyzers are not always available for some trace gases and aerosol compounds. Under these circumstances, other (indirect) methods based on vertical concentration gradients and similarity principles in the surface layer allow for the determination of dry deposition fluxes. Table 54.1 provides an overview of all available methods to determine dry deposition. Only indirect methods that are not covered in other chapters of this Handbook are described in detail here. These include the aerodynamic gradient method (AGM) and the modified Bowen ratio method (MBR). Aside from these, the so-called *inferential method* [54.7, 8] is a composite measurement-model approach that is often used in deposition monitoring networks. It requires knowledge of the surface uptake potential for the trace compound of interest, which has to be derived (*inferred*) from measurements obtained by the other methods mentioned above or by chamber methods (CHAM; see Chaps. 59 and 60).

Table 54.1 Measurement principles for dry deposition

Method	Description	Reference
Eddy covariance (EC)	Direct measurement of the turbulent trace gas flux by measuring the fluctuations in the vertical wind velocity and the trace gas concentration with high frequency	Chap. 55
Relaxed eddy accumulation (REA)	Concentrations are sampled by separating the sampled air into updraft and downdraft reservoirs based on the sign of the vertical wind speed	Chap. 56
Aerodynamic gradient method (AGM)	Measurements of wind velocity, air temperature, and the trace gas concentration at two or more levels (or turbulence characteristics are determined by the EC method)	Sect. 54.3.4
Modified Bowen ratio (MBR) method	Measurements of air temperature and the trace gas concentration at two levels, and the sensible heat flux is measured using the EC method	Sect. 54.3.5
Chamber methods (CHAM)	The trace gas concentration is measured at the inlet and outlet of a dynamic chamber or the trend over time inside a static chamber is monitored, and the surface resistance is subsequently calculated	Chaps. 59 and 60
Dry deposition inferential method (DDIM)	The concentration is measured at one level and then the <i>big leaf multiple resistance approach</i> is applied to estimate the deposition velocity	Sect. 54.3.3

Table 54.2 Parameters that are typically measured when determining dry deposition fluxes. The first three parameters are measured using the EC method at a sampling rate of 10–20 Hz (Chaps. 1 and 55)

Parameter	Description and sensor	Symbol	Unit
3-D wind components	Sonic anemometer (Chap. 55)	u, v, w	m s^{-1}
Sonic temperature	Sonic anemometer (Chap. 55)	T_s	K
Horizontal wind speed	Cup or sonic anemometer (Chap. 9)	u	m s^{-1}
Wind direction	Wind vane or sonic anemometer (Chap. 9)	\circ	
Air temperature	Pt-100 thermometer (Chap. 7)	T	K
Relative humidity	Capacitive hygrometer (Chap. 8)	RH	%
Global radiation	Pyranometer (Chap. 11)	$K \downarrow$	W m^{-2}
Concentration: mass concentration or density	Gas or aerosol analyzer (Chaps. 8 and 16)	ρ_s	$\mu\text{g m}^{-3}$
Concentration: molar concentration or density	Gas analyzer (Chaps. 8 and 16)	c_s	$\mu\text{mol m}^{-3}$

Table 54.3 Required measurements and input parameters for different methods of quantifying dry deposition

Required measurements or input parameters	EC	REA	AGM	MBR	CHAM	DDIM
Concentration: no. of sampling positions/levels	1	2 ^a	≥ 2	2	2	1
Concentration: typical time resolution	0.1 s	30 min	30 min	30 min	30 min	1 h to 1 month
Wind and air temperature: no. of measurement heights	1 ^b	1 ^b	1 ^b /2	2 ^c	–	1 ^d
Wind and air temperature: time resolution	0.1 s	0.1 s	0.1 s/30 min	0.1 s	–	1 h ^d
Displacement height d	–	–	×	–	–	×
Roughness length z_0	–	–	–	–	–	Estimated ^d
Surface resistance r_c	–	–	–	–	–	Estimated ^d

^a Conditionally sampled updraft and downdraft air at the same position
^b Three-dimensional wind measurement
^c Only the air temperature (proxy scalar profile)
^d The multiresistance-based deposition velocity v_D must be calculated (alternatively: use the estimated monthly/annual average value of v_D)

Table 54.4 Output parameters (quantities) of dry deposition measurements

Output	Description and calculation	Symbol	Unit
Deposition flux	Vertical turbulent (mass or molar) flux of trace gases or aerosols	F_c	$\mu\text{mol m}^{-2} \text{s}^{-1}$ $\mu\text{g m}^{-2} \text{s}^{-1}$
Concentration	Mass or molar concentration (density) of the trace compound in the air near the surface	c	$\mu\text{g m}^{-3}$ $\mu\text{mol m}^{-3}$
Deposition velocity	Deposition velocity determined as the ratio of the deposition flux to the measured concentration	v_D	m s^{-1}
Aerodynamic resistance	Turbulent transport bulk resistance between a reference height z_{ref} and the roughness length height z_0	r_a	s m^{-1}
Boundary layer resistance	Molecular–turbulent boundary layer bulk resistance (between z_0 and the solid (plant/soil) surface)	r_b	s m^{-1}
Surface resistance	Bulk residual surface resistance	r_c	s m^{-1}

In all dry deposition methods, the turbulent transport intensity (due to shear stress and buoyancy) is measured or estimated. This is achieved in various ways, depending on the dry deposition method adopted, and usually requires ground-based wind and air temperature measurements. These micrometeorological quantities and the concentration of the compound of interest must be measured at one or several measurement levels (vertical profile) (Tables 54.2 and 54.3). Furthermore, specific time resolutions are needed for these methods, and it may also be necessary to retrieve other input parameters (Table 54.3).

Table 54.4 shows the output parameters derived from the measurements listed in Tables 54.2 and 54.3. The retrieval of these quantities is discussed in Sects. 54.3 and 54.4.

The concepts and methods to quantify dry deposition fluxes presented here are only valid for condi-

tions of approximate stationarity and horizontal homogeneity of the wind, temperature, humidity and concentration fields within the measurement footprint (Chap. 1) [54.9]. Therefore, micrometeorological dry deposition measurements should be made over flat terrain with uniform surface cover. Because of the resulting violation of basic methodological assumptions, none of the methods presented here (except for chambers) should be applied within (or just above) plant canopies [54.1, 10].

It should be noted that chamber methods are not able to measure a representative deposition flux or velocity because the aerodynamic conditions inside the enclosed volume deviate markedly from undisturbed ambient conditions. However, they are suitable for investigating and quantifying the specific surface resistance r_c of the enclosed surface (or canopy) [54.11–13], which can be used in the DDIM.

54.2 History

Dry deposition measurements were initially made using various rather simple methods [54.14]. Historically, scientific progress in quantifying dry deposition fluxes has been closely coupled to advances in chemical measurement techniques [54.15]. Although more sophisticated techniques are now available, advanced versions of some historical methods are still in use today due to logistical or financial limitations. In the following, the most important historical methods are explained, including some of their advantages and disadvantages.

54.2.1 History of Immission and Dry Deposition Measurements

The first records of pollutant concentrations in ambient air, particularly those of O_3 , were produced in the last quarter of the nineteenth century [54.16] (Chaps. 16 and 24). During the era of atmospheric nuclear testing (starting in the late 1940s), the need to assess the risks of radioactive products to humans and the environment led to the use of deposit gauges as measurement devices [54.17] (Chap. 15). The problematic consequences of the acidification of soils and surface waters were discovered in 1967, and were subsequently recognized to be indicative of a large-scale problem with air pollution that required international action [54.18–20]. Later on, interest in immission and dry deposition measurements grew substantially [54.21–24], motivated by growing acid deposition rates of sulfur and nitrogen compounds in Europe and North America, which caused eutrophication and acidification of ecosystems. Although the first pioneering studies that used experimental and theoretical approaches to derive dry deposition fluxes of trace compounds occurred during the 1970s and 1980s [54.7, 8, 25–30], knowledge of the magnitudes of these fluxes for individual compounds, deposition velocities, and the processes that govern surface uptake was still quite limited at that time. Moreover, the time resolutions and precisions of most devices for measuring trace gases were not sufficient to facilitate direct flux measurement methods such as EC and REA (Chaps. 55 and 56). Accurate concentration measurements of some trace compounds were found to be particularly challenging due to their chemical and thermodynamic properties. This was especially the case for the sampling of water-soluble compounds and related semivolatile aerosol species—most prominently HNO_3 and aerosol NO_3^- , but also NH_3 and aerosol NH_4^+ [54.31, 32]. As HNO_3 can adsorb to and desorb from surfaces of inlets and sampling substrates (e.g., filter materials), it is very difficult to perform measurements without encountering some

form of interference [54.33]. Furthermore, the collection of aerosol species on filter packs without upstream (and downstream) scrubbing of related gases may cause significant artifacts (due to evaporation of semivolatile aerosol species from or collection of gaseous compounds such as NH_3 , HNO_3 , and SO_2 on the filters). In the last four decades, these problems have been a persistent impediment to the accurate determination of dry deposition fluxes of water-soluble trace gases and related chemical aerosol compounds.

54.2.2 Historically Relevant Measurement Methods

The first dry deposition measurements of HNO_3 and aerosol chemical compounds were made using surrogate surfaces [54.34–36]. However, this method was found to have substantial drawbacks, as the surface characteristics of the sampling vessel were different from those of natural surfaces, which modulated the surface uptake. Measurements based on foliar extraction (surface washing) were applied for NH_3 and HNO_3 as well as for their aerosol counterparts NH_4^+ and NO_3^- , but such measurements cannot distinguish between gas and aerosol phases [54.14]. In addition, throughfall estimates based on the difference between wet deposition and the washoff of deposited gases and particles were used to estimate dry deposition fluxes to forests [54.37, 38]. However, this method is hampered by the continuous uptake and release of chemical compounds by plant canopies, which results in low accuracy. The filter-pack method—in which a series of teflon and nylon or impregnated filters are typically employed to separate the particulate phase (e.g., NO_3^-) from the gas phase (e.g., HNO_3) and then offline analysis is performed using ion chromatography—is characterized by compactness, simplicity, and low power consumption but also relatively low accuracy [54.39, 40]. The development of this method permitted the measurement of vertical concentration profiles together with micrometeorological quantities over long sampling periods. Fluxes were subsequently derived using the MBR method (Sect. 54.3.5) [54.41, 42], or the DDIM when the concentration was only measured at one level (Sect. 54.3.3) [54.43]. The application of the denuder technique was a major step forward in the sampling of water-soluble trace gases. Dry-coated diffusion denuders were found to be reliable, but they also typically required long integration periods [54.44, 45]. Figure 54.1 shows an early version of a so-called total inorganic nitrate sampler that was capable of differentiating between gas and particulate phases and allowed performing measurements at several levels.

Fig. 54.1 Simplified scheme of an early total inorganic nitrate ($\text{HNO}_3 + \text{aerosol NO}_3^-$) sampler. Particulate nitrate is sampled on a Teflon filter following the passage of the ambient air sample through a vertically aligned coated diffusion denuder that removes HNO_3 . A downstream filter (made of nylon for example) collects nitrate lost from the Teflon filter by volatilization and/or reactions that release HNO_3 (NaCl/W41 filter – NaCl-impregnated Whatman 41 cellulose filter) (after [54.44] with permission from Elsevier)

The techniques mentioned above are only applicable over long sampling periods and require substantial quality control to maintain samples in good condition before offline analysis. More advanced denuder-filter pack setups are currently used for the long-term monitoring of dry deposition fluxes using the DDIM (Sects. 54.3.3 and 54.4.3). Selective and continuous measurements of water-soluble trace gases separated from the particulate phase can be achieved with diffusion scrubber and mist chamber techniques [54.46–48]. Moreover, various drawbacks were overcome by the development of various designs for wet diffusion denuders coupled to on-line ion chromatography systems with continuously renewed collection surfaces [54.32, 49–56].

54.3 Theory

In the following sections, the main processes that control dry deposition as well as the underlying theoretical principles are described. Various measurement methods are outlined, including important equations. The discussion below focuses on deposition to vegetated surfaces, which are the most complex and frequently investigated surfaces, but the methods presented are also used to examine deposition to other surfaces (bare soil, water, snow, and ice).

54.3.1 Influence of Turbulence and Surface Structure on Dry Deposition

The roughness (structure) of the surface strongly influences the efficiency of the dry deposition process. The turbulence induced by smooth surfaces (bare soil, snow, or ice) or short, dense, and homogeneous vegetation is less intense than that induced by a tall and heterogeneous forest environment, including trees of different lengths and open patches. The uptake of trace compounds by a vegetated ecosystem is determined by the structure, density, type, and age of the vegetation. This can be described by the leaf area index and surface

For other compounds, such as SO_2 , O_3 , NO_2 , and PAN, measurements of air concentrations and vertical profiles have been less challenging (Chaps. 16 and 18). For instance, vertical profiles of SO_2 were measured based on the fluorescence principle [54.57], and vertical profiles of O_3 were measured in 1971 using the electrochemical Ehmert technique [54.21, 58]. Since the 1980s, dry deposition fluxes of O_3 have often been determined with the EC method (Chap. 55) using fast-response sensors based on chemiluminescence [54.59–62]; and UV absorption measurements have been performed to provide reference concentrations. In the 1990s, the Luminox technique was used to measure vertical concentration profiles and EC fluxes in order to derive deposition velocities for NO_2 [54.63, 64].

roughness length for example. Uptake pathways can be categorized into [54.65]:

- Uptake controlled by plant physiological processes (stomatal uptake)
- Uptake by epicuticular waxes and water films (non-stomatal uptake)
- Soil uptake.

The efficiency of each uptake process depends on environmental conditions such as the solar radiation, air humidity, and temperature. Uptake through plant stomata is also controlled by the concentration of carbon dioxide (CO_2) and soil water availability.

The dry deposition of aerosol particles is mainly controlled by Brownian diffusion, interception, impaction, and gravitational settling, all of which are dependent on particle size. Additionally, particle deposition is a function of the particle density [54.26]. Dry removal of particles larger than a few micrometers is typically enhanced by the influence of gravitational settling [54.17], while Brownian diffusion influences the deposition rates of particles with diameters $< 0.1 \mu\text{m}$.

As a consequence of particle interception by surface elements and due to inertial impaction processes, any accurate calculation of aerosol fluxes must account for the leaf orientation and morphology, as well as the distribution and movements of in-canopy obstacles, which strongly influence the surrounding aerodynamics [54.17, 66].

54.3.2 Influence of the Chemical Properties of Trace Substances

The dry deposition process is also influenced by chemical interactions at the air–surface interface. Chemical reactions on leaf surfaces or in the leaf interior [54.5, 67–69] can substantially alter the magnitude of the deposition flux. These processes depend on the physicochemical and thermodynamic properties of the substance (its chemical reactivity and solubility in the aqueous phase) as well as on the surface properties (e.g., leaf microstructure, surface reactivity, the presence of epicuticular water films). For instance, very polar gases such as HCl, HNO₃, and NH₃ are strongly adsorbed by nearly all surfaces. In general, dry deposition is enhanced on wet surfaces, and the pH of the wetted surface influences the uptake process [54.70]. In addition, the deposition fluxes of NH₃ and SO₂ can be increased by codeposition processes, where the dissolution of one compound in surface water films enhances the uptake of the other compound [54.71]. The deposited compounds are either chemically decomposed in epicuticular water films or assimilated by the leaf as molecules react with the moist cells in the substomatal cavity and mesophyll [54.70]. The efficiency of each of these processes depends on the chemical properties of the compound and the biological activity of the leaf.

Some trace compounds (e.g., NH₃ or NO₂) are not only deposited and taken up by surfaces; they can also be emitted by vegetation and/or soils. In this case, the exchange between the surface and the atmosphere is bidirectional [54.72]. Whether (net) emission or deposition of these species occurs is controlled by the rates of production and consumption at the surface, for example in plant leaves or epicuticular waxes/water films and/or soils, as well as by the ambient concentration [54.3].

54.3.3 Dry Deposition Inferential Method (DDIM): Application of the Resistance Analogy

Deposition fluxes can be derived using a simplified theoretical framework. Determination of the flux of a chemically conservative trace compound within the

soil–vegetation–atmosphere continuum is based on the so-called *resistance analogy*, which is in accordance to Ohm's law [54.73, 74]. This method is also called the *big leaf multiple resistance approach* [54.7, 8], and can be expressed as

$$F_c = -\frac{1}{r_{\text{tot}}(z_R)} (c(z_R) - c_0), \quad (54.1)$$

where F_c is the flux density, r_{tot} is the total resistance to the exchange of the compound, $c(z_R)$ is the mean concentration at reference height z_R , and c_0 is the so-called compensation point concentration (the virtual equilibrium concentration of the trace compound at the liquid or solid surface). According to the micrometeorological sign convention, positive fluxes are directed upwards (aligned with the z -axis). Thus, deposition (negative flux) occurs if $c_0 < c(z_R)$, whereas the compound is emitted from the surface if $c_0 > c(z_R)$.

If we consider trace compounds for which the surface is a sink under all ambient conditions ($c_0 = 0$), the so-called deposition velocity (v_D) is defined as [54.23, 75]

$$\begin{aligned} v_D(z_R) &= \frac{1}{r_{\text{tot}}(z_R)} = \frac{1}{r_a(z_R) + r_b + r_c} \\ &= -\frac{F_c}{c(z_R)}, \end{aligned} \quad (54.2)$$

where r_a denotes the turbulent atmospheric resistance (due to turbulent exchange processes), r_b is the molecular turbulent resistance (which accounts for the exchange of trace compounds by molecular-turbulent diffusion across the viscous laminar sublayer in the vicinity of the vegetation), and r_c is the canopy resistance (which combines the influence of all uptake processes by the canopy on the deposition flux) [54.8] (Fig. 54.2). The values of v_D , r_{tot} , and c vary with measurement height and over time. Equation (54.2) assumes that the concentration at the soil and/or vegetation is near to zero (or always much lower than the ambient concentration); in other words, there is no emission (e.g., of O₃ and SO₂) from the surface.

The application typically requires the simultaneous operation of an EC station to determine the friction velocity, which is needed to calculate r_a and r_b . Alternatively, near-surface meteorological conditions can be monitored (e.g., the standard deviation of the wind direction, air temperature, solar radiation, etc.; see Tables 54.2 and 54.3). The resistances (54.2) are a function of wind speed and surface roughness, and can be derived as [54.77]

$$r_a(z_R) = \frac{1}{\kappa u_*} \left[\ln \left(\frac{z-d}{z_0} \right) - \Psi_H \left(\frac{z-d}{L} \right) \right]. \quad (54.3)$$

Fig. 54.2 (a) The big leaf multiple resistance scheme analogous to Ohm's law (after [54.76] © C. Ammann). r_{tot} total resistance, r_a turbulent atmospheric resistance, r_b molecular turbulent resistance, r_c canopy resistance (consisting of the stomata resistance r_{stom} , the external leaf surface (or cuticular) resistance r_{ext} , the mesophyll resistance r_{mes} , and the soil resistance r_{soil}). (b) Simplified resistance scheme

The roughness length z_0 and the displacement height d are typically retrieved from wind profile and turbulence measurements as a function of the canopy height (Chap. 1). Also,

$$r_b = \frac{2}{\kappa u_*} \left(\frac{Sc}{Pr} \right)^{\frac{2}{3}}. \quad (54.4)$$

Here, Sc and Pr are the molecular Schmidt and Prandtl numbers, respectively. Sc is a function of the molecular diffusivity of the trace gas [54.8].

As shown in Fig. 54.2, the value of r_c , the effective surface resistance of the whole plant–soil system [54.76], can be expressed as a combination of several resistances in parallel and in series that describe the various pathways for surface uptake, i.e.,

$$r_c = \left[\frac{1}{r_{stom} + r_{mes}} + \frac{1}{r_{soil}} + \frac{1}{r_{ext}} \right]^{-1}. \quad (54.5)$$

The value of r_c is specific to each trace compound and measurement site. As none of the resistances can be measured directly, the accurate retrieval of these individual values is the main challenge when using the DDIM. The value of r_{stom} can be estimated using latent heat fluxes measured with the EC method by inverting the Penman–Monteith equation (Chap. 57) and accounting for the ratio of molecular diffusivities between the compound of interest and water vapor. To correct for the influence of evaporation from soil pores and water films, it was proposed [54.78] that only data for dry conditions with $RH < 60\%$ should be used, as this

is the threshold at which liquid water on surfaces can be assumed to be fully evaporated. Additionally, a correction can be made for soil evaporation by plotting the inverse of r_{stom} against the gross primary production (for further details, see [54.78]). Due to insufficient knowledge of r_{mes} , it is typically set to zero, although recent evidence indicates that r_{mes} is non-negligible for some trace gases such as NO_2 [54.79]. The influence of r_{soil} depends on the soil moisture present, and parameterizations are based on experimental studies [54.80]. However, for sufficiently dense vegetation, the value of r_{soil} can be neglected. The uptake of compounds by external leaf surfaces is expressed as r_{ext} , and is controlled by the presence of epicuticular water films, their chemical composition, and the meteorological conditions [54.70]. Hence, the parameterization of this resistance is very complex [54.69, 81, 82].

For highly water-soluble and sticky gases (e.g., HNO_3) that are readily adsorbed by surfaces, the value of r_c is close to zero, which implies that the deposition velocity reaches the maximum value given by [54.83]

$$v_{Dmax}(z_R) = \frac{1}{r_a(z_R) + r_b}. \quad (54.6)$$

This may generally serve as an upper limit to test the plausibility of measured deposition fluxes. If the resulting v_D is larger than v_{Dmax} , additional sinks may be present between the measurement height and the surface. The inferential method delivers reliable results under daytime conditions over flat terrain, provided that the surface properties and the behavior of the vegetation are well characterized [54.84].

Table 54.5 Examples of typical deposition velocity ranges (values shown are in 10^{-2} m s^{-1}) for various compounds and particles to tall and low vegetation

Compound	Tall vegetation (forest)	Low vegetation (grassland/crops)	References
NO ₂	0.1–1.0	0.1–0.8	[54.3, 63, 64, 79, 85, 86]
HNO ₃	2.0–8.0	0.5–4.0	[54.3, 41, 87–92]
NH ₃	0.5–4.0	0.2–2.5	[54.87, 93–95]
SO ₂	0.2–2.0	0.2–1.5	[54.57, 87, 96–98]
O ₃	0.2–2.0	0.1–1.0	[54.65, 79, 96, 97, 99–102]
PAN	0.1–1.0	0.1–0.8	[54.103–106]
Particles (0.01–0.1 μm) ^a	0.05–1.5	0.02–0.06	[54.17, 107]
Particles (0.1–1 μm) ^a	0.1–2.0	0.01–0.3	[54.17, 107]
Particles (1–10 μm) ^a	0.6–5.0	0.1–4.0	[54.17, 107]
Particles (> 10 μm) ^a	1.0–20.0	2.0–10	[54.17, 107]

^a Mass-related deposition velocities of chemical aerosol compounds (e.g., NO₃⁻, NH₄⁺, and SO₄²⁻) are not given here (for more information on this topic, see [54.108, 109]).

Deposition velocities of aerosols are lower than those for trace gases, such that they are often within the experimental error [54.108]. It was shown that v_D is a function of particle size and can be parameterized with u_* for different size classes, but that there are large discrepancies between various experimental and modeling studies, especially for accumulation-mode particles [54.17]. In general, the deposition velocity for particles can be expressed as follows [54.108, 110]

$$v_D(z_R) = \frac{1}{r_a(z_R) + r_{cp}} + v_{ts}, \quad (54.7)$$

where v_{ts} is the terminal settling velocity (which is most relevant for large particles) and r_{cp} is the surface resistance, which combines the influences of turbulent transport and the collection of the particles by the vegetation within the canopy [54.110]. A detailed expression can be found in [54.111]. Aerosol fluxes are typically differentiated into *number fluxes* and *mass fluxes*, with the latter often used when considering certain chemical aerosol components. The concept expressed in (54.7) can be applied for both flux types, although direct measurements are generally obtained for aerosol number fluxes.

Deposition velocities are generally larger for tall canopies such as forests than for grassland and crops (Table 54.5), which is mainly due to the increased canopy roughness of tall canopies and its effect on turbulence. The highest values are typically observed for HNO₃, NH₃, and particles with diameters > 1 μm .

For trace gases that feature bidirectional fluxes, such as NH₃, the concentration at the soil and vegetation is not zero, so more complex approaches involving the compensation point concentration c_0 (54.1)—a concentration analog of r_c —must be applied [54.6, 112, 113].

54.3.4 Aerodynamic Gradient Method (AGM)

The aerodynamic gradient method (also called the profile method) is based on the flux-gradient theory and requires measured vertical profiles of wind, air temperature, humidity, and the concentration of the compound of interest (Tables 54.2 and 54.3 and Sect. 54.4.2). The turbulent vertical transport of a trace substance within the constant flux layer can be described analogously to Fick's first law, and is expressed as the product of the turbulent diffusion (transfer) coefficient and the vertical air concentration gradient $\partial c / \partial z$ [54.28], i.e.,

$$F_c = -K_H(u_*, z - d, L) \frac{\partial c}{\partial z}, \quad (54.8)$$

where F_c is the flux and K_H is the turbulent diffusion coefficient for sensible heat (Chap. 1) [54.74], which is a function of the friction velocity u_* , the height above the zero plane displacement ($z - d$), and the atmospheric stability parameterized by the Monin–Obukhov length L (Chap. 1). In the classical profile method that was mainly used in the past, the turbulence parameters u_* and L were determined from measurements of horizontal wind speed, air temperature, and moisture, ideally performed at 4–6 levels, using numerical iteration or regression calculations [54.114–116]. Nowadays, the turbulence parameters are typically retrieved from EC measurements of momentum and sensible heat flux using a sonic anemometer-thermometer (Chap. 55 and Tables 54.2 and 54.3). In the simpler case in which concentration measurements are obtained at only two levels z_1 and z_2 , the integration of (54.8) between the two measurement heights yields the integral form of the flux profile relationship that relates the flux directly to the measured concentration difference $\Delta c = c(z_2) - c(z_1)$ between the upper and lower mea-

surement heights [54.28, 117],

$$F_c = - \frac{u_* \kappa}{\underbrace{\ln\left(\frac{z_2-d}{z_1-d}\right) - \Psi_H\left(\frac{z_2-d}{L}\right) + \Psi_H\left(\frac{z_1-d}{L}\right)}_{v_{tr}}} \times [c(z_2) - c(z_1)], \quad (54.9)$$

where κ is the von Kármán constant (0.4) and Ψ_H is the integrated stability correction function for sensible heat. The first term of the product on the right hand side is often referred to as the transfer velocity v_{tr} (m s^{-1}), which represents the inverse resistance of the turbulent transport between the two heights z_1 and z_2 [54.76]. In contrast to the deposition velocity ((54.1) and (54.2)), it only includes turbulent transfer within an air layer and not the entire deposition to the surface. The AGM method assumes that the transfer of heat is similar to the transfer of the compound of interest within the surface layer, although this assumption is not always justified [54.77]. If the concentration profile is measured at more than two heights, a generalized form of the flux-profile relationship (54.9) can be used to evaluate a linear regression of the concentration against the stability-corrected logarithmic height [54.118].

54.3.5 Modified Bowen Ratio Method (MBR)

Another method based on the flux-gradient theory is the MBR. Assuming that the eddy diffusivity (v_{tr} , see (54.9)) for the compound of interest is equal to that for a so-called proxy scalar, the deposition flux is derived from the ratio of the difference between the upper and lower measurement heights for the trace compound of interest (Δc) to the difference in measurement heights for the proxy scalar (Δs) multiplied by the EC flux of the proxy scalar ($F_{s,EC}$) [54.28, 119], i.e.,

$$F_c = F_{s,EC} \frac{\Delta c}{\Delta s}. \quad (54.10)$$

In most cases, the air temperature is used as the proxy scalar, as measurements of vertical temperature profiles and sensible heat fluxes (Table 54.2) are relatively straightforward. However, under certain circumstances it may be advisable to choose a different proxy scalar (e.g., another trace gas such as CO_2 or O_3) that has a similar sink and source distribution to the compound of interest [54.103]. The MBR method is so named because the principle expressed by (54.10) was originally used to derive the Bowen ratio (the ratio of the sensible to the latent heat flux) from the corresponding temperature and water vapor profiles. Although measurements of wind speed or turbulence intensity are not explicitly

used in this method (54.10), it is recommended to check that fully turbulent conditions are prevailing [54.77].

54.3.6 Vertical Flux Divergence Due to Chemical Reactions

The measured or inferred flux may not represent the true surface exchange if there are additional sources or sinks in the air layer below the measurement height(s). This is particularly applicable to chemically reactive compounds. In taller canopies, the emission of nitric oxide (NO) by the soil may create an additional O_3 sink and NO_2 source due to the rapid reaction of these two trace gases [54.120–122]. Moreover, particulate NH_4NO_3 can be formed or can evaporate to the air during the deposition process [54.108] because NH_4NO_3 forms a reversible thermodynamic equilibrium with gaseous NH_3 and HNO_3 that is strongly dependent on the ambient relative humidity and temperature [54.123]. This modulates the vertical distributions of NH_3 and HNO_3 , as the timescale for equilibration between gaseous NH_3 , HNO_3 , and particulate NH_4NO_3 is within the timescale of turbulent transport (a few seconds for submicron particles) [54.124]. However, the methods presented here are based on the assumption that there are no chemical sources and sinks between the measurement height and the surface, which implies that the trace compounds are considered chemically inert tracers with constant fluxes within the atmospheric surface layer [54.73, 77, 125]. If this assumption is violated (i.e., gas-phase chemical sources and/or sinks are encountered between and below the measurement heights), sufficiently accurate fluxes of compounds can be estimated as long as any chemical reactions are much slower than the turbulent transport [54.124, 126]. This can be assessed quantitatively via the Damköhler number [54.127]

$$\text{Da} = \frac{\tau_{\text{turb}}}{\tau_{\text{chem}}}. \quad (54.11)$$

The characteristic turbulent and chemical timescales (τ_{turb} and τ_{chem} , respectively) can be determined according to [54.77, 79, 126, 128] and references therein. More details regarding the chemistry of the NH_4NO_3 - NH_3 - HNO_3 system are given in [54.108]. $\text{Da} > 1$ indicates that chemical reactions are significantly faster than turbulent transport (flux divergence). In this case, a correction for the chemical reactions is required to derive accurate turbulent fluxes of the reactive trace gas [54.129, 130]. The range $0.1 < \text{Da} < 1$ is commonly considered to be a critical range where an impact of chemistry cannot be excluded but should be of minor importance [54.79]. When $\text{Da} < 0.1$, the influence of chemistry can be neglected and the deposition fluxes can be determined as described above.

54.4 Devices and Systems

Table 54.6 summarizes the compounds for which dry deposition fluxes are typically measured and provides a selection of the most commonly used methods. It also specifies the measurement principles of analyzers that are used to determine the composition of the atmosphere [54.131]. More details on the characteristics of the sampling and detection systems employed to measure dry deposition fluxes are given in Sect. 54.4.1. Details on the quantification of particle fluxes are given in [54.17, 109, 110].

54.4.1 Sampling and Detection Systems

This section introduces the various analytical systems utilized with the indirect methods described above (AGM, MBR, DDIM). All of the systems listed below can also be applied to perform immission measurements at a single level or to infer fluxes with the DDIM.

Online Detection Systems (Time Resolution < 1 min)

For trace compounds that are not strongly water soluble, permitting longer inlet tubes, vertical concentration

profiles can be measured with high time resolution for the AGM or MBR method using one analyzer connected to a system of valves and pumps that allow sequential sampling at several levels (Fig. 54.3). In order to obtain a sufficient number of samples for a 30 min averaging interval (Table 54.3), the number of measurement levels should be limited (at least two), and an analyzer with a short response time, high time resolution, and high precision must be used. Examples of analyzers that fulfill these criteria include optical O₃ or NO_x analyzers based on UV absorption and chemiluminescence, respectively (Table 54.6, Chap. 16) [54.134, 144], as well as SO₂ fluorescence analyzers (Table 54.6, Chap. 16), which are applied for sequential measurements of vertical profiles [54.57]. To account for potential nonstationarities during the sampling period, a continuous concentration measurement can be performed with a second analyzer at a reference level. The integration time of the analyzers must be long enough to reduce the background noise of the signal. Furthermore, the tubes and analyzers have to be flushed for a certain time period after switching to another level, as the system needs to adjust to the new concentration.

Table 54.6 Overview of methods and typical measurement principles for the determination of dry deposition fluxes of various air constituents (Chaps. 16 and 18)

Compound	Method	Measurement principles
NO ₂	EC, CHAM+DDIM	Photolytic conversion to NO and subsequent chemiluminescence, Luminox technique, tunable diode laser absorption spectroscopy, laser-induced fluorescence, diffusion tubes (e.g., [54.79, 86, 132–135])
HNO ₃	EC, MBR, AGM, DDIM	Wet annular denuder, denuder-filter packs, diffusion-based samplers, chemical ionization mass spectrometry, thermal dissociation–laser-induced fluorescence (e.g., [54.3, 54, 136–138])
NH ₃	EC, MBR, AGM	Wet annular denuder, denuder-filter packs, diffusion-based samplers (AiR-Rmonia), chemical ionization and proton transfer reaction mass spectrometry, quantum cascade laser absorption spectrometry, differential optical absorption spectroscopy (DOAS), diffusion tubes (e.g., [54.139–141])
SO ₂	EC, MBR, AGM	UV fluorescence, chemical ionization mass spectrometry, diffusion tubes (e.g., [54.57, 98, 142, 143])
O ₃	EC, CHAM+DDIM	Chemiluminescence, UV absorption, diffusion tubes (e.g., [54.13, 62, 134, 144])
PAN	EC, REA, MBR, AGM	Gas chromatography with electron capture detection, thermal dissociation–chemical ionization mass spectrometry (e.g., [54.103, 106])
Chemical aerosol compounds (e.g., NO ₃ ⁻ , NH ₄ ⁺ , SO ₄ ²⁻)	EC, MBR, AGM	Steam-jet aerosol collector, particle-into-liquid sampler, aerosol mass spectrometry (e.g., [54.109, 145–148])
Particle number (0.01–1 μm)	EC, REA	Laser-based optical particle spectrometers, aerodynamic and electromobility spectrometers, condensation particle counter (combined with scanning mobility particle sizer) (e.g., [54.109, 149])
Particle number (1–10 μm)	EC, REA, MBR, AGM	Optical particle detectors (e.g., [54.109])
Dust deposition (2.5–80 μm)	Bulk samplers	Bergerhoff method using a passive sampler (Sigma-2) or other bulk bottle/funnel methods, subsequent offline analysis of heavy metals (measurement period 14–28 days) (e.g., [54.150, 151])
Mercury	REA, AGM, MBR, bulk samplers	Cartridge mercury vapor analyzer, bulk samplers made of glass (e.g., [54.150, 152, 153])

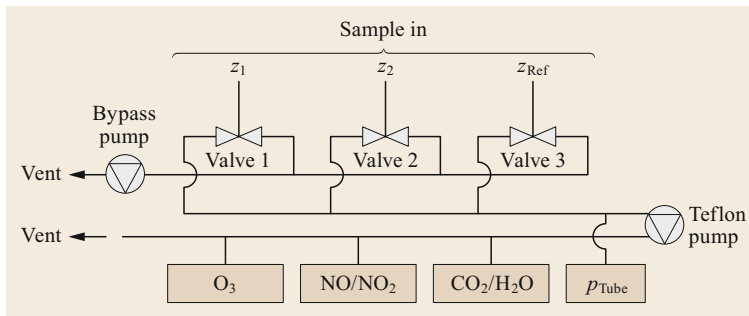

Fig. 54.3 Simplified scheme of the gas flow of a switched vertical trace gas profile (after [54.134] with permission from Elsevier)

To avoid condensation, the inlet tubing should be heated to slightly above ambient temperature.

Semicontinuous Systems with Automated Onsite Analysis (Time Resolution < 1 h)

A device that has become increasingly popular is the so-called wet annular denuder [54.50], which is capable of achieving high collection efficiencies at a relatively high time resolution (15–30 min) [54.54]. This denuder can be combined with continuous aerosol sampling devices such as the steam-jet aerosol collector (SJAC) (Table 54.6) [54.145]. These setups were integrated into transportable measurement devices that include an in-situ analytical unit to selectively and simultaneously measure water-soluble trace gases and corresponding chemical aerosol compounds with high precision ($\leq 10\%$) and high time resolution (15–60 min) (Fig. 54.4) [54.147, 154–157]. The major advantage of these systems is that two levels can be sampled simultaneously, thereby avoiding the potential influence of nonstationarities in the ambient concentrations on the flux determination.

A comparable setup was developed for PAN by modifying a commercially available gas chromatograph

with electron capture detection (GC-ECD). PAN was trapped on two preconcentration capillary columns over the sampling period, and analysis was then performed using the GC-ECD system [54.103, 158]. To ensure the accurate calculation of air concentrations, these systems typically utilize mass flow meters to monitor the flows of liquid solutions and air samples.

Accumulation Systems with Manual Offsite Analysis (Time Resolution 1 week – 1 month)

The DDIM, in particular, allows the determination of the dry deposition over longer time periods using so-called *low-cost methods* that are based on impregnated filter packs and dry-coated denuders. One prominent example is the Denuder for Long-Term Atmospheric Sampling (DELTA) (Fig. 54.5), which was successfully employed within the NitroEurope project to estimate the nitrogen deposition to several ecosystems in Europe [54.159, 160]. The samples are analyzed offsite in the laboratory and air concentrations are calculated using the sampled air volume.

The simplest method of determining dry deposition fluxes and immission concentrations is to use passive sampling techniques with diffusion tubes (Ta-

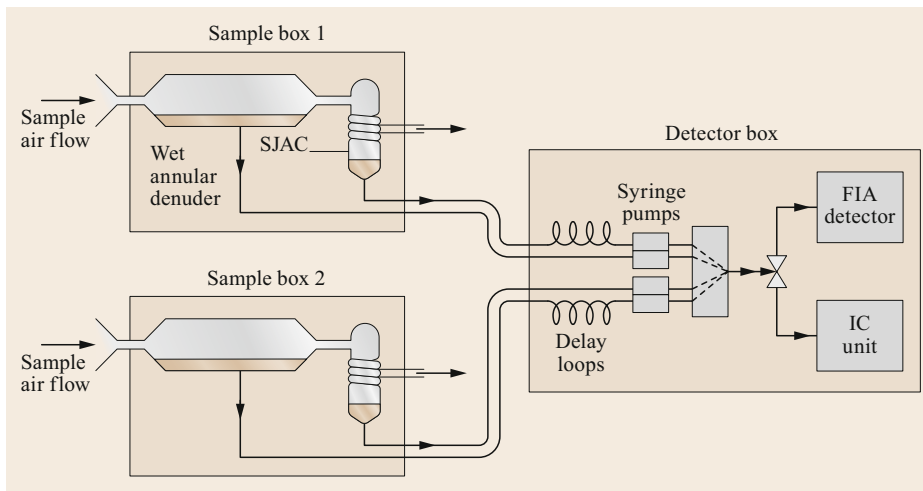

Fig. 54.4 Simplified scheme of the gradient analyzer for aerosols and gases (SJAC steam-jet aerosol collector, FIA flow injection analysis, IC ion chromatograph (after [54.157]))

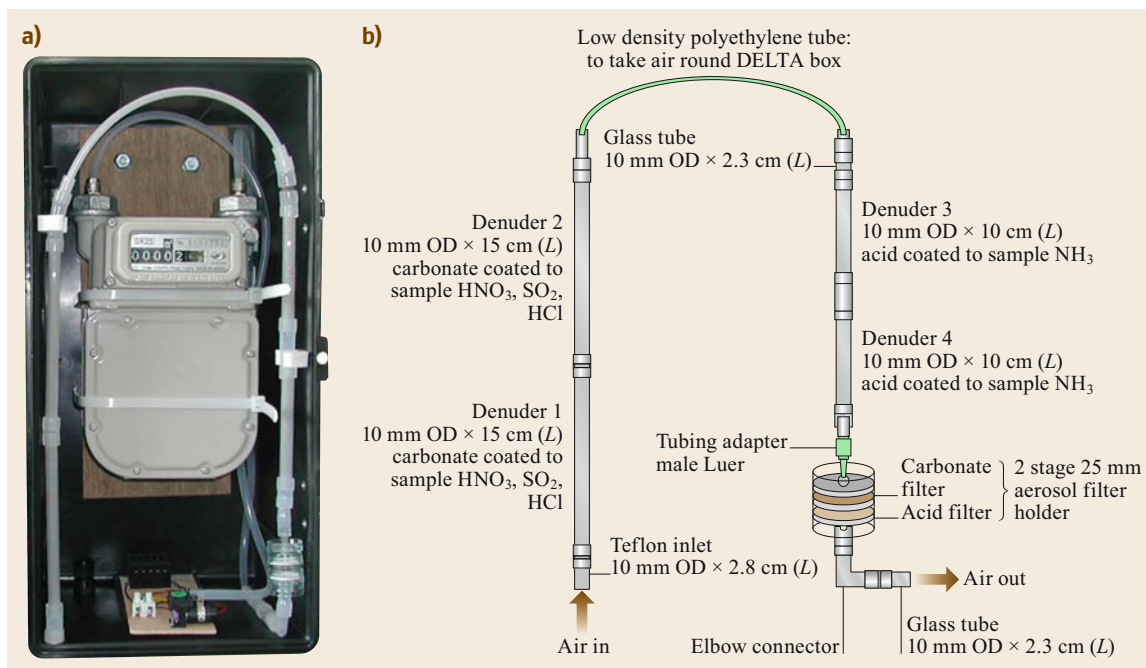

Fig. 54.5 (a) The Denuder for Long-Term Atmospheric Sampling (DELTA), which can be used for monthly measurements of trace gases and aerosols. (b) The sampling train consisting of coated denuders (OD outer diameter, L length) for determining HNO_3 , NH_3 , etc. and coated filters (for determining aerosol species) (after [54.160] with permission from Elsevier)

ble 54.6) [54.161, 162]. The absorbent material is analyzed in the laboratory, and the air concentration can be calculated based on the known diffusion rate and the exposure duration. Diffusion tubes are used for long-term monitoring with integration intervals of 2–4 weeks because sufficient quantities of the respective compounds must be absorbed.

A prerequisite for the application of accumulation systems to retrieve deposition fluxes is that the turbulent exchange conditions should remain reasonably constant throughout the measurement period. For instance, it is difficult to interpret results if the trace gas concentrations sampled during strongly labile conditions are mixed with those sampled during stable stratification.

54.4.2 The Design of Flux-Gradient Systems

While for the DDIM it is only necessary to measure the trace compound concentration at one level, the AGM and MBR require profile measurements at two or more levels. Although the AGM and MBR differ slightly in their approaches to flux determination, they employ very similar experimental setups. Analyzer accuracy and precision are typically not sufficient to permit the use of two different devices for verti-

cal profile measurements [54.1, 157, 158]. Therefore, various setups are applied to measure vertical profiles with one analyzer or using the same analytical unit/procedure (Sect. 54.4.1). Figure 54.6 shows a typical setup of a flux-gradient system with online detection (Fig. 54.3), allowing for the application of AGM and MBR. The height difference between the levels should be maximized to increase the measured concentration gradient and therefore reduce measurement errors, although this must be balanced against the length of the fetch (Sect. 54.5).

The design and setup of a flux-gradient system should generally be optimized to minimize any disturbance of the air flow and turbulence conditions by the mast/tower and the analyzer units as much as possible. This is challenging and may require a compromise if bulky instruments (or shelters for them) are used and short inlet lines are required (e.g., for HNO_3 , NH_3). In all cases, bulky units that could disturb the incoming air flow should be placed at a sufficient distance from the meteorological sensors and sample inlets, preferably away from the main wind direction sectors. In addition, to reduce inlet losses to a minimum, the inlet tube material should be selected according to the trace compound sampled (e.g., teflon for HNO_3 [54.33]).

Fig. 54.6 Typical setup of a flux-gradient system with four measurement heights at a natural grassland site in southwestern Germany. In this example, air temperature and humidity profiles (aspirated psychrometers) as well as the horizontal wind speed profile (2-D sonic anemometers) were measured with individual sensors at each level, while online detection employing a valve switching system for sequential measurements was used to obtain trace gas concentration profiles (inlet funnels); see Sect. 54.4.1 (photo © J.-C. Mayer)

Above rough surfaces such as tall crops or forest canopies, deviations from the ideal flux-gradient relationship occur within the so-called roughness sublayer, which may extend up to twice the canopy height [54.77]. The application of flux-gradient relationships in this layer may lead to an underestimation of scalar fluxes by 10% or more [54.163, 164]. Hence, if possible, profile measurement levels should be positioned above the roughness sublayer.

54.4.3 Design of Immission and Deposition Measurement Networks

The simplest way to estimate a dry deposition flux is to measure the concentration of the trace compound at one level (immission) and subsequently multiply this

by a representative deposition velocity (Table 54.5) for long-term averages of the concentration ((54.1) and (54.2)), e.g., on a monthly or annual basis [54.135]. However, this method is prone to uncertainty, as diurnal fluctuations of turbulence and surface uptake, which strongly depend on environmental variables, are not taken into account. When micrometeorological quantities (or at least standard meteorological parameters) can be measured and requirements are met, it is recommended that the DDIM should be applied in combination with a multiresistance scheme (Sect. 54.3.3) that allows the aerodynamic resistances (r_a and r_b) to be quantified hourly.

National immission monitoring networks are operated by many governmental environment agencies. Additionally, dry deposition measurement networks that are less dense than governmental networks are also operational in, for example, Africa, Australia, Canada, Japan, Europe, and the United States (which contributes to the Global Atmosphere Watch or GAW) program; see Chap. 63). In most of these networks, measurements are limited to particulate and gaseous sulfur and nitrogen species as well as a few aerosol cations. The World Meteorological Organization (WMO) and the GAW program intend to establish laboratory intercomparison methods and specific data quality procedures for immission measurements that are analogous to those that already exist for wet deposition. A list of networks and programs dealing with dry deposition is given in Table 54.7.

A monitoring network to quantify the input of nutrients to agricultural sites was established in Europe in 1947, and data from this network highlighted the importance of transboundary fluxes of acidifying pollutants. This led to the establishment of the Convention on Long-Range Transboundary Air Pollutants (CLRTAP) in 1979. This convention currently includes the European Monitoring and Evaluation Programme (EMEP), a scientifically based and policy-driven program that aims to provide information on the concentrations and deposition of air pollutants by combining measurement and modeling approaches [54.180, 181].

In the US, a network dedicated to measuring dry deposition was established in 1986 by the US Environmental Protection Agency (EPA) to assess the magnitude of and the spatial variability and trends in dry deposition [54.175]. The National Dry Deposition Network (NDDN) consisted of 50 monitoring sites spread across the US. CASTNET was created from NDDN, and started operating in 1991. Aside from obtaining concentration measurements of O_3 at several rural locations, this network mainly focuses on the dry deposition of sulfate, nitrate, ammonium, sulfur dioxide, nitric acid, and base cations. It makes use of the filter pack

Table 54.7 Overview of selected measurement networks and communities that focus on dry deposition, Accessed 21 July 2021

Name	Region	Abbreviation	URL
Acid Deposition Monitoring Network	East Asia	EANET	http://www.eanet.asia/ (e.g., [54.165, 166])

method to subsequently estimate dry deposition using a multilayer model representing an advanced version of the DDIM (Sect. 54.8.1) [54.176, 182].

WMO and GAW currently utilize a measurement–model fusion approach to derive global maps of wet,

dry, and total atmospheric deposition for different chemicals, but this requires high-quality global-scale measurements of atmospheric trace gases, particles, and precipitation as well as the output from chemical transport models for the same parameters [54.183].

54.5 Specifications

The accurate measurement of concentration differences for the substance of interest is the main challenge when applying the AGM and MBR methods. This is especially true for remote environments, where concentrations are very low [54.84] and vertical concentration differences are on the order of 1% to 20% of the mean concentration [54.28]. In order to determine dry deposition fluxes with an accuracy of at least 20% using vertical profile measurements, the precision error of the sensor and/or analyzer should be less than a tenth of the expected concentration difference between the two measurement heights (Table 54.8) [54.77]. The procedure used to determine precision requirements and flux uncertainties can be found in [54.77, 157, 158].

It should be noted that for some trace gases and a low ratio of measurement heights, the minimum detectable fluxes can be larger than the actual fluxes. It is recommended that the ratio of measurement heights z_2/z_1 should be between 4 and 8 for the AGM and MBR methods [54.77]. However, this is only possible above low vegetation. Above forests, this ratio is often ≤ 2 . On the other hand, over very smooth surfaces such as ice and water, the vertical concentration difference for a given measurement height ratio is generally smaller

than that over rough surfaces, and the largest gradients are typically found very close to the surface. In this case, the precision of the instrument must be even better to achieve the same flux accuracy as attained for rough surfaces. Consequently, the AGM and MBR methods require analyzers that are able to resolve very small concentration differences (high precision) over the typical integration time of 30 min (Table 54.3).

Table 54.9 compares all of the methods used to determine dry deposition fluxes (including EC, REA, and CHAM) in terms of their major advantages and disadvantages.

Table 54.8 Typical instrument precision (c_{\min}) and resulting minimum detectable concentration difference and flux (20% error) of different compounds for low ($z_2/z_1 = 8$) and tall ($z_2/z_1 = 1.25$) vegetation under neutral stratification and $u_* = 0.2 \text{ m s}^{-1}$ (the concentration values are in $\mu\text{g m}^{-3}$ and the flux values are in $\mu\text{g s}^{-1} \text{ m}^{-2}$) [54.77]

Compound	c_{\min}	Δc_{\min}	Flux (low veg.)	Flux (tall veg.)
NO ₂	0.1	1.0	0.05	0.1
O ₃	1.0	10.0	0.5	1.0
NH ₃	0.014	0.14	0.007	0.014
HNO ₃	0.2	2.0	0.1	0.2

Table 54.9 Advantages and disadvantages of the different methods of measuring immission/dry deposition (Chap. 1)

Method	Advantages	Disadvantages	Restrictions
EC	Direct method, no relevance of Da , ^a retrieval of r_c and v_D	High analyzer precision and fast response time	Sufficient footprint area, turbulent conditions
REA	Applicable for water-soluble/sticky compounds, ^b retrieval of r_c and v_D	Selection of the proxy scalar, high analyzer precision	Sufficient footprint area, scalar similarity, no local influence on integral turbulence characteristics [54.72]
AGM	Applicable for water-soluble/sticky compounds, retrieval of r_c and v_D	Scalar similarity, ^c high analyzer precision	Da , sufficient footprint area, turbulent conditions, stationarity
MBR	Applicable for water-soluble/sticky compounds, retrieval of r_c and v_D	Scalar similarity, ^c high analyzer precision	Da , sufficient footprint area, turbulent conditions, stationarity
CHAM	Direct retrieval of r_c	Corrections for chemical reactions ^d	Plot/leaf scale
DDIM	Inexpensive, simple installation and maintenance	Estimation or parameterization of r_c or v_D	Existence of a compensation point concentration

^a See Chap. 55 for details
^b See Chap. 56 for details
^c Assumption that heat or proxy scalar transfer is similar to the transfer of the compound of interest is not always justified
^d See Chaps. 59 and 60 for details

54.6 Quality Control

Several quality control procedures must be performed in-situ and after the field measurements (Table 54.10; Chap. 3). Besides regular calibrations (Sect. 54.7), periodic *side-by-side* measurements (SbS) are required to validate profile-based flux measurements. In these measurements, the inlets that are usually installed at different measurement levels are brought to the same height (side-by-side) and operated for a number of hours in this configuration. This is the most reliable method of identifying potential systematic errors between the different measurement levels and quantifying the precision (detection limit) of the measured concen-

tration difference for the AGM and MBR methods (cf. Table 54.8). It is mandatory to use this test to check whether an analyzer can be used for vertical profile measurements at a specific location.

Online vertical trace gas profiles that are obtained using a switching procedure with just one analyzer may be exposed to rapid concentration changes between the different measurement levels. Hence, in-situ tests should be performed to characterize the response of the system. For reactive trace gases such as the NO-NO₂-O₃ triad, the conditions within the inlet tubes are of particular relevance because chemical conversions might occur.

Table 54.10 Typical quality control (QC) procedures for analyzers used for immission and dry deposition measurements (see also Chap. 3)

Analyzer	Procedure/test	Reason
Online detection systems	Quantification of various error sources SbS measurements Significance of Δc (<i>t</i> -test, signal-to-noise ratio [54.144]) Characterization of system response time Consideration of chemical reactions in inlet tubing Da Stationarity test Outlier test	Errors in $c(z_R)$ and micrometeorological quantities Check for potential effects of different inlet lines and filters Sufficient instrument precision Sufficient instrument response Chemical reactions in inlet tubing bias measurements Chemical divergence Insufficient turbulent conditions Potential instrument failure, contaminated or clogged inlets
Semicontinuous systems with automated onsite analysis	Quantification of various error sources SbS measurements	Errors in $c(z_R)$ and micrometeorological quantities Sufficient instrument precision
Accumulation systems with manual offsite analysis	Complete denuder coating QC of analytical system in laboratory Intercomparison with online systems Outlier test	Incomplete trace gas capture Accuracy of $c(z_R)$

These depend on:

- The residence time of the sampled air in the inlet tubes
- The tubing material
- The trace gas concentrations.

Consequently, corrections for chemical reactions in the inlet tube may be necessary [54.184]. Moreover, stationarity tests should be performed if sequentially measured data points are combined into averages for half-hourly intervals (Chap. 55).

54.7 Maintenance

Fast online detection and semicontinuous systems with automated onsite analysis are typically deployed during intensive observation periods because maintenance requirements are relatively high. Consequently, the measurement systems must be maintained at least weekly and sometimes also daily by qualified personnel. The analyzers should be calibrated regularly with certified concentration standards. Additionally, the limit of detection should be determined periodically, for instance by sampling field blanks or zero air.

When operating accumulation systems with manual offsite analysis, regular calibrations of the analytical equipment in the laboratory must be performed. Coated filters and denuders should be prepared under extremely clean conditions. Field blanks of these measurement systems should be taken on a monthly basis (or between subsequent samples). As listed in Table 54.11, maintenance intervals for these systems are much larger than those for online detection and semicontinuous systems with automated onsite analysis.

Table 54.11 Maintenance of analyzers used for immission and dry deposition measurements (see also Chap. 3)

Maximum interval	Online detection	Semicontinuous with automated onsite analysis	Accumulation with manual offsite analysis
1 week	Check sampling flow rates (or line pressure) Check drying agents, chemicals, and other consumables Download raw data and check its plausibility visually	Check liquid and air flow rates Check chemical solutions and other consumables Download raw data and check its plausibility visually	
1 month	Check for tubing leaks Calibration Exchange inlet filters System response tests SbS measurements	Check for tubing leaks Field blanks Calibration Clean inlet material SbS measurements	Check sampling flow rates Field/transport blanks Check for tubing leaks Calibration and blanks of analytical equipment in the laboratory
1 year	Full service of analyzer	Full service of analyzer	

54.8 Application

The following section outlines some typical applications and related objectives of dry deposition measurements.

54.8.1 Annual Cycles and Nitrogen Budgets of Ecosystems

Investigations of annual cycles and seasonal variations are generally performed within the framework of long-term studies (or measurement networks) using accumulation systems with manual offsite analysis, long integration times, and subsequent application of the DDIM (or more advanced versions that are used as modules within atmospheric chemistry and transport models or multilayer models) (Sect. 54.4.3) [54.159, 175, 185].

However, in some studies, semicontinuous systems with automated onsite analysis have also been deployed for long-term measurements [54.186]. Advanced versions of these systems are currently employed for the long-term characterization of atmospheric chemistry and to monitor the deposition of nitrogen and sulfur with high time resolution [54.155, 187, 188].

The importance of dry deposition measurements is revealed when analyzing nitrogen storage and its evolution in ecosystems over time as a result of global change. Although the nitrogen input to ecosystems from dry deposition is small compared to the amounts of nitrogen cycled between soil and vegetation, it can substantially affect ecosystem functioning and biodiversity given that it is the limiting nutrient for plant growth in

many natural and seminatural ecosystems. Increasing N inputs to terrestrial ecosystems may cause:

- Ecosystem eutrophication and acidification
- A reduction in biodiversity
- Increased carbon storage
- Enhanced leaching of nitrate and soil nutrients
- Intensified trace gas exchange [54.189, 190].

Likewise, deposition of O_3 may cause biodiversity losses in natural ecosystems and crop yield losses in agricultural areas [54.191, 192]. Purely ecologically oriented studies often overlook the availability of methods for determining dry deposition, even though it is an important component of the overall nitrogen budget [54.193]. This may be due to the complexity of the various dry deposition measurement techniques that are used for individual compounds. There are barely any long-term studies that have applied state-of-the-art techniques such as EC, AGM, or MBR in combination with the determination of, e.g., nitrogen fixation, retention, and export processes to establish the overall nitrogen budget of an ecosystem. Within the framework of the NitroEurope project, nitrogen inputs and outputs together with nitrogen turnover in plants and soils as well as net greenhouse gas exchanges were measured for different European ecosystems [54.194, 195]. Long-term studies using the DDIM provide important information on the atmospheric nitrogen input into ecosystems and may help to identify when critical loads are exceeded.

54.8.2 Daily Cycles and Process Studies

When online or semicontinuous systems with automated onsite analysis are used (Sect. 54.4.1), it is possible to analyze diurnal cycles, as shown for HNO_3 and NH_3 in Fig. 54.7. The application of the AGM or MBR method for intensive observation periods that typically last for a few days to several weeks enables process-level studies, in particular investigations of surface uptake and chemical interactions. When there is substantial chemical divergence, fluxes of total nitrate/ammonium are sometimes determined to derive the total nitrogen input [54.196], or the influences of chemical reactions on the derived fluxes are assessed through modeling approaches [54.124, 129, 130, 197].

Such process studies potentially provide the basis for developing new parameterizations for r_c and its components for different surface types and meteorological conditions [54.70, 80, 87, 144]. An important step in the detailed analysis of r_c (or its inverse, the canopy conductance g_c) is the partitioning into stom-

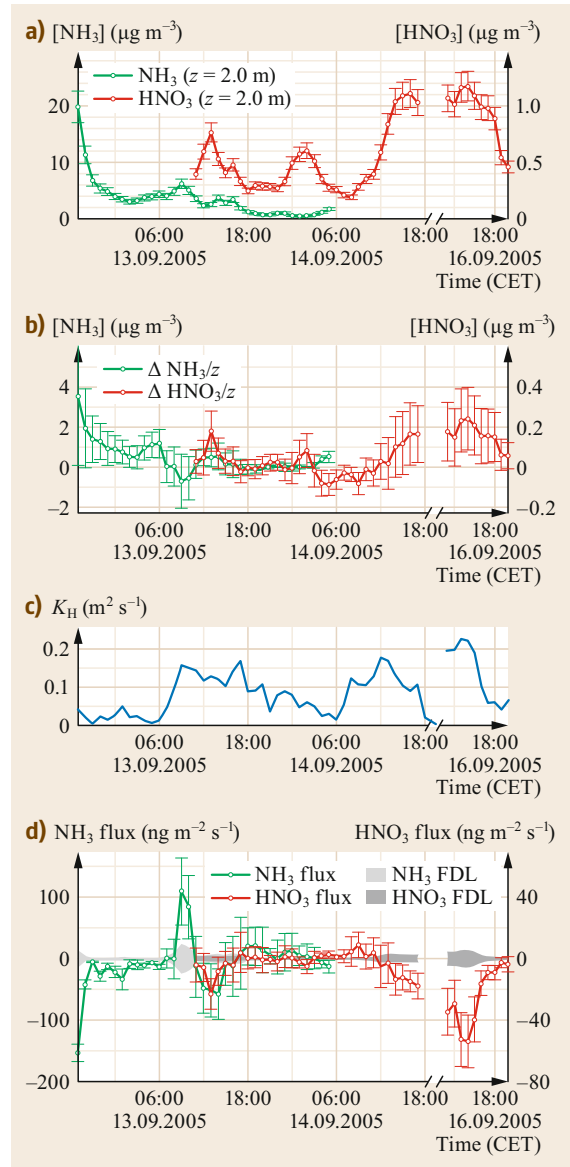

Fig. 54.7 (a) Measured concentrations, (b) vertical concentration differences, (c) turbulent exchange coefficient, and (d) fluxes determined with the AGM method for NH_3 and HNO_3 at a managed grassland site in southern Germany. Calculated flux detection limits (FDL) are shaded gray and correspond to the minimum detectable fluxes retrieved from side-by-side measurements (Sect. 54.6) (after [54.147] © 2009, reprinted with permission)

atal and nonstomatal deposition pathways (Fig. 54.8). These new insights can be used to apply the DDIM at comparable sites or to facilitate the improvement of inferential models, or they can be applied in atmospheric chemistry and transport models [54.198, 199].

Fig. 54.8a,b Canopy conductance (g_c) and partitioning into stomatal (g_s) and nonstomatal (g_{ns}) conductances (inverses of the resistances in Fig. 54.2) for (a) PAN and (b) O₃, as derived from MBR and EC measurements of the respective deposition fluxes at a natural grassland site in southwestern Germany (after [54.103] © A. Moravek et al. 2015, Creative Commons Attribution 3.0 License)

54.9 Future Developments

The major challenge in the forthcoming years will be to spatially intensify immission and dry deposition measurements, particularly in hot-spot regions where considerable emissions of air pollutants cause high deposition rates in nearby natural ecosystems. This is crucial to obtaining spatial and temporal information on patterns and trends as well as to monitoring the magnitudes of critical loads and level exceedances, thus forming the basis for decisions by policy makers. In order to achieve this goal, inexpensive low-power online systems (e.g., semiconductor-based ozone sensors and electrochemical NO₂ sensors [54.200]) with high time resolutions must be developed. The main requirements are sufficient accuracy and a need for only minimal maintenance, permitting standalone application over long time periods. For water-soluble and sticky compounds, the use of open-path instruments without inlet lines and pumps would be a major step

forward as it would improve accuracy at high time resolution [54.141, 201, 202].

Another challenge that must be addressed is the quantification of dry deposition in urban areas to complement current standard immission measurements [54.203, 204]. Additionally, remote-sensing methods to determine spatially resolved regional immission fields should be developed. New techniques such as satellite observations of the Earth and other remote-sensing instruments (e.g., drones) can be used to augment ground-based measurements (Chap. 28) [54.205–207].

The development of methods to quantify the nonstomatal surface resistances (e.g., leaf surface chemistry) in a mechanistic way would lead to a great improvement in the accuracy of dry deposition fluxes estimated using the DDIM. Furthermore, corrections for chemical flux divergence must be investigated in more detail.

Ivonne Trebs

Environmental Research and Innovation (ERIN)
Luxembourg Institute of Science and Technology (LIST)
Belvaux, Luxembourg
ivonne.trebs@list.lu

Working as a lead engineer in the Environmental Research and Innovation Department of the Luxembourg Institute of Science and Technology (LIST), Ivonne Trebs measures and models evapotranspiration from the biosphere. She is a recipient of the Otto Hahn Medal of the Max Planck Society, and was a MINERVA Junior Research Group Leader at the Max Planck Institute for Chemistry, where she studied the surface–atmosphere exchange of reactive nitrogen compounds.

Christof Ammann

Climate and Agriculture
Agroscope Research Institute
Zürich, Switzerland
christof.ammann@agroscope.admin.ch

Christof Ammann is Senior Scientist at the Swiss Federal Research Institute Agroscope, and leads a research team on agricultural greenhouse gas emissions. His interdisciplinary research focuses on field measurements of the exchange of reactive/nonreactive trace gases between the biosphere and the atmosphere using various measurement techniques. Since 2011, he has been a member of the Swiss Federal Commission on Air Hygiene—the clean air advisory board of the Swiss Government.

Jürgen Junk

Environmental Research and Innovation (ERIN)
Luxembourg Institute of Science and Technology (LIST)
Belvaux, Luxembourg
juergen.junk@list.lu

Jürgen Junk is a climatologist who has been working at the Luxembourg Institute of Science and Technology (LIST) since 2007. He received his PhD from the University of Trier (Germany) in 2010 and is now responsible for LIST's air quality projects. He has a special interest in biometeorology, in particular the behavior of nanoparticles in the near-surface atmosphere, their chemical compositions, and their impact on human health.

Eddy-Covariance

55. Eddy-Covariance Measurements

Matthias Mauder , Thomas Foken , Marc Aubinet , Andreas Ibrom 

The eddy-covariance method represents the only direct way to measure the turbulent fluxes of momentum, temperature, trace gases, and particles between the land surface and the atmosphere. It is a direct measurement of the net carbon-dioxide budget and dry deposition. For that purpose, it is widely used in networks of long-term ecosystem observatories around the world and is the centerpiece of intensive field campaigns investigating biosphere-atmosphere exchange processes. The instrumentation typically consists of a 3-D sonic anemometer/thermometer and one or more additional gas analyzers that are able to measure the high-frequency fluctuations of the scalar to be transported. These instruments are mounted on a meteorological mast to sample the turbulent field under the assumption that eddies are carried along with the mean wind. Further prerequisites of the method are horizontal homogeneity, steady-state conditions and well-developed turbulence. For successful application of the method, a series of quality tests and flux corrections is required, which will be presented together with commonly used instrumentation and postprocessing software. Moreover, we will provide a historical overview and provide guidelines for site selection and setup and the necessary maintenance procedures.

Turbulent energy and matter fluxes between the land surface and the atmosphere are of increasing interest for climate and ecological studies. The components of the energy balance are important forcing parameters for both areas of research. Particularly, direct measurement of the latent heat flux is one of the most important quantities (Chap. 57). In the context of climate change research, also the fluxes of other greenhouse gases, mainly carbon dioxide and methane, and the dynamics of ecosystems have become highly important ([55.1]; Chap. 64). Therefore, the eddy-covariance technique has become widely used as the only direct method for measuring biosphere-

atmosphere exchange on the ecosystem scale. It is typically applied in the surface layer, which is approximately 20–50 m high in the case of unstable stratification and a few meters in stable stratification [55.2, 3]. In this layer, fluxes are approximately constant with height, and atmospheric turbulence is the dominant transport mechanism; hence, measurements taken on different ground-based platforms (Chap. 6) are assumed to be representative of underlying surface fluxes. Besides these ground-based systems, the eddy-covariance method can also be used on tall towers and airborne platforms for measuring fluxes over larger areas (Chap. 48).

55.1 Measurement Principles and Variables

This section describes the basics of the eddy-covariance method and the dimensions and transformations of different units, mainly for scalar fluxes.

55.1.1 Principles of Flux Measurements

The description of turbulent fluxes in the following theory Sect. 55.3 requires the decomposition of the time series of each variable x into a mean part, \bar{x} , and a fluctuating part, x' , the so-called Reynolds decomposition (Fig. 55.1). This can be written as

$$x = \bar{x} + x', \quad (55.1)$$

where

$$\bar{x} = \frac{1}{T} \int_t^{t+T} x(t') dt', \quad (55.2)$$

where t is the time and T the averaging interval.

Under several assumptions, notably ergodicity and steady-state conditions (Sect. 55.3.1), the vertical flux within an averaging interval of approximately 10–30 min may be given by

$$F_x = \overline{wx} = \overline{w\bar{x}} + \overline{w'x'}, \quad (55.3)$$

Fig. 55.1 Reynolds decomposition of the value x into its mean part \bar{x} and its fluctuation, x' (after [55.2])

where w is the vertical wind velocity component, and x is either the horizontal wind velocity u in the direction of the mean flow in the case of a momentum flux or a scalar in the case of scalar fluxes, such as the sensible heat flux, the latent heat flux, or trace gas fluxes. Typically, sampling frequencies of about 10–20 Hz are used in order to capture the smallest relevant turbulent fluctuations. This flux is identical to the covariance

$$\overline{w'x'} = \frac{1}{N-1} \left[\sum_i (w_i - \bar{w})(x_i - \bar{x}) \right], \quad (55.4)$$

when the product of the mean values in (55.3) is zero, e.g., for the vertical flux in the horizontally homogeneous case, where $\bar{w} = 0$ (for simplicity, some known effects that challenge this condition were neglected).

55.1.2 Measurement Variables

An overview of the variables measured with the eddy-covariance technique is provided in Table 55.1. Scalars are measured in different units by the different types of devices. These quantities are related by the ideal gas and the Dalton laws.

Only the dry molar mixing ratio and the dry mass mixing ratio are conserved quantities in the presence of changes in temperature, pressure, and water vapor content [55.6]. The dry mass mixing ratio can be transformed into the dry molar mixing ratio through a multiplication by the molar mass ratio of dry air to component s . Unfortunately, out of the above mentioned variables, only the mass density and molar density are directly measured in the field by gas analyzers (Table 55.3). Since these quantities are not conserved during heat conduction, air compression/expansion or evaporation/condensation and water vapor diffusion,

Table 55.1 Measured variables with turbulence sensors with 10–20 Hz sampling frequency, including alternative names for the same quantities, which are sometimes used in ecological applications, in round brackets [55.4]

Variable	Description and sensor	Symbol	Unit
Vertical wind velocity	Sonic anemometer (Chap. 9)	w	m s^{-1}
Horizontal wind components	Sonic anemometer (Chap. 9)	u, v	m s^{-1}
Temperature	Cold wire thermometer (Chap. 7)	T	K
Sonic temperature	Temperature calculated from the speed of sound; sonic anemometer (Chap. 9)	T_s	K
Scalar: mass density (mass concentration)	Gas analyser (Chaps. 8 and 16)	ρ_s	kg m^{-3}
Dry air mass density	Thermometer, hygrometer, pressure sensor (Chaps. 7, 8 and 10)	ρ_d	kg m^{-3}
Scalar: molar density (molar concentration)	Gas analyzer (Chaps. 8 and 16)	c_s	mol m^{-3}
Scalar: molar mixing ratio	The ratio of the constituent mole number to the total number in the mixture; gas analyser (Chaps. 8 and 16)	χ	mol mol^{-1}
Scalar: dry molar mixing ratio (molar dry fraction)	The ratio of the constituent mole number to those of dry air; gas analyzer (Chaps. 8 and 16)	χ_s	mol mol^{-1}
Scalar: dry mass mixing ratio (mass dry fraction)	The ratio of the mass of the constituent to the mass of dry air; gas analyzer (Chaps. 8 and 16)	χ_{sm}	kg kg^{-1}

Table 55.2 Typical fluxes measured with the eddy-covariance method

Flux	Description and calculation	Symbol	Dimension
Shear stress	Component of the stress tensor in the direction of the mean wind velocity $\tau = \rho \sqrt{(\overline{w'u'})^2 + (\overline{w'v'})^2} \approx -\rho \overline{w'u'_h}$ with u'_h : wind velocity fluctuation in direction of the mean horizontal wind velocity	τ	$\text{kg m}^{-1} \text{s}^{-2}$
Friction velocity	Shear stress in the dimension of a velocity $u_* = \sqrt[4]{(\overline{w'u'})^2 + (\overline{w'v'})^2} = \sqrt{-\overline{w'u'_h}}$	u_*	m s^{-1}
Buoyancy flux ^a	The flux includes the buoyancy effect by temperature and humidity, ignoring the small difference between the sonic temperature and virtual temperature (Chap. 7)	$\overline{w'T'_s}$	m K s^{-1}
Sensible heat flux ^a	For calculation from buoyancy flux, see Sect. 55.3.2	$\overline{w'T'}$	m K s^{-1}
Latent heat flux ^b	Water vapor flux with water vapor partial pressure e or specific humidity q (Chap. 8)	$\overline{w'e'}$ $\overline{w'q'}$	hPa m s^{-1} $\text{kg kg}^{-1} \text{m s}^{-1}$
Trace gas fluxes	Trace gas flux in different units dependent on the sensor (Chaps. 8 and 16), see Tables 55.1 and 55.3	$\overline{w'c'_s}$ $\overline{w'\rho'_s}$ $\overline{w'\chi'_s}$ $\overline{w'\chi'_{sm}}$	$\text{mol m}^{-2} \text{s}^{-1}$ $\text{kg m}^{-2} \text{s}^{-1}$ $\text{m mol mol}^{-1} \text{s}^{-1}$ $\text{m mol mol}^{-1} \text{s}^{-1}$

^a Transformation in energetic units for sensible heat flux (buoyancy flux), for details, see Chap. 5

$$Q_H = c_p \rho \overline{w'T'} = c_p \frac{p}{R_d T_v} \overline{w'T'} = 1004.832 \frac{p}{287.0586 T_v} \overline{w'T'} \quad [\text{W m}^{-2}],$$

c_p : specific heat at constant pressure, ρ : air density, R_d : gas constant for dry air, T_v : virtual temperature (can be replaced by T with an error < 1% on the resulting flux)

^b Transformation in energetic units for latent heat flux; for details, see Chap. 5

$$Q_E = \lambda \rho \overline{w'q'} = \lambda \frac{p}{287.0586 T} \overline{w'q'} = \lambda \frac{p}{287.0586 T} \frac{0.62198}{p} \overline{w'e'} \quad [\text{W m}^{-2}].$$

Table 55.3 Conversion factors between different variables characterizing scalar intensity (use p in hPa in the following equations) [55.5], alternative names for the same quantities, which are sometimes used in ecological applications, are provided in round brackets [55.4]

	Dry molar mixing ratio (molar dry fraction, dry air mole fraction) χ_s (mol mol ⁻¹)	Dry mass mixing ratio (mass dry fraction) χ_{sm} (kg kg ⁻¹)	Molar density (molar concentration) c_s (mol m ⁻³)	Mass density (mass concentration) ρ_s (kg m ⁻³)
χ_s	1	$\frac{m_s}{m_d} = \frac{m_s}{0.0289645}$	$\frac{p_d}{R^*T} \approx \frac{p \times 100}{8.3145T}$	$\frac{m_s p_d}{R^*T} \approx \frac{m_s p \times 100}{8.3145T}$
χ_{sm}	$\frac{m_d}{m_s} = \frac{0.0289645}{m_s}$	1	$\frac{m_d p_d}{m_s R^*T} \approx \frac{p \times 100}{287.0586 m_s T}$	$\frac{m_d p_d}{R^*T} \approx \frac{p \times 100}{287.0586T}$
c_s	$\frac{R^*T}{p_d} \approx \frac{8.3145T}{p \times 100}$	$\frac{m_s R^*T}{m_d p_d} \approx \frac{287.0586 m_s T}{p \times 100}$	1	m_s
ρ_s	$\frac{R^*T}{m_s p_d} \approx \frac{8.3145T}{m_s p \times 100}$	$\frac{R^*T}{m_d p_d} \approx \frac{287.0586T}{p \times 100}$	$\frac{1}{m_s}$	1

variations may appear even in the absence of production, absorption, or transport of the respective measured component in the atmosphere. The necessary corrections [55.7–9] will be discussed in Sect. 55.3.2.

The typical fluxes measured with the eddy-covariance technique are shown in Table 55.2, and the calculation of different units for scalars is given in Table 55.3. Thereby the transformation from the dry molar mixing ratio or dry mass mixing ratio into molar density or mass density is only an approximation, shown for the example of the calculation of the mass density from the dry mass mixing ratio

$$\rho_s = \frac{m_s p_d}{R^*T} = \chi_{sm} \frac{m_d p_d}{R^*T}, \tag{55.5}$$

where R^* is the universal gas constant, m_s is the molar mass of the scalar, p_d is the partial pressure of dry air, and m_d is the molar mass of dry air.

The pressure of dry air is not available and must be replaced by the difference of the air pressure and the partial pressure of water vapor ($p - e$) for which an approximation with the virtual temperature (T_v) (Chaps. 7 and 8) is possible

$$\begin{aligned} T_v &= T \left(1 + q \frac{R_w - R_d}{R_d} \right) = T(1 + 0.608q) \\ &\approx T \left(1 + 0.38 \frac{e}{p} \right), \end{aligned} \tag{55.6}$$

with the specific humidity q , and R_w and R_d the gas constants for water and dry air, respectively. The error of the above approximation is negligible in comparison to the error of using p instead of p_d , since

$$p_d = (p - e) = p - p \frac{T_v - T}{0.38T} = p \left(1 - \frac{T_v - T}{0.38T} \right). \tag{55.7}$$

According to Table 5.18 the virtual temperature excess $T_v - T$ of saturated humid air is in the order of about 1–5 K. Therefore, the second summand of (55.7) is in the order of about 0.01–0.05, following the error of this approximation is maximal 5% but in most of the cases < 2%. The calculations according to Table 55.3 are only possible for mean quantities. For fluctuations of the scalars, the fluctuations of temperature and water vapor must be taken into account ([55.6, 9], Sect. 55.3.2).

55.1.3 Site Considerations

The assumptions of horizontally homogeneous surfaces and steady-state conditions are the most limiting factors with respect to site considerations. Surface representative eddy-covariance flux measurements require a certain extension of the homogeneous area (*fetch*) in the wind direction and the footprint (source weight distribution function, see Chap. 1) area, which should be over a uniform underlying surface to match the requirements for all stability conditions. Both effects from internal boundary layers and influences by obstacles should be avoided (Chap. 1). The fetch requirement is most critical for the selection of the measurement site and the measurement height above the surface. This is especially relevant for forest sites, where additional characteristics of tall vegetation must be taken into account. Here, it is primarily important to place the eddy-covariance system either above the roughness sublayer (Chap. 1) or within the upper part of the roughness sublayer, because otherwise, the measured flux may be disturbed by effects from single roughness elements and no longer represents the flux from the entire ecosystem under study. Additionally, in the lower parts of the roughness sublayer, Monin–Obukhov similarity is no longer applicable, which is prerequisite for some of the necessary flux corrections.

55.2 History

The eddy-covariance method was proposed by *Raymond B. Montgomery* (1910–1988) [55.10], *William Christopher Swinbank* (1913–1973) [55.11], and *Alexander Mikhailovich Obukhov* (1918–1989) [55.12] for measuring exchanges of heat, mass, and momentum between a flat, horizontally homogeneous surface and the overlying atmosphere. For such an ideal surface, the net transport between the surface and atmosphere can be treated as 1-D, and the vertical flux density represents the total flux, which can be calculated by the covariance between turbulent fluctuations of the vertical wind speed and the quantity of interest.

Instrumentation limitations hampered the early implementation of this approach. In 1949, *Konstantinonov* [55.12] developed a wind vane with two hot-wire anemometers to measure the shear stress (Fig. 55.2). A similar instrument – but already for the sensible and latent heat flux – was constructed by *W.C. Swinbank* [55.11] in 1951 (Fig. 55.3). First, time series of the fluctuations of wind direction, wind velocity, temperature, and humidity were shown, and even the sensible heat flux was calculated from this data. Significant problems were the different response times of the sensors and the problem of the fast registration. At the time, and in the following 10–15 years, the time series were recorded with a galvanometer with a mirror on photographic paper. This system was updated in Australia by the middle of the 1960s, e.g., with a propeller anemometer for the measurement of the vertical wind fluctuation with a similar response time to the thermocouples [55.13, 14].

The full potential of the eddy-covariance method only emerged after the development of sonic anemometers, for which the basic equations were given by *Richard M. Schotland* (1927–2006) [55.16]. After the development of the first sonic thermometer [55.17], a vertical

Fig. 55.2 Wind vane with two hot wire anemometers (90° angle) for the measurement of the friction velocity based on *Konstantinonov's* work in 1949 (after [55.12, 15])

sonic anemometer with a 1 m path length [55.18] was used during the O'Neill experiment in 1953 [55.19]. The design of today's anemometers was developed by *Viktor Markovich Bovscheverov* (1905–1995) [55.20], and later by *Jagadish Chandran Kaimal* (1930–2021) and *Jost A. Businger* [55.21] and *Yasushi Mitsuta* [55.22]. These phase-shift anemometers have now been replaced by running time anemometers with delay time measurements [55.23]. For more details of the development of sonic anemometer technique see Chap. 9.

Early micrometeorological experiments in the 1950s to 1970s were designed to study fundamental aspects of atmospheric turbulence over homogeneous surfaces [55.24–26], whereas studies in the 1980s investigated the turbulent fluxes of momentum, and sensible and latent heat over heterogeneous surfaces. Similar experiments were conducted in the USA (FIFE, [55.27]), France (HAPEX, [55.28]), and in Russia (KUREX, [55.29]). These experiments became the basis of many further micrometeorological experiments [55.2] that needed researchers who were highly experienced in micrometeorology and sensor handling. During this period also most of the necessary theory, corrections, and quality tests were developed; see Sect. 55.3.

At the beginning of the 1990s, the first closed and open-path gas analyzers were commercially available mainly for water vapor and carbon dioxide and replaced custom-made sensors (for the history of fast response humidity sensors: Chap. 8; for all other trace gases: Chap. 16).

The technical feasibility of continuous eddy-flux measurements arose in the 1990s with the development of new generation sonic anemometers [55.55, 62]

and infrared gas analyzers for water vapor and carbon dioxide, reliable and sufficiently fast data acquisition systems, together with the first comprehensive software packages for the eddy-covariance method [55.41]. In the early 1990s, the eddy-covariance method became more and more widely used by the ecological community for the measurement of the energy, carbon dioxide, and water vapor exchange between ecosystems and the atmosphere. The first long-term measuring towers

were installed, which formed the seed for the international FLUXNET network [55.61], and introductions into the eddy-covariance method for nonmicrometeorologists were written [55.60, 63, 64]. In parallel, the development of new analyzer types allowed an extension of the investigated trace gas spectrum and even atmospheric particles (Chaps. 8, 16, 17, and 18).

Some milestones in the development of the eddy-covariance method are given in Table 55.4.

55.3 Theory

The theory of the eddy-covariance technique is the subject of several textbooks [55.2, 3, 65, 66], which also contain many references to further papers. Therefore, only the most important topics are briefly discussed in this section.

55.3.1 Conservation Equations and General Definitions

Conservation equations for dry air mass, momentum, temperature, and air constituents are given in the lit-

erature [55.3, 65, 67]. Since the method is not applied directly at the surface, which exchanges scalars with the atmosphere, but at a certain height above the surface and partially also above heterogeneous terrain, further assumptions must be made. In the simplest case, these terms balance each other or become negligibly small. For flat terrain, the net flux of a scalar exchanged by the surface is

$$F_\chi = \underbrace{\overline{\rho_d w' \chi'_{sm}}}_{\text{I}} \Big|_{z_m} + \underbrace{\int_0^{z_m} \overline{\rho_d \frac{\partial \chi_{sm}}{\partial t}} dz}_{\text{II}}, \quad (55.8)$$

with χ_{sm} as the dry mass mixing ratio and $\overline{\rho_d}$ as the density of dry air. Term I is the flux at the upper boundary of the volume element measured with the eddy-covariance method. Term II is the storage change between the surface and the measurement height, which can be ignored for the momentum flux. However, for sensible heat, water vapor, and other gases, such as carbon dioxide, its contribution can be significant. In particular, in the morning hours, when the accumulated gasses in the air column underneath the sensor is dispersed into the boundary layer, the storage change term (calculated from the change in time of the partial density of the investigated matter integrated over the whole profile underneath the eddy-covariance system) may become important.

In heterogeneous or sloped terrain, the net flux is equal to the flux at the upper boundary of the control volume (term I), the storage term II, and also a horizontal (term III) and vertical (term IV) advection term, plus the horizontal flux divergence (term V)

$$\begin{aligned} F_\chi = & \underbrace{\overline{\rho_d w' \chi'_{sm}}}_{\text{I}} \Big|_{z_m} + \underbrace{\int_0^{z_m} \overline{\rho_d \frac{\partial \chi_{sm}}{\partial t}} dz}_{\text{II}} \\ & + \underbrace{\int_0^{z_m} \left[\overline{\rho_d u' \frac{\partial \chi_{sm}}{\partial x}} + \overline{\rho_d v' \frac{\partial \chi_{sm}}{\partial y}} \right]}_{\text{III}} + \underbrace{\int_0^{z_m} \left[\overline{\rho_d w' \frac{\partial \chi_{sm}}{\partial z}} \right]}_{\text{IV}} \\ & + \underbrace{\int_0^{z_m} \left[\overline{\rho_d \frac{\partial u' \chi'_{sm}}{\partial x}} + \overline{\rho_d \frac{\partial v' \chi'_{sm}}{\partial y}} \right]}_{\text{V}}. \end{aligned} \quad (55.9)$$

In this form, the method is called the *generalized eddy-covariance method* [55.2, 65].

Especially in complex terrain, the quantification of the advection terms is still the subject of ongoing research and extensive experiments [55.68, 69]. Due to

the large errors in the determination of the advection terms, there is a large risk that applying these terms will introduce large errors to the flux estimates [55.70]. To avoid this risk, data that is considerably affected by advection, e.g., such data collected at night under low-turbulence conditions, can be discarded and gap filled [55.71]. The challenge remains to define quantitative criteria that safely identify low-turbulence conditions and also apply adequate gap filling. Due to the lack of better practical knowledge on when exactly advection becomes a dominating influence, empirical methods have been developed [55.60]. In the case of CO₂ flux measurements, such objective criteria were defined based on u_* threshold values. Beyond a site-specific u_* threshold value, it is usually observed that the normalized flux becomes independent of u_* [55.72]. Measurements taken at conditions with u_* smaller than this threshold value are excluded and parameterized with empirical gap-filling algorithms in order to calculate monthly or annual fluxes [55.73, 74].

55.3.2 Flux Calculation, Corrections, and Conversions

The eddy-covariance method is a direct measurement method solely based on first principles [55.2, 3, 65]. However, the derivation of the mathematical algorithm is based on a number of simplifications so that the method can only be applied if certain assumptions are fulfilled. The quality of the measurements primarily depends more on the site conditions and the application of necessary corrections, rather than on the presently available highly sophisticated measurement systems [55.75]. The most limiting conditions are the assumptions of horizontally homogeneous surfaces and steady-state conditions. The latter restrictions cannot be corrected; they are subject of the quality control (Sect. 55.6) to identify data that need to be discarded.

Preparation of Raw Data

The preparation of the input data starts with the exclusion of missing values and outliers, which can be found by plausibility tests, checking whether a measurement value is within predefined limits given by the expected meteorological conditions and the range of the instrument or the data acquisition system (Chap. 2). Further tests should detect unfavorable meteorological conditions or technical problems of the instruments, whereby separating these two factors is often difficult [55.58]. Spikes, i.e., values that are significantly above the normal variation of the measured value but still within the possible range, are often electronically caused. The usual *despiking* test is based on the determination of the standard deviation of the variable (σ).

All individual values $> 3.5\sigma$ [55.76] are considered as spikes. If single spikes are large, it is recommended that the test be repeated two to three times, because otherwise the estimated σ is overestimated if they are included. To make this test even more effective, running standard deviations are used for flux calculations. Measurement series with $> 1\%$ of spikes should not be used. More robust is the application of the absolute deviation from the median (MAD) [55.77], $\text{MAD} = \text{median}_i (|x_i - \text{median}_j (x_j)|)$, where all values that are larger or lower than a multiple of the MAD-value, are identified as spikes

$$\text{median}(x) - \frac{q\text{MAD}}{0.6745} \leq x_i \leq \frac{q\text{MAD}}{0.6745} + \text{median}(x), \quad (55.10)$$

where 0.6745 is the corresponding value of the normal distribution by Gauss. It is recommended to use $q = 7$ for this application [55.75].

Even if measurement signals are recorded on the same data logger records, it may occur that the data sampled at the same point of time are not stored at the same point in time. This can be partially corrected in the software of the data logger, but such time delays can vary over time. A typical example is a measurement system where air is drawn in through a tube from close to the measurement volume of the sonic anemometer down to a displaced analyzer. Then, depending on the travel time of the air sample in the tube, the concentration measurements are recorded significantly later than the wind speed component. The time lag can be determined with a *cross-correlation* analysis, and the concentration time series are shifted relative to the vertical wind measurements by the time difference of the maximum cross correlation. If the signal is too small, correlation maxima may appear at unlikely time differences. In this context, it is important to note that intake tubes should not be longer than necessary. This would lead to systematically overestimated flux values, which may be particularly critical for N_2O or CH_4 budgets. The synchronization of the wind speed and the scalar measurement must be done before any further calculations are made. From the synchronized data, initial covariances can be calculated.

High-Pass Filtering after Block Averaging or Detrending

Data from sensors in an eddy-covariance system are routinely processed to calculate fluctuations from the mean; see (55.3). Historically, different averaging and detrending operators have been applied to this end. Several methods are available to separate the active, turbulent transport that we treat as eddy flux from the slower,

deterministic atmospheric motions, flux instationarity due to changing weather conditions, and instrumental drift. Amongst others ways, linear detrending, a spectral high-pass filter, or a recursive running mean are often used by practitioners in order to extract the turbulent part from a time series [55.41]. The choice of detrending method depends, thus, on the understanding of the nature of low-frequency contributions to the covariance by the practitioner. Sometimes, a clear spectral gap is found between the time scales of atmospheric variability ([55.78] and Chap. 1), which, however, often appears not to be as evident, especially above rough surfaces and at unstable stratification. This circumstance normally makes it difficult to draw a clear line between turbulence and variability due to weather. On top of this problem, sensor drift might add an artificial bias to the low-frequency parts of the time series, which should also be removed before the calculation of covariances.

Fortunately, in many cases, spectral turbulence models can be easily defined with some certainty from measured 30 min turbulence spectra, often aggregated for classes of atmospheric stratifications [55.79]. If the model of the peak frequency is well parameterized, it is safe to apply modest detrending algorithms, because the low-frequency loss of turbulence that is caused by such high-pass filters can easily be calculated and restored from the known high-pass filter transfer functions of these operations [55.80]. Examples for the beneficial, i.e., noise-reducing, effects from using detrending methods compared to simple block averaging have been provided by [55.81].

Some scientists prefer using only block averaging by calculating the arithmetic mean over a certain time period [55.81, 82] because of potential conflicts with the Reynold's decomposition and the uncertainties of applying spectral models to low-frequency domains, where the data is noisy. Block averaging is, like linear detrending and recursive filtering, a high-pass filter, with the spectral cutoff depending on the nonoverlapping averaging time. For a rough estimation, its average length can be estimated by, e.g., the ogive method for any site [55.45, 46, 83, 84]. However, by selecting a fixed length of the averaging interval, this method implicitly puts an assumption on the low-frequency turbulent contributions, i.e., that turbulent time scales are constant at a site and that the signal in lower frequencies than captured by block averaging can be neglected. This assumption is challenged by the observed dependency of the wind speed normalized peak frequency on atmospheric stratification, with lower values at unstable conditions. As the eddy-covariance system samples the turbulent signal in natural frequencies, the low-frequency loss is inversely related to the wind speed. Not considering this dependency with the length of

the averaging time means that the coverage of low-frequency signals measured by the eddy-covariance system depends on atmospheric conditions. This bias is only considered when correcting for the high-pass filtering effects.

From this it follows that whatever the high-pass filter method is being used, i.e., detrending, recursive filtering, or block averaging, effects need to be corrected with the appropriate high-pass filter correction method based on a site and measurement height-specific spectral model that covers the relevant spectral domains.

Low-Pass Filtering and Other Corrections

This section describes corrections that must be applied to measurements because practical instrumentation cannot fully meet the requirements of the underlying micrometeorological theory. Typically, measurements are conducted in a finite sampling volume rather than at a single point, and the maximum frequency response of the sensors may be smaller than the highest frequencies of the turbulent eddies responsible for the heat and mass transport. Both of these instrument limitations cause a loss of the high-frequency signal. Errors also arise in calculating fluxes of trace gas quantities using open-path analyzers because of spurious density fluctuations arising from the fluxes of heat and water vapor. This chapter gives an overview of how these sources of error can be eliminated or reduced using some model assumptions and additional measurements.

Here, we assume that an initial preprocessing of the raw velocity and scalar time series has been completed, including despiking and an adjustment of possible time delays. The acoustic temperature measured by sonic anemometers must be corrected for an increased sonic travel time due to winds blowing orthogonally to the measurement path (cross wind) [55.37, 85]. Current sonic anemometers include this *crosswind correction* in their firmware, but this is not the case for some older anemometers. It is also assumed that the coordinate system has been rotated to ensure zero vertical wind velocity over a certain averaging time (Sect. 55.1.1). This rotation is called a tilt correction [55.86, 87] or coordinate rotation [55.50] and can be applied to two or three axes, where the three-axis rotation is not recommended. The *double-rotation* method may be suitable for flat sites with a low vegetation canopy [55.81]. Currently, the *planar-fit method* [55.51] is often used, which overcomes some deficiencies of the double-rotation method above tall vegetation or at low-wind speed conditions, and it also accounts for a possible instrument caused offset of the w -component.

Furthermore, a correction for density fluctuations is applied (*WPL correction* according to Webb, Pearman, and Leuning, formerly also called Webb correc-

tion) [55.9]. Technically, this is rather a unit conversion for the measurement of gas concentration per unit volume instead of per unit mass, and it compensates for rapid changes of temperature and air composition caused by the turbulent fluxes. After the first publication, several authors discussed this problem, often controversially. A clarification of the problem was given by Leuning [55.7, 8]. The correction is necessary because fluctuations in temperature and humidity cause fluctuations in trace gas concentrations that are not associated with the flux of the trace gas that we wish to measure (correlated dilution/expansion/condensation of the gas sample due to spectral similarity with water vapor and heat). The correction to the measured flux can be large, i.e., the additive correction may significantly change the CO₂ flux calculated using the covariance of vertical velocity and partial density. A very careful application of this correction is essential for all trace gas fluxes as discussed below, unless these are measured in units of mass or molar mixing ratio.

For open-path sensors, the corrected flux of a scalar quantity, e.g., CO₂ or CH₄, is calculated after

$$F_s = \overline{w'\rho'_c} + \mu \frac{\overline{\rho_s}}{\overline{\rho_d}} \overline{w'\rho'_w} + (1 + \mu\sigma) \overline{\rho_s} \frac{\overline{w'T'}}{\overline{T}}, \quad (55.11)$$

with the correct flux of scalar quantity F_s , the mass density of a scalar quantity ρ_s , the mass density of dry air ρ_d , the density of water vapor ρ_w , and

$$\mu = \frac{m_d}{m_w} = 1.6; \quad \sigma = \frac{\overline{\rho_w}}{\overline{\rho_d}}. \quad (55.12)$$

For practical purposes, the general formula (55.8) can be simplified for the correction of H₂O-fluxes/latent heat fluxes

$$F_w = (1 + \mu\sigma) \left(\overline{w'\rho'_w} + \overline{\rho_w} \frac{\overline{w'T'}}{\overline{T}} \right). \quad (55.13)$$

In (55.11) and (55.13), ρ'_w and T' represent fluctuations of water vapor and temperature inside the measurement volume. For low trace gas fluxes this additive correction can be in the order of magnitude of the actual flux [55.88].

For closed-path sensors, only the water vapor dilution component is necessary, because temperature fluctuations are effectively dampened in the tubes [55.89]. Here, the dampened water vapor flux rather than the actual water vapor flux in the atmosphere needs to be used in the modified (55.11) [55.90, 91].

Conversion of buoyancy flux into sensible heat flux is known as *SND correction* after the three authors

Schotanus, Nieuwstadt, and DeBruin [55.37], formerly also called the Schotanus correction. It is based on the transformation of sonic or acoustic temperature (T_s) to actual air temperature. The sonic temperature is given as (Chaps. 7 and 9) [55.21, 92]

$$T_s = T(1 + 0.531q) \approx T \left(1 + 0.33 \frac{e}{p} \right), \quad (55.14)$$

where q is the specific humidity, p is atmospheric pressure, and e is the partial pressure of water vapor; the numerical values differ slightly because of the application of the International Temperature Scale of 1990 (ITS-90). For the SND correction of the sensible heat flux in kinematic units without the crosswind correction, which is often included in this equation, it follows

$$\overline{w'T'} = \frac{\overline{w'T'_s}}{1 + \frac{0.51c_p\bar{T}}{\lambda Bo}}, \quad (55.15)$$

with the *Bowen* ratio Bo , being the ratio of the sensible over the latent heat flux. Therefore, measurements of humidity and the water vapor flux are needed to calculate the sensible heat flux [55.92].

An important correction to the actual available turbulence spectra is the adjustment of the spectral losses of the measurement system. Hence, effects due to time resolution (time constant) of the sensor, the path-length averaging, and the separation between different sensors must be corrected. This *low-path filter correction* is typically applied using transfer functions (Chap. 2). For each eddy-covariance sensor configuration, there are separate filters for the time constant, the measurement path length, and the sensor separation, which must be determined. The convolution of these single spectral filter functions is the total filter transfer function [55.38, 93]. The method can also be applied using different transfer functions accordingly [55.64, 79]. For a chosen measurement system, it is also possible to use a simple analytical correction for a site that takes into account the observed spectra [55.94, 95]. However, such simplified corrections should only be applied with care, because they need to be adapted to the specific site conditions. Past experience showed that this approach often ignores essential causes of frequency loss, e.g., the impact of a rain cap [55.96, 97] and the tube length [55.98], and leads to systematic biases. In these conditions, an alternative is to base the correction on empirical transfer functions obtained by computing the ratio of the measured (co)spectra with an ideal (co)spectrum. Considering that high-frequency losses on vertical velocity and temperature are small, the measured sensible heat cospectra may be used as a reference [55.60, 99].

Often, a sampling time of 30 min is not long enough to measure the low-frequency part of the fluxes, particularly in the presence of heterogeneity-induced secondary circulations. Given the reservations mentioned above when addressing the high-pass filter effects of an eddy-covariance system, it can be tested whether the flux has its maximum value within the usual averaging time. This is done using the so-called *ogive test* [55.45, 46, 83]. It is calculated using the cumulative integral of the cospectrum of the turbulent flux beginning with the highest frequencies. If the value of the integral approaches a constant value (flux) for low frequencies, and if an enhancement of the averaging interval gives no significant changes, then no additional correction is necessary. Otherwise, the choice of a different averaging interval may be considered for the covariance calculation. The ogive test is only meaningful if the fluxes are not too small and steady-state conditions can be assumed [55.100].

There is often considerable loss of flux data when open-path gas analyzers are used at sites where rain, fog, mist, and snow impair measurements of trace gas concentrations. Closed-path gas analyzers provide an attractive alternative because of lower rates of data loss, but such measurement systems require significantly different corrections for time delays, low-pass filtering, and density effects compared to those needed for open-path systems. Temperature fluctuations in tubings with high thermal conductivity are reduced to 1% of their initial value when the ratio of tubing length to radius $L_t/r_t > 1200$ for laminar flow in the tube and when $L_t/r_t > 500$ for turbulent flow [55.89]. When temperature fluctuations at all frequencies are eliminated by the air sampling system, there is no need for the respective part of the WPL correction, but still effects from water vapor fluctuations in the sample on the scalar concentration need to be taken into account, if such a correction is not already included in the instruments firmware. Complete elimination of temperature fluctuations may not be achievable for practical lengths of tubing with walls of low thermal conductivity, in which case some unknown fraction of the $\overline{w'T'}$ density correction must be applied. The solution is to measure the temperature and pressure fluctuations within the gas analyzer at the same 10 or 20 Hz normally used for flux determination.

Corrections that Should be Used with Care

An overview of all corrections, conversions, and tests is given in Table 55.5. This table also includes a number of corrections that should not or only be used with care. These corrections are partly related to single instruments. Some very specific corrections are discussed in Sect. 55.4. The *angle of attack correction* assumes that turbulence elements move through

Table 55.5 Data handling and corrections

Method	Description	References
Preparation of the raw data		
Despiking	Deleting and replacing of outliers in the raw data with standard deviation or MAD, the latter is more effective	[55.75, 76]
Synchronization	Correction of possible time delays between different sensors	[55.99, 101]
Averaging operator	Either block averaging or another appropriate high-pass filtering method needs to be selected, and the corresponding high-pass filter correction applied	[55.81]
Necessary and recommended corrections		
Crosswind correction	Correction of the influence of the wind perpendicular to the sonic path on the sonic temperature measurement, usually part of the sonic anemometer firmware	[55.37, 85]
Double rotation	Rotation into the mean wind direction and to achieve $\overline{w} = 0$, applied for each averaging interval, recommended for flat terrain and continuously running measurement programs	[55.50, 102]
Planar-fit rotation	Rotation into the mean wind direction and parallel to a plane following the streamlines to achieve $\overline{w} = 0$, applied for longer averaging periods, recommended for complex terrain and research programs	[55.51, 102]
SND correction	Transformation of the buoyancy flux into the sensible heat flux (compulsory)	[55.37]
WPL correction	Correction of the moisture influence on density fluctuations, compulsory for open, enclosed and closed path; correction for temperature influence only compulsory for open and enclosed path gas analyzers	[55.7–9]
Low-pass filter correction	Correction of the spectral losses of fluxes at high frequencies, different methods possible, strongly recommended	[55.38, 64, 99]
High-pass filter correction (ogive test)	Correction of the loss of fluxes of periods larger than the averaging time, strongly recommended, but only under steady-state conditions	[55.45, 46, 80, 83, 84]
Enclosed/Closed-path gas analyzer correction	Correction of frequency loss and still existing density fluctuations, strongly recommended	[55.89–91]
Cross sensitivity correction	Oxygen cross sensitivity of the krypton hygrometer	[55.103, 104]
Iterative correction	Repeating of the correction in an iterative cycle, $\approx 1\%$ correction of fluxes	[55.105]
Corrections that should be used with care and not recommended corrections		
Specific heat correction	Wrong assumption that fluctuations of the specific heat have an effect on fluxes	[55.99, 106]
Modification of the WPL correction due to the unclosed energy balance	Should not be used as long as no correction procedure for the unclosed energy balance is available	[55.99, 107]
Aliasing correction	The aliasing correction of the spectral correction [55.38] is wrong	[55.99]
Transducer-shadow effect	Probe-induced flow distortion of the sonic anemometer transducer	[55.108–110]
Angle of attack correction	Flow distortion correction for each single measurement according to a wind tunnel flow distortion analysis, probably not directly transferable to the turbulent atmosphere	[55.99, 111, 112]
Burba correction	Correction of sensor self-heating of the LiCor 7500 gas analyzer, use only with care in cold environments	[55.99, 113]
Sonic anemometer heating corrections	The heating of the sonic anemometer has probably an influence on fluxes, the problem is under investigation	[55.113, 114]
Digitalization error	Limited digitalization (relevant for historical measurements)	[55.58, 115]

the sonic anemometer on waveform patterns and, thus, reach the anemometer at a specific angle. The correction approach is based on wind-tunnel measurements under quasi-laminar conditions [55.111]. These measurements were repeated in a turbulent field with inclined sonic anemometers [55.112], but the measurement setup was questionable [55.116, 117]. These corrections should, therefore, only be applied with care.

Flow distortion by the sonic anemometer probe has been a well-known problem since the beginnings of sonic anemometry [55.118]. The reasons are the

installations of the sensors and the size of the transmitters/receivers. In general, a large ratio of the path length, d , to the transmitter/receiver diameter, a , of at least $d/a = 20$ is required to minimize the influence of flow distortion. Furthermore, the angle, θ , between the wind vector and the transmitter–receiver path should be large [55.50, 108, 119]. These results are based on wind tunnel investigations for a sonic anemometer with orthogonal measurement paths [55.109]. Recently, some papers explained a reduction of the vertical wind velocity by *transducer-shadow effects* [55.110, 120, 121]

and proposed to apply the correction. This correction is currently only available for the CSAT3 anemometer and an orthogonal configuration with 25 cm path length [55.119]. It is also still under validation, and we do not recommend it generally for standard applications.

The sensor head of the LiCor 7500 open-path gas analyzer is heated and, therefore, generates expansion of the air sample within the sampling volume, which has an influence on the application of the WPL correction [55.122, 123]. Apart from a correction using additional fine-wire thermometers within the measurement volume [55.124] or the comparison with a closed path sensor [55.113, 125], no general consensus has been reached yet as to which method is the most effective and efficient. In general, these corrections depend on wind speed and the inclination of the sensor. Therefore, such *self-heating correction* should only be applied with great care.

Corrections for CH₄ and N₂O Analyzers

In recent years, fast response sensors for trace gases other than CO₂ have become commercially available. Particularly, analyzers for the non-CO₂ greenhouse gases (GHG) CH₄ and N₂O are gaining more and more attention in climate-change research. As for the CO₂/H₂O analyzers, these sensors are also based on molecular absorption spectra. However, since atmospheric concentrations of these gas species are much smaller than, e.g., for CO₂, a more specific radiation source is necessary to minimize cross sensitivity with other gasses, and this is why these sensors generally use lasers instead of noncoherent radiation sources. In this context, two basic measurement principles can be distinguished [55.126]:

- Tunable diode laser (TDL) spectroscopy, where the output wavelength of the laser is tunable over a certain spectral range, so that the laser can scan across a specific absorption band of a molecule. For many of those analyzers, the actual measurement is carried out in an optical cell at a very low pressure. This has the disadvantage of requiring high-power pumps but leads to a wanted narrowing of the absorption bands and, therefore, better separation between different gas species. Examples for this type of analyzer are the Campbell TGA-100/200 or the Aerodyne Quantum Cascade Laser (QCL). The Licor LI-7700 also uses a tunable laser source but in an open-path measurement setup, similar to the LI-7500 but with a longer path length and at ambient pressure.
- Cavity ring-down spectroscopy (CRDS) or off-axis integrated cavity output spectroscopy (ICOS), allow

for considerably larger path lengths per unit volume of the optical cavity and, thus, lower gas concentration detection limits. The devices operate at low pressures (1/10 of ambient), which requires powerful vacuum pumps. The intensity decay rate of radiation trapped in an optical cavity is measured, which is a function of the concentration of a gas species that absorbs radiation at that specific wavelength. The CRDS principle is applied, for example, by the PICARRO analyzers, whereas ICOS is used by the Los Gatos Fast Greenhouse Gas Analyzer.

The corrections required for CH₄ and N₂O analyzers are the same as for the commonly used H₂O or CO₂ analyzers, depending whether they have an open or closed measurement path. Analyzers that do not measure H₂O in the cells are problematic, not only because of the WPL correction but also because of water-vapor line broadening effects that, if unconsidered, would contaminate the signal with effects from turbulent water-vapor concentration fluctuations. In order to reduce uncertainty regarding these effects, sometimes a scrubber is deployed between the tube inlet and the measurement cell to remove water vapor from the sampling air. However, only if all temperature and pressure fluctuations are eliminated and humidity is completely removed, do the application of the WPL and line broadening correction become redundant.

The laser spectroscopic gas analyzers need to keep the physical conditions in the measurement cell or cavity constant with very high precision. To reach the highest precision of the gas concentration analysis, physical fluctuations of the sensor environment should be avoided, and, thus, this sensitive equipment is best kept in air-conditioned enclosures. However, for real applications, this often means that the distance between the gas analysis and the air sampling itself and, consequently, the lengths of the tubes, are large compared to other closed-path eddy-covariance applications. The appropriate characterization of the low-pass filter effects and the time lag between the gas analysis and the wind speed measurement is of comparably larger importance for such systems.

In principle, the methods to characterize the low-pass filtering effects do not differ between non-CO₂ GHG and CO₂. In all cases, the tube effects are mainly related to the velocity profiles in the tube and the mixing in the cells/cavities, rather than to surface effects. The effects can largely be kept within acceptable and rather constant limits by applying large air-sampling flow rates. However compared to CO₂ and H₂O, the non-CO₂ GHG flux levels are very often very low, making it necessary to carefully select the time series to be used for the spectral analysis. A usually lower

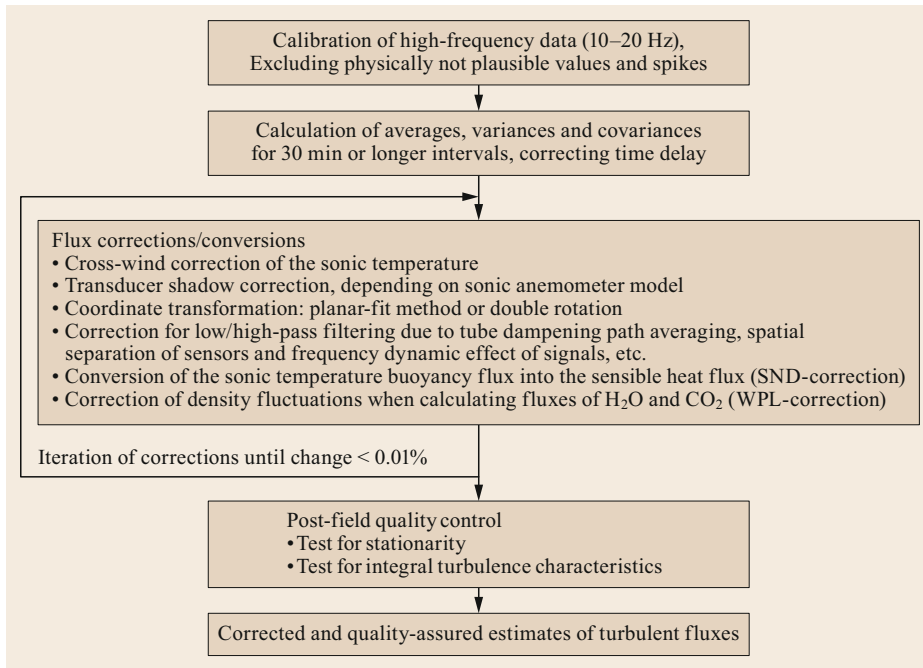

Fig. 55.4 Postfield data processing (after [55.105] with permission from Schweizerbart'sche Verlagsbuchhandlung)

signal-to-noise ratio in non-CO₂ GHG turbulent flux measurements leads to higher contributions of noise to power spectra, which has to be considered when deriving spectral transfer functions from power spectra. Generally, a smaller data basis of usable spectra makes the estimation of spectral transfer functions more difficult and uncertain.

For closed-path instruments, a correct determination of the time delay between the analyzer signal and the sonic signal is crucial to obtain accurate flux estimates. This turns out to be difficult in situations where the fluxes are episodic on a low background flux level, such as often observed with non-CO₂ GHGs. At low fluxes, covariance maximization results in erratic time lags and flux calculation. Therefore, as with spectral analysis, careful selection of time series for empirical time lag estimation is needed. To experimentally estimate a feasible window size for the lag-time search, step-change experiments are useful. In these experiments, a well measurable gas concentration is sporadically and abruptly diluted with a constant fraction of synthetic air, leading to a fast and constant drop in concentration. The time constant of the eddy-covariance system can then be derived from the deviance between the true signal at the tube intake and the measured signal in the analyzer.

The results from empirical time-lag determination indicated that some non-CO₂ GHG analyzers are affected by large drifts of their internal computer clocks. This can be easily derived from steadily increasing em-

pirical lag times, which, suddenly, fall back to zero at a date shift or at times the computer clock is externally adjusted. Some analyzers even eventually stop fast response data transmission, while performing computationally intensive operations, such as storing spectra on their internal hard disks. The challenges of data synchronization are more severe with sensors that sample large amounts of raw data (molecule spectra) and fit this data to spectral models to form a single trace gas concentration value. Future increased computing capacity should solve these kinds of problems very soon. However, for the time being, a user should be aware of the risk of such analyzer imperfections and carefully study time stamps that are mostly available with fast response data.

55.3.3 Overall Data Corrections and Data Handling

Many corrections depend on atmospheric stability or need the turbulent fluxes as input parameters. Therefore, the corrections often are performed iteratively. Although the math is tedious, it was shown [55.127] that the above corrections can be solved without iteration (Table 55.5) as a set of simultaneous equations. Figure 55.4 shows a schematic for how to organize the system of raw data correction, covariance correction as discussed in this section, and data quality tests (Sect. 55.6). This *iteration* typically has an effect of $\leq 1\%$ on the fluxes.

This exemplary flowchart (Fig. 55.4) of eddy-covariance calculation is realized in many software tools. Overviews of the available tools together with all possible sensors and calculations are available in the literature [55.2, 65, 128]. Software intercomparison studies show that the selection of the available alternative options is more important for obtaining com-

parable flux estimates than the software itself, as long as a well-tested and widely used software package is used [55.129]. Some level of expertise is required to choose the appropriate settings for a specific site and a specific sensor setup, so that using the default settings is not generally recommended. Furthermore, only well-documented software packages should be used.

55.4 Devices and Systems

The main instrument for all flux measurements is a 3-D sonic anemometer (Chap. 9) that can be combined with different sensors for scalars. In this section, only a brief description is given; for more details, see Chaps. 7–9 and 16. Figure 55.5 shows as an example the combination of a sonic anemometer with an open-path gas analyzer. An overview of recently available sensors is given in Table 55.6, and recommended additional measurements are listed in Table 55.7. In the following section, the typical configurations are briefly discussed.

55.4.1 Sonic Anemometers

In basic research, sonic anemometers with a selected inflow sector to exclude flow distortion are often used (Chap. 9). For most applications, wind direction-

independent omnidirectional sonic anemometers are sufficient, but these are generally more affected by flow distortions of the vertical velocity component due to mountings and sensor heads. For flux measurements, it is important that interfering parts of devices are kept at a minimum, in particular below the measurement path for the vertical component of the wind, because the vertical oscillations of relatively small turbulence elements are much faster than the horizontal movements of larger turbulence elements. This difference can be noted in the frequency shift of the spectral maximum for vertical and horizontal wind fluctuations by more than one order of magnitude.

55.4.2 Measurement of the Sensible Heat Flux

Most sonic anemometers also measure the fluctuations of the speed of sound, and therefore allow a computation of the so-called sonic temperature (which is nearly identical with the virtual temperature; Chap. 7). The flux calculated with this temperature is the buoyancy flux, typically about 10–20% greater than the sensible heat flux. The sensible heat flux can be determined by applying additional corrections, which need additional moisture measurements. Direct temperature measurements made with thin thermocouples or freely spanned resistance wires (diameter < 15 μm to reduce the radiation error, see Chap. 7) are more expensive.

55.4.3 Measurement of the Latent Heat Flux

Additional hygrometers are used for the determination of the latent heat flux (evapotranspiration). Such devices are currently mostly optical devices (Chap. 8).

Fig. 55.5 Typical installation of a sonic anemometer and an open-path gas analyzer (here CSAT3 with LiCor 7500). The probe to the left of the sonic anemometer volume is a fast-response fine-wire temperature sensor (photo © T. Foken) ◀

Table 55.6 Typical instruments for scalar flux measurements (open-path instruments, if not specified otherwise)

Scalar flux	Instrument type	Commercially available type
Sensible heat flux	Cold-wire thermometer (Chap. 7)	Not available
Buoyancy flux	Sonic anemometer (sonic temperature; Chap. 7)	All types of sonic anemometers
Latent heat flux	UV-hygrometer, Lyman-alpha source (Chap. 8)	Not available
Latent heat flux	UV-hygrometer, krypton source (Chap. 8)	KH20 (Campbell Sci. Inc.)
Latent heat flux and CO ₂ flux	IR-spectrometer (Chap. 8)	LI-7500 (LI-COR), EC-150, IRGASON (Campbell Sci. Inc.)
Latent heat flux and CO ₂ flux (closed-path instrument)	Closed-path IR-spectrometer (Chaps. 8 and 16)	LI-7000, LI-7200 (LI-COR), EC-155 (Campbell Sci. Inc.)
CH ₄ flux	IR spectrometer (Chap. 16)	LI-7700 (LI-COR)
CH ₄ flux (closed-path instrument)	Closed-path laser spectrometer (Chap. 16)	QCL (Aerodyne) Model 911-0010 (Los Gatos) G2311-f (PICARRO)
N ₂ O flux (closed path instrument)	Closed-path laser spectrometer (Chap. 16)	QCL (Aerodyne) Model 913-1054 (Los Gatos)

Table 55.7 Additionally required measurements

Sensor type	Reason/Usage	Remark
Inclinometer	Control of the leveling of the instruments, for application of planar-fit rotation [55.51], recommended	Included in some sonic anemometers
Pressure sensor (low-frequency)	Necessary for concentration calculation	Chap. 10
Temperature sensor (low-frequency)	Reference temperature, sonic temperature often not accurate enough, for corrections	Chap. 7
Humidity sensor (low-frequency)	Reference humidity, humidity of some analyzers is not accurate enough, for corrections and control	Chap. 8

These have either an open measurement path or are a closed path contained in an optical measurement cell. The open-path hygrometer is mounted near the sonic anemometer, and the closed-path instrument is usually placed some meters away, while the air is sucked in from below the sonic anemometer. Open-path instruments operate in the UV or the IR range, and closed-path instruments work only in the IR range. UV devices should be used for low-humidity conditions (water vapor pressure 0–20 hPa) and IR devices for more moist air (5–40 hPa). The effort for maintenance and calibration for all devices is considerable.

55.4.4 Measurement of the CO₂ Flux and Fluxes of Other Air Constituents

The CO₂ gas analyzers generally operate in the IR range and always measure water vapor as well, which is necessary due to overlapping absorption bands between CO₂ and water vapor molecules and line broadening effects from water vapor on the CO₂ spectra. Similar to pure hygrometers, open and closed-path instruments are available. Recently, there has been a trend to combine the advantages of both principles by using a very short intake tube (< 1 m), which is often called an enclosed-path system. However, even for such a short tube length, the dampening of high-frequency fluctuations can be

considerable [55.130]. The dampening can be strongly reduced by minimizing the rain cap volume [55.96, 97]. Another trend is the integration of the gas analyzer into the sonic anemometer in so-called compact systems. Fast response optical devices for other gaseous components (e.g., ozone, methane, nitrous oxide, sulfur dioxide) are also available, and the deposition flux can be measured in a similar way. Tunable diode lasers, which are commercially available for carbon isotopes 12 and 13, methane, nitrous oxide, and other gases, are being increasingly applied [55.131, 132].

55.4.5 Guidelines for Designing an Eddy-Covariance System

The turbulent fluctuations of the components of the wind vector and of scalar parameters must be measured at a high sampling frequency, so that the turbulence spectra (Chap. 1) can be extended to 10–20 Hz. The measurement or sampling time depends on the atmospheric stratification, the wind velocity, and the measurement height. For measurement heights of 2–5 m, at least 10–20 min would be required for daytime unstable stratification (summer) and about 30–60 and sometimes as high as 120 min for nighttime stable stratification due to intermittency. Although the peak of the cospectral density is shifted towards high frequencies

Table 55.8 Advantages and disadvantages of the different setups

Devices	Advantages	Disadvantages
Sonic anemometer with separated open-path gas analyzer	Very few high-frequency dampening effects (only due to path averaging and sensor separation) Only cleaning of sensor required for maintenance Low power consumption	Disturbed by water droplets, ice, and dirt on the optical windows or within the measurement path Heating of the window
