
**Springer Handbook
of Atmospheric
Measurements**

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Atmospheric Measurements

Thomas Foken (Ed.)

With 752 Figures and 526 Tables

Foreword

Taking measurements in the atmosphere means to work in a “non-periodic”, chaotic environment. Consequently, it is impossible to repeat any measurements under same conditions, because every state of the atmosphere is unique and will never occur again. Another consequence is the basic impossibility to find a representative location for a measurement because of the non-linear scale interaction in the atmosphere. Processes on any scale interacts with those on all other scales. The basic requirement of reproducibility, any laboratory experiment has to meet, can, therefore, never be fulfilled by measurements in the atmosphere.

To address this dilemma atmospheric scientists have learned to think in spatial and time scales and to select such information from measurements which is relevant for the scale of interest. This is achieved by selecting suitable designs of the field experiments, station networks, instrumentation, and data processing. Therefore, the requirements on observation systems and the applied observation technologies are progressing continuously with the state of science and technology.

The World Meteorological Organization (WMO) has established under the “WMO Integrated Global Observing System” (WIGOS) a process to monitor these “rolling” requirements and to document them with the web-based “Observing Systems Capability Analysis and Review Tool” (OSCAR). OSCAR provides a structure along scales, applications, and variables and is an open tool to which everybody can contribute.

Systematic meteorological observations were established when scientists began to develop classifications (taxonomies) of natural phenomena. Up to day, we still use a cloud classification scheme inspired by the British pharmacist *Luke Howard*, who developed its basic version at the beginning of the nineteenth century. Meanwhile we have learned to describe and predict the state of the atmosphere with quantitative methods based on physical principles formulated with mathematical equations. Consequently, we are not able today to use phenomenological descriptions anymore. Today we need information on physically well-defined variables. From my perspective, this is the challenge for the further development of observing systems and the required measurement techniques. It is also an opportunity to improve and extend our knowledge about the atmosphere.

This book supplements the guidance provided by the intergovernmental Technical Commission for Observation, Infrastructure and Information Systems (COIIS) of the World Meteorological Organization (WMO), which is tasked as a specialized UN organization “to promote standardization of meteorological and related observations. . .” (Article 2 of WMO Convention).

Preface

The *Springer Handbook of Atmospheric Measurements* is the result of many rounds of discussion with renowned scientists and the publisher, with the intention of developing a reference work that comprehensively covers all aspects of measurements in the atmosphere and at its interface with plants, soil, and water, including some general aspects of metrology. I was happy to bring to this project my nearly 50 years of experience in atmospheric measurements, with a strong focus on micrometeorology, and my more than 25 years of experience working in the standardization of meteorological measurements for VDI (The Association of German Engineers) and DIN (the German Institute of Standardization).

Several developments have made this handbook necessary and timely. Most of the classical in-situ instruments have been replaced by electrical measuring devices. Not only has the toxicity of mercury led to international agreements preventing its use in barometers and thermometers, but the reduction in visual weather observations has resulted in a requirement for low-maintenance electrical sensors and automatic stations. Besides the use of discrete sensors for the various meteorological elements at classical weather and climate stations, more compact sensors are now available. These incorporate all of the sensors into a small weather station with dimensions of 10–30 cm. Furthermore, so-called smart sensors with wireless connectivity and satellite positioning data enable anyone to measure meteorological parameters. The issue of quality control is then shifted from the single sensor to the network, and the crowdsourcing approach necessitates intelligent software to separate biased from accurate data.

Remote sensing instruments were the exclusive domain of meteorological services or scientific institutions, but more recently they have—with the exception of some very complicated instruments and instruments that are in development—passed into more general use. Besides weather radar, ceilometers and radar wind profilers have recently become standard instrumentation in meteorological networks. The fast development of the wind power industry has supported the development of Doppler wind lidars, and these instruments have become much smaller and even relatively inexpensive.

Similarly, throughout their long history, meteorological observations have been the task of meteorologists alone—until recently. Nowadays, agencies that carry out environmental monitoring use meteorological data and have their own networks, as does industry.

With the ability to measure fluxes, ecologists have become an important group that apply atmospheric measurements. The handbook therefore also includes specific measurements at the interface between the atmosphere and the biosphere and pedosphere.

As already mentioned, quality control and standardization are important procedures for ensuring that highly accurate meteorological information with high spatial resolution is made available. This is not only a task for calibration laboratories. It is important that the developers and implementers of software tools understand the complicated structure of the atmosphere in terms of the vertical and horizontal fields of meteorological elements, particularly in heterogeneous areas such as cities and their surroundings.

This handbook is divided into five parts. Part A is an introduction to the handbook, with chapters covering the structure of the atmosphere, the basics of measurements, the fundamentals of quality control, and the standardization of measurements. Furthermore, quantities that are necessary for measurements in the atmosphere and the soil are provided in abundant tables. Some of those tables are also available online. All quantities are given in accordance with the International Temperature Scale (ITS-90).

Part B includes all in-situ measurement methods, and starts with an overview of ground-based platforms. Besides classical measurements such as temperature, humidity, wind, pressure, radiation, precipitation, and visibility, sensors for electricity, trace gases, aerosols, stable isotopes, and radioactivity are also described. Only basic information is provided for the latter category because other monographs are available for trace gas and aerosol measurements. A final chapter covers the relatively new technique of optical-fiber-based measurements in addition to classical odor and visual observations.

Parts C and D are devoted to remote sensing techniques, which are separated into ground-based and aircraft/satellite-based techniques. An introduction to airborne platforms is included. The discussion of ground-based measurements (Part C) includes sodar, RASS, different types of lidar, radar, scintillometers, spectrometric methods that use light of different wavelengths and microwaves. Furthermore, tomographic methods that use sound waves, and electromagnetic waves of satellite navigation systems, are chapters of the handbook. Because aircraft- and satellite-based methods have become more and more important for an-

alyzing a very large number of meteorological elements and properties of the Earth's surface, they are considered separately in Part D, in spite of some overlap with earlier discussions of lidar, radar, and methods based on microwaves, visible light, or infrared light.

Part E is largely atypical for a book concerning atmospheric measurements. It describes the combination of different sensors for specific applications and measurements at the interface between the atmosphere and the underlying surface. First, horizontally distributed observations—including classical weather stations, crowdsourcing, and mesometeorological networks—are considered, followed by vertical measurement systems such as aerological measurements and composite profiling. Here, horizontally moving systems are aircraft, unmanned aircraft systems, and ground-based moving systems. Subsequent chapters focus on special applications such as measurements of different types of renewable energy and urban measurements, and then on measurement techniques for and applications of fluxes: fog deposition, dry deposition, the eddy-covariance technique and similar measurements, lysimeter and evapotranspiration measurements and calculations, and chamber measurements at plants and the soil surface. Finally, short chapters describe measurements in soil and water.

Part F—the final part of this handbook—discusses networks, which play important roles in rendering measurements comparable and achieving a high standard of measurement quality. The two chapters in Part F give an overview of networks of atmospheric and ecological measurements.

Given the timeframe of the present edition of this handbook, it was not possible to provide complete coverage of all instruments used for atmospheric measurements. However, the editor and Springer are hopeful that, in a future edition, the minor gaps in coverage will be filled by recruiting authors who are able to take on the time-consuming task of providing new chapters on instruments not discussed here.

Some comments on the organization of this handbook may be helpful. Most of the chapters are struc-

ured in the same way for easier orientation of the reader, although the subject matter of some chapters meant that they could only broadly follow this schema. Section 1 of each chapter gives a short overview of the measured variables and their dimensions as well as the main measurement principles. Section 2 is a historical part, which we included not only because this is quite interesting but also because many techniques have not been in use for the last 10–50 years. For currently used measurement methods, Section 3 presents the theory and Section 4 the applicable devices. In most of the chapters, the advantages and disadvantages of the various relevant sensors or methods are also listed at the end of Section 4. In the majority of the chapters, Section 5, on specifications, allows the reader to rapidly review the measurement ranges, accuracies, or response times of the devices and methods in tabulated form. Quality control, calibration, and reference standards are discussed in Section 6, and Section 7 gives an overview of necessary maintenance actions along with the appropriate time intervals. Some selected examples of applications of the devices and methods are shown in Section 8, and further developments are discussed in Section 9. Monographs, overview papers, and standards are available for many of the techniques, and these are listed in the Further Reading section. Every chapter ends with a long list of references.

I want to thank the 140 authors and, in particular, the corresponding authors for their significant contributions to this handbook, as well as the more than 60 reviewers for their helpful reviews of all chapters. Many thanks are due to Dr. Judith Hinterberg for developing the concept of the handbook, and to Ursula Barth, both from Springer Nature Heidelberg, for the intensive communication with me and the authors and Jeannette Krause (le-tex, Leipzig) for the preparation of the final manuscript. Last but not least, I thank my wife and our family for their sympathy and support of this project over the last four years.

Bayreuth, Germany
August 2021

Thomas Foken

About the Editor

Thomas Foken is retired Professor of Micrometeorology at the University of Bayreuth (Bayreuth Center of Ecology and Environmental Research), Germany. He obtained his doctoral degree (Dr rer nat) from Leipzig University in 1978 and his second doctoral degree (Dr sc nat) from the Humboldt University of Berlin in 1990. He headed the Laboratories of Boundary Layer Research and Land Surface Processes of the Meteorological Service of the GDR and the German Meteorological Service (DWD) at the Observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). In 1997, Thomas Foken was appointed Professor of Micrometeorology at the University of Bayreuth. He has taught courses on micrometeorology in Berlin, Potsdam, and Bayreuth. His main research areas are related to the interaction between the Earth's surface and the atmosphere, and the measurement and modeling of energy and matter fluxes, with a strong focus on measurement devices. He has organized and participated in experiments at the international level, e.g. in Russia, USA, Tibet, and Antarctica. He has published in peer-reviewed journals as well as textbooks and has made significant advancements in the application of the eddy-covariance method. These scientific contributions have been recognized through various awards, including the Dionyz Stur Medal in Silver of the Slovak Academy of Science, the Award for Outstanding Achievements in Biometeorology of the American Meteorological Society, the Honor Badge of the Association of German Engineers (VDI), and Honorary Membership of the Hungarian Meteorological Society. In recent years, he has been consultant for Arctic and forest fire projects, and lecturer at the Eötvös Loránd University Budapest. In Germany, Thomas Foken is responsible for the standardization of atmospheric in-situ measurement techniques (VDI/DIN, ISO). As a specialist for climate and climate change in Northern Bavaria, he is regularly invited to give lectures for school students at events organized by the Fridays for Future movement.

Contents

List of Abbreviations	XLI
List of Symbols	LV
Part A Basics of Atmospheric Measurement Techniques	
1 Introduction to Atmospheric Measurements	
<i>Thomas Foken, Frank Beyrich, Volker Wulfmeyer</i>	3
1.1 Measuring Meteorological Elements	4
1.2 History	7
1.3 The Structure of the Atmosphere	9
1.4 Devices, Systems, and Typical Specifications	23
1.5 Applications	26
1.6 Future Developments	27
1.7 Further Reading	28
References	28
2 Principles of Measurements	
<i>Wolfgang Foken</i>	33
2.1 Basics of Measurements	34
2.2 History	34
2.3 Errors in Measurement	34
2.4 Regression Analysis	38
2.5 Time Domain and Frequency Domain for Signals and Systems	39
2.6 Dynamics of Measuring Systems	40
2.7 Analog and Digital Signal Processing	44
2.8 Hardware for Digital Measurement Systems	46
2.9 Further Reading	47
References	47
3 Quality Assurance and Control	
<i>Cove Sturtevant, Stefan Metzger, Sascha Nehr, Thomas Foken</i>	49
3.1 Principles and Definition	50
3.2 History	51
3.3 Elements of Quality Management	52
3.4 Application	77
3.5 Future Developments	84
3.6 Further Reading	85
References	85
4 Standardization in Atmospheric Measurements	
<i>Simon Jäckel, Annette Borowiak, Brian Stacey</i>	93
4.1 Background and Definitions	93
4.2 History	94
4.3 Principles and Procedures	96
4.4 Standardization in the Field of Atmospheric Measurements	98

4.5	Future Developments	103
4.6	Further Reading	104
	References	104
5	Physical Quantities	
	<i>Thomas Foken, Olaf Hellmuth, Bernd Huwe, Dietrich Sonntag</i>	107
5.1	Selection of Parameters	108
5.2	History and Thermodynamic Standards	108
5.3	Units and Constants	111
5.4	Parameters of Air, Water Vapor, Water, and Ice	115
5.5	Parameterization of Optical Properties of Clouds	130
5.6	Absorption Coefficients for Water Vapor, Ozone, and Carbon Dioxide	141
5.7	Parameters of Soil	142
5.8	Time and Astronomical Quantities	146
5.9	Tables in Other Chapters	147
5.10	Future Developments	148
5.11	Further Reading	148
	References	148
Part B In situ Measurement Techniques		
6	Ground-Based Platforms	
	<i>Olaf Kolle, Norbert Kalthoff, Christoph Kottmeier, J. William Munger</i>	155
6.1	Principles of Platforms	156
6.2	History	157
6.3	Theory	158
6.4	Platforms and Sensor Installations	160
6.5	Specification	174
6.6	Quality Control and Safety	175
6.7	Maintenance	175
6.8	Applications	176
6.9	Future Developments	178
6.10	Further Readings	179
	References	180
7	Temperature Sensors	
	<i>Thomas Foken, Jens Bange</i>	183
7.1	Measurement Principles and Parameters	184
7.2	History	187
7.3	Theory	190
7.4	Devices and Systems	196
7.5	Specifications	201
7.6	Quality Control	202
7.7	Maintenance	203
7.8	Applications	204
7.9	Future Developments	205
7.10	Further Reading	206
	References	206

8 Humidity Sensors	
<i>Dietrich Sonntag, Thomas Foken, Holger Vömel, Olaf Hellmuth</i>	209
8.1 Measurement Principles and Parameters	210
8.2 History	212
8.3 Theory	217
8.4 Devices and Systems	222
8.5 Specifications	233
8.6 Quality Control	234
8.7 Maintenance	236
8.8 Application	237
8.9 Future Developments	238
8.10 Further Readings	238
References	238
9 Wind Sensors	
<i>Thomas Foken, Jens Bange</i>	243
9.1 Measurement Principles and Parameters	244
9.2 History	245
9.3 Theory	249
9.4 Devices and Systems	257
9.5 Specifications	262
9.6 Quality Control	263
9.7 Maintenance	266
9.8 Application	267
9.9 Future Developments	269
9.10 Further Reading	270
References	270
10 Pressure Sensors	
<i>Anni Torri, Thomas Foken, Jens Bange</i>	273
10.1 Measurement Principles and Parameters	274
10.2 History	275
10.3 Theory	278
10.4 Devices and Systems	283
10.5 Specifications	290
10.6 Quality Control	291
10.7 Maintenance	292
10.8 Application	292
10.9 Future Developments	293
10.10 Further Reading	294
References	294
11 Radiation Sensors	
<i>Klaus Behrens</i>	297
11.1 Measurement Principles and Parameters	298
11.2 History	303
11.3 Theory	315
11.4 Devices and Systems	320
11.5 Specifications	339
11.6 Quality Control	341
11.7 Maintenance	348

11.8 Applications.....	349
11.9 Future Developments	352
11.10 Further Reading	353
References	353
12 In-situ Precipitation Measurements	
<i>Arianna Cauteruccio, Matteo Colli, Mattia Stagnaro, Luca G. Lanza, Emanuele Vuerich</i>	359
12.1 Measurement Principles and Parameters.....	360
12.2 History.....	362
12.3 Theory	367
12.4 Devices and Systems	370
12.5 Specifications	375
12.6 Quality Control, Uncertainty, and Calibration	376
12.7 Maintenance.....	392
12.8 Application.....	394
12.9 Future Developments	396
12.10 Further Reading	397
References	397
13 Visibility Sensors	
<i>Martin Löffler-Mang, Klaus Heyn</i>	401
13.1 Measurement Principles and Parameters.....	402
13.2 History.....	403
13.3 Theory	405
13.4 Devices and Systems	414
13.5 Specifications	417
13.6 Quality Control.....	418
13.7 Maintenance.....	421
13.8 Application.....	423
13.9 Future Developments	426
13.10 Further Reading	427
References	428
14 Electricity Measurements	
<i>Giles Harrison, Alec Bennett</i>	431
14.1 Measurement Principles and Parameters.....	432
14.2 History.....	432
14.3 Theory	434
14.4 Devices and Systems	441
14.5 Specifications	448
14.6 Quality Control.....	448
14.7 Maintenance.....	450
14.8 Applications.....	452
14.9 Future Developments	453
14.10 Further Reading	453
References	453

15 Radioactivity Sensors	
<i>Jacqueline Bieringer, Thomas Steinkopff, Ulrich Stöhlker</i>	457
15.1 Measurement Principles and Parameters.....	458
15.2 History.....	459
15.3 Theory.....	460
15.4 Devices and Systems.....	463
15.5 Specifications.....	467
15.6 Quality Control.....	468
15.7 Maintenance.....	469
15.8 Application.....	469
15.9 Future Developments.....	470
15.10 Further Reading.....	471
References	471
16 Gas Analysers and Laser Techniques	
<i>Dwayne Heard, Lisa K. Whalley, Steven S. Brown</i>	475
16.1 Measurement Principles and Parameters.....	476
16.2 History.....	478
16.3 Theory.....	480
16.4 Devices and Systems.....	486
16.5 Specifications.....	494
16.6 Quality Control.....	495
16.7 Maintenance.....	496
16.8 Applications.....	498
16.9 Future Developments.....	502
16.10 Further Reading.....	502
References	502
17 Measurement of Stable Isotopes in Carbon Dioxide, Methane, and Water Vapor	
<i>Ingeborg Levin, Matthias Cuntz</i>	509
17.1 Measurement Principles and Parameters.....	510
17.2 History of Stable Isotope Measurements in Atmospheric CO ₂ , CH ₄ and H ₂ O.....	512
17.3 Theory.....	513
17.4 Devices and Systems.....	516
17.5 Specifications.....	523
17.6 Quality Control.....	524
17.7 Maintenance.....	525
17.8 Application.....	525
17.9 Future Developments.....	527
17.10 Further Readings.....	527
References	527
18 Measurement of Fundamental Aerosol Physical Properties	
<i>Andreas Held, Alexander Mangold</i>	533
18.1 Measurement Principles and Parameters.....	534
18.2 History.....	537
18.3 Theory.....	537
18.4 Devices and Systems.....	542
18.5 Specifications.....	552

18.6	Quality Control	553
18.7	Maintenance	555
18.8	Application	556
18.9	Future Developments	558
18.10	Further Reading	558
	References	559
19	Methods of Sampling Trace Substances in Air	
	<i>Christopher Pöhlker, Karsten Baumann, Gerhard Lammel</i>	565
19.1	Measurement Principles and Parameters	566
19.2	History	568
19.3	Theory	570
19.4	Devices and Systems	576
19.5	Specifications	589
19.6	Quality Control	590
19.7	Maintenance	592
19.8	Application	593
19.9	Future Developments	596
19.10	Further Reading	596
	References	596
20	Optical Fiber-Based Distributed Sensing Methods	
	<i>Christoph K. Thomas, John Selker</i>	609
20.1	Measurement Principles and Parameters	610
20.2	History	613
20.3	Theory	614
20.4	Devices	619
20.5	Specifications	623
20.6	Quality Control	624
20.7	Maintenance	625
20.8	Applications	626
20.9	Future Developments	629
20.10	Further Reading	629
	References	629
21	Odor Measurements	
	<i>Ralf Petrich, Axel Delan</i>	633
21.1	Measurement Principles and Parameters	634
21.2	History	635
21.3	Theory	635
21.4	Devices and Systems	638
21.5	Specifications	639
21.6	Quality Control	640
21.7	Maintenance	641
21.8	Application	641
21.9	Future Developments	642
21.10	Further Readings	642
	References	642

22 Visual Observations	
<i>Thomas Foken, Raymond Rülke</i>	645
22.1 Principles of Visual Observations	645
22.2 History	646
22.3 Theory	647
22.4 Observed Parameters	647
22.5 Quality Control	655
22.6 Application	655
22.7 Future Developments	655
22.8 Further Readings	656
References	656
Part C Remote-Sensing Techniques (Ground-Based)	
23 Sodar and RASS	
<i>Stefan Emeis</i>	661
23.1 Measurement Principles and Parameters	662
23.2 History	665
23.3 Theory	666
23.4 Devices and Systems	670
23.5 Specifications	674
23.6 Quality Control	675
23.7 Maintenance	677
23.8 Applications	677
23.9 Future Developments	679
23.10 Further Reading	680
References	680
24 Backscatter Lidar for Aerosol and Cloud Profiling	
<i>Christoph Ritter, Christoph Münkel</i>	683
24.1 Measurement Prinziples and Parameters	684
24.2 History	686
24.3 Theory	687
24.4 Devices and Systems	700
24.5 Specifications	706
24.6 Quality Control	707
24.7 Maintenance	709
24.8 Applications	710
24.9 Further Reading	714
References	714
25 Raman Lidar for Water-Vapor and Temperature Profiling	
<i>Volker Wulfmeyer, Andreas Behrendt</i>	719
25.1 Measurement Principles and Parameters	720
25.2 History	721
25.3 Theory	722
25.4 Devices and Systems	725
25.5 Specifications	728
25.6 Quality Control	729

25.7	Maintenance.....	731
25.8	Applications.....	731
25.9	Future Developments	733
25.10	Further Reading	733
	References	734
26	Water Vapor Differential Absorption Lidar	
	<i>Scott M. Spuler, Matthew Hayman, Tammy M. Weckwerth</i>	741
26.1	Measurement Principles and Parameters.....	742
26.2	History.....	743
26.3	Theory	744
26.4	Devices and Systems	749
26.5	Specifications	751
26.6	Quality Control	751
26.7	Maintenance.....	752
26.8	Applications.....	752
26.9	Future Developments	753
26.10	Further Readings	754
	References	754
27	Doppler Wind Lidar	
	<i>Oliver Reitebuch, R. Michael Hardesty</i>	759
27.1	Measurement Principles and Parameters.....	760
27.2	History.....	762
27.3	Theory	765
27.4	Devices and Systems	773
27.5	Specifications	782
27.6	Quality Control	783
27.7	Maintenance.....	784
27.8	Applications.....	785
27.9	Future Developments	790
27.10	Further Readings	791
	References	791
28	Spectrometers	
	<i>Klaus Schäfer, Mark Wenig, Mark A. Zondlo, Axel Murk, Konradin Weber</i> ..	799

Part E Complex Measurement Systems – Methods and Applications

43 Atmospheric Measurements for Different Purposes	
<i>Bodo Wichura, Thomas Foken</i>	1187
43.1 Principles of Atmospheric Measurement Station Classification	1188
43.2 History.....	1190
43.3 Theory	1190
43.4 Devices and Systems	1192
43.5 Specifications	1195
43.6 Quality Control.....	1195
43.7 Maintenance.....	1195
43.8 Applications.....	1196
43.9 Future Developments	1196
43.10 Further Reading	1197
References	1197
44 Crowdsourcing	
<i>Matthias Budde</i>	1199
44.1 Measurement Principles and Parameters.....	1200
44.2 History.....	1201
44.3 Theory	1202
44.4 Devices and Systems	1207
44.5 Specifications	1212
44.6 Quality Control.....	1213
44.7 Maintenance.....	1217
44.8 Applications.....	1218
44.9 Future Developments	1227
References	1227
45 Mesometeorological Networks	
<i>Jerald A. Brotzge, Christopher A. Fiebrich</i>	1233
45.1 Measurement Principles and Parameters.....	1234
45.2 History.....	1235
45.3 Theory	1235
45.4 Devices and Systems	1237
45.5 Specifications	1239
45.6 Quality Control.....	1240
45.7 Maintenance.....	1240
45.8 Applications.....	1242
45.9 Future Development	1243
45.10 Further Readings	1244
References	1244
46 Aerological Measurements	
<i>Holger Vömel, Masatomo Fujiwara</i>	1247
46.1 Measurement Principles and Parameters.....	1248
46.2 History.....	1250
46.3 Theory	1254
46.4 Devices and Systems	1260
46.5 Specifications	1268

46.6	Quality Control	1270
46.7	Maintenance	1272
46.8	Application	1272
46.9	Further Development	1275
46.10	Further Readings	1276
	References	1276
47	Composite Atmospheric Profiling	
	<i>Christoph Kottmeier, Bianca Adler, Norbert Kalthoff, Ulrich Löhnert, Ulrich Görtsdorf</i>	1281
47.1	The Relevance of Composite Atmospheric Measurements	1282
47.2	History	1285
47.3	Theory	1287
47.4	Observation Platforms	1291
47.5	Specifications	1294
47.6	Quality Control	1294
47.7	Maintenance	1295
47.8	Applications	1295
47.9	Future Developments	1299
47.10	Further Reading	1299
	References	1300
48	Aircraft-Based Flux Density Measurements	
	<i>Raymond L. Desjardins, Devon E. Worth, Ian MacPherson, Matthias Mauder, Jens Bange</i>	1305
48.1	Measurement Principles and Parameters	1306
48.2	History	1307
48.3	Theory	1308
48.4	Devices and Systems	1310
48.5	Specifications of Sensors for Flux Density Measurements	1313
48.6	Quality Control	1314
48.7	Maintenance	1315
48.8	Applications	1315
48.9	Future Developments	1320
48.10	Further Reading	1321
48.A	Appendix	1321
	References	1325
49	Unmanned Aircraft Systems	
	<i>Jens Bange, Joachim Reuder, Andreas Platis</i>	1331
49.1	Measurement Principles and Parameters	1332
49.2	History	1332
49.3	Theory	1333
49.4	Devices and Systems	1334
49.5	Specifications	1339
49.6	Quality Control	1339
49.7	Maintenance	1340
49.8	Applications	1341
49.9	Future Developments	1344
49.10	Further Readings	1344
	References	1344

50 Ground-based Mobile Measurement Systems	
<i>Eberhard Parlow, Thomas Foken</i>	1351
50.1 Measurement Principles and Parameters	1352
50.2 History	1353
50.3 Theory	1354
50.4 Devices and Systems	1358
50.5 Specifications	1361
50.6 Quality Control	1361
50.7 Maintenance	1362
50.8 Application	1362
50.9 Future Developments	1365
50.10 Further Readings	1365
References	1366
51 Measurement Systems for Wind, Solar and Hydro Power Applications	
<i>Stefan Emeis, Stefan Wilbert</i>	1369
51.1 Measured Parameters	1370
51.2 History	1371
51.3 Theory	1373
51.4 Devices and Systems	1377
51.5 Specifications	1382
51.6 Quality Control	1383
51.7 Maintenance	1383
51.8 Application	1384
51.9 Future Developments	1386
51.10 Further Readings	1386
References	1387
52 Urban Measurements and Their Interpretation	
<i>Sue Grimmond, Helen C. Ward</i>	1391
52.1 Measurement Principles and Variables	1392
52.2 History	1394
52.3 Theory	1396
52.4 Devices and Systems	1400
52.5 Specifications	1407
52.6 Quality Control	1408
52.7 Maintenance	1409
52.8 Applications	1409
52.9 Future Developments	1412
52.10 Further Reading	1413
References	1413
53 Fog Deposition	
<i>Shih-Chieh Chang, Robert S. Schemenauer</i>	1425
53.1 Measurement Principles and Parameters	1426
53.2 History	1430
53.3 Theory	1432
53.4 Devices and Systems	1436
53.5 Specifications	1438
53.6 Quality Control	1439

53.7	Maintenance.....	1440
53.8	Applications.....	1441
53.9	Further Developments	1441
53.10	Further Reading	1442
	References	1442
54	Immission and Dry Deposition	
	<i>Ivonne Trebs, Christof Ammann, Jürgen Junk</i>	1445
54.1	Measurement Principles and Parameters.....	1446
54.2	History	1448
54.3	Theory	1449
54.4	Devices and Systems	1454
54.5	Specifications	1458
54.6	Quality Control	1459
54.7	Maintenance.....	1460
54.8	Application.....	1460
54.9	Future Developments	1462
54.10	Further Reading	1463
	References	1463
55	Eddy-Covariance Measurements	
	<i>Matthias Mauder, Thomas Foken, Marc Aubinet, Andreas Ibrom</i>	1473
55.1	Measurement Principles and Variables	1474
55.2	History	1477
55.3	Theory	1478
55.4	Devices and Systems	1486
55.5	Specifications	1489
55.6	Quality Control	1489
55.7	Maintenance.....	1494
55.8	Application.....	1494
55.9	Future Developments	1495
55.10	Further Readings	1496
	References	1496
56	Alternative Turbulent Trace Gas Flux Measurement Methods	
	<i>Janne Rinne, Christof Ammann, Elizabeth Pattey, Kyaw Tha Paw U, Raymond L. Desjardins</i>	1505
56.1	Measurement Principles and Parameters.....	1506
56.2	History.....	1507
56.3	Theory	1509
56.4	Devices and Measuring Systems.....	1516
56.5	Specifications	1522
56.6	Quality Control	1523
56.7	Maintenance.....	1523
56.8	Application.....	1524
56.9	Future Developments	1525
56.10	Further Readings	1525
	References	1525

57 Evapotranspiration Measurements and Calculations	
<i>Richard Allen, Thomas Foken, Ayse Kilic, Ricardo Trezza, Samuel Ortega-Farias</i>	1531
57.1 Principles of Evapotranspiration Determination	1532
57.2 History.....	1532
57.3 Theory	1535
57.4 Devices and Methods	1555
57.5 Specifications	1556
57.6 Quality Control.....	1556
57.7 Maintenance.....	1559
57.8 Application.....	1560
57.9 Future Developments	1561
57.10 Further Reading	1561
References	1562
58 Lysimeter	
<i>Sascha Reth, Oscar Perez-Priego, Heinz Coners, Reinhard Nolz</i>	1569
58.1 Principles and Parameters.....	1570
58.2 History.....	1571
58.3 Theory	1572
58.4 Devices and Systems	1574
58.5 Specifications	1578
58.6 Quality Control.....	1578
58.7 Maintenance.....	1579
58.8 Applications.....	1579
58.9 Future Developments	1581
58.10 Further Reading	1581
References	1582
59 Plant Chamber Measurements	
<i>Oscar Perez-Priego</i>	1585
59.1 Measurement Principles and Parameters.....	1586
59.2 History of Chamber Measurements	1587
59.3 Theory	1587
59.4 Devices and Systems	1591
59.5 Specifications	1593
59.6 Quality Control.....	1593
59.7 Maintenance.....	1594
59.8 Application.....	1594
59.9 Future Developments	1597
59.10 Further Readings	1598
References	1598
60 Soil Chamber Measurements	
<i>Jens-Arne Subke, Lars Kutzbach, David Risk</i>	1603
60.1 Measurement Approaches, Principles, and Parameters	1604
60.2 History of Soil Chamber Measurements.....	1606
60.3 Theory	1608
60.4 Devices and Systems	1612
60.5 Specifications	1616
60.6 Quality Control.....	1616

60.7	Maintenance.....	1619
60.8	Application.....	1619
60.9	Future Developments	1621
60.10	Further Readings	1621
	References	1621
61	Soil Measurements	
	<i>Bernd Huwe, Christina Bogner, Thomas Foken</i>	1625
61.1	Measurement Principles and Parameters.....	1626
61.2	History.....	1630
61.3	Theory	1631
61.4	Devices, Systems, and Analyses	1634
61.5	Specifications	1646
61.6	Quality Control	1647
61.7	Maintenance.....	1647
61.8	Applications.....	1648
61.9	Further Developments	1650
61.10	Further Reading	1651
	References	1651
62	Water Measurements	
	<i>Volker Mohrholz, Anita Flohr</i>	1657
62.1	Measurement Principles and Parameters.....	1658
62.2	History.....	1660
62.3	Theory	1662
62.4	Devices and Systems	1667
62.5	Specifications	1673
62.6	Quality Control.....	1674
62.7	Maintenance.....	1675
62.8	Application.....	1676
62.9	Future Developments	1678
62.10	Further Reading	1678
	References	1678
 Part F Measurement Networks		
63	Networks of Atmospheric Measuring Techniques	
	<i>Rolf Philipona</i>	1687
63.1	Relevance and Parameters of Networks	1688
63.2	History.....	1691
63.3	Network Structure	1693
63.4	Other Important Networks.....	1699
63.5	Quality Control.....	1708
63.6	Maintenance.....	1709
63.7	Application.....	1709
63.8	Future Developments	1710
63.9	Further Reading	1710

64 Integration of Meteorological and Ecological Measurements	
<i>Hans Peter Schmid, Corinna Rebmann</i>	1713
64.1 Relevance and Parameters of Networks	1714
64.2 History	1716
64.3 Structures of Notable Networks	1717
64.4 Temporal and Spatial Scales	1720
64.5 Quality Control of Ecological Measurement Networks	1720
64.6 Maintenance	1721
64.7 Applications	1721
64.8 Further Developments	1721
64.9 Further Reading	1722
References	1722
Subject Index	1727

List of Abbreviations

1-D	one-dimensional	AHSRL	Arctic High-Spectral Resolution Lidar
2-D	two-dimensional	AI	artificial intelligence
3-D	three-dimensional	AIRMoN	Atmospheric Integrated Research Monitoring Network
3DVar	3-D variational	AIRS	Atmospheric Infrared Sounder
4-D	four-dimensional	AIS	Air Ion Spectrometer
4DVar	4-D variational	ALADIN	Atmospheric Laser Doppler Instrument
		ALADINA	Application of Light-weight Aircraft for Detecting In Situ Aerosol
A			
A-TOM	acoustic travel-time tomography	ALC	Automatic Lidar and Ceilometers
A-Train	afternoon train	ALINE	America Lidar Network
A/D	analog/digital	ALISSA	L'Atmosphère Par Lidar Sur Saliout
A2D	Aladin Airborne Demonstrator	ALOMAR	Arctic Lidar Observatory
AATSR	Advanced Along Track Scanning Radiometer	AMDAR	Aircraft Meteorological Data Relay
		AMF	ARM mobile facility
ABI	advanced baseline imager	AMF	air mass factor
ABL	atmospheric boundary layer	AMMA	African Monsoon Multidisciplinary Analysis
AC	alternating current		
AC	air capacity	AMNet	Atmospheric Mercury Network
ACARS	Aircraft Communications Addressing and Reporting System	AMoN	Ammonia Monitoring Network
		AMR	antenna-mounted receiver
ACCC	Aluminum Conductor Composite Core	AMS	aerosol mass spectrometer
ACE	Aerosol–Cloud–Ecosystem	AMSR	Advanced Microwave Scanning Radiometer
ACMS	Aircraft Condition Monitoring System		
ACONS	Aircraft-Fixed Orthonormal System	AMSU	Advanced Microwave Sounding Unit
ACP	Absolute Cavity Pyrgeometer	AOD	aerosol optical depth
ACS	auto-correlation spectrometers	AOM	acousto-optic modulator
ACTRIS	Aerosols, Clouds and Trace Gases Research Infrastructure	AOS	acousto-optical spectrometers
		AOT	aerosol optical thickness
AD2CP	Acoustic Doppler Dual Current Profiler	APAR	airborne phased array radar
ADC	analog digital converter	APD	avalanche photodiode
ADCP	acoustic Doppler current profiler	API	application programming interface
ADD	aircraft-derived data	APi-TOF	Atmospheric Pressure Interface Time-of-flight
ADER	Ambient Dose Equivalent Rate		
ADONS	aerodynamic coordinate system	APRS	Automated Packet Reporting System
ADP	acoustic Doppler profiler	APS	aerodynamic particle sizer
ADR	amplitude domain reflectometry	aqSOA	aqueous secondary organic aerosol
ADS	automatic dependent surveillance	ARE	acoustic received echo
ADV	acoustic Doppler velocimeter	ARISE	Arctic Radiation IceBridge Sea and Ice Experiment
AERI	Atmospheric Emitted Radiance Interferometer		
		ARM	Atmospheric Radiation Measurement
AERONET	Aerosol Robotic Network	ART	Algebraic Reconstruction Technique
AESA	active electronically scanned array	ARTS	Atmospheric Radiative Transfer Simulator
AFC	automatic frequency control		
aFC	available field capacity	ASAP	Automated Shipboard Aerological Program
AFIB	aerodynamic fluxes using iterative energy balance	ASCAT	Advanced Scatterometer
		ASCENDS	Active Sensing of CO ₂ Emissions over Nights, Days and Seasons
AFTIR	Airborne FTIR		
AGAGE	Advanced Global Atmospheric Gases Experiment	ASCII	American Standard Code for Information Exchange
AGC	automatic gain control	ASL	above sea level
AGL	above ground level	ASL	atmospheric surface layer
AGM	aerodynamic gradient method	ASOS	Automated Surface Observing System
AHI	Advanced Himawari Imager		

ASR	Absolute Sky-scanning Radiometer	BR	Bowen ratio
ASR	Arctic System Reanalysis	BRDF	bidirectional reflectance distribution function
ASTAR	Arctic Study of Tropospheric Aerosol and Radiation	BREB	Bowen ratio energy balance
ASTER	Advanced Spaceborne Thermal Emission and Reflection Radiometer	BREEAM	building research establishment environmental assessment method
ASTEX	Atlantic Stratocumulus Transition Experiment	BRF	body reference frame
ASY	asymmetry parameter	BS	biosensor
AT	acoustic tomography	BSRN	Baseline Surface Radiation Network
ATC	air traffic control	BSU	beam steering unit
ATD	arrival time difference	BT	Bluetooth
ATLID	Atmospheric Lidar	BT	brightness temperature
ATMS	Advanced Technology Microwave Sounder	BUFR	binary universal form for the representation of meteorological data
ATOVS	Advanced TIROS Operational Vertical Sounder	BWT	beam widening telescope
ATS	Applications Technology Satellite		
ATS	Applications Technology System	C	
AUV	Autonomous Underwater Vehicle	CAENEX	Complete Atmospheric Energetics Experiment
AVAPS	Airborne Vertical Atmospheric Profiling System	CAL	calibration factor
AVHRR	Advanced Very High Resolution Radiometer	CAL/VAL	calibration and validation
AVIRIS	Airborne Visible/Infrared Imaging Spectrometer	CAL/VAL	Cloud–Aerosol Lidar with Orthogonal Polarization
AVIRIS-NG	Next-Generation Airborne Visible/Infrared Imaging Spectrometer	CALIPSO	Cloud–Aerosol Lidar and Infrared Pathfinder Satellite Observation
AVV	Allgemeine Verwaltungsvorschrift	CAMS	Copernicus Atmosphere Monitoring Service
AW	available water	CAPE	convective available potential energy
AWS	Automatic Weather Station	CAPMoN	Canadian Air and Precipitation Monitoring Network
		CAPS	Cavity-attenuated Phase-shift Spectroscopy
B		CARIBIC	Civil Aircraft for the Regular Investigation of the Atmosphere Based on an Instrument Container
BADM	Biological, Ancillary, Disturbance, and Metadata	CASIE	Characterization of Arctic Sea Ice Experiment
BAPMoN	Background Air Pollution Monitoring Network	CASTNET	Clean Air Status and Trends Network
BB	broadband	CAT	clear-air turbulence
BBCES	Broadband Cavity-enhanced Spectrometer	CATS	cloud–aerosol transport system
BBR	Broad Band Radiometer	CBD	central business district
BBS	bulletin board systems	CBL	convective boundary layer
BC	black carbon	CC	cloud-to-cloud
BCE	Before the Common Era	CCA	constant-current anemometer
BD	beam dump	CCD	charge-coupled device
BDC	Brewer–Dobson circulation	CCN	cloud condensation nucleus
BDS	BeiDou Navigation Satellite System	CCOR	clutter correlation
BE	beam expander	CDD	cooling degree days
BEARPEX	Biosphere Effects on Aerosol and Photochemistry Experiment	CDR	climate data record
BITE	built-in test equipment	CDR	circular depolarization ratio
BL	boundary laser	CDT	Central Daylight Time
BLE	Bluetooth low energy	CE	Common Era
BLS	boundary-layer scintillometer	CERES	Clouds and the Earth’s Radiant Energy System
BOMEX	Barbados Oceanographic and Meteorological Experiment	CES	cavity-enhanced spectroscopy
BOREAS	Boreal Ecosystem–Atmosphere Study	CESAR	Cabauw Experimental Site for Atmospheric Research
BPLO	backpropagated local oscillator	CET	Central European Time

CF	Climate and Forecasting	CT	computer-assisted tomography
CF	fractional cloud cover	CT	cloud type
CFC	chlorofluorocarbon	CTA	constant-temperature anemometer
CFD	computational fluid dynamics	CTBT	Comprehensive Nuclear-Test-Ban Treaty
CFH	cryogenic frostpoint hygrometer	CTD	conductivity-temperature-depth
CFHC	carbon-fiber heated cable technology	CTH	cloud top height
CFL	constant flux layer	CTM	chemical transport modeling
CFSR	Climate Forecast System Reanalysis	CTS	chirp transform spectrometers
CG	cloud to ground	CubeRRRT	CubeSat Radiometer Radio Frequency Interference Technology Validation
CHAM	chamber method	CVA	constant-voltage anemometer
CHIOTTO	continuous high-precision tall tower observations of greenhouse gases	CW	continuous wave
CIMR	Copernicus Imaging Microwave Radiometer	CWC	condensed water content
CIMS	chemical ionization mass spectrometry	CWOP	Citizen Weather Observer Program
CIN	convective inhibition		
CLARREO	Climate Absolute Radiance and Refractivity Observatory	D	
CLD	chemiluminescence detector	DA	data assimilation
ClearLo	Clean Air for London	DAPPLE	Dispersion of Air Pollution and its Penetration into the Local Environment
CLRTAP	Convention on Long-Range Transboundary Air Pollution	DARE	direct aerosol radiative effect
CNC	Condensation Nucleus Counter	DART	discrete anisotropic radiative transfer
CNR	carrier-to-noise ratio	DAS	Direct Absorption Spectroscopy
COBALD	Compact Optical Backscatter and Aerosol Detector	DASE	differential absorption of scattered energy
COD	cloud optical depth	DBH	diameter at breast height
CODAR	Coastal Ocean Dynamics Applications Radar	DBLS	double-beam laser scintillometer
CODE	California Ozone Deposition Experiment	DBS	Doppler beam swinging
COHO	highly coherent oscillator	DC	direct current
CONRAD	Convection Development in Operational Radar Products	DCM	4-(dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4h-pyran
COOP	Cooperative Observer Program	DD	double difference
COPS	Convective and Orographically-induced Precipitation Study	DDA	discrete dipole approximation
COR	coherent on receive	DDIM	dry deposition inferential method
COST	European Cooperation in Science and Technology	DDPIR	double direction precision infrared radiometer
COT	cloud optical thickness	DDS	direct digital waveform synthesis
CPC	condensation particle counter	DE	detection efficiency
CPL	Cloud Physics Lidar	DEA	Disjunct Eddy Accumulation
CPR	Cloud Profiling Radar	DEBITS	Deposition of Biogeochemically Important Trace Species
CPU	Central Processing Unit	DEC	Disjunct Eddy Covariance
CR	catch ratio	DELTA	Denuder for Long-Term Atmospheric Sampling
CR	color ratio	DER	cloud droplet effective radius
CR	capillary rise	DFG	Difference Frequency Generation laser spectroscopy
CRDS	Cavity Ring-down Spectroscopy	DFIR	double fence intercomparison reference
CRLB	Cramer Rao lower bound	DFR	differential frequency ratio
CRN	clutter ratio narrow	DFS	dynamic frequency selection
CRNS	cosmic-ray neutron sensor	DFT	discrete Fourier transform
CRS	cloud radar system	DHI	diffuse horizontal irradiance
CRT	cathode ray tube	DIAL	differential-absorption lidar
CRTM	Community Radiative Transfer Model	DIC	dissolved inorganic carbon
CS	citizen science	DIF	Directory Interchange Format
CSAR	cryogenic solar absolute radiometer	DIN	Deutsche Industrienorm
CSC	concentrating solar technologies	DIW	deionized water
CSET	Cloud System Evolution in the Trades	DIY	do-it-yourself
CSIP	Convective Storms Initiation Project	DMA	differential mobility analyzer
CSP	concentrating solar power		

DMPS	differential mobility particle sizer	EMEP	European Monitoring and Evaluation Programme
DNI	direct normal irradiance	EMF	electromotive force
DNS	direct numerical simulation	EMI	electromagnetic interference
DOAS	differential optical absorption spectroscopy	EN	European standard
DOF	degrees of freedom	ENTA	Environmental and Networking Technologies and Applications
DOI	digital object identifier	EO	Earth observation
DORIS	Doppler Orbitography and Radiopositioning Integrated by Satellite	EOL	Earth Observing Laboratory
DOY	day of the year	EOS	Earth Observing System
DP	depth of percolation	EPC	electronic pressure controller
DPR	dual-frequency precipitation radar	EPOS	Earth Parameter and Orbit System
DQO	data quality objective	EPS	EUMETSAT Polar System
DSD	drop-size distribution	EPS-SG	EUMETSAT Polar System—Second Generation
DSM	digital surface model	ERF	Environmental Response Function
DSP	digital signal processor	ERP	Earth rotation parameter
DSY	design summer year	ESAS	Earth Science and Applications from Space
DTS	distributed temperature sensing	ESM	electric supplementary material
DWL	Doppler Wind Lidar	ESM	mobile experience sampling
DWR	dual-wavelength ratio	ESTAR	Electronically Scanned Thinned Array Radiometer
DYN	dynamic range	ET	evapotranspiration

E

EA	eddy accumulation	ETM+	Enhanced Thematic Mapper Plus
EAA	electrical aerosol analyzer	EUMETNET	European Meteorological Network
EAUNET	Acid Deposition Monitoring Network in East Asia	EUPHORE	European Photoreactor
EARLINET	European Aerosol Research Lidar Network	EURDEP	European Radiological Data Exchange Platform
EBCM	extended boundary condition method	EUV	Extreme Ultraviolet
EBEX	Energy Balance Experiment	EVA-GRIPS	Evaporation at Grid-Pixel Scale
EC	eddy covariance	EVI	Enhanced Vegetation Index
EC	Executive Committee	EXCO	extinction coefficient
ECC	electrochemical concentration cell	EXRAD	ER-2 X-Band Radar
ECD	electron capture detector		
ECMWF	European Centre for Medium-Range Weather Forecasts		
ECV	essential climate variable		
EDFA	erbium-doped fiber amplifier		
EDOP	ER-2 Doppler Radar		
EEFlux	Earth Engine Flux		
EEPS	Engine Exhaust Particle Sizer		
EESS	Earth Exploration Satellite Service		
EFEDA	European Field Experiment in a Desertification-Threatened Area		
EG-CLIMET	European Ground-Based Observations of Essential Variables for Climate and Operational Meteorology		
EIA	extended-interaction amplifier		
EIK	extended-interaction klystron		
EIKA	extended-interaction klystron amplifier		
ELDORA	Electra Doppler Radar		
ELF	extremely low frequency		
ELPI	electrical low-pressure impactor		
ELVOC	extremely low-volatility organic compound		
EM	electromagnetic		
eMAS	Enhanced MODIS Airborne Simulator		

F

FA	fractional absorption
FAGE	Fluorescence Assay by Gas Expansion
FAPAR	Fraction of Absorbed Photosynthetically Active Radiation
FAR	false alarm rate
FASTEM	fast microwave emissivity model
FBG	fiber Bragg grating
FC	field capacity
FCA	full correlation analysis
FCDR	fundamental climate data records
FD	forced diffusion
FDI	frequency-domain interferometry
FDL	flux detection limit
FDMS	filter dynamic measurement system
FDR	frequency domain reflectometry
FET	field-effect transistors
FFT	Fast Fourier Transform
FFTS	Fast Fourier Transform Spectrometer
FGGE	First GARP Global Experiment
FHP	five-hole probe
FIA	flow injection analysis
FIFE	First ISLSCP Field Experiment

FIR	finite impulse response	GF (s.c.)	glass fiber filter coated with s.c.
FIR	fog interception rate	GHG	greenhouse gas
FLEX	FLuorescence EXplorer	GHI	global horizontal irradiance
FLEX	Fluorescence Explorer	GHOST	Global Horizontal Sounding Technique
FLUXNET	Network of FLUX Measurement Sites	GIS	Geographic Information System
FM	flow meter	GLAS	Geoscience Laser Altimeter System
FMCW	frequency-modulated continuous wave	GLONASS	Global Navigation Satellite System
FMCW radar	frequency-modulated continuous-wave radar	GLORIA	Gimballed Limb Observer for Radiance Imaging in the Atmosphere
FMICW	frequency-modulated interrupted continuous wave	GM	Geiger–Müller
FMPS	fast mobility particle sizer	GM	gradient method
FMS	frequency modulation	GMD	geometric mean diameter
FNBW	first null beam width	GMI	GPM Microwave Imager
FO	fiber-optic	GMS	Geostationary Meteorological Satellite
FOM	figure of merit	GMT	Greenwich Mean Time
FORTRAN	Formula Translation	GNSS	Global Navigation Satellite System
FOV	field of view	GO3OS	Global Ozone Observing System
FPGA	field-programmable gate array	GOCE	Gravity Field and Steady-State Ocean Circulation Explorer
FPH	frostpoint hygrometer	GOES	Geostationary Operational Environmental Satellite
FRAND	fair, reasonable, nondiscriminatory	GOEME	Global Ozone Monitoring Experiment
FRP	fire radiative power	GOMS	Geostationary Operational Meteorological Satellite
FSOI	forecast sensitivity to observation index	GORN	Liaison Group on Radar Networking
FSS	forward scatter signal	GOS	Global Observing System
FT	free troposphere	GOSAT	Greenhouse Gases Observing Satellite
FTIR	Fourier-transform Infrared Spectroscopy	GPM	Global Precipitation Measurement
FTIR	Fourier-Transform Infrared Spectroscopy	GPS	Global Positioning System
FTP	file transfer protocol	GPSRO	GPS Radio Occultation
FTS	Fourier-transform Spectrometer	GRACE-II	Gravity Recovery and Climate Experiment II
FVFD	fractional vertical flux divergence	GRAS	GNSS Receiver for Atmospheric Sounding
FWHM	full width at half maximum	GRP	glass-fiber reinforced plastic

G

GAARS	Global Atmospheric Aerosol and Radiation Study	GRUAN	GCOS Reference Upper-Air Network
GaAsP	gallium arsenide phosphide	GSO	geosynchronous orbit
GACM	Global Atmospheric Composition Mission	GTI	global tilted irradiance
GARP	Global Atmospheric Research Program	GTS	Global Telecommunication System
GAW	Global Atmosphere Watch	GUAN	GCOS Upper-Air Network
GAW-PFR	Global Atmosphere Watch–Precision Filter Radiometer	GUM	Guide to the Expression of Uncertainty in Measurement
GAWSIS	GAW Station Information System	GURME	GAW Urban Research Meteorology and Environment Project
GC	gas chromatography	GV	Gulfstream V
GCM	Global Climate Model	GW	ground water
GCOS	Global Climate Observing System		
GCRF	Geocentric Celestial Reference Frame		
GDACCS	Geometrical Displacement and Conduction Current Sensor		
GDP	Global Drifter Program		
GEO-CAPE	Geostationary Coastal and Air Pollution Event		
GEOSS	Global Earth Observing System of Systems		
GERB	Geostationary Earth Radiation Budget Experiment		
GEWEX	Global Energy and Water Exchanges		

H

HADCP	horizontal ADCP
HALO	High Altitude and Long Range Research Aircraft
HAMP	HALO Microwave Package
HAPEX	Hydrologic Atmospheric Pilot Experiment
HAR	High-Altitude Radar
HATPRO	Humidity and Temperature Profiler
HATS	Halocarbons and other Atmospheric Trace Species

HCI	human–computer interaction	ICL	Interband Cascade Laser
HCP	height corrected pressure	ICM	Implementation and Coordination Meeting
HCR	HIAPER Cloud Radar		
HD	hazard distance	ICON-LEM	Icosahedral Nonhydrostatic Large Eddy Model
HD	high dose		
HDD	heating degree days	ICOS	Integrated Carbon Observation System
HDF	Hierarchical Data Format	ICOS	Integrated Cavity Output Spectroscopy
HDF5	Hierarchical Data Format, version 5	IE	intercomparison exercise
HDPE	high-density polyethylene	IF	intermediate frequency
HDSS	High-Definition Sounding System	IF	interference filter
HEPA	high-efficiency particulate air	IFC	intensive field campaign
HF	high frequency	IFD	intermediate frequency digitizer
HFC	hydrofluorocarbon	IFS	integrated forecast system
HIAPER	High-Performance Instrumented Airborne Platform for Environmental Research	IGACO	Integrated Global Atmospheric Chemistry Observation
HIRDLS	High-Resolution Dynamics Limb Sounder	IGBT	insulated gate bipolar transistor
		IGRA	infrared absorption gas analyzer
HIRS/4	High-Resolution Infrared Radiation Sounder	IGY	International Geophysical Year
		IHOP	International Water Vapor Project
HITRAN	High-Resolution Transmission Molecular Absorption Database	IIR	infinite impulse response
		IIR	Imaging Infrared Radiometer
HIWRAP	High-Altitude Imaging Wind and Rain Airborne Profiler	IL	interception loss
		ILS	instrumental line shape
HMMS	Horizontal Mobile Measurement System	IMIS	Integrated Measuring and Information System for the Surveillance of Environmental Radioactivity
HOM	highly oxidized multifunctional molecule		
		IMPROVE	Interagency Monitoring of Protected Visual Environments
HOPE	HD(CP) ² Observational Prototype Experiment		
		IMS	International Monitoring System
HPBW	half-power beam width	IMS	ion-mobility spectroscopy
HPLC	high-performance liquid chromatography	IMU	inertial measurement unit
		IN	ice nucleus
HRDL	High Resolution Doppler Lidar	INDAAF	International Network to Study Deposition and Atmospheric Chemistry in Africa
HREA	Hyperbolic Relaxed Eddy Accumulation		
HS	heterogeneous sensor	INS	inertial navigation system
HSB	Humidity Sounder for Brazil	IOMS	instrument odor measurement system
HSR	high spectral resolution	IoT	internet of things
HSRL	High Spectral Resolution Lidar	IP	internet protocol
HTDMA	Hygroscopic Tandem Differential Mobility Analyzer	IPAB	International Programme for Antarctic Buoys
HWS	horizontal wind speed	IPC	International Pyrheliometer Comparison
HYMEX	Hydrological Cycle in the Mediterranean Experiment	IPDA	integrated path differential absorption
		IPgC	International Pyrgeometer Comparison
		IPM	inflection point method
		IPS	International Pyrheliometric Scale
		IPT	integrated profiling technique
		IR	infrared
IABP	International Arctic Buoy Program	IRGA	infrared gas analyzer
IAGC	instantaneous automatic gain control	IRIS	Infrared Integrating Sphere Radiometer
IAGOS	In-service Aircraft for Global Observing System	IRMS	Isotope Ratio Mass Spectrometry
		IRS	Inertial Reference System
IASI	Infrared Atmospheric Sounding Interferometer	IRSR	interim reference sunshine recorder
		IRT	infrared thermometer
IC	ion chromatograph	ISA	ICAO standard atmosphere
IC	ion chromatography	ISD	ice crystal size distribution
IC	intracloud	ISL	inertial sublayer
IC	interception capacity	ISLSCP	International Satellite Land Surface Climatology Project
ICESat-II	Ice, Cloud, and Land Elevation Satellite II		
ICI	Ice Cloud Imager		

ISR	intermediate storage reservoir	LF	low frequency
ITC	integral turbulence characteristics	LGB	Lehmann–Groß–Bahn
ITOS	Improved TIROS Operational System	LHC	lefthanded circular
ITRF	international terrestrial reference frame	LHN	latent heat nudging
ITS	International Temperature Scale	LI	lifted index
ITS-90	International Temperature Scale 90	lidar	light detection and ranging
IWC	ice water content	LIF	laser-induced fluorescence
IWP	ice water path	LIN	linear channel
IWV	integrated water vapor	LIP	laser-induced phosphorescence
I&Q	In-phase & Quadrature	LIPGLOS	laser-induced phosphorescence of (methyl)glyoxal spectrometry

MBR	modified Bowen ratio method	MOZAIC	Measurement of Ozone and Water Vapour on Airbus In-service Aircraft
MC	Monte Carlo	MPD	MicroPulse DIAL
MCM	master chemical mechanism	MPL	Micro-Pulse Lidar
MCP	microchannel plate	MPLNET	Micro-Pulse Lidar Network
MCS	mobile crowdsourcing	MPM	microwave propagation model
MCSE	minimum chi square estimation	MPSS	Mobility Particle Size Spectrometer
MDN	Mercury Deposition Network	MR	measurement result
MDS	minimum detectable signal	MRA	Mutual Recognition Arrangement
MELTEX	Impact of Melt Ponds on Energy and Momentum Fluxes between Atmosphere and Sea Ice	MRT	Magnetic Resonance Tomography
		MRU	Motion Reference Unit
MEMS	microelectromechanical system	MS	mesosphere
MESH	maximum estimated size of hail	MS	mass spectrometer
METEOSAT	Meteorological satellite	MSG	METEOSAT Second Generation
MetOp	Meteorological Operational Satellite	MSI	Multispectral Imager
MetOp-SG	Meteorological Operation Satellite, Second Generation	MSI	Multispectral Instrument
METRIC	Mapping Evapotranspiration at High Resolution Using Internalized Calibration	MSL	mean sea level
		MSP	Mie spectrometer
METROMEX	Metropolitan Meteorological Experiment	MSS	Multispectral Scanner
		MST	mesosphere-stratosphere-troposphere
MFC	mass flow controller	MST	Mountain Standard Time
MFP	multihole flow probe	MSU	Microwave Sounding Unit
MFRSR	multifilter rotating shadowband radiometer	MTBF	Mean Time Between Failures
		MTG	METEOSAT Third Generation
MG	measurement guideline	MTI	Moving Target Indicator
MH	mixing height	MTP	Microwave Temperature Profiler
MHS	Microwave Humidity Sounder	MUSIC	MULTiple Signal Classification
MIMIC	Microwave and Millimeter-wave Integrated Circuit	MVIRI	METEOSAT Visible and Infrared Imager
		MW	microwave
MIMO	Multiple-input Multiple-output	MWI	Microwave Imager
MIR	mid-infrared	MWR	microwave radiometry
MISR	Multi-angle Imaging SpectroRadiometer	MWR	microwave radiometer
MITRA	monitor to measure the integral transmittance	MWS	microwave sounder
		MWS	microwave scintillometer
ML	mixed layer	MZI	Mach–Zehnder Interferometer
MLE	maximum likelihood estimation		
MLH	mixed-layer height	N	
MLS	maximum length sequence		
MLS	Microwave Limb Sounder	NADP	National Atmospheric Deposition Program
MLT	mean local time	NAIS	Neutral Cluster and Air Ion Spectrometer
MM	multimode	NARVAL	Next-Generation Aircraft Remote Sensing for Validation
MMIC	Monolithic Microwave-integrated Circuit	NAST-I	NPOESS Airborne Sounder Testbed Interferometer
MODE-S EHS	Mode-Selective Enhanced Surveillance Data	NAWDEX	North Atlantic Waveguide and Downstream Impact Experiment
MODIS	Moderate Resolution Imaging Spectroradiometer	NBL-K	nocturnal boundary-layer Keeling plot
MODTRAN	MODerate resolution atmospheric TRANsmission	NDACC	Network for the Detection of Atmospheric Composition Change
MONS	Meteorological Orthonormal Coordinate System	NDDN	National Dry Deposition Network
MOPA	master oscillator power amplifier	NDSC	Network for the Detection of Stratospheric Change
MOPITT	Measurements of Pollution in the Troposphere	NDVI	Normalized Difference Vegetation Index
MOR	meteorological optical range	NEDT	noise equivalent differential temperature

NEE	Net Ecosystem Exchange
NEON	National Ecological Observatory Network
NetCDF	network common data form
NEWA	Network for Environmental and Weather Application
NEXRAD	Next-generation Radar
NF	noise figure
NH	northern hemisphere
NIM	Nuclear Instrumentation Module
NIP	Normal Incidence Pyrheliometer
NIR	near-infrared
NMC	National Meteorological Center
NMHC	non-methane hydrocarbons
NOHD	Nominal Ocular Hazard Distance
NPOESS	National Polar-orbiting Operational Environmental Satellite System
NRC	National Radiation Center
NRCS	normalized radar cross-section
NRWI	non-rain water input
NSBL	nocturnal stable boundary layer
NTC	negative temperature coefficient
NTN	National Trends Network
NWC SAF	Nowcasting SAF
NWM	Numerical Weather Model
NWP	Numerical Weather Prediction

O

OA-ICOS	off-axis integrated cavity output spectroscopy
OD	optical depth
ODIM	OPERA Data Information Model
OFDS	Optical-fiber-based Distributed Sensing
OLCI	Ocean and Land Colour Instrument
OLI	Operational Land Imager
OMI	Ozone Monitoring Instrument
OMPS	Ozone Mapping and Profiler Suite
OMS	optical-microwave scintillometer
OMT	orthomode transducer
OPC	optical particle counter
OPD	optical path difference
OPERA	Operational Programme for the Exchange of Weather Radar Information
OPO	optical parametric oscillator
OPS	optical particle spectrometer
ORACLES	Observations of Aerosols above Clouds and Their Interactions
OSCAR	Observing Systems Capability Analysis and Review Tool
OSCR	ocean surface current radar
OSI SAF	Ocean and Sea Ice SAF
OU	odor unit
OVOC	oxygenated VOC
OWS	ocean wind speed

P

P(p.a.)	p.a.-coated paper filter
PAH	polyaromatic hydrocarbon
PAN	peroxyacetyl nitrate
PAR	Photosynthetically Active Radiation
PARASOL	Polarization and Anisotropy of Reflectances for Atmospheric Science coupled with Observations from a Lidar
PASS	Photoacoustic Soot Spectrometer
PATH	Precipitation and All-Weather Temperature and Humidity
PAX	Photoacoustic Extinctionmeter
PBDE	polybrominated diphenyl ether
PBL	planetary boundary layer
PBP	Pellin–Broca prism
PBS	polarizing beam splitter
PC	personal computer
PCB	polychlorinated biphenyl
PCDD	polychlorinated dibenzodioxin
PCDF	polychlorinated dibenzofuran
PD	public domain
PDCA	plan–do–check–act
PDE	partial differential equation
PDF	portable digital format
PDT	Pacific Daylight Time
PE	polyethylene
PE	permutation entropy
PE-HD	polyethylen high density
PECAN	Plains Elevated Convection at Night
PERCA	peroxy radical amplifier
PF	photo-fragmentation
PFA	perfluoroalkoxy
PFB	polyphase filter-bank
PFN	pulse forming network
PG	potential gradient
PIA	path-integrated attenuation
PIMS	programmable ion mobility spectrometer
PIR	Precision Infrared Pyrometer
PLS	polystyrene latex sphere
PM	Penman–Monteith
PM	particulate matter
PMM	probability matching method
PMS	Particle Measuring Systems
PMT	photomultiplier tube
PNNL	Pacific Northwest National Laboratory
POFD	probability of false detection
POLDER	Polarization and Directionality of the Earth's Reflectances
POP	persistent organic pollutant
POSH	Probability of Severe Hail
PP	polypropylene
PPFD	Photosynthetic Photon Flux Density
PPGIS	Public Participatory Geographic Information Systems
PPI	plan position indicator
PPLN	periodically poled lithium niobate
PPP	precise point positioning
PPP	public–private partnerships

PPP	pulse-pair processing
PRF	pulse repetition frequency
PRT	pulse repetition time
PS	participatory sensing
PS	Primary Standard
PSAP	Particle Soot Absorption Photometer
PSD	particle-size distribution
PSP	precision spectral pyranometer
PTC	positive temperature coefficient
PTFE	polytetrafluoroethylene
PTR	proton transfer reaction
PUF	polyurethane foam
PV	photovoltaic
PVC	polyvinyl chloride
PW	precipitable water
PW	pulse width
PWD	present weather detector
PWS	personal weather station
PWV	precipitable water vapor
PZT	lead zirconate titanate

Q

QA	quality assessment
QA	quality assurance
QBO	quasi-biennial oscillation
QC	quality control
QCL	quantum cascade laser
QCLAS	quantum cascade laser absorption spectroscopy
QE	quantum efficiency
QMS	quadrupole mass spectrometer
QNH	atmospheric pressure adjusted to sea level
QPC	quadratic phase coding

R

RA	regional association
radar	radio direction and ranging
RAF	Research Aviation Facility
RANS	Reynolds-averaged Navier–Stokes
RASS	Radio-Acoustic Sounding System
RASS	Radio-acoustic Sounding System
RASTA	Radar System Airborne
RAWS	remote automatic weather station
RC	resistor-capacitor
RCC	Regional Calibration Centre
RDF	radio direction finder
RE	radiative effect
REA	Relaxed Eddy Accumulation
REPARTEE	Regents Park and Tower Environmental Experiment
REV	representative elementary volume
REW	readily evaporable water
REWS	rotor-equivalent wind speed
RF	radio frequency
RFI	radio-frequency interference

RG	rain gauge
RHC	righthanded circular
RHI	range-height indicator
RIM	range imaging
RMS	root mean square
RMSE	root-mean-square error
RODOS	Realtime Online Decision Support System
ROE	receiver-over-elevation (gear)
RP	receiver protectors
RPA	remotely piloted aircraft
RPAS	remotely piloted aircraft system
RPM	revolutions per minute
RPT	resonant pressure transducer
RR	rotational Raman
RRC	regional radiation center
RS	radiosonde
RS	remote sensing
RSI	rotating shadowband irradiometer
RSL	roughness sublayer
RSP	Research Scanning Polarimeter
RSP	Rayleigh spectrometer
RSP	rotating shadowband pyranometer
RSR	rotating shadowband radiometer
RT	radiative transfer
RTE	radiative transfer equation
RTTOV	radiative transfer for ATOVS
RTTOV-gb	ground-based radiative transfer for TIROS operational vertical sounder
RUC	rapid update cycle
RV	research vessel
RVH	recirculating ventilation and heating
RVR	runway visual range
RWIS	roadway weather information system
RWP	radar wind profiler

S

SA	spaced antenna
SAF	Satellite Application Facility
SAFIRE	Service des Avions Francais Instrumentés pour la Recherche en Environnement
SAI	surface area index
SAMUM	Saharan Mineral Dust Experiment
SAPHIR	Simulation of Atmospheric Photochemistry in a large Reaction Chamber
SAR	Synthetic Aperture Radar
SASBE	site atmospheric state best estimate
SBL	stable stratified boundary layer
SbS	side by side
SBS	stimulated Brillouin scattering
Scale-X	Scale-crossing Land-surface and Boundary Layer Processes
SCD	slant column density

SCIAMACHY	Scanning Imaging Absorption Spectrometer for Atmospheric Cartography	SORA	Specific Operations Risk Assessment
SCLP	Snow and Cold Land Process	SOWER	Sounding of Ozone and Water in the Equatorial Region
SCMS	Small Cumulus Microphysics Study	SPN	sunshine pyranometer
SCU	scatter meter calibration units	SPOT	Satellite Pour l'Observation de la Terre
SDS-WAS	Sand and Dust Storms Warning Advisory and Assessment System	SQI	signal quality index
SEBAL	Surface Energy Balance Algorithms for Land	SR	surface renewal
SEVIRI	Spinning Enhanced Visible and Infrared Imager	SRAL	Synthetic Aperture Radar Altimeter
SF	stemflow	SS	single scattering
SFC	Standard Fog Collector	SSA	single-scattering albedo
SGP	Southern Great Plains	SSM	solid-state modulator
SH	southern hemisphere	SSM/I	Special Sensor Microwave/Imager
SHADOZ	Southern Hemisphere Additional Ozonesondes	SSMIS	Special Sensor Microwave Imager/Sounder
SHD	slant hydrostatic delay	SSPA	solid-state power amplifier
SI	International System of Units (Système international d'unités)	SSS	sea surface salinity
SIA	sea-ice-air	SST	sea surface temperature
SIC	sea ice concentration	SSW	sudden stratospheric warming
SIP	sorbent-impregnated PUF	ST	stratosphere
SIRT	simultaneous iterative reconstruction technique	STALO	Stable Local Oscillator
SIS	shortwave incoming surface radiation	STAR	simultaneous transmit and receive
SIWV	slant-integrated water vapor	STD	slant total delay
SJAC	Steam-jet Aerosol Collector	STINHO	Structure of Turbulent Processes Under Inhomogeneous Surface Conditions
SK	skewness	sUAS	small unmanned aircraft system
SL	surface layer	SUI	Solar Ultraviolet Imager
SLS	surface-layer scintillometer	SUMO	Small Unmanned Meteorological Observer
SLSTR	Sea and Land Surface Temperature Radiometer	Suomi-NPP	National Polar-orbiting Partnership
SM	single mode	SUV	sport utility vehicle
SM-DTS	soil moisture distributed temperature sensing	SVD	singular value decomposition
SMA	social media analytic	SVF	sky-view factor
SMACEX	Soil Moisture Atmosphere Coupling Experiment	SVN	Apache Subversion
SMAP	Soil Moisture Active-Passive	SVOC	semivolatile organic compound
SML	surface mixed layer	SVP	Surface Velocity Program
SMMR	scanning multichannel microwave radiometer	SVPB	surface velocity program barometer
SMOS	Soil Moisture and Ocean Salinity	SWAT	Soil and Water Assessment Tool
SMPS	Scanning Mobility Particle Spectrometer	SWC	water content of soil
SMR	submillimeter radiometer	SWD	slant wet delay
SND	Schotanus-Nieuwstadt-DeBruin	SWE	snow water equivalent
SNODAR	Surface Layer Non-Doppler Acoustic Radar	SWOT	Surface Water and Ocean Topography
SNR	signal-to-noise ratio	SWR	standing wave ratio
SO	observatory service	SYNOP	Surface Synoptic Observations
SOA	secondary organic aerosol	SYRSOC	synergistic remote sensing of cloud
SOC	system on chip	SZA	solar zenith angle
sodar	sonic detection and ranging	S&H	sample and hold
SONAR	sound navigation and ranging		
SONET	Sun/sky-radiometer Observation Network		
SOP	standard operating procedure		
		T	
		T(IC)	Teflon filter for ion chromatographic analysis
		T(XRF)	Teflon filter for x-ray fluorescence analysis
		TAC	traditional alphanumeric code
		TBG	tipping-bucket gauge
		TBR	tipping-bucket rain gauge
		TCCON	Total Carbon Column Observing Network

TCDR	thematic CDR		Intensity with a Constellation of Smallsats
TC ⁴	Tropical Composition, Cloud and Climate Coupling	TROPOMI	TROPOspheric Monitoring Instrument
TDCF	table-driven code form	TRY	test reference year
TDDR	Total Direct and Diffuse Radiometer	TS	total scattering
TDL	tunable diode laser	TSEB	two source energy balance
TDLAS	Tunable Diode Laser Absorption Spectroscopy	TSG	test signal generator
TDLIF	thermal desorption laser-induced fluorescence	TSG	thermosalinograph
TDLS	tunable diode laser spectroscopy	TSI	total solar irradiance
TDR	time-domain reflectometry	TSP	total suspended matter
TDSI	time-dependent stochastic inversion	TSP	total suspended particles
TEA	Technology for Enabling Awareness	TTS	thermodynamic temperature scale
TEA	transverse-excited, atmospheric pressure	TV	television
TELSEM ²	Tool to Estimate the Land Surface Emissivity from the Microwaves to the Millimeter Waves	TVS	tornado vortex signature
TEM	transmission electron microscope	TWT	traveling-wave tube
TEOM	tapered element oscillating microbalance	TWTA	travelling-wave tube amplifier
TEOS-10	International Thermodynamic Equation of Seawater – 2010	TX	transmitter
TERENO	Terrestrial Environmental Observatories		
TES	Tropospheric Emission Spectrometer	U	
TESSEM ²	Tool to Estimate Sea Surface Emissivity from Microwave to Submillimeter Waves	UA	unmanned aircraft
TEW	total amount of water that can be evaporated	UA	unmanned autonomous
TFT	thin-film transistor	UARS	Upper Atmospheric Research Satellite
TGA	trace gas analyzer	UAS	unmanned aircraft system
TIR	thermal infrared	UAV	unmanned aerial vehicle
TIROS	Television Infrared Observation Satellite	UBL	urban boundary layer
TIRS	thermal infrared sensor	UCL	urban canopy layer
TKE	turbulent kinetic energy	UFP	ultrafine particle
TLE	transient luminous event	UHF	ultra-high frequency
TLSE	total least squares estimation	UHI	urban heat island
TLT	true local time	ULF	ultra low frequency

WIS/WIGOS	WMO Integrated Global Observation System	Y	
WLAN	Wireless Local Area Network	YAG	yttrium aluminum garnet
WLSE	weighted least squares estimation	Z	
WMO	World Meteorological Organization	ZHD	zenith hydrostatic delay
WMO–SPICE	World Meteorological Organization Solid Precipitation Intercomparison Experiment	ZTD	zenith total delay
WMS	wavelength modulation	ZWD	zenith wet delay
WOCE	World Ocean Circulation Experiment		

List of Symbols

All symbols used in each chapter are explained within that chapter itself, allowing each chapter to be read independently of this list of symbols. However, some basic symbols are identical in most of the chapters and are listed below. Because of the different scientific communities that have contributed to this handbook, some of the parameters may be represented by different symbols in some chapters.

Latin symbols

a	absolute humidity	kg m^{-3}
a_G	molecular heat conductance coefficient in soil	$\text{W m}^{-1} \text{K}^{-1}$
a_T	molecular heat conductance coefficient in air	$\text{W m}^{-1} \text{K}^{-1}$
Bo	Bowen ratio	
c	sound speed	m s^{-1}
c	speed of light in vacuum	m s^{-1}
c	concentration (general)	*
c_p	specific heat at constant pressure	$\text{J kg}^{-1} \text{K}^{-1}$
c_v	specific heat at constant volume	$\text{J kg}^{-1} \text{K}^{-1}$
C_G	volumetric heat capacity	$\text{W s m}^{-3} \text{K}^{-1}$
C_H	Stanton number	
C_{nn}	structure parameter of refraction	$\text{m}^{-2/3}$
C_{TT}	structure parameter of temperature	$\text{K m}^{-2/3}$
d	displacement height	m
d	measuring path	m
DOY	day of the year: Jan. 1 = 1	
e	base of the natural logarithm	
e	water vapour pressure	hPa
E	water vapour pressure at saturation	hPa
E	electric field	V m^{-1}
E	Irradiance, direct solar radiation	W m^{-2}
ET	Evapotranspiration	W m^2 or mm
E_d	diffuse solar radiation	W m^{-2}
E_g	global radiation	W m^{-2}
F	sensor surface area	m^2
F	force	kg m s^{-2}
F	flux (general)	*
F_c	dry deposition	$\text{kg m}^{-2} \text{s}^{-1}$
f	function (general)	*
f	frequency	s^{-1} or Hz
f	Coriolis parameter	s^{-1}
f	enhancement factor	
f_g	cut frequency	s^{-1} or Hz
f_s	sampling (Nyquist) frequency	s^{-1} or Hz
g	acceleration due to gravity	m s^{-2}
H	wave height	m
h	Planck's constant	Js
I	Intensity	*
J	Photolysis frequency	s^{-1}
k	absorption coefficient	m^{-1}
k	Boltzmann constant	J K^{-1}

k	thermal conductivity	$\text{W m}^{-2} \text{K}^{-1}$
L	Obukhov length	m
L	characteristic length scale	m
m	mixing ratio, mass fraction	kg kg^{-1}
M_a, m_d	molar mass of dry air	kg mol^{-1}
M_w, m_w	molar mass of water vapor	kg mol^{-1}
m_s	molar mass of a scalar	kg mol^{-1}
MOR	meteorological optical range	m
n	index of refraction	
N	particle number	m^{-3}
Nu	Nusselt number	
N_A	Avogadro constant	mol^{-1}
P	Particle scattering phase function	
p	air pressure	hPa
p_s	static air pressure	hPa
Pr	Prandtl number	
Pr_t	turbulent Prandtl number	
q	specific humidity	kg kg^{-1}
Q_E	latent heat flux	W m^{-2}
Q_E	latent heat flux expressed as a water column	mm
Q_G	ground heat flux	W m^{-2}
Q_H	sensible heat flux	W m^{-2}
r_a	turbulent atmospheric resistance	s m^{-1}
r_b	molecular-turbulent resistance	s m^{-1}
r_c	canopy resistance	s m^{-1}
r_s	stomatal resistance	s m^{-1}
R	resistance	Ω
R	radius	m
R, RH	relative humidity	%
R, R^*	universal gas constant	$\text{mol kg}^{-1} \text{K}^{-1}$
R_d	gas constant of dry air	$\text{J kg}^{-1} \text{K}^{-1}$
R_w	gas constant of water vapour	$\text{J kg}^{-1} \text{K}^{-1}$
Re	Reynolds number	
RF	Relative fugacity	
s_c	temperature dependence of specific humidity at saturation	$\text{kg kg}^{-1} \text{K}^{-1}$
S	solar constant	W m^{-2}
t	time	s
t	temperature	$^{\circ}\text{C}$
t_d	dewpoint temperature	$^{\circ}\text{C}$
t_w	wet-bulb temperature	$^{\circ}\text{C}$
T	absolute temperature, temperature difference	K
T_s	sonic (acoustic) temperature	K
T_v	virtual temperature	K
U	Voltage	V
U	Magnitude of the wind (module)	m s^{-1}
u	wind speed (general)	m s^{-1}
u	longitudinal/zonal component of the wind velocity	m s^{-1}
u_h	horizontal wind velocity	m s^{-1}
u_*	friction velocity	m s^{-1}
v	lateral/meridional component of the wind velocity	m s^{-1}
v_g	lateral component of the geostrophic wind	m s^{-1}
v_D	deposition velocity	m s^{-1}

V	Volume	m^3
V	characteristic velocity	m s^{-1}
V_N	standard visual range	m
w	vertical component of the wind velocity	m s^{-1}
x	measurement value	*
x	horizontal direction (length, fetch)	m
y	horizontal direction (length, perpendicular to x)	m
Z	geopotential height	gpm
Z	equation of time	min
z	height (general, geometric)	m
z_i	mixed-layer height	m
z_0	roughness parameter, roughness height	m

Greek symbols

α, ρ	albedo	
α	cubic thermal expansion coefficient	K^{-1}
β	backscatter coefficient	$\text{m}^{-1} \text{sr}^{-1}$
δ	Height of the internal boundary layer	m
ε	energy dissipation	$\text{m}^2 \text{s}^{-3}$
ε	emissivity	
θ	potential temperature	K
θ_v	virtual potential temperature	K
κ	von-Kármán constant	
κ	wave number	
λ	wavelength	m
λ	latent heat of evaporation for water	J kg^{-1}
λ	geographical longitude	°
μ	dynamic viscosity	$\text{kg m}^{-1} \text{s}^{-1}$
ν	kinematic (molecular) viscosity	$\text{m}^2 \text{s}^{-1}$
ρ	mass density	kg m^{-3}
σ_{SB}	Stefan-Boltzmann constant	$\text{W m}^{-2} \text{K}^{-4}$
σ_x^2	variance of the random variable x	*
τ	momentum flux	$\text{kg m}^{-1} \text{s}^{-2}$
τ	time constant	s
τ	optical thickness	m
φ	geographical latitude	°
φ_m	universal function for momentum	
φ_H	universal function for heat	
Φ	geopotential	$\text{m}^2 \text{s}^{-2}$
χ	mole fraction, mixing ratio	
Ω	Earth angular velocity	s^{-1}

Indices

a	air
d	dry
i	ice, sublimation
v	water vapor
w	water (also wet bulb)
0	standard values in meteorology, surface value

Other symbols

$\bar{\theta}$	time average of random variable θ
$\langle \theta \rangle$	ensemble average of random variable θ
$\theta' = \theta - \langle \theta \rangle$	zero-mean fluctuation of random variable θ
\vec{u}	vector of the variable u

Remark

1. Introduction to Atmospheric Measurements

Thomas Foken , Frank Beyrich, Volker Wulfmeyer 

Measurements in the atmosphere differ from measurements in other media because of the thermodynamic and radiative properties of air (e.g., low density, low heat capacity, and transparency to a large part of the electromagnetic spectrum) and the fact that the air is almost always in (often turbulent) motion. The vertical and horizontal distributions of meteorological elements and the spatial and temporal scales of processes strongly influence the selection of appropriate measurement methods and devices. This chapter gives a brief overview of the different ways of classifying atmospheric measurements, the relevant states and processes that influence measurements in the atmosphere, and basic measurement techniques (including some fundamental aspects of the performance and interpretation of these techniques). It focuses in particular on the so-called atmospheric boundary layer, since most measurements are performed in this region and most human activities take place there.

The weather and the climate crucially influence human life, ecosystems, and the environment. Agriculture, water management, energy production and transmission, traffic, health services, tourism, and other sectors of modern human society require high-quality meteorological services. Useful meteorological data and services are obtained by performing measurements and observations. These provide the basis for understanding Earth-system processes and for the development, operation, and verification of various types of models, ranging from complex global and regional numerical weather prediction and climate models to relatively simple parametric models used in engineering appli-

cations. Therefore, atmospheric data are collected not only by meteorological services but also by many other institutions, companies, and private users. Scientists need atmospheric data in different fields of research beyond meteorology and climatology; examples include remote sensing, biogeoscience, hydrology, and soil science. Many relevant applications require high-quality data and the use of the best measuring methods. Furthermore, climatological studies require data that can accurately be compared over long time periods (many decades)—it is important to ensure that climatological trends are not influenced by changes in instrumentation.

Because air is almost always in motion, measurements performed at a certain point in the atmosphere are always influenced by processes occurring not only at or close to this point but also over a larger domain, the size of which depends on the type and position of the measurement (especially the height above the surface). Therefore, when it is necessary to perform atmospheric measurements over land (i.e., to select appropriate sen-

sors and methods, sites, and measurement heights as well as the appropriate time resolution and averaging), it is important to consider the distributions and variability of meteorological elements in space and time over a wide range of scales above a mostly heterogeneous underlying surface, as far as measurements over land are concerned.

1.1 Measuring Meteorological Elements

The atmosphere can be described as a multiphase physicochemical system consisting of molecular nitrogen and oxygen, water in its three phases as well as a variety of trace gases, aerosol particles, and hydrometeors. *Meteorological elements* (or variables) are physical and chemical properties of air that characterize its thermodynamic state (e.g., pressure and temperature) and dynamics (wind), the composition of the atmosphere (trace gas concentrations, including humidity), and the processes that occur in it (e.g., fluxes of energy, momentum, and matter, as well as cloud physics). Measurements are usually performed to quantify these variables or to determine integral and macroscopic properties of the atmosphere (e.g., the cloud base height and type, and the visibility). Measurements are also performed to quantify processes at the interface between the atmosphere and the underlying surface (i.e., at the surfaces of water, rocks, soil, vegetation, snow, and ice). A variety of instruments and observation methods are available to determine these variables (chapters in Part E of this book). For many applications, multiple instruments are organized into sensor clusters, measurement systems, and networks (chapters in Part F of this book).

When performing measurements in the atmosphere, the basic principles of metrology (Chap. 2) and quality assurance and control (Chap. 3) are applied, and standardization may also be necessary (Chap. 4). These topics, together with tables of physical constants and atmospheric properties (Chap. 5), comprise the content of Part A of this book.

The measurements discussed in this book can be categorized into those performed with in-situ sensors and those obtained with remote sensing techniques. When measurements are carried out in-situ, the sensor is situated within the atmospheric volume that is being probed. The sensor may be fixed at a particular location or it may be moving along a measuring path. Such measurements require a sensor platform, which is typically a ground-based mast, tower, tripod, bar, or buoy (Chap. 6). Alternatively, in-situ sensors can be

carried by tethered or free-flying balloons, kites, and airborne platforms such as unmanned aerial systems, helicopters, and aircraft (Chaps. 37 and 49).

Remote sensing systems perform measurements in regions of the atmosphere that are located away from the sensor. They typically make use of the known propagation characteristics of light, radio, or sound waves in air to derive the values of atmospheric variables. These systems may be located at the Earth's surface (ground-based systems; Part C of this book) or on airborne or spaceborne platforms, such as satellites or space stations (Part D of this book). Remote sensing techniques can be further categorized into active and passive systems depending on whether they actively transmit the radiation used to derive the atmospheric properties or they simply detect radiation emitted from the atmosphere or from other sources (e.g., from the Sun or other stars).

Table 1.1 provides a basic overview of the methods used to derive the values of meteorological state and process variables from instrumental measurements, along with references to the different chapters of this book that discuss the techniques in detail. Besides instrumental measurements, visual observations and manual measurements are still performed to characterize the weather, visibility, cloud type and cover, snow depth and cover, etc. However, these visual observations are in the process of being replaced with more reproducible instrument-based techniques (Chap. 22). Different sensors can be combined in weather stations and profiling systems (Part E of this book), and these stations can be arranged in networks for a variety of applications (Part F of this book).

Figure 1.1 illustrates the variety of measuring methods and platforms used in the Global Observation System (GOS, Chap. 63). Similar diagrams could be presented for networks or experiments focusing on the so-called *mesoscale* (about 100–10 000 km²; see Sect. 1.3.3) or for measurements at the soil–vegetation–atmosphere interface for ecosystem studies.

Table 1.1 Overview of in-situ and remote sensing techniques used to measure variables in the atmosphere and at the interface between the atmosphere and the underlying surface (DIAL: differential absorption lidar; GNSS: Global Navigation Satellite System; HF: high frequency; IR: infrared; RASS: radio-acoustic sounding system; TDR: time-domain reflectometry)

^a Turbulent fluxes can also be determined from profile measurements of wind, temperature, humidity, and trace gases. The method used is described in detail in Chap. 54 and briefly in Sect. 1.3.1.

^b Momentum flux is also relevant in the nonturbulent atmosphere (gravity waves)

^c Flux measurements can be performed with combinations of different remote sensing techniques; see the relevant chapters

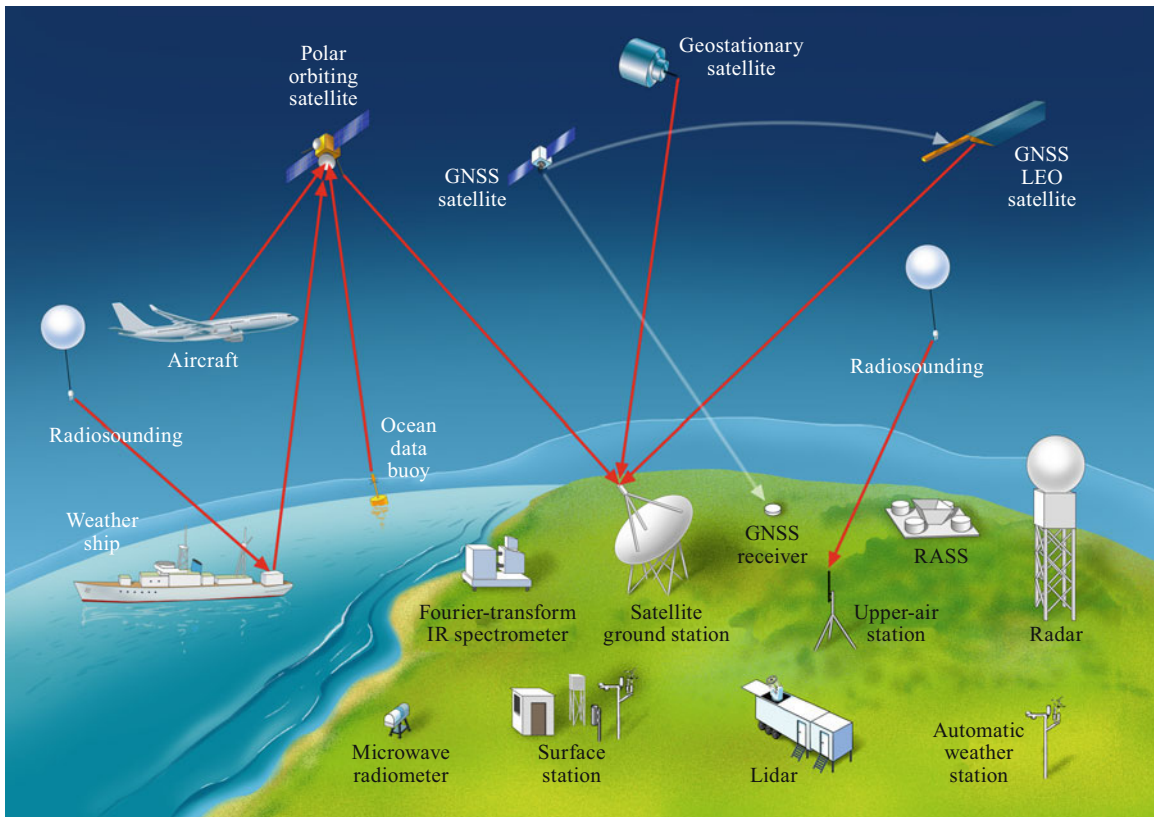

Fig. 1.1 Scheme of the Global Observing System (GOS) of the World Meteorological Organization (WMO) that illustrates how the most important in-situ systems and passive and active remote-sensing systems are used synergistically (after [1.1], reproduced with permission from John Wiley & Sons, Inc.)

1.2 History

The history of meteorology and measurements in the atmosphere has been described in many publications [1.2, 3]. A comprehensive timeline up to the middle of the last century is provided in [1.4]. Many of the measurement techniques and methods used early in the history of meteorology are not used anymore, but they are still important for understanding the atmospheric measurements performed today. Therefore, each chapter of this book has a small history section. Only a few aspects of general interest, mostly based on European history, are discussed below.

1.2.1 Historical Measurements

The first meteorological observations to be described and documented occurred in ancient times (e.g., in the *Meteorologica* written by *Aristotle* [1.5]). The first hygrometers were likely developed in the Western Han dynasty of ancient China between 200 BCE and

10 CE [1.6]. During the Renaissance period, great advances were made in the natural sciences, and some of the first instruments were constructed and built by *Leonardo da Vinci* (1452–1512) and *Galileo Galilei* (1564–1642). These instruments were thermometers, barometers, hygrometers, and wind vanes (see the chapters on temperature, pressure, humidity, and wind). By the middle of the seventeenth century, the academy at Florence had accumulated a collection of various instruments [1.7].

In a meteorological context, the thermometers made by *Gabriel Daniel Fahrenheit* (1686–1736), *René-Antoine Ferchault de Réaumur* (1683–1757), and *Anders Celsius* (1704–1744) are particularly well known. After first attempting to create water barometers, *Evangelista Torricelli* (1608–1647), a student of Galilei, developed the mercury barometer. In Europe, the first hair hygrometer was invented by *Benedict de Saussure* (1740–1799), and the first applicable psychrometer was

developed by *Ernst Ferdinand August* (1795–1870). Rain gauges have been employed since ancient times in India and China, but the first cylindrical gauges were used by *Benedetto Castelli* (1577–1644) in Perugia. The first wind vanes were constructed by *Egnato Danti* (1537–1586) in Bologna, and the rotation anemometer was developed by *Michael Lomonosow* (1711–1765). *Robert Hooke* (1635–1703) developed a combination of different instruments known as the weather clock. By the end of the eighteenth century, a combination of instruments for measuring several meteorological elements simultaneously was available, and it was used during scientific expeditions such as that performed by *Alexander von Humboldt* (1769–1859) to South America. The first systematic weather observations were also carried out during this period [1.8, 9].

From the seventeenth to the nineteenth centuries, meteorological variables were measured in various units that depended on the time period and location in which the measurements were performed. The most important of these units are described in the historical parts of the relevant chapters.

1.2.2 First Measurement Networks

Around 1660, *Robert Hooke* (1635–1703) provided the first instructions for weather observations. In addition to the date and time of the observation, he recommended recording the temperature, humidity, pressure, and coverage (amount) and genera (types) of clouds, as well as special observations. One of the oldest records of weather observations covering several years were made by an abbot, *Mauritius Knauer* (1613 or 1614–1664), from the Langheim monastery in Germany. The records were for the period 1652–1658, and were published in 1700 as the so-called Hundred-Year Calendar. Unfortunately, this erroneous and misleading expression is still in use today. This calendar was based on the incorrect assumption that the weather is governed by the Sun, the Moon, and the five planets known at that time (Mercury, Venus, Mars, Jupiter, and Saturn), implying that weather patterns repeat every seven years.

In 1723, the English physicist *James Jurin* (1684–1750) published an invitation for meteorological observations. The Royal Society in London and the academies of science in Berlin and St. Petersburg responded to this invitation. In 1771, *Johann Heinrich Lambert* (1728–1777) at the Berlin Academy of Sciences proposed the creation of a worldwide meteorological network.

One of the first meteorological networks was organized by *Karl Theodor*, Elector of Bavaria (1724–1799), who initially founded a scientific academy at Mannheim in 1763 before establishing the first meteo-

rological society, the *Societas Meteorologica Palatina*, in 1780 [1.8, 10]. *Johann Jakob Hemmer* (1733–1790) developed this network with 36 stations in Europe, two in North America, and one in Greenland. This network had a significant influence on, for example, the standardization of the times of the day at which climatological observations are performed (07:00 LT, 14:00 LT, and 21:00 LT; with LT being the local time). Data from that network were published for the period 1781–1792. Indeed, the temperature measurements that have been carried out at the Hohenpeißenberg in Germany (at 989 m ASL) since 1781, which represent the longest time series of temperature measurements at a mountain site worldwide, were influenced by the work of the *Societas Meteorologica Palatina*. Further mountain stations were established almost a century after the Hohenpeißenberg; e.g., in 1881 at Hochobir, in 1876 at Puy de Dôme, and in 1886 at Sonnblick [1.8]. Since the second half of the eighteenth century, continuous time series of meteorological observations have been available, such those from Basel (1761), Prague (1775), and Vienna (1775) [1.11].

Smaller networks have operated over short periods, such as that initiated by *Johann Wolfgang von Goethe* (1749–1832) in Duchy of Saxe-Weimar-Eisenach in 1821–1832. That network included the weather station at Jena, which started operating in 1813 and is still in operation today. Another network, founded in Saxony by *Karl Christian Bruhns* (1830–1881), comprised 22 stations and operated from 1863 to 1876. In 1826, *Heinrich Wilhelm Brandes* (1777–1834) constructed the first weather map based on weather observations made across Europe at 18 h on December 24, 1821 [1.12].

Following the development of hot-air balloons, *Gay-Lussac* (1787–1850) performed the first balloon cruises for scientific purposes in 1804. *James Glaisher* (1809–1903) went up to a height of 8839 m in 1862. At the end of the nineteenth century, a network of aerological stations using balloons and kites as sensor platforms was established, and the era of radiosoundings began around the year 1930 (Chap. 46).

1.2.3 The Establishment of Global Meteorological Organizations

The founding of the *Accademia del Cimento* in Florence in 1654 and the *Societas Meteorologica Palatina* in 1780 provided the impetus for international cooperation in the field of meteorological measurements. By the mid-nineteenth century, meteorological services existed in most of the developed nations. Another initial step on the path to organized international cooperation in this field was a conference on marine meteorology held in Belgium in 1853.

The year 1872, when *K.C. Bruhns* (Leipzig), *C. Jelinek* (Vienna), and *H. Wild* (St. Petersburg) invited meteorologists to Leipzig, marked the start of the era of regular international meteorological conferences. Participants agreed on a Permanent Meteorological Committee, which was established during the 1873 International Meteorological Congress in Vienna, and *C.H.B. Buys-Ballot* (Utrecht) was elected as the first president of the International Meteorological Conference (later renamed the *International Meteorological Organization*, IMO). The second conference was held 1879 in Rome. At that time, it was not possible that countries officially invited to a next conference. Therefore, *Wild* and *Scott* (England) organized the next congress in Munich in 1891. A series of conferences of the heads of meteorological services were then held until 1935. The founding of a permanent secretariat was declared in Vienna in 1926, and a general secretary was established in 1929. The secretariat was initially located in De Bilt, but was moved to Lausanne in 1939. The outcome of the 12th Conference of Directors of the nongovernmental IMO in Washington, DC in 1947 was a document proposing the creation of a new intergovernmental organization. With the foundation of the *World Meteorological Organization* (WMO) in 1951, the secretariat moved to Geneva (for further details, see e.g., [1.13–16]). In 1947, the IMO initiated the preparation of a guide to international meteorological instrument and observing practices, several editions of which have since been published [1.17]. This guide is an important reference work on the standard meteorological measurement and observation practices. In 1951, at the First Congress of the WMO, the Commission for Instruments and Methods of Observation

(CIMO) was founded. This provided another example of the strong focus on international coordination and standardization in the field of atmospheric measurements that started with the conference at Leipzig almost 80 years earlier.

1.2.4 Historical Textbooks on Meteorological Measurements

Measurement practices and devices have been discussed in most meteorological textbooks since the sixteenth century [1.4]. Probably the first modern textbook on sensors for atmospheric measurements was edited by *E. Kleinschmidt* in 1935 [1.18], and included contributions from *F. Albrecht*, *P. Duckert*, *W. Grundmann*, *M. Robitzsch*, and *R. Süring*. More than 30 years later, a similar textbook with many historical contributions was written by *W.E.K. Middleton* [1.9]. Furthermore, the *Meteorological Handbook*, edited by *F. Linke* and *F. Baur* [1.19], has a large instrumental part written by *W. Grundmann* and *F. Woelfle*. The first book about remote sensing techniques was edited by *D. Lenschow* in 1986 [1.20], and is still a standard textbook for these techniques. Another very interesting textbook is the one edited in 1980 by *F. Dobson*, *L. Hasse*, and *R. Davis* [1.21], in which the authors linked the different measuring techniques with air–sea interaction processes. Over the last 20 years, several textbooks on atmospheric measurements have been published [1.22–27], each with a very specific focus on particular methods and devices. The present book aims to provide a more general and comprehensive overview of the status and application of meteorological measurements in a uniform format of all chapters.

1.3 The Structure of the Atmosphere

The vertical and horizontal structure of the atmosphere and the typical timescales of atmospheric phenomena influence the design and performance of atmospheric measurement techniques. These properties must be taken into account to ensure that measurement techniques provide high-quality data that can be used for different purposes. For instance, the locations of different atmospheric layers and the vertical gradients of thermodynamic variables must be considered when deciding on the measurement range, measurement levels, and the vertical spacing of profile measurements. The timescales of atmospheric processes determine the measurement frequencies, averaging times, and appropriate response times of sensors.

The uncertainty of a meteorological measurement is due to the error of the sensor as well as the spatiotemporal variability in the meteorological element being measured. Some typical situations and examples together with their theoretical foundations are discussed in the following sections. More details are provided in relevant textbooks [1.28–32].

Each meteorological process has typical spatial and temporal scales. The reason for this is the underlying physics and the spectral organization of atmospheric turbulence and wavelike processes, where relevant wavelengths (spatial extents) relate to distinct durations (frequencies). The principle of scale classification was formulated by *Isidoro Orlanski* [1.33]. There

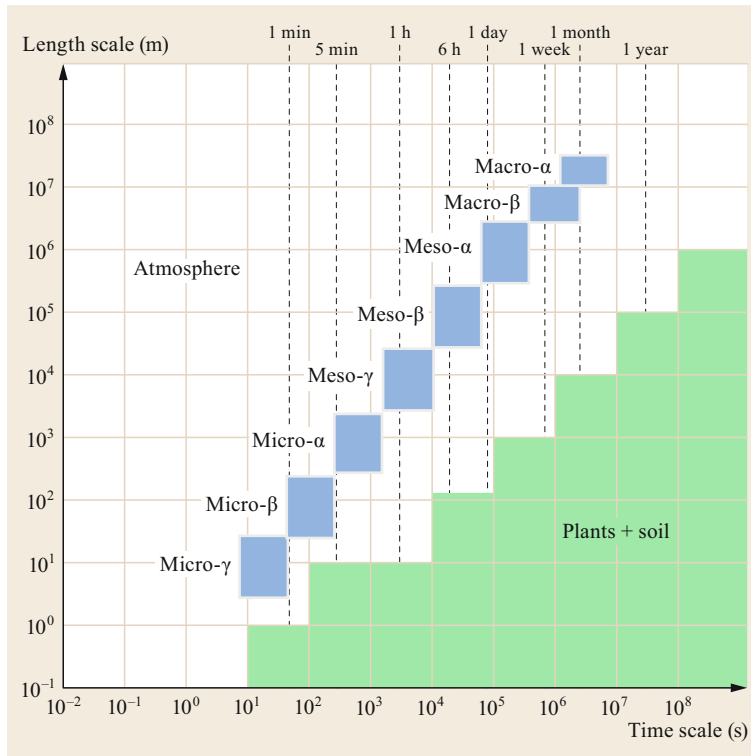

Fig. 1.2 Temporal and spatial scales of atmospheric, biospheric, and soil processes. *Blue boxes* indicate atmospheric scales [1.33], each with a range of one order of magnitude (micro- γ to macro- α scales are shown). The scales of plant and soil processes involved in exchanges of energy and matter with the atmosphere [1.34] are shown as the *green area* [1.35, 36] (after [1.37] with permission of © Author(s) CC Attribution 3.0 License)

is typically a close link between atmospheric processes and their characteristic spatial and temporal scales: large phenomena typically have long durations whereas local processes occur on short timescales. This contrasts with other compartments of the Earth system; for instance, hydrological processes in soils (Chaps. 58, 60, and 61) and plant ecosystems (Chap. 59) may occur over large timescales but at rather small spatial scales (Fig. 1.2). Therefore, it is an experimental challenge to combine measurements of the soil–vegetation system with measurements of the atmosphere. Examples of relevant scale-dependent processes are presented in Table 1.2. Some processes may occur at different scales depending on the specific situation. For instance, the extent of the circulation of a sea breeze depends on the sizes of the water and land bodies involved, thermal differences, and the background wind regime.

1.3.1 Vertical Distribution of Meteorological Elements

The typical vertical structure of the atmosphere is shown in Fig. 1.3. Except for the thermosphere, which begins at a height of around 80 km, the air in the atmosphere is not ionized and can be considered a homogeneous gas mixture. The vertical air column is subdivided into several characteristic layers based on

the typical mean vertical temperature profile [1.29, 31]. In the lowest layer, the troposphere, the temperature changes with altitude at an average rate of -6.5 K km^{-1} . The temperature remains nearly constant (about 220 K) with height in the lowest part of the stratosphere. It then increases to about 270 K in the upper stratosphere before decreasing with height in the mesosphere to below 200 K. The temperature finally increases with height in the thermosphere. The interfacial zones between these layers are called the tropopause, stratopause, and mesopause, respectively. Pressure and density decrease almost logarithmically with height.

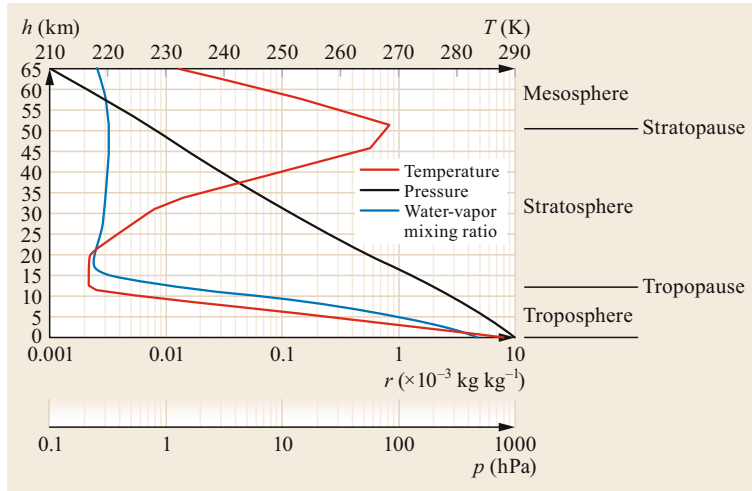

Structure of the Stratosphere and Mesosphere

The stratosphere is a stably stratified layer between the tropopause and the stratopause at a height of approximately 50 km. Its temperature increases with height from about 220 K to nearly 270 K. This increase in temperature with altitude is due to the absorption of solar ultraviolet radiation by the ozone layer. About 20% of the mass of the atmosphere is contained in the stratosphere.

The temperatures in the stratosphere vary with an annual cycle due to the absorption of solar radiation in combination with meridional exchange processes. The largest variation in temperature takes place over the poles in the lower stratosphere; variations at lower and

Table 1.2 Scales of atmospheric processes and phenomena (after [1.33])

Scale	Time	Space	Process
Macro- α	> 10–30 d	> 10 000 km	Standing waves
Macro- β	3 to 10–30 d	2000–10 000 km	Rosby waves, tidal waves, large high-pressure systems
Meso- α	12–72 h	200–2000 km	Low-pressure systems, fronts, hurricanes
Meso- β	3–12 h	20–200 km	Low-level jets, squall lines, inertial waves, cloud clusters, vorticity banners
Meso- γ	30–180 min	2–20 km	Thunderstorms, deep convection, urban effects, clear air turbulence, thermally driven flows (valley winds, sea breezes)
Micro- α	5–30 min	200–2000 m	Gravity waves, tornadoes
Micro- β	1–5 min	20–200 m	Wakes, coherent structures, dust devils, boundary-layer turbulence
Micro- γ	< 1 min	< 20 m	Roughness, surface-layer turbulence

**Fig. 1.3** Vertical distributions of the mean temperature (T), pressure (p), and water vapor mixing ratio (r) in the lowest 65 km of the atmosphere, based on the US Standard Atmosphere [1.38, 39] (Table 5.9)

higher altitudes are smaller. The wind system is mainly driven by quasi-biennial changes in wind direction from west to east, the zonal quasi-biennial oscillation (QBO) [1.40], and the meridional Brewer–Dobson circulation (BDC) [1.41].

The mesosphere is the layer above the stratopause. In the mesosphere, the temperature decreases with altitude. This effect is due to a gradual reduction in solar heating and increasing cooling through radiative emission by CO_2 . The top of the mesosphere, called the mesopause, is the coldest part of Earth’s atmosphere. Temperatures at the mesopause can fall to as low as 170 K, depending on the latitude and season. The exact upper and lower boundaries of the mesosphere also vary with latitude and season, but it usually ends at a height of around 100 km except in mid- and high latitudes during summer, when it descends to a height of about 85 km.

Structure of the Troposphere

The atmospheric measurements discussed in this book relate mainly to the troposphere, which ranges in thickness between about 5 km in the polar regions and approximately 16 km in the tropics. Most weather phe-

nomena occur within this layer. The upper part of the troposphere is called the free troposphere (free atmosphere), and is stably stratified except in regions with strong, deep convection. The wind in the free troposphere is generated by the pressure gradient in this layer and Coriolis forces (geostrophic wind).

The lowest part of the troposphere (near to the ground) is called the atmospheric boundary layer (ABL). It is “[...] directly influenced by the Earth’s surface and responds to surface forcings at timescales of about an hour or less” [1.32]. The ABL has a typical thickness of about 1–2 km during the daytime over land and about 0.7 km over the oceans. In the daytime ABL, the potential temperature and specific humidity are nearly constant with height due to strong vertical mixing of the air by turbulence. The ABL is usually capped by a statically stable layer or temperature inversion. Strong temperature, humidity, and wind gradients often occur across a relatively shallow interfacial layer separating the ABL from the free troposphere. This layer is part of the entrainment zone, where air from the free troposphere mixes into the ABL [1.42]. The thickness of the entrainment zone is typically approximately 10% of the depth of the ABL, but it can be much

larger under certain conditions. Entrainment processes have been shown to propagate down to the surface layer. The nighttime stable ABL over land has a typical depth of 100–200 m, but for very stable stratification, it can be just 10 m thick (or even less). The structure and temporal evolution of the ABL are most strongly influenced by turbulence.

In the ABL, the wind speed decreases from its geostrophic value in the free troposphere to zero at the surface, and the wind turns counterclockwise (in the Northern Hemisphere) by about 15° – 60° (depending on the atmospheric stability). Thermal interaction with the surface also influences the structure of the ABL. The temperature may therefore decrease by 1–5 K within the lowest 100 m over strongly heated surfaces (strongly unstable stratification); on the other hand, it may increase by 10 K or more within the lowest 100 m when there is strong surface cooling [1.32].

The lowest part (approximately the lowest 10%) of the ABL is called the surface layer (SL). Historically, this layer has also been called the constant-flux layer or Prandtl layer because the turbulent flux was assumed to remain approximately constant with height within the SL. This makes it possible to estimate surface turbulent fluxes from gradient or profile measurements of mean variables within this layer. The SL is highly turbulent, and molecular exchange processes only dominate within a few millimeters of the surface. Above tall vegetation or buildings, the constant flux layer assumption becomes invalid due to high friction, so the surface layer must be subdivided (Fig. 1.4). Turbulent mixing is increased in the roughness sublayer (also called the mixing layer), which extends from immediately above the canopy up to roughly twice the canopy height [1.43]. If the vegetation is not too high, a surface layer may develop above the mixing layer, but with a reduced thickness.

Scaling in the Atmospheric Boundary Layer

In order to derive the requirements for measurements in the lower troposphere, it is important to characterize the typical variability of atmospheric variables in the ABL and its sublayers with time and height. Due to solar heating during the daytime over land, the SL is characterized by unstable conditions that result in a decrease in temperature with height, whereas the SL is almost always stably stratified during the night due to radiative cooling at the surface, which often results in an increase in temperature with height. In the SL, the typical variability in temperature and moisture with height can be described using so-called surface scaling variables, namely the dynamic temperature and dynamic

Magnitude of height (m)	Layer of the troposphere	
10 000	Free troposphere	
1000	Capping inversion	Entrainment zone
	Upper layer	
10–100	Turbulent layer	Surface layer
	Roughness sublayer	
0.01	Viscous sublayer	
0.001	Laminar boundary layer	

Fig. 1.4 Structure of the troposphere and the ABL (after [1.28, 44]). The shaded area is the relatively thin capping inversion (interfacial layer) between the free troposphere and the upper layer. The roughness sublayer does not develop over short vegetation

moisture scales

$$\theta_*^{\text{SL}} = -\frac{(\overline{w'\theta'})_s}{u_*} \quad (1.1)$$

$$q_*^{\text{SL}} = -\frac{(\overline{w'q'})_s}{u_*}, \quad (1.2)$$

where θ is the potential temperature (the temperature corrected for the effect of the variation in pressure with height, see below), q is the specific humidity, u_* is the friction velocity, and $(\overline{w'\theta'})_s$ and $(\overline{w'q'})_s$ are the turbulent fluxes of temperature and humidity at the surface, respectively.

Typically, during nighttime, $u_* \approx 0.1 \text{ m s}^{-1}$ and the sensible and latent heat fluxes are $\pm 20 \text{ W m}^{-2}$, so $\theta_*^{\text{SL}} \approx 0.15 \text{ K}$ and $q_*^{\text{SL}} \approx 0.08 \times 10^{-3} \text{ kg kg}^{-1}$. These are very small fluctuations that need to be resolved. During the daytime, the variability is somewhat larger. Using typical values over vegetated surfaces of $u_* \approx 0.3 \text{ m s}^{-1}$, 100 W m^{-2} for the sensible heat flux, and 300 W m^{-2} for the latent heat flux for the climatic conditions in the temperate zone, $\theta_*^{\text{SL}} \approx 0.3 \text{ K}$ and $q_*^{\text{SL}} \approx 0.4 \times 10^{-3} \text{ kg kg}^{-1}$, which provide important requirements for the temporal and spatial resolutions of measurement devices. The size of the eddies to be resolved scales with the height above the surface, and measurement lengths of at least one magnitude smaller than the measurement height are required in the lowest few meters to capture the full spectrum of fluctuations.

In the mixed layer (ML), a suitable scaling variable for velocity is Deardorff's convective velocity scale w_* [1.45], which can be used to derive scaling variables

for temperature and moisture according to

$$w_* = \left[\frac{gz_i}{\theta_v} \left(\overline{w'\theta'_v} \right)_s \right]^{1/3}, \quad (1.3)$$

$$\theta_*^{\text{ML}} = - \frac{\left(\overline{w'\theta'} \right)_s}{w_*}, \quad (1.4)$$

$$q_*^{\text{ML}} = - \frac{\left(\overline{w'q'} \right)_s}{w_*}, \quad (1.5)$$

where θ_v is the virtual potential temperature, g is the acceleration due to gravity, z_i is the mixed layer height, and $\left(\overline{w'\theta'_v} \right)_s$ is the buoyancy flux at the surface.

For instance, for a CBL (convective boundary layer) with a depth of 1000 m, a surface heat flux of 100 W m^{-2} , and a mean virtual potential temperature of 300 K, $w_* \approx 1.4 \text{ m s}^{-1}$, meaning that the temperature and moisture fluctuations are generally smaller than those in the unstable SL (see above), which in turn yields $\theta_*^{\text{ML}} \approx 0.06 \text{ K}$ and $q_*^{\text{ML}} \approx 0.1 \times 10^{-3} \text{ kg kg}^{-1}$. These values set stringent requirements on the accuracy of instruments; however, the spatial and temporal resolutions of the measurement devices are relaxed because the size of the energy-carrying eddies scales with the height above the ground.

For many applications, it is very important to obtain information on the strength of the inversion at the top of the CBL and to estimate scaling functions in the entrainment zone. The vertical extent of an inversion is typically a few 100 m, and the inversion strength is between 0.001 and 0.1 K m^{-1} . Therefore, inversion detection requires measurements with a high vertical resolution of a few decameters and a high relative accuracy of the derived temperature, particularly for weak inversions. The scaling of wind, temperature, and moisture fluctuations is still an active area of research and is of great interest when studying entrainment fluxes. It is expected that velocity fluctuations scale with w_* and the wind shear strength. Furthermore, moisture and temperature fluctuations scale not only with w_* and wind shear but also with the temperature and moisture gradients across the entrainment zone [1.46]. Due to these gradient relationships, the moisture and temperature fluctuation profiles reach their maxima at the top of the CBL. Recent measurements of well-developed CBLs suggest that the atmospheric standard deviations of temperature and moisture in the entrainment zone are $0.5\text{--}1.0 \times 10^{-3} \text{ kg kg}^{-1}$ [1.46, 47] and $0.5\text{--}1.0 \text{ K}$, respectively [1.46, 48].

Vertical Profiles in the Surface Layer

A brief description of typical vertical profiles in the surface (Prandtl) layer is presented below. For more details, please refer to relevant textbooks [1.28, 30, 32, 44].

These vertical profiles are shaped by the turbulent exchange of momentum, heat, and trace gases. The wind gradient near the surface in the case of neutral stratification is

$$\frac{\partial u}{\partial z} = \frac{u_*}{\kappa z}, \quad (1.6)$$

where u is the wind speed, z is the height, u_* is the friction velocity, and the von Kármán constant is $\kappa = 0.4$. The height dependence of the wind speed gradient implies that the wind speed is proportional to the logarithm of the height, i.e.,

$$\frac{\partial u}{\partial \ln z} = \frac{u_*}{\kappa}. \quad (1.7)$$

There is a similar relationship for the temperature gradient,

$$\frac{\partial T}{\partial \ln z} = \text{Pr}_t \frac{\overline{w'T'}}{\kappa u_*}, \quad (1.8)$$

where T is the temperature, the turbulent Prandtl number $\text{Pr}_t \approx 0.8\text{--}0.95$, and the sensible heat flux in kinematic units (m K s^{-1}) is expressed as the covariance $\overline{w'T'}$ of the turbulent fluctuations of the vertical wind speed w' and the temperature T' ; compare with (1.1). Similar equations hold for water vapor and other trace gases. Integrating (1.7) and (1.8) between two levels gives

$$u(z_1) - u(z_2) = \frac{u_*}{\kappa} \ln \frac{z_1}{z_2} \quad (1.9)$$

and

$$T(z_1) - T(z_2) = \text{Pr}_t \frac{\overline{w'T'}}{\kappa u_*} \ln \frac{z_1}{z_2}. \quad (1.10)$$

Above closed canopies or built-up areas, the reference level for these profile formulae is the upper part of the vegetation or building structures. For instance, for measurements above a canopy (or buildings), all geometric heights must be reduced by the so-called zero-plane displacement height, which is assumed to be two-thirds of the canopy height.

Upon extrapolating the logarithmic wind profile to the surface, the wind speed will be zero at z_0 , which is called the roughness length ($u(z_0) = 0$)

$$u(z) = \frac{u_*}{\kappa} \ln \frac{z}{z_0}. \quad (1.11)$$

The roughness length is a function of the characteristics of the underlying surface and is on the order of 10^{-4} – 10^{-3} m for water, 10^{-2} m for short grass, 10^{-1} m for cropland, and 1 m for forest [1.28]. An estimate of z_0 is required when selecting measurement heights in the (lower) surface layer. For the temperature profile, a fictional roughness length can be defined that corresponds to the length at which the temperature approaches the value at the surface. This length is at least one order of magnitude smaller than the roughness length for the wind profile.

The equations above are only valid for near-neutral stratification. Applying the so-called universal functions of momentum $\varphi_m(\zeta)$ and $\varphi_H(\zeta)$ of Monin–Obukhov similarity theory [1.49] as well as sensible heat exchange to profile equations (1.3) and (1.4), we obtain

$$\frac{\partial u}{\partial \ln z} = \frac{u_* \varphi_m(\zeta)}{\kappa} \quad (1.12)$$

and

$$\frac{\partial T}{\partial \ln z} = \text{Pr}_t \frac{\overline{w'T'} \varphi_H(\zeta)}{\kappa u_*}, \quad (1.13)$$

where $\zeta = z/L$ is the Obukhov stability parameter with the Obukhov length

$$L = -\frac{u_*^3}{\kappa \frac{g}{T} \overline{w'T'}}. \quad (1.14)$$

Today, universal functions that were first proposed by Businger and subsequently modified by Höögström [1.50] are widely used. For further details on this topic, including the integration of (1.12) and (1.13) and necessary modifications for the roughness sublayer, please refer to relevant textbooks [1.28, 29, 32].

Figures 1.5 and 1.6 show typical vertical wind and temperature profiles near the surface for stable, neutral, and unstable stratification as well as typical differences in wind speed and temperature at different levels with respect to the meteorological standard measuring levels at 10 m for wind and 2 m for temperature [1.17]. Some implications for the performance of atmospheric measurements can be derived from these profiles. For example, for neutral stratification over grass, the wind speed at a height of 2 m is only 77% of the wind speed at the reference height of 10 m. The typical measuring error for temperature of 0.1 K includes a tolerance for the standard measurement height (2 m) of about ± 0.2 m.

Fig. 1.5 Wind speed profile normalized to the value at 10 m for neutral stratification over short grass ($z_0 = 1$ cm). The profiles are similar for slightly stable and unstable stratification

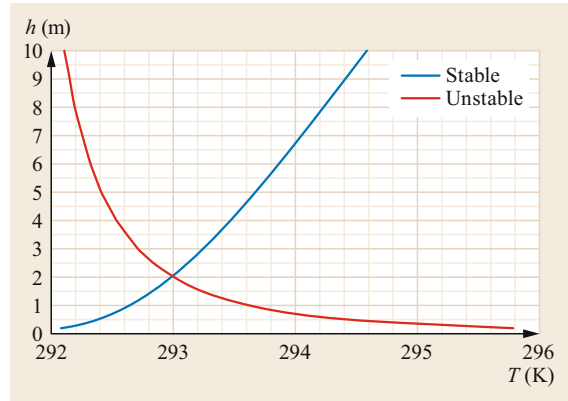

Fig. 1.6 Typical temperature profiles for stable ($u_* = 0.15 \text{ m s}^{-1}$, $Q_H = -20 \text{ W m}^{-2}$, $z/L = 0.13$ at 2 m height) and unstable ($u_* = 0.20 \text{ m s}^{-1}$, $Q_H = 200 \text{ W m}^{-2}$, $z/L = -0.56$ at 2 m height) stratification (Q_H is the sensible heat flux)

Generalized Temperature and Pressure Variables

Due to compression or expansion, the temperature of a vertically displaced air parcel is higher near the surface and lower in the upper layer of the boundary layer or the upper layer of the troposphere. In order to compare temperatures or to determine the stratification of the atmosphere, it is important to correct the temperature for the effect of pressure variations with height. This can be done by transforming the absolute temperature into the potential temperature θ via *Poisson's* equation [1.29, 31, 51]

$$\theta = T \left(\frac{p_0}{p} \right)^{\frac{R_d}{\varphi}}, \quad (1.15)$$

where R_d is the gas constant for dry air, c_p is the specific heat at constant pressure, and $p_0 = 1000$ hPa. For some applications it can be useful to replace p_0 with the surface pressure, which gives $T = \theta$ at the surface. At a height of 10 m, the difference between the temperature and the potential temperature is about 0.1 K. Therefore, when analyzing the stability of the atmosphere, temperature measurements performed above 10 m should be transformed into potential temperatures. Typical examples include measurements carried out at the tops of tall towers and radiosonde measurements (Chap. 46).

Because the acceleration due to gravity depends on the latitude and height above sea level, it is often replaced with the mean constant gravitational acceleration at sea level $g_0 = 9.81 \text{ m s}^{-2}$ [1.52]. Based on this, a generalized height scale, the so-called geopotential height Z [1.51], can be defined as the geopotential

$$\Phi(z) = \int_0^z g(z') dz', \quad (1.16)$$

normalized by the constant gravitational acceleration $g_0 = 9.81 \text{ m s}^{-2}$, i.e.,

$$Z = \frac{\Phi}{g_0}. \quad (1.17)$$

The pressure at a particular height Z can be approximately calculated from the pressure at sea level $p_0 = p(Z=0)$ using the mean virtual temperature T_v (Chap. 7) between sea level and Z and the barometric equation

$$p(Z) = p(Z=0) e^{-\frac{g_0}{R_d T_v} Z}. \quad (1.18)$$

In the lower troposphere, the geopotential height differs only slightly from the geometric height. In addition, depending on the required accuracy, the virtual temperature can be replaced with the actual temperature (Chap. 10).

1.3.2 Horizontal Distribution of Meteorological Elements

The horizontal distribution of meteorological elements depends on the synoptic situation but mainly on the topography and the land cover. This dependence is particularly pronounced close to the surface. By definition, effects of the surface on the structure of the atmosphere are confined to the ABL. Inside the ABL, the effects of different surface types usually decrease with height and can become very small or undetectable; they are blended above a certain level known as the *blending*

height [1.53]. This blending height is assumed to occur between a few decameters and about 100 m above a surface of low vegetation. Its precise value depends on the size of patches of vegetation with uniform surface characteristics, on the magnitude of the difference in surface properties between different surface patches, and on the wind speed. In the case of strong convection under weak wind conditions, surface signatures can be observed across the whole boundary layer (for more details on this topic, see [1.54, 55]). Below the blending height, obstacles and changes in surface characteristics that induce the formation of internal boundary layers strongly influence meteorological variables and must be considered when performing meteorological measurements.

Influence of Obstacles near the Surface

Obstacles have a remarkable influence on meteorological measurements. Their ability to disturb the fields of meteorological variables is most pronounced on the downwind side but can also be detected on the windward side. Therefore, in general, measurements that are presumed to be representative of a large area with undisturbed flow conditions should be performed far from large obstacles. However, this is often impossible in forests, mountainous regions, and urban environments. For classical meteorological measurements, especially flux measurements, any direct influence of obstacles should be suppressed as much as possible.

Rough approximations and recommendations for distances from the sensor to the nearest obstacle have been developed for wind measurements based on German standards [1.56] and on the European Wind Atlas [1.57]. They are presented in Chap. 9. For measurements of energy fluxes, the recommended distances should be increased by a factor of 2–5. It should be noted that the sensor platform itself (tower, balloon, or aircraft) often acts as an obstacle that can influence the measurements (Chaps. 6 and 37).

Internal Boundary Layers

Land surfaces are often heterogeneous: surface characteristics differ markedly between neighboring patches with different land uses. Different patches have other thermal and dynamic properties, meaning that those patches also differ appreciably in their heat and momentum fluxes. This can result in significant local variations in near-surface wind and temperature profiles over a patchy landscape. Due to the horizontal mean wind, these different profiles are shifted downstream, forming a layer of discontinuity called an internal boundary layer. Several sharp changes in surface properties over short distances may result in a complex lower ABL structure, as illustrated in Fig. 1.7.

Fig. 1.7 Generation of internal boundary layers above an inhomogeneous surface (after [1.32])

The formation of internal boundary layers leads to discontinuities in the vertical profiles of atmospheric state variables. Close to the ground, conditions are in equilibrium with the local surface. Above the discontinuity zone, the profiles are influenced by the surfaces upwind of the site. The development of mechanical internal boundary layers is influenced by the roughness lengths over neighboring surfaces. The height of a mechanical internal boundary layer depends on the fetch (the distance to the roughness change; for more on this, see [1.28, 32, 58, 59]). According to internal boundary layer theory, the height depends on the roughness lengths and the friction velocities on both sides of the change in surface roughness [1.60]. For many practical applications, the depth of the new equilibrium layer δ can be predicted by the empirical relation [1.61]

$$\delta = 0.3 \text{ m}^{0.5} \sqrt{x}, \quad (1.19)$$

where δ and the fetch x are in meters.

Just as a mechanical internal boundary layer is caused by a step change in surface roughness, a thermal internal boundary layer develops downstream of a step change in surface temperature. Such changes may be triggered by differences in land-use characteristics, soil moisture content, or turbulent exchange conditions. However, these layers are not as significant as the mechanical internal boundary layers, except when the thermal properties change dramatically when moving from surface to surface, such as from cold water to heated land.

Thermal inhomogeneities in the vertical temperature profile that are not associated with advection develop in the late afternoon, when the temperature of the first few meters above the surface decreases and a shallow surface-based inversion develops. The height of the inflection point between stable stratification near the surface and unstable stratification in the upper layer grows over time. In this flat inversion layer, the sensible heat flux is directed downwards, whereas it is still upwards above the inversion [1.62]. This is the iner-

tial process for the development of a nocturnal stable boundary layer. In the early morning, a similar effect occurs when a shallow unstable layer develops close to the ground due to radiative heating of the surface while there is still a stable nocturnal boundary layer above. The unstable layer typically lasts for a much shorter time than the stable layer in the evening, which has a duration of many hours. This phenomenon is relevant to the measurement and modeling of gradients near to the surface and in the lower part of the ABL.

Clear signatures from a specific surface are often only detectable above for a certain distance downwind of the change in surface characteristics. At larger horizontal distances, they merge at the blending height (see above). Experimentally, internal boundary layers can be identified as discontinuities in the vertical profiles of wind speed and temperature. The presence of internal boundary layers must be carefully considered when planning measurements of the conditions above a given surface (e.g., when measuring the turbulent fluxes of momentum, heat, and trace gases).

Spatial Representativeness of Meteorological Measurements near the Surface and in the Atmospheric Boundary Layer

Measurements at a given site can be considered to be spatially representative if the measured variable does not vary significantly over a certain distance around the site. The typical spatial variability varies significantly for different elements [1.28] and may also depend on the meteorological and site conditions. For instance, global and diffuse radiation show very little spatial variability in the absence of clouds and over flat terrain, but greater variability can occur in mountainous regions [1.63], and very high variability can be observed under heterogeneous cloud cover. Net radiation is strongly dependent on the albedo of the underlying surface as well as its temperature and moisture. Considerable spatial variability may occur even if the downward short-wave and downward long-wave radiative fluxes appear to be horizontally homogeneous.

The wind field is mainly determined by the large-scale pressure distribution, but it is modified close to the surface by the topography, surface roughness, and obstacles, all of which can lead to significant small-scale differences. The air temperature and moisture in a uniform air mass at a particular height show very little horizontal variation except close to the surface. Such temperature and moisture variability close to the surface is particularly strong during high insolation and during nights with significant radiative cooling. Thus, the nocturnal temperature minima near the ground can show remarkable variation, even over small distances.

Table 1.3 Aspects of micro- and meso- γ scale horizontal variability of meteorological elements near to surfaces away from forests and urban areas (after [1.28])

Meteorological element	Range and reason for variability	Conditions for low variability
Global and diffuse radiation	Generally small	Free horizon, no clouds
Net radiation	Partly significant due to differences in albedo and surface temperature, especially in mountainous regions	Unlimited horizon and uniform underlying surface
Wind velocity and wind direction	Partly significant in complex terrain, over strongly varying roughness, and in the presence of obstacles	Large fetch over uniform surfaces, no obstacles
Temperature and air humidity	Often small	Open landscape
Minimum temperature, temperature near the surface, temperature of the upper soil layers	Partly significant, especially in valleys and hollows (and at very small scales); mainly for stable stratification	Open landscape
Precipitation	Often significant, but for stratiform clouds mostly in the range of the measurement error	Open landscape

The horizontal variability of precipitation strongly depends on the synoptic situation. Steady rain ahead of a warm front often results in a relatively homogeneous horizontal distribution of the measured precipitation, while very strong small-scale differences can occur in connection with showers or thunderstorms. Precipitation patterns are also strongly influenced by the orography and land surface heterogeneity.

The main reasons for potentially significant spatial variability of meteorological elements close to the surface are summarized in Table 1.3.

At a certain height (about 50–100 m) that is above the blending height [1.53], measurements are assumed to be representative of a larger area than just that represented by the local underlying surface. This is relevant to profile measurements performed at tall towers or the use of ground-based remote-sensing techniques, as well as to measurements performed along horizontal paths with aircraft or using scintillometers.

Footprint Concept for the Surface Layer. Measurements performed at a particular position in the SL probe the surface properties upwind of the sensor rather than those immediately below it. The effective area of influence is called the *footprint* [1.64]. While the footprint phenomenon has been known of for a long time, the term itself is only about 30 yr old. The footprint function f , which relates the source area Q_η of a measured signal η (scalar, flux) to its spatial extent and its intensity distribution (as illustrated in Fig. 1.8), is given by

$$\eta(x_m, y_m, z_m) = \iint_{-\infty}^{\infty} Q_\eta(x', y', z' = z_0) \times f(x_m - x', y_m - y', z_m - z_0) dx' dy'. \quad (1.20)$$

Footprint models can be classified based on their dimensions and theoretical basis. Dimensions are given

Fig. 1.8 Footprint areas of measurements obtained in the direction upwind of the measuring position. The measurements were performed at three different heights at a tower. The grid elements relate to the land-use distribution (after [1.65], reproduced with permission from Elsevier)

for the source and the footprint. The first (and simplest) one-dimensional models used a line source and determined the footprint along a horizontal axis upwind of the sensor. They integrated the footprint along the cross-wind component. However, more sophisticated models that are applicable to heterogeneous surfaces and various heights have recently been developed.

Two easy-to-use models are recommended for practical applications. Basic estimates can be obtained using the simple analytical model proposed by *Kormann and Meixner* [1.66, 67]. A more sophisticated *Lagrangian* model with backward trajectories has been developed by *Kljun et al.* [1.68]; a parameterized version of this model was recently updated [1.69].

One important application of footprint models is to obtain the footprint climatology for a selected measurement site. Therefore over a long time period footprint datasets, each covering a 30–60 min period, are required to calculate the footprint climatology. It then becomes possible to identify the land-use types in the area that contribute to the measured fluxes. In a similar way, footprint models can be linked with the data qual-

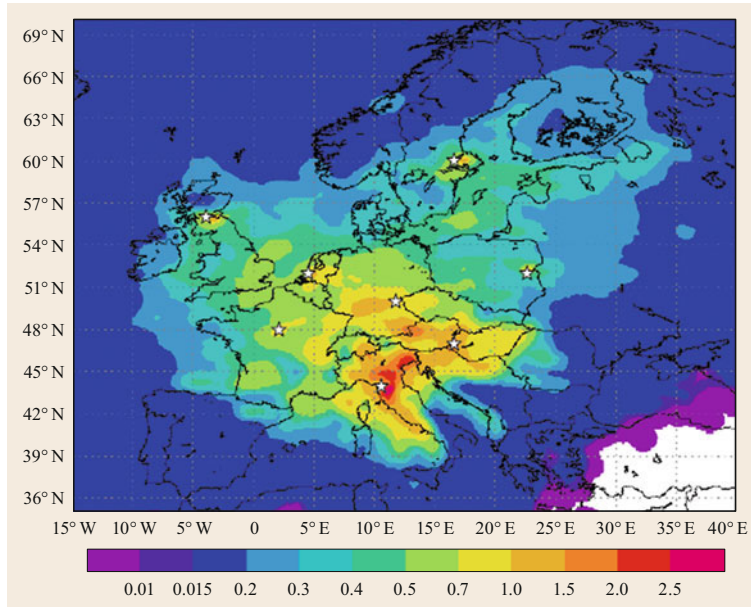

Fig. 1.9 Tall tower measurement stations and their footprint in the European tall tower network (from the project “Continuous high-precision tall tower observations of greenhouse gases”, called CHIOTTO). The color of each pixel indicates the footprint function and its contribution as a percentage of the largest value detected. Pixels with > 0.2 – 0.3% of the maximum contribute significantly. The towers included in CHIOTTO are located in Orleans (France), Ochsenkopf (Germany), Hegyhatsal (Hungary), Florence (Italy), Cabauw (the Netherlands), Bialystok (Poland), Norunda (Sweden), and Griffin (UK) (after [1.70], reproduced with permission from Dr. Vermeulen)

ity to identify possible areas with low data accuracy, which is often used for flux measurements (Chap. 55). Footprint models are especially helpful when planning experiments that are to be performed in complex terrain [1.64].

Footprint Concept for the Boundary Layer. Tall tower networks have been established at continental scales in various land regions around the world to facilitate the global monitoring of atmospheric greenhouse gas concentrations. A footprint modeling framework was established to interpret the resulting data. Inverse Lagrangian footprint modeling strategies allow to affiliate the contributions of emissions from agricultural, forest, and urban regions to a particular concentration measurement [1.71]. For the European tall tower project “Continuous high-precision tall tower observations of greenhouse gases”, called CHIOTTO, the source distribution was calculated using a Lagrangian trajectory model at the European scale (Fig. 1.9; [1.72]). Similar approaches can be applied for measurements performed along a path, such as those carried out using aircraft [1.73] (for an overview of this topic, see [1.64]).

Spatial Representativeness of Meteorological Measurements Above the Atmospheric Boundary Layer. Above the ABL, the horizontal variability of atmospheric variables is significantly reduced due to the vanishing influence of the highly variable (land) surface as a lower boundary. The variability is essentially determined by atmospheric processes at the meso- γ and

larger scales. Except for fronts and cells or deep convection systems, and away from larger mountain ranges, measurements of basic atmospheric variables in the free atmosphere can often be considered to be spatially representative at scales of 10^2 – 10^3 km.

The variability of atmospheric variables at these scales is mainly driven by the large-scale heterogeneity of landmasses, land–sea contrasts, orography, and by the presence of deep convection and synoptic-scale structures. Consequently, mesoscale variability is observed, as defined in Fig. 1.2, starting at the meso- γ scale.

Another way to assess horizontal variability in the atmosphere is through high-resolution reanalysis based on atmospheric models, though the quality of these simulations is limited by the performance of sub-grid-scale parameterizations. Consequently, the study of the mesoscale variability of atmospheric variables in the free troposphere is still an important research area in the atmospheric sciences. A safe approach concerning the accuracy and resolution of meteorological measurements is to apply the same requirements as for measurements in the ABL, given due to the higher temporal and spatial variability of ABL processes.

1.3.3 Temporal Variability of Meteorological Elements

Most atmospheric variables show considerable variability over a wide range of timescales, ranging from changes in the climate at the Earth’s surface (10^2 – 10^6 years) to turbulent fluctuations with charac-

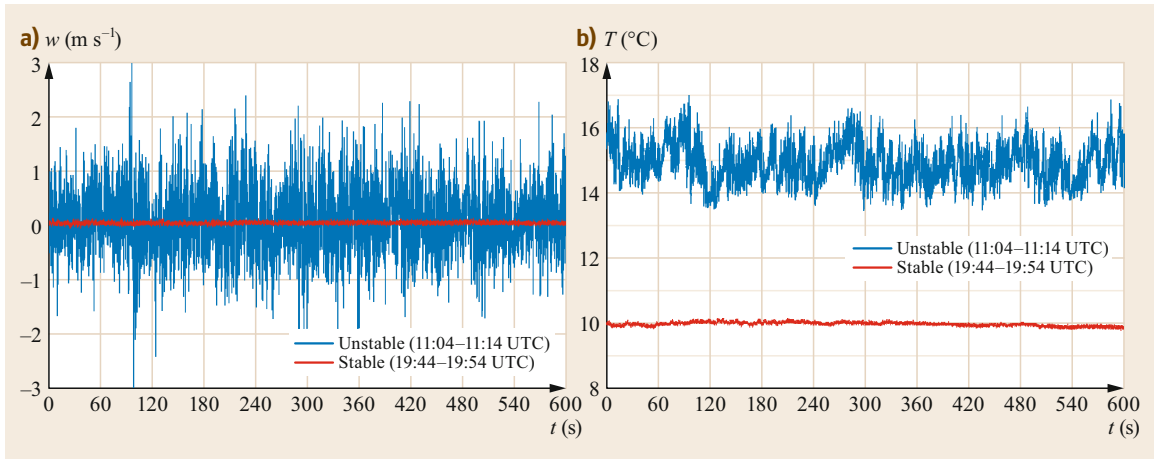

Fig. 1.10a,b Time series of the vertical wind vector component (a) and air temperature (b) at 2.4 m AGL for unstable and stable stratification over a 10-min time period at 20 Hz resolution on 01.05.2018 in Falkenberg (data from the German Meteorological Service at the Lindenberg Meteorological Observatory – Richard-Aßmann-Observatory)

teristic timescales of 10^{-1} – 10^2 s. Changes over periods of more than 10^1 – 10^2 years are beyond the scope of this book as such a timescale exceeds the lifetime of any meteorological instrument used thus far. Analyzing changes over timescales that are beyond the period for which instrumental measurements are available is the task of paleoclimatology. On the other hand, it is possible to assess climate change and climate variability over the last 100–150 years based on instrumental measurements. Such studies require accurate and well-documented reproducible measurements. In climate analysis, the statistics for atmospheric variables over a period of at least 30 years are considered. The period 1961–1990 is generally used as the official reference period. Climate statistics—in particular extreme values—are important considerations when designing measurement programs, as they influence the required measurement ranges of meteorological sensors.

Factors that determine the temporal variability of any atmospheric variable on intermediate timescales include the geographical coordinates (latitude and height) of a location and its position in relation to larger water bodies and mountain ranges. These factors strongly determine the magnitudes of annual and diurnal cycles and the variability due to the predominant weather systems in the area.

Processes that occur on timescales of about an hour or less are often related to atmospheric turbulence [1.74], which is a specific feature of atmospheric flows with air parcels (turbulent elements or turbulent eddies that are much larger than molecules), the characteristics of which vary irregularly and randomly around a mean state. Studies of turbulence require sensors or measurement systems with (very) high spatial and tem-

poral resolutions as well as high resolution with respect to the measured variable.

Turbulent elements can be seen, for example, in high temporal resolution plots of wind and temperature time series (Fig. 1.10). The intensity of the fluctuations depends strongly on the stratification. The fluctuations are much more pronounced under unstable conditions, when phenomena with different timescales are present. Short-period fluctuations are typically about $\pm(1-2)$ K around the mean temperature and about $\pm(10-20)\%$ around the mean horizontal wind speed (or larger in weak wind conditions). A comprehensive description of turbulent processes in the atmosphere is given in [1.75].

Of special importance is the inertial subrange, which is characterized by isotropic turbulence and a steady decrease in the energy density with increasing frequency. Between about 0.01 and 5 Hz, there is no dominant direction of motion for turbulent elements. In the inertial subrange, the turbulent kinetic energy is redistributed from larger to smaller eddies in a well-defined way according to *Kolmogorov's* $-5/3$ law [1.76]. The existence of the inertial subrange and its characteristics is crucial to the principles of several remote sensing techniques (see Parts C and D of this book).

To characterize the turbulence, each measured value x is represented as the sum of a mean part \bar{x} and a randomly fluctuating part x' ; in other words,

$$x = \bar{x} + x' . \quad (1.21)$$

This equation is called Reynolds' decomposition. Meteorological measurements are typically aggregated into average values over 10, 30, or 60 min. If this average represents the mean atmospheric conditions, \bar{x}

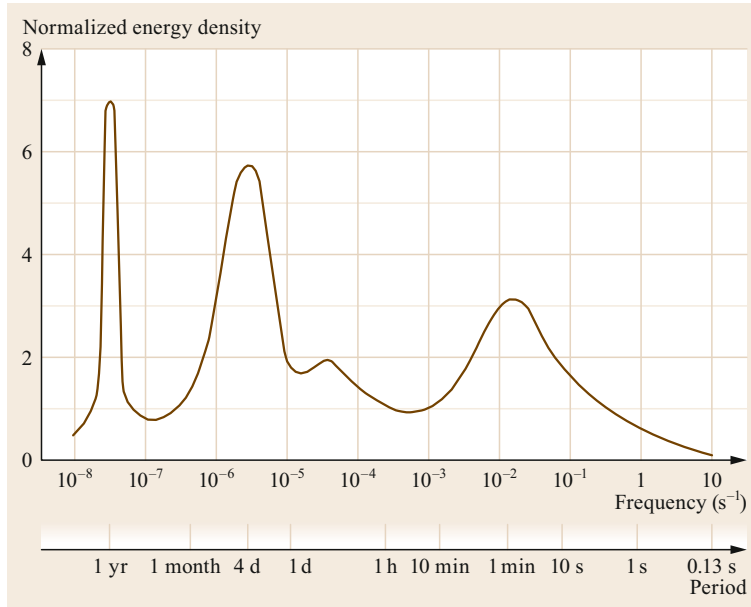

Fig. 1.11 Schematic plot of an energy spectrum of atmospheric motions (after [1.77]). Frequencies $> 10^{-3}$ Hz correspond to turbulent energy exchange. The other maxima correspond to an annual cycle, the typical cycles of circulation in the mid-latitudes, and the diurnal cycle

must be zero. In order to measure the turbulence and determine the turbulent fluxes of momentum, energy, and trace gases, the statistics of x' must be analyzed. This requires sampling rates of between about 1 Hz and several kHz depending on the technique applied and the measurement height above the ground.

An energy spectrum for a time series of wind measurements is shown in Fig. 1.11 (based on [1.78]). It exhibits four pronounced maxima due to an annual cycle, changes in high- and low-pressure systems over timescales of 3–6 d in the mid-latitudes, the diurnal cycle, and the turbulent transport of energy, momentum, and trace gases at frequencies ranging from 0.0001 to 10 Hz.

One of the most obvious examples of temporal variability in atmospheric phenomena is the diurnal cycle exhibited by many meteorological variables over land, which is largely caused by the regular diurnal variation of incoming short-wave radiation and the transformation of radiative energy at the Earth's surface. It is thus most pronounced in the surface layer under a clear sky and in the presence of weak-to-moderate wind conditions. Close to the surface, the temperature can easily vary by 20 K or more within 24 h, and the relative humidity can change from $< 50\%$ to saturation. Surface winds at night may be light or even calm, while those during the daytime may be highly variable with substantial gustiness. The opposite diurnal behavior of the wind speed is often observed several hectometers above the ground, with moderate winds occurring during the daytime but increased winds (between 10 and 20 m s^{-1}) at night due to inertial oscillations. Convection during

the daytime may result in the generation of cumulus clouds, which can form extended stratocumulus layers below the capping inversion in the afternoon, thereby reducing insolation. These layers often dissolve in the (late) afternoon due to subsidence.

This diversity of processes that occur at different heights and over different timescales and their effect on the structure of the ABL is illustrated in Fig. 1.12, which includes turbulence, waves, and large-scale subsidence. Therefore, aside from adequate time averaging, appropriate sensor localization and spatial averaging are often necessary.

1.3.4 Scale Representativeness of Atmospheric Measurements

Scaling principles are fundamental to measurements of atmospheric processes and the use of measured data. The measurement frequency and the spatial coverage and resolution of the measurements must be related to the changes in the meteorological elements over time and to the spatial representativeness. This applies at all scales, and the sampling theorem (Chap. 2) implies that phenomena can only be observed if measurements are performed over spatial and temporal scales that are smaller than those represented by the phenomenon itself.

It is important to know the spatial and temporal representativeness of any atmospheric measurement performed using in-situ and remote sensing measurement techniques (Table 1.4). Spatial representativeness is important in all applications. For in-situ and remote sensing techniques, the sensor platform determines the

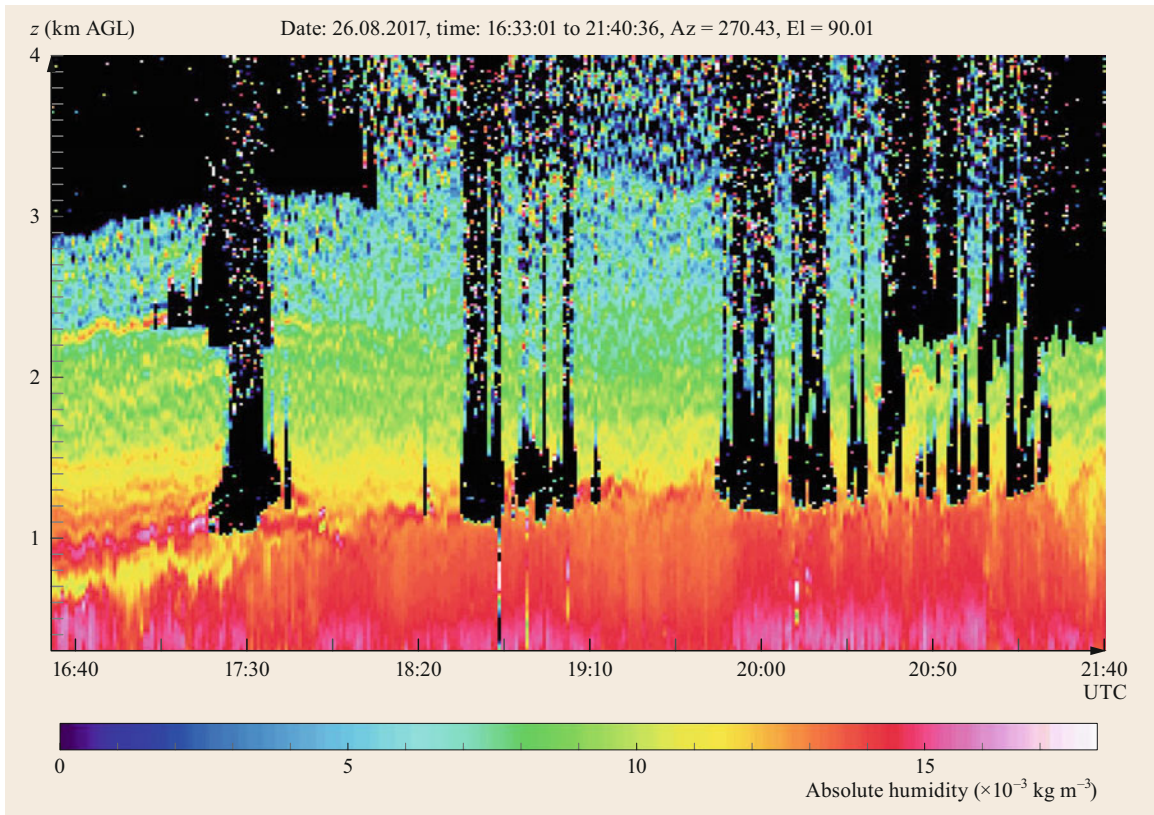

Fig. 1.12 Highly variable structure of the absolute humidity in the atmospheric boundary layer and the lower troposphere as measured with a differential absorption lidar on 26.08.2017, in Oklahoma, USA. *Black and white areas* correspond to detector overload caused by strong backscattering from clouds. The local time is UTC -5 h. The temporal resolution of the measurements is 10 s and the height resolution is 60 m. The figure shows the evolution of the CBL in the late morning including entrainment of residual layers from the previous day up to 6 pm UTC. Turbulent eddies are resolved often resulting in the formation of clouds as well as entrainment of dry air between the clouds. During daytime, a CBL depth of approx. 1.4 km is reached (reproduced with permission from F. Späth, Institute of Physics and Meteorology, University of Hohenheim, Germany)

Table 1.4 Scale representativeness of different in-situ and remote sensing systems; the *gray shading* shows the degree of scale assignment (after [1.28])

Sensor system	Macro- β scale	Meso- α scale	Meso- β scale	Meso- γ scale	Micro- α scale	Micro- β scale	Micro- γ scale
Radiosonde	Gray						
Boundary layer sonde			Gray				
Tower > 100 m			Gray	Gray			
Mast < 50 m				Gray	Gray	Gray	
Turbulence sensors (near surface)						Gray	Gray
Satellite	Gray						
Radar wind profiler		Gray	Gray	Gray			
Sodar				Gray	Gray		
RASS			Gray		Gray		
Lidar			Gray		Gray	Gray	

scale (see Chaps. 6 and 37), whereas the footprint determines the scale near the ground. Furthermore, most ground-based remote-sensing techniques have insufficient resolution near the surface. The scale representativeness of the measurement system is very important if its data are to be used as input variables for atmospheric models. The smaller the scales resolved by a model, the more important it is for the data to have sufficiently high vertical, horizontal, and temporal resolution to force and to evaluate the model.

In practice, the spatial density of a measurement network is always a compromise between the desire to resolve the variability and cover phenomena across all scales of interest and the practical limitations on doing so (resulting from logistic, instrumental, and economic factors). As an example, the spatial density of the global aerological network of radiosondes (Chap. 46) over land can provide the input data needed to drive macro- and meso- α scale numerical weather prediction (NWP) models of the Northern Hemisphere, but the data obtained by this network over the oceans and over most regions of the Southern Hemisphere is insufficient to initialize such models. Moreover, the temporal separation between consecutive soundings (typically 12 h) does not allow the diurnal cycle of the ABL to be properly characterized. However, it is adequate to describe temporal changes in the free troposphere (except for fronts). Data from radar wind profilers (Chap. 31) can be used to explore the temporal variability of the wind, but such networks only exist in certain regions of Europe, the US, and East Asia. Measuring techniques for the ABL and processes occurring at micro scales and at the meso- γ scale require a high spatial density of observations, which can be provided by some mesoscale networks (Chap. 45). Airborne measurements performed with commercial aircraft are a valuable supplement to the classical aerological network, as they provide relatively dense data coverage, both spatially and temporally, along standard traffic routes and close to some major airports (Chap. 43). However, most of the major airports are situated in the Northern Hemisphere, so these airborne measurements cannot fill the gap in upper air data for the Southern Hemisphere. Aircraft measurements realized with research aircraft are able to cover a range of scales, depending on the type of aircraft—small unmanned aircraft systems (UAS) are usually operated inside the ABL at the meso- γ scale and below, and special aircraft have been built and equipped for long-range, high-altitude flights to explore the meso- α to macro- β scales. However, an aircraft cannot provide vertical profile data for most of its flight unless it is equipped with remote sensing systems. Research aircraft are generally employed for process studies and do not provide continuous data series over

long time periods. These few examples illustrate the importance of considering the scale representativeness of each measurement technique when planning, performing, and analyzing atmospheric measurements.

1.3.5 Scale Requirements for Data Assimilation

Because weather phenomena are classified according to their spatial and temporal scales, the scales of climate and weather prediction models must be classified in a similar way. This means that the horizontal and vertical grid resolutions must be related to the time steps for the various models. The real horizontal resolution of a model is typically on the order of $6\Delta x$ where Δx is its horizontal grid increment [1.79]. There are similar relationships for global spectral models [1.80]. In order to resolve the relevant wavenumbers on the grid, a time step of seconds must typically be employed, which is a factor of 100 smaller than the grid increment in meters [1.81]. Therefore, it is possible to estimate the ability of a spectral or grid-based model system to resolve weather phenomena, as shown in Table 1.2. For example, large-scale circulation models are assigned to the macro- β range. Classical weather forecasts corresponded to the meso- α scale, but with the development of high-resolution models such as the Icosahedral Non-hydrostatic Large Eddy Model (ICON-LEM) of the German Meteorological Service (DWD) [1.82], they have been assigned to the meso- β and meso- γ scales. Quasi-operational modes of forecast models such as ICON-LEM are progressing to the micro- α scale.

The successful assimilation of measurement data depends on the consistency of the temporal and spatial scales between the model grid boxes affected by the observation as well as the representativeness and accuracy of the measurements (for more details, see [1.83]). The time interval between consecutively measured data and the spatial resolution and coverage of the data should correspond to the temporal and spatial evolutions of the model variables in the data assimilation interval as well as to the levels used in the vertical model. Observations (and error estimates) are usually interpolated to the model grid [1.84]. Representativeness errors are difficult to assess, and are easier to estimate if the observing system has high temporal and spatial resolution or even a scanning capability. For instance, for lidar measurements, the representativeness error can be estimated from the atmospheric variance observed during an averaging time set to the grid box size divided by the horizontal wind speed. Furthermore, depending on the complexity of the sensors, an error covariance matrix of the measurement must be provided. This is easier for in-situ sensors and active remote-sensing systems because

of their direct derivation of the variable of interest and the negligible sensitivity to other parameters.

The required density of observations depends mainly on the resolution and coverage of the model. Unfortunately, considering the typical resolution of the mesoscale models discussed above, there is currently no observing system network that can fulfill the needs of mesoscale data assimilation. The accuracy of the

observations must exceed the accuracy of the model background error covariance matrix. If this is a high-quality matrix with a reasonable flow-dependent update (e.g., achieved with a local ensemble transform Kalman filter), it is sufficient to operate a network of temperature and moisture profiles separated by a few hundred km to achieve a positive impact on weather forecasts on the meso- γ scale [1.85].

1.4 Devices, Systems, and Typical Specifications

This section provides a brief and general overview of in-situ sensors and remote sensing systems and their basic characteristics. For more on this topic, and discussions of sensors not mentioned here, please refer to the relevant chapters in this book. Further specifications and maintenance requirements are also outlined in those chapters. General remarks about quality assurance and quality control are provided in Chap. 3.

In-situ measurements (Part B of this book) are typically performed relatively close to the surface or on towers up to a few hundred meters in height. They are also performed on airborne platforms such as aircraft and balloons. Standard measuring heights have been recommended for many meteorological elements [1.17], so that measurements are comparable. The most important sensors and their basic characteristics are listed in Table 1.5.

Several process variables such as some turbulent fluxes cannot be measured with a single instrument. These are determined either from synchronous measurements performed with different sensors, from parameterizations that rely on mean values measured with

slow-response sensors, or using specially constructed devices (e.g., lysimeters). These methods are presented in detail in Part E; a brief overview is given in Table 1.6.

Active remote-sensing techniques are increasingly being applied in meteorology. These techniques make use of the scattering and extinction of sound waves and electromagnetic waves (in different spectral regions, from ultraviolet, visible and infrared light, to micro waves and radio waves) that propagate in the atmosphere. They are usually operated in a monostatic configuration (i.e., the transmitter and receiver are either identical or collocated). The signal originates from backscattering at an angle of 180° . Sound and electromagnetic waves can be scattered by molecules (a very important component of the lidar signal), hydrometeors and particles (clouds and raindrops, aerosols, dust, and insects), or density inhomogeneities in the air. Scattering elements normally move with the mean wind, causing the frequency of the sound or electromagnetic signal to shift due to the Doppler effect. The basic variables analyzed for sodar, lidar, and radar measurements are the intensity and the frequency of the backscattered

Table 1.5 Selected in-situ measurements and recommended characteristics for performing standard measurements (for more details, see the relevant chapters)

Parameter	Most relevant sensor type	WMO recommended height for standard measurements [1.17]	Uncertainty	Response time (time constant)
Temperature	Pt resistance with radiation screen	2.0 m	1 K	1 min
	Pt resistance, ventilated with radiation screen	2.0 m	0.1 K	10 s
Relative humidity	Capacitive sensor, ventilated with radiation screen	2.0 m	1%	30 s
Wind speed and direction	Cup anemometer with wind vane	10.0 m	0.2 m s^{-1} , 3°	10 s^a
	Sonic anemometer	10.0 m	0.1 m s^{-1} , 2°	$< 0.1 \text{ s}$
Pressure	Electric sensor	Exact height above sea level must be known	0.1 hPa	10 s
Precipitation	Precipitation gauge	1.0 m	0.1 mm, resolution of about 10%	1 min
Global radiation	Pyranometer	about 2.0 m	10 W m^{-2}	10 s

^a dependent on wind speed, see Sect. 9.3.1

Table 1.6 Surface fluxes determined from measurements obtained with multiple sensor types, and the typical characteristics of those sensors when they are used near to the surface

Parameter	Typical sensors used	Typical accuracy (%)	Typical sampling rate	Typical aggregation time
Evapotraspiration/ latent heat flux	Sonic anemometer, fast-response humidity sensor	10–15	0.05–0.1 s	10–30 min
	Net radiometer, and profile measurements with anemometers and psychrometers	10–20	1–10 s	10–30 min
	Net radiometer, anemometer and psychrometer (parameterization)	20–50	10–60 min	1 h to 1 month ^a
	Lysimeter	5–10	≥ 1 h	1 d
Sensible heat flux	Sonic anemometer	5–10	0.05–0.1 s	10–30 min
	Net radiometer and profile measurements with anemometers and ventilated thermometers	10–20	1–10 s	10–30 min
Trace gas fluxes/ dry deposition	Sonic anemometer, gas analyzer	10–15	0.05–0.1 s	10–30 min
	Gas analyzer (parameterization)	20–50	10–60 min	1 h to 1 month ^a
Wet deposition	Wet-only sampler	10–20	≥ 1 h	≥ 1 h

^a dependent on the method

signal. Additional variables can be derived for some systems, such as the spectral shape and width and the polarization. Recently, some active remote-sensing instruments have begun to provide reliable data at heights of less than 10–50 m AGL due to extended scanning capabilities. When such instruments are unavailable, in-situ measurements are necessary to perform measurements at low altitudes.

In contrast to active remote-sensing techniques, passive techniques use natural sources of radiation such as the Sun, Moon, stars, and even the atmosphere. Monitoring the absorption lines of different gases in the electromagnetic spectrum makes it possible to deter-

mine integrated gas concentrations in the column above the sensor and across the whole atmosphere.

Figure 1.13 shows the electromagnetic and acoustic frequency ranges in which different remote-sensing methods typically operate. Remote-sensing measurements are performed from the ground (Part C of this book) or by using airborne platforms (aircraft and satellites; Part D of this book). Most remote-sensing techniques are able to measure different meteorological elements. A brief overview of these techniques is given in Table 1.7. For more details, please refer to the relevant chapters of parts C and D of this book. Overviews of this subject are also given in [1.24, 25, 86].

Table 1.7 Selected ground-based remote sensing techniques for measuring basic dynamic and thermodynamic atmospheric variables and some of their typical specifications (with information from [1.1, 25, 86], for more details see the relevant specific chapters, zenith angle < 30°)

Remote sensing system	Variables derived/uncertainty			Height range		Height resolution	Averaging time ^b
	Horizontal wind vector	Temperature	Humidity	Lower limit	Upper limit ^a		
Active systems							
Sodar (with RASS)							
• Minisodar (3–4.5 kHz)	0.05–0.3 m s ⁻¹			10–30 m	200–300 m	5–10 m	5–30 min
• Classical sodar (1.0–3.0 kHz)	0.3–0.5 m s ⁻¹			30–60 m	800–1000 m	20–50 m	10–30 min
• Sodar/RASS		0.5–1 K		30–60 m	400–600 m	20–50 m	10–30 min
Radar (with RASS)							
• 50 MHz	1–3 m s ⁻¹			0.2–3 km	15–20 km	150–1000 m	10–60 min
• 400 MHz	0.2–1.3 m s ⁻¹			300–600 m	10–15 km	150–500 m	10–60 min
– with RASS		0.5–1 K		300–600 m	2–4 km	150–500 m	10–60 min
• 1000 MHz	0.2–0.8 m s ⁻¹			100–200 m	3–6 km	50–200 m	10–30 min
– with RASS		0.5–1 K		100–300 m	1–2 km	50–200 m	10–30 min
Lidar							
• Direct detection Doppler wind lidar	0.5–3 m s ⁻¹			0.1–10 km	10–80 km	100–2000 m	10–30 min
• Coherent Doppler wind lidar, continuous wave	0.1–1 m s ⁻¹			10–20 m	100–200 m	0.1–20 m	1–10 min
• Coherent Doppler wind lidar, pulsed wave	0.1–1 m s ⁻¹			20–100 m	2–10 km	20–100 m	1–10 min
• Raman lidar		0.5–1 K	2–20%	50–500 m	8–15 km	7.5–600 m	10 s–30 min
• DIAL			2–10%	50–150 m	4–10 km	30–600 m	10 s–30 min
Passive systems							
Infrared spectrometer/interferometer							
Microwave radiometer		1–2 K	5–30%	c	3–4 km	50–1000 m	1–10 min
Sun/star/lunar photometer		0.5–2 K	0.2–1.5 g m ⁻³	c	3–5 km	10–3000 m	1–10 min
GNSS			≈ 1 kg m ⁻²	c			
			2–5 kg m ⁻²	c	2–30 km	100–1000 m	30 min–24 h

^a The numbers indicate the technical height range, the actual range strongly depends on the atmospheric conditions and may be considerably lower

^b The temporal resolution of the individual measurements is sometimes significantly higher. The averaging interval specified here is necessary to obtain data with the uncertainty given e.g. for the wind vector

^c Basically, provide column-integrated values, smooth profiles may be obtained from multifrequency or scanning systems

1.5 Applications

This section discusses *classical* applications of meteorological measurements in fields such as weather forecasting, climate monitoring, aviation, and agriculture. However, applications of meteorological measurements aimed at exploiting solar, wind, and water energy are becoming increasingly prominent; these are the subject of Chap. 51. One major challenge in this field is to combine meteorological measurements with performance data from power stations.

1.5.1 Meteorological Measurement Databases and Visualization

Databases are an important tool for organizing meteorological data and making that data readily available to a broad user community. They have widely replaced diaries and printed media over the last 20–30 years. Such databases are often available online. Databases can be used to retrieve a meteorological measurement or observation made at a specific time and specific location (characterized by its geographic coordinates: latitude, longitude, height of the site above sea level, height of the measurement above ground). Further information relevant to the analysis and interpretation of meteorological data is also stored in databases, including site characteristics (e.g., land cover, vegetation height, and conditions in the surroundings), sensor characteristics (e.g., sensor type and calibration), measurement errors and uncertainties, and maintenance activities (e.g., cleaning and alignment). This additional information is called metadata and should be always linked in the database to the measured values. Only well-documented datasets can be applied for a multitude of purposes.

For some applications, and in some areas of research, optimal visualization of the data is crucial. For instance, besides typical weather maps, horizontal distributions of meteorological parameters with listed numbers or isolines are used. Illustrations of more than one element are typically created when analyzing the vertical profile (Chaps. 46 and 47). In climatology, line graphs are typically generated for continuously measured parameters (such as temperature) and bar charts are drawn for parameters measured as accumulated values (such as precipitation). In geography, the climate diagram proposed by *Walter and Lieth* [1.87]—where the graphs for temperature and precipitation are organized to facilitate the classification of months or climates into dry and wet—is very popular.

The so-called *Hovmöller* diagram is increasingly being used to present fluxes and meteorological data in ecology because it affords a quick overview of relevant temporal and spatial scales [1.88]. The diagram was orig-

inally devised as a means to illustrate the evolution of meteorological parameters over time as a function of latitude, longitude, or height [1.89]. A more sophisticated but very instructive way to study spatial-frequency relationships is the Wheeler–Kiladis diagram [1.90].

1.5.2 Networks and Experiments

In order to achieve the spatial coverage and resolution required by a particular application, sensors and measurement systems are often organized into networks. The dimensions of such networks range from the meso- γ to the macro- α scale, and the number of sensors or stations included in such networks typically range between 10^1 and 10^3 . Prominent examples are urban air quality and climate-monitoring networks (Chap. 52), regional-scale networks (Chap. 45), continental-scale networks (e.g., the Atmospheric Radiation Measurement (ARM) [1.91] Climate Research Facility and the European Wind Profiler Radar Network), and global networks (e.g., synoptic weather stations across the globe, the Baseline Surface Radiation Network (BSRN), and the Global Climate Observing System (GCOS) including the Reference Upper-Air Network (GRUAN); Chap. 63). However, there is still a strong need to develop networks for observing water vapor, temperatures, and wind profiles at the meso- γ and meso- β scales.

In many cases, comprehensive information on the structure of the atmosphere and on atmospheric processes can only be derived from measurements performed by a combination of sensors or measurement systems. Examples range from automatic weather stations that integrate sensors for a variety of standard meteorological variables (e.g., temperature, humidity, wind, pressure, and precipitation) to integrated vertical profiling stations (e.g., the CloudNet approach see Chap. 63, or the ARM Mobile Facility [1.91]).

Detailed studies of specific atmospheric processes are often not possible using operational meteorological measurement systems due to the high spatial resolution required, the need to measure nonstandard variables, and the application of techniques that require human operators (e.g., tethered balloon and aircraft measurements). Such studies have been performed for decades as field experiments.

The first large field experiments, performed in the middle of the last century, were mostly limited to surface and boundary layer studies over flat and uniform terrain. However, over the last 30 years, many meteorological field experiments have been conducted over heterogeneous landscapes, and have often included boundary layer and chemical measurements (see [1.28,

Table 1.8 Routine measurements performed by meteorological networks for typical applications (further specifications are given in Chap. 43). ✓ indicates that the data are only used for verification purposes (based on documentation from the German Meteorological Service, DWD)

92] for an overview of these experiments). Recently, many experiments have been conducted in cities or urban agglomerations to investigate heat islands or air pollution [1.93]. The availability of ground-based and airborne remote-sensing techniques and aircraft measurements has led to a new class of experiments focusing on cloud microphysics and air chemistry in the troposphere and stratosphere. Special experiments (frequently organized by the WMO) are also performed to characterize and compare different sensors and measurement systems (Chaps. 11 and 12).

1.5.3 Applied Meteorology and Other Disciplines

Besides weather prediction and climate monitoring, there is a broad need for meteorological data in many

areas of society, ranging from classical agro- and hydrometeorology to air quality and water management, energy production and transmission, traffic, tourism, and the insurance sector, as illustrated by Table 1.8. This table also shows the data required for model assimilation and verification in weather prediction and for climate services.

Ecological studies are a fast-growing area of application of meteorological measurements. Therefore, this book also includes chapters on measurements at the interface between the ecosystem and the atmosphere. Unfortunately, there is a large gap between scales in the atmosphere and those in the canopy and the soil (Sect. 1.3 and Fig. 1.2). It is therefore still a major challenge to combine atmospheric measurements with soil and plant measurements (for more on this topic, see [1.28, 30, 94, 95]).

1.6 Future Developments

The number and variety of practically applied techniques for measuring meteorological elements are decreasing. Only the most stable and easy-to-handle systems are widely used. Indeed, many of the measurement principles that were popular in the past are only mentioned in the history sections of the chapters of this book.

Many remote sensing techniques are now commercially available for a reasonable price. They have replaced in-situ techniques (mainly on towers) and offer new possibilities for a variety of applications, such as renewable energy technologies. Besides classical precipitation radar, other techniques such as wind profiling

radar and lidar techniques for the measurement of wind, temperature, and humidity profiles have been incorporated into operational networks.

Meteorological services use automation extensively in their observational networks, and classical visual observations are being replaced by alternative approaches.

Before replacing older sensor techniques with new measuring principles and sensors, it is important to carry out detailed comparison experiments. This is particularly important for measurements of meteorological elements that are used to characterize the climate and to detect signals of climate change (Tables 1.1 and 1.3). Such comparisons are required to ensure that long time series of climate observations are homogeneous and free of trends or breaks due to sensor changes.

It is becoming increasingly popular to use compact sensors or sensor systems for many practical applications in the medium-cost sector. These sensors measure many elements in a small volume—often even wind and precipitation, which are normally separated from other

measurements (Chaps. 9, 12). Manufacturers offer different measurement techniques for the same element. Both of these factors have suppressed the implementation of such sensors in larger networks, which remains an issue to be solved.

Besides these general tendencies, sensor-specific problems and perspectives are discussed in the relevant chapters of this book from the measurement of meteorological elements up to complex networks.

Atmospheric measurements are a fast-growing sector of the applications of measuring techniques. Sensors for meteorological variables are included in many everyday products such as cellphones and cars, as well as in many technical applications such as control systems in buildings. Measurements for these applications normally do not follow the recommendations for measurements in the atmosphere, but there is the potential to make these data available for meteorological applications through the use of sophisticated mathematical-statistical models. This approach is known as *crowdsourcing* (Chap. 44).

Thomas Foken

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

Frank Beyrich

Meteorologisches Observatorium
Lindenberg –
Richard-Aßmann-Observatorium
Lindenberg, Germany
frank.beyrich@dwd.de

Frank Beyrich has been Head of the Boundary Layer Processes Group at the Meteorological Observatory Lindenberg of the German Meteorological Service (DWD) since 1997. He organized the LITFASS field experiments in 1998, 2003, and 2009 that focused on the area-averaging of energy fluxes over a heterogeneous land surface. He has been performing atmospheric research with scintillometers since 1994, when he received his PhD at Freie Universität Berlin.

Volker Wulfmeyer

Institute of Physics and Meteorology
University of Hohenheim
Stuttgart, Germany
volker.wulfmeyer@uni-hohenheim.de

Volker Wulfmeyer is Professor and Chair of Physics and Meteorology at the University of Hohenheim. The research goals of his team include: high-resolution, seamless weather and seasonal forecasting as well as climate projections; understanding of land-atmosphere feedback and turbulent transport processes in the planetary boundary layer; and the development and application of 3D scanning active remote sensing systems for water-vapor, temperature, and wind measurements.

Principles of

2. Principles of Measurements

Wolfgang Foken 

Modern metrology involves three aspects: practical techniques for measuring physical data, international conventions for scale units, and the theoretical background for measurements and signal processing. This chapter covers the most important themes of the third aspect as well as some notes on international conventions. After a short historical overview, the general theoretical principles of measurements are described. This includes the concept of uncertainty as well as the influence of signal dynamics on the result of a measurement or the possibilities of regression analyses. Furthermore, this chapter deals with the transmission behavior of measuring systems. From this point of view, the properties of a measuring system are described in both the time and frequency domains. Because of the general use of digital data processing systems, the influence of sampling and discretization on the measured analog signal is also presented.

Modern metrology is an interdisciplinary technology that is essential to natural science and engineering as a form of quality assurance.

Metrology involves three important aspects:

- *Practical metrology* covers all the application-oriented aspects, e.g., how to measure physical data like temperature, flow, humidity, and pressure.
- *Statutory metrology* deals with regulations, standardizations, and international conventions (Chap. 4).
- The *theory of measurements* includes the questions of dynamics, signal analysis, and the theory of uncertainty.

This chapter focuses on the last aspect.

In a broader sense, metrology is a special category of testing methods – more precisely, it is dimensional testing. This might be done by means of counting or comparing. The measuring process is characterized by capturing physical data. These data are eventually represented by a combination of the measured value and a scale unit that should be in agreement with international conventions. Therefore, this procedure is always a comparison of the measured value with a standard unit.

2.1 Basics of Measurements

Evidently, the measurement of physical quantities seems to be a distinct practical process. But our common sense tells us that each measurement is not precise. Therefore, theoretical considerations help evaluate the results of measurements. In this context, the theory of errors and the dynamics of measuring systems are of great significance. To solve these problems, mathematical statistics and probability theory are necessary.

The dynamic behavior of the measured quantity and measurement system both require a description of the measuring process in the time domain as well as in

the frequency domain. In this context, signal analytical methods such as the Fourier transformation expand the significance of the measurement results. Digital signal and data processing make it very easy to transform time domain signals into frequency domain signals using the fast-Fourier-transformation (FFT). Unfortunately, the digitalization process of the analog signals creates special errors both in time and amplitude. Therefore, it is necessary to have a closer look at the digital measuring chain.

2.2 History

Measurements for the purpose of determining distances, counting, or weighing were well known in all ancient advanced civilizations. There was a strong interrelation between measurement and cultural development. Distances and weights were important in everyday life. Often, the human body provided the units. Examples are the cubit and the yard, which refers to the distance from the nose of Henry I, King of England in the 12th century, to his thumb. Even 100° on the Fahrenheit temperature scale refers to the normal temperature of the human body (37.7°C). Often, weather and astronomical phenomena were observed and recorded by the leaders of the respective religion and later by scientists.

In ancient Greece, philosophy and natural science were not separated. This is illustrated by the rough translation of the paraphrase ascribed to the ancient Greek philosopher *Platon* (427–347 BCE):

Objective observation combined with logical thinking is the source of every finding in natural science. The best tool against misperceptions is to measure, count, or weight. That is a thing of the spirit and the ability of thinking [2.1].

Temperature recordings became more precise when it became possible to make glass capillaries. It is known that 17th century scientists used these capillaries. For instance, the Italian professor of medicine *Santorio Santorio* (1561–1636) measured body temperature [2.2] and the German scientist *Otto von Guericke* (1602–1686) used a gas thermometer for weather observations using a seven-section temperature scale (very cold, cold, cool, medium, lukewarm, warm, and very warm) [2.3].

Measurement technology is not a standalone science. Nowadays, measurement technology provides a considerable contribution to the further development of the natural sciences and engineering. Within nearly every part of science and technology, measurement develops into pure electrical data processing. Nonelectrical quantities are transformed into electrical signals. Sensors are the link between physical quantities and electrical data processing. The most important benefit of electrical signals is the fact that it is possible to measure the two quantities *frequency* and *time* with very high precision.

2.3 Errors in Measurement

Generally, measurements are more or less accurate. The error can be defined as the deviation Δx of the measured value x from the fictive true value x_w .

Figure 2.1 shows a scheme of the multiple influences on a measuring system symbolized as a black box.

Different types of errors influence the result of a measuring process. Therefore, the results should not

be accepted without an appropriate error analysis. The errors in measurement can be divided in different categories (unless they are gross errors or mistakes):

- *Representation errors*

If there exists a deterministic correlation only within certain limits between the measured quantity and the measured value, but the quantity runs

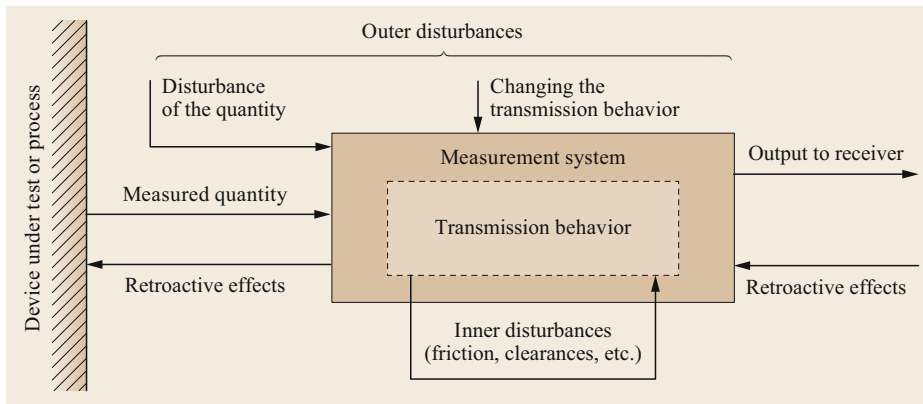

Fig. 2.1 The measuring system is influenced by disturbances

out of these limits, then this type of errors arises. For example, some measuring systems for flow show correct values only within fixed limits of the Reynolds number.

- **Static and dynamic errors**

Provided that the measuring system delivers a constant value for a time-constant quantity, the deviation between the nominal value and the measured value is defined as the static error.

If the measured quantity varies in time, the relation between a measured quantity and measured value is characterized by a differential equation. As a consequence, a dynamic error results.

- **Errors from digital data processing**

The discretization of amplitude and time results in two special errors: the quantization error and the aliasing effect. These will be discussed in detail in Sect. 2.3.

- **Systematic error and random error**

For analog practical metrology, these two categories of errors are of particular importance. Generally, systematic errors are attributed to the measuring system. Random errors are caused by randomized variations of multiple independent influencing factors.

- **Guaranteed error limits**

Manufacturers of measuring instruments specify the accuracy by means of these guaranteed error limits. The error limit is given by a percentage from the upper limit of the range of a measuring device.

2.3.1 Systematic Errors

Multiple repetitions of a measurement under constant conditions always result in an equal deviation from the true value x_w . Intentionally changing the measuring conditions leads to predictable change to the deviation

Δx . If it is possible to identify these systematic errors, the true value can be calculated by a correction of the measured value x

$$x_w = x - \Delta x \quad \text{resp.} \quad x_w = x \left(1 - \frac{\Delta x}{x} \right). \quad (2.1)$$

Δx and $\Delta x/x$ are the absolute systematic error and the relative systematic error, respectively.

Causes of Systematic Errors

- Nonstochastic environmental influences: imperfect stability of the measuring conditions, retroactive effects from the measuring system to the process, etc.
- Imperfectness of the measuring device: nonlinearity, hysteresis error, inaccurate zero balance, etc.
- Unsatisfactorily skilled experimenter: insufficient theoretical knowledge, prepossession (measuring the values one wishes to measure), etc.

Avoidance of Systematic Errors

- Precise review of the theoretical correlation concerning the measuring process
- Targeted changes to the conditions that should not influence the measured value
- Use of a totally different principle to measure the quantity

Error Propagation for Systematic Errors

Often a quantity y can't be measured, but there exists a unique functional dependency on several measured quantities x_i containing systematic errors

$$y = f(x_1, x_2, \dots, x_n) \quad \text{with} \quad x_i = x_{i,w} - \Delta x_i, \quad (2.2)$$

$$\begin{aligned} \Delta y &= y - y_w \\ &= f(x_{1,w} + \Delta x_1, x_{2,w} + \Delta x_2, \dots, x_{n,w} - \Delta x_n) \\ &\quad - f(x_{1,w}, x_{2,w}, \dots, x_{n,w}). \end{aligned} \quad (2.3)$$

To determine the systematic error of y it is necessary to use so-called error propagation. Usually the error is very small. Therefore, it is possible to expand y in a Taylor series truncated after the first element

$$\Delta y = \frac{\partial f}{\partial x_1} \Delta x_1 + \frac{\partial f}{\partial x_2} \Delta x_2 + \dots + \frac{\partial f}{\partial x_n} \Delta x_n. \quad (2.4)$$

For simple unique functional dependencies, such as a linear combination or a product of x_i , we find the following rules for error propagation

$$\begin{aligned} \text{If } & y = a_1 x_1 + a_2 x_2 + \dots + a_n x_n, \\ \text{then } & \Delta y = a_1 \Delta x_1 + a_2 \Delta x_2 + \dots + a_n \Delta x_n, \\ \text{or if } & y = a_1 x_1^{\alpha_1} a_2 x_2^{\alpha_2} \dots a_n x_n^{\alpha_n}, \\ \text{then } & \frac{\Delta y}{y} = \alpha_1 \frac{\Delta x_1}{x_1} + \alpha_2 \frac{\Delta x_2}{x_2} + \dots + \alpha_n \frac{\Delta x_n}{x_n}. \end{aligned} \quad (2.5)$$

2.3.2 Random Errors

We know from experience that measurements are not exactly reproducible even under constant conditions. Through multiple repetitions of a measurement, the results fall within a certain range of variation. It is possible to formulate three general reasons for this variation:

- The measured quantity is a stochastic quantity itself (e.g., the statistical interpretation of the gas pressure in a closed volume due to impacts of the gas molecules on the walls).
- A number of physical, chemical, or biological systems show a specific chaotic behavior. Small deviations of the outer conditions induce large orderless fluctuations (e.g., double pendulums under large deflections). This effect is described as deterministic chaos.
- If there are a variety of factors influencing the measuring process, then the measurements are not reproducible. These factors should be independent of each other and unascertainable. In this case we are talking about random errors. These errors are described using statistical principles.

Density Function and Probability Distribution Function

Usually, the measured x_i are collected in cohorts of size Δx_k . This procedure yields a histogram. Due to normalization to the respective class size of the columns in the histogram, the areas of these columns are proportional to the number of values within the respective class.

The relative frequency h_k is defined as the quotient of the measured value n_k in the cohort k to the total number of measurements n normalized to the class size Δx_k . If passing n to infinity and Δx_k to zero, the relative frequency is converted to the continuous density function $h(x)$. Integration of the density function yields a probability distribution function $H(x)$. The definition of the density function is closely connected to stochastic theory, in particular to the question concerning the probability of finding an arbitrary measured value within specified limits.

Compare the following formulas

$$h_k = \frac{n_k}{\Delta x_k n}, \quad \lim_{\substack{n \rightarrow \infty \\ \Delta x_k \rightarrow 0}} h_k = h(x)$$

$$\text{and } H(x_1 < x \leq x_2) = \int_{x_1}^{x_2} h(x) dx, \quad (2.6)$$

$$H(x) = H(x \leq x_1) = \int_{-\infty}^{x_1} h(x) dx$$

$$\text{with } H(-\infty < x \leq \infty) = \int_{-\infty}^{\infty} h(x) dx = 1. \quad (2.7)$$

Statistical Universe and Sample

In the field of metrology, any possible measurement of a quantity is termed the statistical universe. Any finite number of these measurements is termed a sample.

The statistical postulates for the mean \bar{x} and the mean variation S , calculated from samples, can be interpreted as estimations of the expectation value μ and the standard deviation σ , respectively.

From the sample data it is possible to calculate a density function and distribution function. Based on these data, a distribution model hypothesis for the statistical universe can be formulated. The most important distribution model, especially for continuous measurement values, is the normal, or Gaussian, distribution.

After measuring the values of a sample, it is necessary to clarify which is the best estimate for the characteristic parameters of the distribution model. To solve this question, the following postulates are helpful [2.4]:

- Assuming an infinite number of values within the sample, the estimates should be equal to the values of the universe.
- The estimate with the least mean variation should be the best one.

Mean and Deviation of the Normal (Gaussian) Distribution

According to the two postulates above, the mean \bar{x} is the estimate of the expectation value μ

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i \quad \text{and} \quad \mu = \lim_{n \rightarrow \infty} \bar{x}. \quad (2.8)$$

In the same way, the mean variation S of the sample can be considered the estimate of the standard deviation σ . The square of σ is known as variance

$$S^2 = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2$$

$$\text{and } \sigma^2 = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{i=1}^n (x_i - \mu)^2. \quad (2.9)$$

S and \bar{x} are parameters of the sample, while σ and μ are parameters of the statistical universe.

Density Function and Probability Distribution Function of the Normal Distribution

With the help of the estimates for σ and μ , the density function and the distribution function of the normal distribution are predictable

$$h(x) = \frac{1}{S\sqrt{2\pi}} e^{-\frac{(x-\bar{x})^2}{2S^2}}$$

$$\text{and } H(x) = \frac{1}{S\sqrt{2\pi}} \int_{-\infty}^{x_1} e^{-\frac{1}{2}\left(\frac{x-\bar{x}}{S}\right)^2} dx. \quad (2.10)$$

Because the mean and the mean variation are specific parameters for each measuring task, it is useful

to find a universal normalization. The substitution $t = (x - \bar{x})/S$ fulfills this purpose and yields a normalized density function $h(t)$ and the distribution function $H(t)$. The integral $H(t)$ is not solvable but tabulated [2.5]

$$H(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x_1} e^{-\frac{t^2}{2}} dx. \quad (2.11)$$

Figure 2.2 shows these normalized functions. The abscissa is divided in multiples of S . The mean is converted to zero and the maximum of the density function is converted to 0.398

$$h(t)_{\max} = S h(x)_{\max} \frac{1}{\sqrt{2\pi}} = 0.398. \quad (2.12)$$

Error Propagation of Random Errors

The calculation of error propagation for random errors is the same as for systematic errors. The quantity y can't be measured directly, but there exists a unique functional dependency on several measurable quantities x_i with random errors. Mean and mean variation are the result of

$$\bar{y} = f(\bar{x}_1, \bar{x}_2, \dots, \bar{x}_n)$$

$$\text{and } S_y = \sqrt{\sum_{i=1}^n \left(\frac{\partial y}{\partial x_i} S_{x_i} \right)^2}. \quad (2.13)$$

Mean Variation of the Mean

With the help of the following calculations it is possible to quantify the reliability of the estimate for the expectation value. After calculating the mean variation of the single measurements S_x , it is necessary to determine the

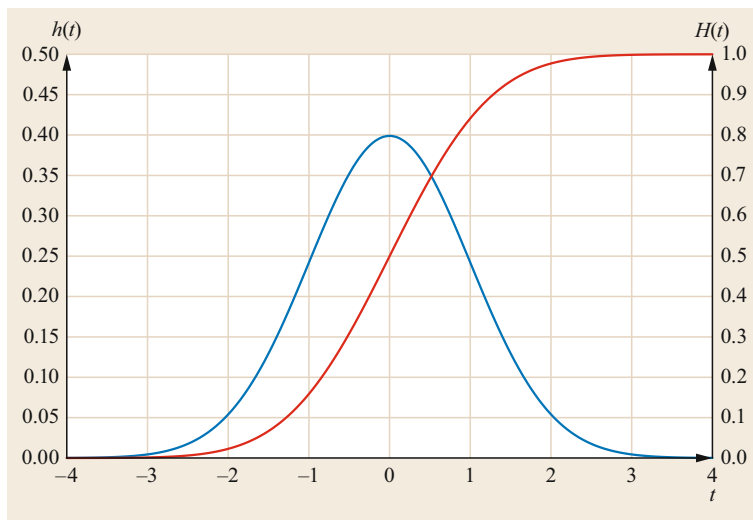

Fig. 2.2 Normalized density function (blue) and distribution function (red) of the normal distribution $t = (x - \bar{x})/S$

Table 2.1 *t*-Factors for common confidence ranges and selected sample sizes

<i>n</i>	Confidence range		
	68.3%	95.5%	99.7%
5	1.15	2.88	6.62
10	1.06	2.33	4.09
50	1.01	2.06	3.16
100	1.00	2.03	3.08
200	1.00	2.02	3.04

mean error of the mean, i.e., the mean variation $S_{\bar{x}}$. The statistical correlation between $S_{\bar{x}}$ and S_x is the result of

$$S_{\bar{x}} = t \frac{S_x}{\sqrt{n}}, \quad (2.14)$$

where n is the number of measurements. With the help of the Student's distribution it is possible to determine the *t*-factor depending on the number of measurements and the selected confidence range. For a huge number of degrees of freedom (the number of measurements in a sample), the Student's distribution turns into the normal distribution. Generally speaking, $S_{\bar{x}}$ defines the range in which to find the true value with the selected statistical certainty (confidence range).

Table 2.1 shows selected values of the Student's distribution for the most common confidence ranges and several sample sizes [2.5].

2.4 Regression Analysis

The regression analysis is closely connected to the theory of random errors. At this point, the discussion is limited to the linear dependency between two variables x and y . The starting point is the linear relation $y = mx + n$.

Drawing the pairs of variates (x_i, y_i) on an xy plot results in a cluster of points. This cluster shows a more or less linear dependency.

The aim is now to find the best linear equation to describe the dependency between x and y by minimizing the so-called error squares. There are two possible ways to determine the best linear dependency.

Assuming that the values x_i are nearly free from errors, an error equation follows that has to be minimized

$$\begin{aligned} \varepsilon_i &= y(x_i) - y_i \quad \text{and} \\ \sum_{i=1}^n \varepsilon_i^2 &= \sum_{i=1}^n (mx_i + n - y_i)^2 \implies \text{MINIMUM}. \end{aligned} \quad (2.16)$$

2.3.3 Statement of a Final Result

Frequently a quantity y has to be calculated from several quantities x_i . Some of these quantities x_i are affected by random errors (type A), while others are affected by errors that can't be calculated with the help of statistical methods (type B). Uncertainties of type B might be obtained from former measurements, a calibration process, or manufacturer specifications. Based on the *ISO Guide to the Expression of Uncertainty in Measurement*, it is possible to formulate a final result [2.6]

$$\begin{aligned} y &= f(\bar{x}_i) \pm u_C \\ &\text{with combined standard uncertainty} \\ u_C &= \sqrt{u_A^2 + u_B^2}, \end{aligned} \quad (2.15)$$

where u_A and u_B are the uncertainties of type A or type B, respectively.

Finally, it is possible to apply an extended standard uncertainty u instead of u_C for a fixed confidence range ($u = ku_C$). The factor $k = 1$ represents a confidence range of 68.3%, which is appropriate for the natural and engineering sciences. For the reliability of systems, a confidence range of 95% ($k = 2$) or even 99% ($k = 3$) is often used.

This procedure results in two equations for m and n to determine the best linear correlation

$$\begin{aligned} m &= \frac{\sum x_i \sum y_i - n \sum x_i y_i}{(\sum x_i)^2 - n \sum x_i^2} \quad \text{and} \\ n &= \frac{\sum x_i \sum x_i y_i - \sum y_i \sum x_i^2}{(\sum x_i)^2 - n \sum x_i^2}. \end{aligned} \quad (2.17)$$

Otherwise, if it is possible to determine the values y_i with a higher accuracy, we find the following error equation

$$\varepsilon_i = x(y_i) - x_i = \frac{y_i - n}{m} - x_i. \quad (2.18)$$

Fig. 2.3a,b Idealized time function (a) and spectrum (b) of the signal $A = A_1 \sin(\omega t) + A_2 \sin(2\omega t)$ with $\omega = 2\pi f$; $f = 1000$ Hz and $A_{1,2} = 1$

2.5 Time Domain and Frequency Domain for Signals and Systems

Typically, measured quantities are nonstatic values, especially for vibrations but even for pressure measurements or temperature fluctuations. For such dynamic signals, the pure time function isn't sufficient to describe the dynamic behavior of the measuring process symbolized in Fig. 2.2. Therefore, the time functions are transformed from the time domain to the frequency domain. This process (Fourier transformation) yields a frequency spectrum.

Generally, periodic signals show a line spectrum. Otherwise, nonperiodic signals (stochastic signals, transient signals) show continuous spectra. Fortunately, many signals are periodical or contain at least periodical components. From the mathematics, we know that periodical signals can be expanded into a Fourier series as a sum of harmonic functions (sine and cosine functions). If we know the behavior of the measuring systems for harmonic functions, the result is applicable to all periodic signals.

Figure 2.3 shows the time function and spectrum of a simple (idealized) periodical signal, while the Fourier series consists only of two harmonic components with equal amplitudes.

Generalized measuring systems may be regarded as a special signal processing system. The measured physical quantity, e.g., the corresponding measured signal, is the input of the measuring system. According to the transmission behavior of the measuring system, an output signal arises that may be used for a display as well as for automatic control purposes. Usually, input and output signals are already electrical signals.

A simplified system may be regarded as a so-called *linear time-invariant (LTI) system*. For this reason, there exists a mathematical correlation between the input signal $x_c(t)$ and output signal $x_a(t)$ in the time domain and between the input spectrum $X_E(\omega)$ and the output spectrum $X_A(\omega)$ in the frequency domain. The transfer behavior of the system is described by the pulse response $g(t)$ in the time domain and the frequency response $G(\omega)$ in the frequency domain. The link between the time and frequency domain is always given by the Fourier transformation $F(\omega)$ or its own inverse function $F^{-1}(\omega)$. Figure 2.4 shows this principle. The mathematical operation convolution is marked with a $*$.

Fig. 2.4 Linear time-invariant system in the time and frequency domains

2.6 Dynamics of Measuring Systems

There are different possibilities for defining the dynamic of a measuring system. The definition of the transfer function as a differential equation is the most general one

$$e_0 x_e(t) + e_1 \frac{dx_e(t)}{dt} + \dots + e_m \frac{d^m x_e(t)}{dt^m} = a_0 x_a(t) + a_1 \frac{dx_a(t)}{dt} + \dots + a_n \frac{d^n x_a(t)}{dt^n} \quad (2.19)$$

For LTI systems, the coefficients e_i and a_i are constants. The left-hand side of the equation describes the input signal of the measuring system and the right-hand side describes the output signal.

Fig. 2.5 Principle of temperature measurements with contact to the test medium (m = mass of the sensor, c = specific heat capacity, F = surface area of the sensor inside the medium, α = heat transfer coefficient (medium–sensor), ϑ_c = temperature of the medium under test, ϑ_a = displayed temperature)

For simple systems it is possible to determine the transfer function analytically with the help of fundamental physical relations such as heat balances or equations of motion. Figure 2.5 shows the principle of a temperature measurement with contact to the medium under test. This principle is applicable to nearly all temperature sensors except, for instance, radiation pyrometers.

The example in Fig. 2.5 may be solved using the heat balance of the applied heat and the stored heat (the discharged heat is neglected)

$$\alpha F (\vartheta_c - \vartheta_a) = 0 + mc \frac{d\vartheta_a}{dt}$$

resp. $\vartheta_c = \vartheta_a + \tau \frac{d\vartheta_a}{dt}$

with $\tau = \frac{mc}{\alpha F}$. (2.20)

This equation represents a transfer function according to (2.19); however, most of the coefficients are zero. The value τ is known as a time constant. The highest order of the differential (2.20) is equal to 1. Therefore, those systems are characterized as first-order systems. For more complex systems, it becomes nearly impossible to set up the transfer function analytically.

2.6.1 Test Functions

Assuming they are LTI systems, it is appropriate to use simple test functions to identify the behavior of measuring systems. For nearly all measurement quantities, these functions are at least approximately simple to create. Table 2.2 shows the most common test functions.

The pulse function and the related response function (pulse response) are of particular importance. The normalized pulse function is known as the ideal Dirac

Table 2.2 Test functions

Pulse function $\rho(t)$	Step function $\varepsilon(t)$	Ramp function $\delta(t)$

Table 2.3 Response functions

Formula of the response function	Graphic representation
Step response $x_a(t) = kx_e(t) \left(1 - e^{-\frac{t}{\tau}}\right)$, with $x_{e,\text{step}}(t) = x_0 = 1$; $x_{a,\text{step}}(t) = k \left(1 - e^{-\frac{t}{\tau}}\right)$	
Pulse response $x_{a,\text{pulse}}(t) = \frac{d}{dt} \left[k \left(1 - e^{-\frac{t}{\tau}}\right) \right] = \frac{k}{\tau} e^{-\frac{t}{\tau}}$	
Ramp response $x_{a,\text{ramp}}(t) = \int_0^t \left[k \left(1 - e^{-\frac{t}{\tau}}\right) \right] dt = kt - k\tau \left(e^{-\frac{t}{\tau}} - 1\right)$	

pulse. The Dirac pulse can be created from a rectangular pulse with a pulse width Δt and a height $1/\Delta t$ by applying $\Delta t \rightarrow 0$.

Starting from the pulse function, the step function and the ramp function are obtained by integration. In the opposite direction, the ramp functions can be transformed into the others by differentiation. For LTI systems, the same rules are applicable to the corresponding response functions of the measuring system.

2.6.2 Response to Test Function for a First-Order System

Because the step function is easy to obtain, it is best to start with this function. That means we have to solve the first-order transfer function according to (2.19). Pulse response and ramp response can be obtained by differentiation or integration of the step response, respectively. The analytical solutions and the corresponding graphs are summarized in Table 2.3.

2.6.3 Step Responseprotect of Second-Order Systems

As a general rule, mechanical systems with movable masses may be described according to (2.19) as second-order systems (oscillatory system) with the spring rate k , the damping coefficient c , and the mass m

$$x_e(t) = kx_a(t) + c\dot{x}_a(t) + m\ddot{x}_a(t). \quad (2.21)$$

Figure 2.6 shows the step response (unit step) for different damping (two different damping coefficients and aperiodic oscillations). For higher damping, the system runs into the borderline case. One example of the oscillating behavior is a wind vane, but the same relations are valid for mechanical chart recorders or galvanometers.

2.6.4 Frequency Response for a First-Order System

By applying a measuring system (LTI system) with a sinusoidal signal of any frequency and constant amplitude, the output is also a sinusoidal signal of the same frequency, but the amplitude and the phase shift depend on the frequency.

For further discussion it is useful to shift to a complex description of the input and output signal of the measuring system

$$\begin{aligned} x_e(t) &= \hat{x}_e e^{j\omega t} \equiv X_e(j\omega), \\ x_a(t) &= \hat{x}_a e^{j(\omega t + \varphi)} \equiv X_a(j\omega). \end{aligned} \quad (2.22)$$

$X_e(j\omega)$ und $X_a(j\omega)$ are the spectra of the signals. The complex frequency response $G(j\omega)$ is defined as the ratio of output spectrum to input spectrum, where the

Fig. 2.6 Step response for a second-order system with different damping coefficients in terms of unit time and unit amplitude

amount of $G(j\omega)$ is termed amplitude response and the phase relation is termed phase response

$$\begin{aligned} G(j\omega) &= \frac{X_a(j\omega)}{X_e(j\omega)} = \frac{\hat{x}_a e^{j(\omega t + \varphi)}}{\hat{x}_e e^{j\omega t}} = \frac{\hat{x}_a}{\hat{x}_e} e^{j\varphi} \\ &= |G(j\omega)| e^{j\varphi}. \end{aligned} \quad (2.23)$$

To determine the frequency response of a first-order system we use the general transfer function according to (2.19) and the complex descriptions from (2.22)

$$\begin{aligned} kx_e(t) &= x_a(t) + \tau\dot{x}_a, \\ \hat{x}_a e^{j(\omega t + \varphi)} + j\omega\tau\hat{x}_a e^{j(\omega t + \varphi)} &= k\hat{x}_e e^{j\omega t} \quad \text{leads to} \\ \hat{x}_a(1 + j\omega\tau) e^{j\varphi} &= k\hat{x}_e. \end{aligned} \quad (2.24)$$

According to (2.23), the amplitude response and the phase response are calculable

$$\begin{aligned} G(j\omega) &= \frac{k}{1 + j\omega/\omega_g}, \\ |G(j\omega)| &= \frac{k}{\sqrt{1 + (\omega/\omega_g)^2}}, \\ \tan \varphi(\omega) &= -\frac{\omega}{\omega_g} \quad \text{with} \quad \omega_g = \frac{1}{\tau}. \end{aligned} \quad (2.25)$$

To obtain the graphs of the amplitude and the phase response in Fig. 2.7, it is useful to apply the following boundary conditions

$$\begin{aligned} \omega \ll \omega_g &\rightarrow |G| = k, \\ \omega = \omega_g &\rightarrow |G| = k \frac{1}{\sqrt{2}}, \\ \omega \gg \omega_g &\rightarrow |G| \approx \frac{1}{\omega}. \end{aligned}$$

2.6.5 Frequency Response for a Second-Order System

In principle it is possible to calculate the frequency response of a second-order system in the same way as for a first-order system. A second-order system may be considered as a simple mass oscillator with a harmonic force exciting the mass. Therefore, the equation of motion for the first-order system becomes

$$kx_a + c\dot{x}_a + m\ddot{x}_a = \hat{F} e^{j\omega t}. \quad (2.26)$$

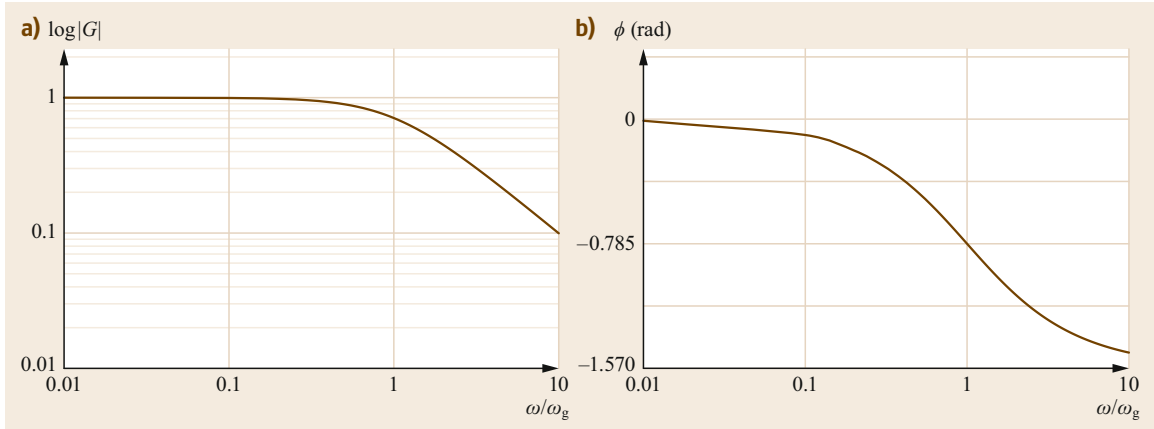

Fig. 2.7a,b Generalized amplitude (a) and phase response (b) of a first-order system (with $k = 1$)

Fig. 2.8a,b Generalized amplitude (a) and phase response (b) of a second-order system (with $k = 1$)

With the assumptions from (2.23), the amplitude response and the phase response are calculable

$$G(j\omega) = \frac{X_a(j\omega)}{F(j\omega)} = \frac{\hat{x}_a}{\hat{F}} e^{j\varphi} = \frac{1}{(k - \omega^2 m) + j\omega c} \quad \text{and}$$

$$|G(j\omega)| = \frac{1}{\sqrt{(k - \omega^2 m)^2 + (\omega c)^2}},$$

$$\varphi = \arctan \left[\frac{-\omega c}{k - \omega^2 m} \right]. \quad (2.27)$$

To obtain the graphs of the amplitude and the phase response in Fig. 2.8, it is useful to apply the following boundary conditions

$$\omega \rightarrow 0: \quad |G| \rightarrow \frac{1}{k},$$

$$\omega = \omega_0: \quad |G| = \text{maximally}, \quad \left[\omega_0 = \sqrt{\frac{k}{m}} \right],$$

$$\omega \rightarrow \infty: \quad |G| \approx \frac{1}{\omega^2 m} \quad \text{because of} \\ (\omega^2 m)^2 \gg (\omega c)^2.$$

2.7 Analog and Digital Signal Processing

The world around us is an analog one, at least for our observational skills. Usually, measured signals from sensors are analog values. In most cases sensors provide electrical voltages or currents depending on any physical quantity. Nevertheless, in most areas, digital technology has been established, including measurement technology. There are objective reasons for this development. Besides real technical reasons, the economic benefits of digital technology are important.

Table 2.4 compares analog and digital technology.

2.7.1 Analog Measurement Chain

In most cases, the sensing elements or transducers provide analog electrical signals. In other words, the electrical properties of the transducers vary as a function of physical values like temperature, humidity, or displacement.

Simplified, the analog measurement chain consists of the four principle elements shown in Fig. 2.9.

The transducer converts the physical value into an electrical signal. Often it is necessary to use filters to reduce noise or to select a special frequency range. Depending on the sensor output, it is useful to convert an electrical current, an electrical charge, or an ohmic resistance into a voltage signal. Usually these electrical

voltage signals are very small. Therefore, it is necessary to use electrical amplifiers. At the end of the measuring chain the signal value is displayed or used to control actuators.

2.7.2 Digital Measurement Chain

Figure 2.10 shows a typical measurement processing chain in the digital world.

The central element is the interface between the analog signal and the corresponding digital word. The state of the art is a digital word length of 16 bit. The step from the analog signal to the digital word needs time (analog/digital (A/D) converter). Therefore, the sample and hold (S&H) unit keeps the analog signal fixed during this time-consuming procedure.

In order to handle signals in the digital world, a quantization of time as well as amplitude is necessary. In other words, the continuous time function of the measured signal is mapped to a finite set of digital words of different digital word length stored in the memory of the digital measuring system. Obviously, this approach induces a loss of information. This might be interpreted as a special form of error to be discussed later.

Quantization Error

Figure 2.11 illustrates an example of the development of quantization error during the analog-to-digital procedure for a 2-bit and 3-bit A/D converter. The two rows on the right side of Fig. 2.11 are the binary codes of the analog signal represented by numerical values.

Obviously, the given amplitude range is divided into three possible steps for the 2-bit A/D converter and into seven steps for the 3-bit A/D converter. According to Fig. 2.11, the number of possible steps is equal to $(2^N - 1)$, where N is equal to the number of bits for the digital word. Simplified, in Fig. 2.11, the step always takes place at the analog values that represent half of the step width.

As a result, without loss of generality, the quantization error always varies between plus and minus of the half-step width represented by the least significant bit (LSB). Therefore, the quantization error q is defined by

$$-\frac{\text{LSB}}{2} \leq q < \frac{\text{LSB}}{2} \tag{2.28}$$

Table 2.4 Analog and digital technology comparison

Analog technology	Digital technology
Theoretical infinitely high resolution for the amplitude	Possibly high precision of the digital display (limited by the number of decimal places/length of the digital word)
Processing and calculating speed are practically in real time (limited by the signal propagation delay)	Processing and calculating speed are <i>not</i> in real time (controlled by the clock frequency)
Uncomplicated signal conversion	Signal transmission largely interference-free
Signal transformations only conditionally obtainable (connected with high effort)	Simple obtainment of rather complex signal transformations
Complex technology for the electrical connection (electrical connection partly not obtainable as an integrated circuit)	Cost-effective solutions for the electrical-connection technology and programmable microcomputer technology

Fig. 2.9 Simplified analog measurement chain

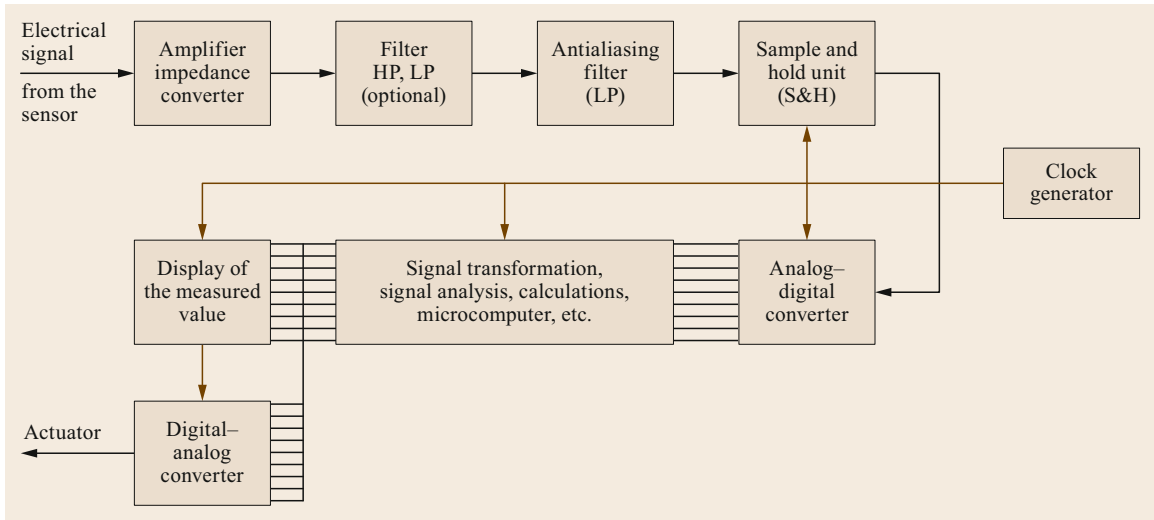

Fig. 2.10 Typical digital measurement processing chain (HP: high-pass filter, LP: low-pass filter, S&H: sample and hold)

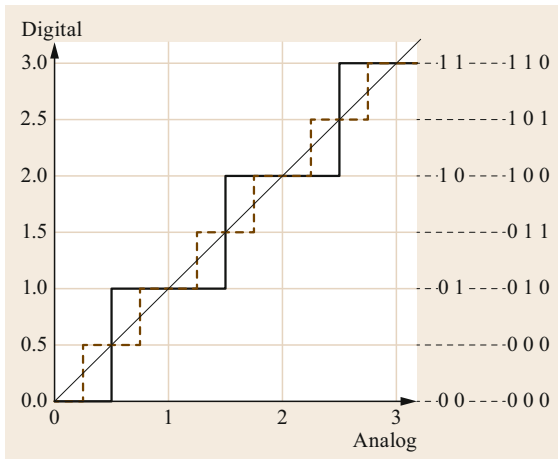

Fig. 2.11 Principle of A/D converting for 2-bit and 3-bit converters

The LSB in Fig. 2.11 has a significance of $2^0 = 1$ (2-bit A/D converter) or $2^{-1} = 0.5$ (3-bit A/D converter).

The quantization error is mapped to the range of the analog value, for instance, to the voltage range U_M of the A/D converter. Finally, the relative and absolute quantization errors can be determined

$$F_q = \frac{U_M}{2^N - 1}, \quad F_{q,\text{rel}} = \frac{1}{2^N - 1},$$

$$\text{for high numbers of } N \quad F_{q,\text{rel}} \approx \frac{1}{2^N}. \quad (2.29)$$

Digital word lengths of 8, 10, or 16 bit are typical for common A/D converters. This results in quantization errors of 0.4%, 0.1%, and 0.015%, respectively.

These are the theoretical minima of the quantization error because in reality it is impossible to adjust the analog value (voltage value) to the full voltage range of the A/D converter. In other words, the quantization error rises inverse to the *used* length of the digital word.

Aliasing Effects

As well as the discretization of the amplitude, the discretization of time generates a specific error. This error is called the aliasing error. To understand this problem, it is necessary to have a closer look at the sampling of the analog value in the time and frequency domains. Figure 2.12 illustrates these two processes.

A prerequisite is that the analog signal is band-limited. In other words, the signal spectrum contains no higher frequencies than a fixed upper cut-off frequency f_g .

The sampling process may be considered a multiplication of the signal with a so-called sampling function (equidistant sequence of delta functions/Dirac pulses). This leads to the sampled signal, which exists only at the points of time where the sampling function is unequal to zero.

The transition into the frequency range (Fourier transformation) provides the spectra of the measured signal and the sampling function, respectively. For practical reasons we only use the positive part of the Fourier integral.

Usually, measured signals are not periodic. We know from the mathematics that the spectra of those functions are continuous. However, the sampling function is in fact a periodic function with discrete lines at the integral multiples of the sampling frequency.

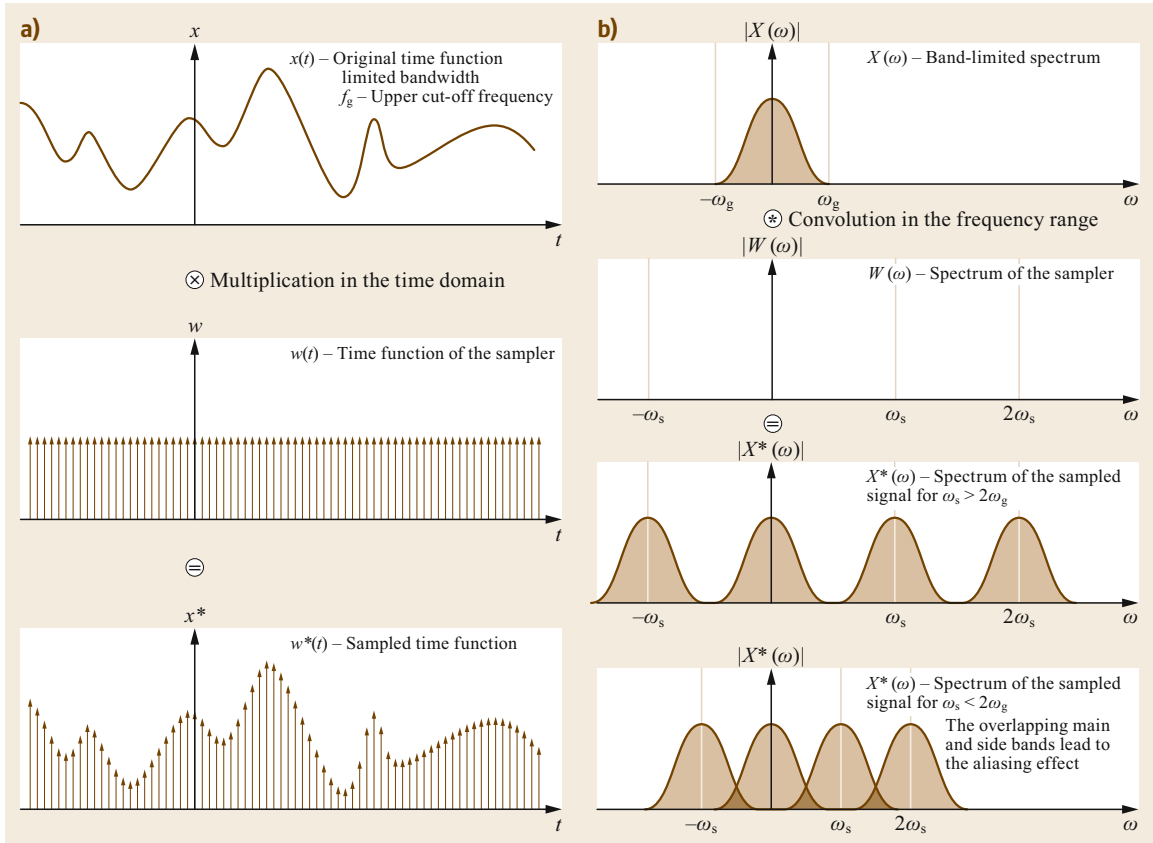

Fig. 2.12a,b Sampling procedure in the time (a) and frequency (b) domains

In the time domain, the signal function is multiplied by the sampling function. In the frequency domain the equivalent mathematical operation is the convolution (*). Simplified, it is possible to say that the convolution combines the properties of the two functions. The envelope of the spectra of the sampled function has the same shape as the continuous spectrum of the original signal, but the shape of the signal is echoed at the discrete lines of the spectrum of the sampler. Figure 2.12b highlights two possible versions of this process. Depending on the frequency of the sampler, we consider the periodic shapes of the signal spectrum as overlapping or not overlapping. Obviously, if the sampling frequency f_s is higher than twice the cut-off frequency f_g , no overlapping occurs. This boundary condition is known as *sam-*

pling theorem (Nyquist–Shannon sampling theorem)

$$f_s \geq 2f_g \tag{2.30}$$

The sampling frequency f_s is also known as the Nyquist frequency.

The overlapping of the periodic shapes of the spectrum is called aliasing. The aliasing effect results in an overestimation near the cut-off frequency of the signal. This effect is also considered an error, the so-called aliasing error.

For digital measuring systems, the sampling frequency is often defined as $f_s = 2.56f_g$.

To prevent these errors, it is necessary to use a low-pass filter according to the sampling theorem. This is the antialiasing filter within the measuring chain of Fig. 2.10.

2.8 Hardware for Digital Measurement Systems

Sensors for typical quantities, e.g., temperature, pressure, or humidity, usually deliver an analog voltage. A voltage-to-current converter transmits the sen-

sor signal over larger distances to any display unit or analyzing unit based on the 4–20 mA standard [2.7].

Fig. 2.13 Principle structure of smart sensors

Moreover, the digital technology provides the opportunity to integrate signal conditioning, A/D converting, and a standardized interface within the sensor housing. Often this new type of sensor is named a *smart sensor* [2.8] (Chap. 44). Sometimes these sensors are combined with internal data storage, e.g., these sensors have their own data logger system. An advanced block diagram is shown in Fig. 2.13.

For the communication interface, a lot of possible opportunities are found. The most common interfaces are USB or WLAN [2.9]. For standalone solutions it is also possible to store the measured data on an internal SSD card to analyze them later on an external analyzing system.

For more complex tasks with many, different sensors, standalone data loggers are usually the best solution. Often these loggers have an integrated *real-time clock* providing all data with a time stamp. Data loggers have a large number of different possibilities to connect sensors, for instance, voltage inputs, either grounded or differential, inputs for various thermocouples, capacitive sensors, and resistance sensors.

To communicate with a supervising computer system, various bus systems are available. The Ethernet interface is very common to construct distributed systems for network technology. With the help of cloud services, the measured data may be available worldwide.

Wolfgang Foken is a retired Professor of Measurement Technology at the Faculty of Automotive Engineering at the University of Applied Sciences in Zwickau, Germany. He received his Diploma in Physics from Leipzig University (1979). His research interests are the problems of noise and vibrations of vehicles, including their psychoacoustic effects. He is a member of the Acoustical Society of Germany and led the working group of Automotive Acoustics for several years.

Quality Assurance

3. Quality Assurance and Control

Cove Sturtevant , Stefan Metzger , Sascha Nehr , Thomas Foken 

Quality assurance and control is fundamental to ensuring the scientific usefulness of atmospheric measurements. Quality is relevant to all stages of data generation, from site selection and system design to all physical components of a measurement system (including their calibration, operation, and maintenance) as well as data handling and processing. This chapter describes useful practices and techniques for a comprehensive quality management program that is designed to minimize problems and quantify quality along the entire data generation chain. Widely applicable methods of post-field data quality control for instrumented (in-situ), visual, and remotely sensed observations are presented. The chapter concludes with example applications of QA/QC in measurement networks, and a discussion of common data problems. Finally, future developments in quality assurance and quality control are presented.

Atmospheric data are collected by many different entities and exchanged locally or worldwide for use in a wide range of applications. Examples include basic research, agricultural operations, fire danger forecasting, numerical weather prediction, air pollutant dispersion, and global climate models, to name but a few. Assuring and characterizing data quality and adhering to international or community standards where applicable is imperative for reliable analysis and interpretation. The quality of atmospheric data can be adversely affected at nearly every point in the data generation chain. For instance, poor data quality may result from a bad choice of site, poor instrument selection and config-

uration, inadequate maintenance, sensor malfunctions, environmental fouling, data processing errors, or unsatisfactory delivery to users. A quality management system is needed to determine and assure the quality of atmospheric measurements. However, such a system can and should be based on a scaled approach that considers the project goals, intended data use, and resources available. The policies and procedures implemented to assure and control quality can almost always be improved. The specific details of a quality management system should be tailored to fit the priorities and requirements of the project or application.

3.1 Principles and Definition

Quality assurance (QA) and quality control (QC) are important topics in technology and science (see also Chap. 4). Therefore, general principles have been developed that are applicable in almost all fields. This section introduces the basics of QA and QC with specific relevance to the field of atmospheric measurements.

3.1.1 Defining Quality

Several terms relating to quality that are used in this chapter and throughout this handbook are defined below.

Quality

This is the degree to which a set of inherent characteristics fulfills requirements [3.1].

Inherent characteristics are defined as aspects of an atmospheric measurement system for which requirements exist, such as the performance characteristics and operating conditions of the sensors, details of the measurement location and configuration, how the sensors are maintained, and how data are collected, stored, processed, and provided to users.

Data Quality

This is the degree to which data are fit for use by data consumers [3.2].

The end product or service of an atmospheric measurement system is most often data. For this reason, the term *quality* in this context typically refers to the data. Because different applications have different requirements for data coverage, uncertainty, etc., it is the data consumer who decides what is fit for use. Thus, the assignment of data quality is specific to the use case. High-quality data is “intrinsically good, contextually appropriate for the task, clearly represented, and accessible to the data consumer” [3.2].

Quality Management

This is the process of specifying and performing the methods required to achieve the necessary quality [3.3].

Quality management focuses on achieving consistently high quality of atmospheric data and services by specifying and performing the methods used to achieve, maintain, and improve the required quality. Thus, quality management includes quality planning, quality assurance, quality control, and quality improvement.

Quality Planning

This is the process of identifying quality requirements and how to fulfill them.

Quality planning includes defining the objective(s) of the atmospheric measurements, generating requirements to ensure the objective will be met, and specifying the resources and procedures that will be used to meet the requirements and test that they are met.

Quality Assurance

This is the process of checking for compliance with all planned and systematic activities implemented within the quality management system (and demonstrated as needed) in order to provide adequate confidence that an establishment meets the quality requirements [3.1].

Compliance in this context means purposefully controlling all factors that have a direct impact on the quality of the end product or service.

Quality Control

The operational techniques and activities that are used to fulfill the quality requirements [3.1].

Quality control of data is the best-known aspect of QA/QC (quality assurance/quality control) in atmospheric measurements, and involves examining the data to verify it meets the quality requirements. When the quality requirements are not met, quality control options include flagging data as suspect, correcting the data, or deleting it. However, quality control is not limited to the final data. It involves controlling the quality of all processes and products in the data generation chain by monitoring their performance and taking action when needed to meet quality requirements.

Quality Improvement

This is the process of purposefully changing methods and/or procedures in order to improve quality and its consistency.

Improvements in the quality of atmospheric measurements are made possible by monitoring the quality or performance of all aspects of the data generation chain that have a direct impact on the quality of the end product or service.

3.1.2 Principles of Quality Management

The goal of any quality management system is to ensure that end products and services are of consistently high quality by identifying objectives, determining the resources and methods required to meet them, and linking policies and procedures implemented throughout the organization. The International Organization for Standardization (ISO) provides a set of international standards and guidelines for quality management in the ISO 9000 series [3.4] (see Chap. 4). An organization may certify to

ISO 9001 [3.5]—which specifies the requirements for an effective quality management system—by demonstrating that the required elements are in use. Seven quality management principles [3.4] form the foundation for any quality management system, and the requirements of ISO 9001 are based upon them. These principles are not ordered steps but rather characteristics to incorporate throughout all aspects of a project or organization in order to promote and improve quality. How the principles are prioritized will depend on the specific goals at hand. The seven principles are:

Customer Focus

Deliver data and services that meet or exceed user needs and expectations. This creates confidence in the data and the organization.

Leadership

Unify goals and strategies across the organization and create an environment that facilitates the attainment of quality objectives. This includes providing adequate resources and establishing a culture that values quality.

Engagement of People

Recognize, involve, and empower everyone's role in managing quality.

Process Approach

There are no isolated aspects of quality. Recognize and utilize the connectedness of processes and their impact on quality.

Improvement

Look ahead to upcoming needs. Identify, plan, and act upon processes and products that need improvement.

Evidence-Based Decision Making

Collect and analyze data and information to assess and improve quality.

Relationship Management

Identify dependencies and communicate with stakeholders about quality. Collaborate with them to improve quality.

3.2 History

The earliest efforts to control the quality of atmospheric measurements involved standardizing weather observations, which began with the establishment of the first meteorological networks in the eighteenth century [3.6]. For example, James Jurin of the Royal Society developed a scheme for standardized weather reports for locations in England, Europe, North America, and India in 1723, and the first meteorological society, *Societas Meteorologica Palatina* (Meteorological Society of Mannheim, formed in 1780), set local times for weather observation. Standardized instruments and weather observations expanded during the nineteenth century to include measurements of precipitation, dry and wet bulb air temperatures, cloud cover and movement, wind speed and direction, and barometric pressure [3.7]. By the mid-nineteenth century, meteorology had become an exacting science with standardized, calibrated instrumentation and regulated observers. Precision, accurate record-keeping, and rigorous numerical analysis were strongly promoted by the British Meteorological Society (formed in 1850). Regular international conferences among meteorologists were initiated in 1872 at Leipzig to facilitate the development and communication of standardized methods, and the Permanent Meteorological Committee, later called the International Meteorological Organization

(IMO), was established during the 1873 Vienna International Meteorological Congress (see also Chap. 1).

In the twentieth century, general progress in quality paradigms facilitated international standardization for many industries, including meteorology. Working at Bell Laboratories in the mid-1920s, Walter Shewhart expanded the concept of quality to processes involved in manufacturing [3.8]. He was also the first to apply statistical methods to quality control [3.9, 10]. Simultaneously, international trade was growing, and 25 countries met in 1946 to discuss the unification of industrial standards. This resulted in the establishment of the International Organization for Standardization in 1947. That same year, the IMO began preparing the Guide to International Meteorological Instrument and Observing Practices, which focused on standardized measurements. 1950 saw the formation of the World Meteorological Organization (WMO), and the First Congress of the WMO formed the Commission for Instruments and Methods of Observation (CIMO) in 1951 to provide technical standards for meteorological instrumentation as well as guidelines to ensure that data are quality controlled and comparable. The result was the 1954 release of the first edition of the Guide to Meteorological Instruments and Methods of Observation (WMO-No. 8). The latest edition of this guide

was published in 2014, and the most recent update was released in 2017 [3.11].

Another major contribution of the WMO to quality in atmospheric measurements was the establishment of reference standards, which can be traced to the CIMO conference of 1977 in Hamburg [3.12]. Probably the first initiative originated in 1985 from the Radiation Commission. *Fritz Kasten* [3.13] proposed a system of standards with different quality levels: primary standards, secondary standards, and finally traveling standards. Such an initiative was highly important because the burgeoning discussion of climate change necessitated more accurate radiation instruments. Therefore, the Baseline Surface Radiation Network (BSRN) was founded in 1994 to establish standards for radiation instruments [3.14]. The initiation of this network helped to significantly increase the data quality and accuracy of radiation measurements [3.15] (see Chaps. 11 and 63), and provided an example of how to classify instruments and standards for other devices within the WMO and in other areas such as flux measurements [3.16] (see Chaps. 64 and 55).

The advent of automated weather stations—which expanded data gathering substantially—resulted in a need to control the quality of the collected data. Operational development of automated weather stations in the USA began in 1939 [3.17]. Transmitting data via telegraph and radio Morse code, these stations collected measurements of air pressure, temperature, relative humidity, wind speed and direction, and rainfall. The development of meteorological character codes (pub-

lished in the WMO Manual on Codes [3.18]) facilitated the timely, standardized transmission and international exchange of meteorological observations. Until the late twentieth century, the focus of data QC was the statistical identification of outliers [3.19]. An evolution towards complex data quality assurance began in the 1980s, involving several tests and a decision tree for data flagging [3.20–24]. Today, advanced methods such as machine learning are being developed to identify outliers and errors in data with little human input [3.25].

Work aimed at improving the quality of atmospheric measurements continues today through the expansion of highly standardized, cross-disciplinary environmental networks such as Integrated Carbon Observation System (ICOS) and National Ecological Observatory Network (NEON), whereby network stations employ standardized infrastructure, instrumentation, measurement protocols, and processing methods. This coordination among stations makes it possible to answer grand questions in environmental science that span numerous disciplines and spatial and temporal scales [3.26, 27]. The antecedents of these highly standardized networks began—and continue today—as data sharing efforts among independent stations. For example, the FLUXNET network [3.28], which began as a means of sharing data on land–atmosphere fluxes of heat, water vapor, and carbon dioxide, helped to advance the standardization of measurement variables, computational algorithms, and data formats. The resultant comparability of data among stations revealed that, globally, photosynthesis is more sensitive than respiration to drought [3.29].

3.3 Elements of Quality Management

Quality management begins well before the first measurement is made, and is maintained throughout the data generation chain (Fig. 3.1). The first step is to define the objectives of the project, which are used to generate the requirements. Measurements to ensure that the requirements are met are then planned. Planning the measurements is often the hardest yet most important part, as ensuring the quality of the final data requires advanced planning of the site, instruments, and their configuration, the measurement details, and how instruments will be calibrated and maintained. In addition, planning should include how data will be processed, managed, and delivered to users, and how the project will be monitored to ensure the requirements are met and that high-quality data are obtained. There are often tradeoffs in costs and human resources that should be reconciled during the planning process, and tests are performed to verify that the measurement plan will

work. Once planning is complete, the site can be set up and configured, and operations can begin. Since most measurements are now automated, the effort required to operate a project has largely shifted to maintenance and to monitoring and controlling the quality of data. The expertise and effort required to perform these tasks should not be underestimated.

It is easy to see how the seven principles of quality management (see Sect. 3.1.2) are incorporated in this workflow. The goals of the data user inform the requirements of the measurement system and how data are delivered (*customer focus*). Quality becomes central to the project through planning and quality-focused operation (*leadership*). All personnel, from project planners to maintenance staff, have roles to play in ensuring quality (*engagement of people*). Performance monitoring allows continuous improvement of quality (*improvement; evidence-based decision making*). Audits facili-

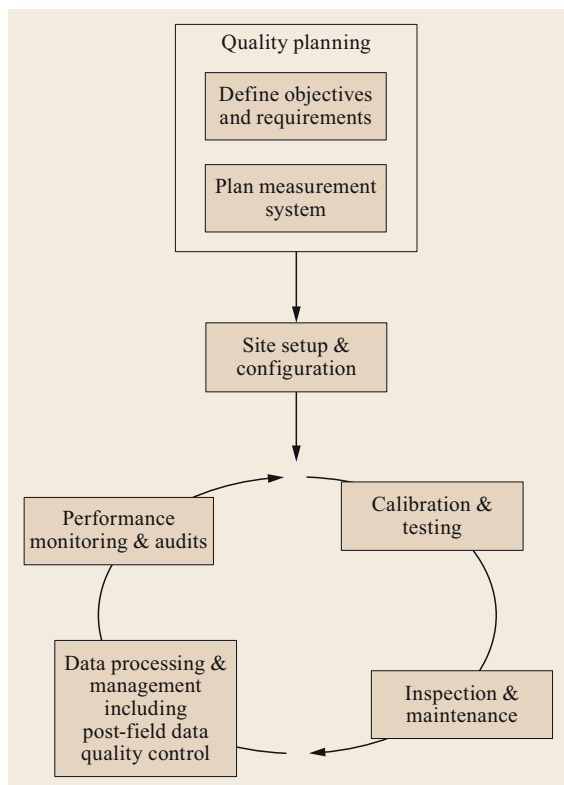

Fig. 3.1 Workflow for quality management

tate communication with and quality improvement in internal and external dependencies (*relationship management*). Finally, the interconnectedness of the system is explicit (*process approach*). The elements of this workflow are described detail in the following sections.

3.3.1 Quality Planning

Atmospheric measurements focus on answering selected questions that lead to a better understanding of the state and temporal evolution of the continuously changing atmosphere (see Chap. 1). Thus, it is of the utmost importance to first precisely define the objective of the atmospheric measurements, because it is the basis for deriving the minimum requirements for the data characteristics, which are then used to determine the measurement system requirements. These challenging tasks are accomplished by means of quality planning in accordance with the seven principles of quality management.

This section provides an overview of the major steps involved in quality planning, while the remaining sections go into greater detail about the quality considerations involved in the individual aspects of a measurement program.

Define Objective

Quality planning is primarily determined by the measurement objective. In general terms, atmospheric measurements are performed for basic research, the development or application of technology, or to check compliance with (legally) binding limit values. This differentiation is important, as the reason for performing atmospheric measurements influences the options available to meet the objective and the performance criteria of the applied measurement techniques.

Strict measurement standards are not prescribed for basic research studies. However, the research questions dictate how strict the measurement requirements must be, considering the statistical power required to evaluate hypotheses and make robust conclusions. Centuries of scientific study have yielded rigorous state-of-the-art atmospheric measurement methods that are employed in long-term monitoring programs (Global Atmosphere Watch of the WMO [3.30]), regional programs (European Monitoring and Evaluation Program [3.31]), and national networks (see Chap. 63). Even if the research conducted does not belong to these programs, state-of-the-art methods should be followed to maximize the quality and comparability of the data and the resulting robustness of analyses. Many of these monitoring programs and measurement networks have their own QA/QC guidelines (as outlined in Sect. 3.4.1). The objectives and constraints of basic research studies or monitoring programs may even contribute to the development of new measurement technologies. For example, a new measurement technology may be deployed as research instrumentation with hardly any knowledge of its performance characteristics. Results from comprehensive instrument intercomparisons (see Sect. 3.3.3) within a monitoring program can demonstrate equivalence or superiority to an established measurement technique. Accordingly, the development of a new technology can also be the primary objective of atmospheric measurements.

In order to demonstrate compliance, the frequency with which pollutant concentrations exceed safe limits for ecosystems and human health (determined via legally binding air quality standards) is reported. This concept facilitates law enforcement. However, developing ambient air quality standards requires more than adopting a set of limit values for airborne pollutants. First and foremost, it is important to characterize the physical state of the atmosphere, since the air, water vapor, and numerous organic and inorganic atmospheric trace constituents (gaseous, liquid, and solid) are always in motion (see Chap. 1). In addition to being physically transported, these trace constituents undergo chemical transformations. Thus, it is mandatory to link the ambient air quality standards with measurement meth-

ods, sampling site locations and frequency of sampling, quality control measures, and statistical data analysis. This link is established by prescribing official measurement method standards that are enforced by (for example) national laws or ordinances.

When defining the objective of atmospheric measurements, it is helpful to develop scientific or technical use cases for the data. Use cases are concrete examples of the objective that help to guide the development of requirements relating to the following building blocks: (i) site(s); (ii) hardware and firmware; (iii) software; (iv) measurement and evaluation strategy; and (v) people-to-people interactions. Good planning involves the integrative/iterative design of (i)–(v) to maximize the quality of the data and return on investment. Use cases include predicting atmospheric quantities or events, answering a specific scientific question, or using the data to accomplish a task. Creating a use case involves (i) giving it a name and briefly describing its scope, (ii) identifying the actors involved, (iii) specifying any preconditions, (iv) defining the basic and any alternate workflows for the steps taken to accomplish the use case goal, (v) identifying any exceptions that will prevent the goal from being accomplished, and (vi) specifying the conditions that indicate a successful outcome [3.32].

Develop Requirements

In all of the measurement objectives outlined above (basic/applied research, technology development, and checking compliance with legally binding limit values), the aim (from a data quality perspective) is to achieve predefined data quality attributes. These data quality attributes are defined in relation to the data user's needs. Accordingly, data are of sufficient quality if they satisfy the stated and implied needs (i.e., meet the objective). A proper quality management program ensures that data requirements for the intended application are met. Good data are not necessarily excellent, but it is essential that their quality is known and demonstrable. Table 3.1 gives an overview of the core data quality attributes.

One aim of atmospheric measurements is to attain results that are spatially and temporally representative according to the objective. In this context, the measurement results must reflect the actual conditions in the spatiotemporal domain of interest [3.41]. A further example is the representativeness with respect to legally binding limit values/guide values (see the discussion of spatial and temporal representativeness in Chap. 1).

However, quality planning goes far beyond specifying representativeness or the other core data quality attributes listed in Table 3.1. Section 3.3.2 outlines how data quality attributes are further addressed in site selection and configuration.

Table 3.1 Core data quality attributes

Data requirement	Description
Internal consistency	Theoretical compatibility of the estimated value with other parameter values derived from the same observations
Validity	Extent to which an assessment achieves its aims by measuring what it is supposed to measure and producing results which can be used for their intended purpose [3.33]
Spatial/temporal representativeness	Ability of a series of observations to provide an unbiased estimate of a parameter of a specified statistical population [3.34]
Completeness	Extent to which the information provided enables the data user to draw conclusions in accordance with the goal and scope definition [3.35]
Coverage	Spatial and/or temporal distribution of measurement locations in the area under investigation [3.36]
Availability	Property of being accessible and usable upon demand by an authorized entity [3.37]
Traceability	Ability to relate the result of a measurement to appropriate measurement standards—generally international or national standards—through an unbroken chain of comparisons [3.38]
Timeliness	Undelayed and frequent availability of data for the intended use to support information needs and quality management decisions [3.39]
Reliability	Degree to which data are provided in an agreed or expected manner during a defined time period under specified conditions [3.40]

Hitherto, the concept of quality has related to the explicit and implicit needs of the data user for a specific use (*user perspective*). At this point, it is important to distinguish between data quality and measurement uncertainty, and to understand how these concepts are related. In terms of scientific measurement, the uncertainty quantifies how much is unknown about the measurements. In contrast, quality is subjective and defined according to the desired data use. The requirements relate uncertainty to quality by defining the maximum uncertainty that the data can exhibit while meeting the objective.

Unless required by law or a governing body, requirements should focus on the characteristics of the measurements and not the specific methods of achieving them. For example, rather than specifying the exact measurement method or sensor to be used, the perfor-

Table 3.2 Overview of instrument characteristics that are applied to characterize and quantify the performance of a measurement system based on the concept of uncertainty (see also Chap. 2)

Instrument characteristic	Description
Accuracy	Proximity of the result of a measurement to the true value of the measurand [3.42]. This expresses the systematic uncertainty of measurement [3.43]
Precision	Level of agreement among a set of results of the same measurand [3.42]. This expresses the random uncertainty of measurement [3.43]
Sensitivity	Quotient of the change in the response of a measuring system to the corresponding change in the value of the quantity being measured [3.44]
Linearity	Straight-line relationship between the (mean) result of the measurement (the signal) and the quantity to be determined [3.45]
Reproducibility	Level of agreement between the results of measurements of the same measurand carried out under changed measurement conditions (see [3.46])
Repeatability	Level of agreement between the results of successive measurements of the same measurand carried out under the same measurement conditions (see [3.46]). Often used to assess the precision
Temporal resolution	Equipment-related variable describing the shortest time interval from which independent signal information can be obtained [3.47]
Threshold	Minimum input signal value below which no change in the output signal can be detected [3.48]
Drift	Change over time of a characteristic (generally an output quantity) of the measuring system [3.49]
Stability	Ability of a measurement system to retain its performance throughout its specified operating time [3.48]
Range or span	The particular values of a quantity that a measurement system is designed to measure [3.48]
Speed of response	Rapidity of the response of a measurement system to changes in the measured quantity [3.48]
Measuring lag	Retardation of or time delay in the response of a measurement system to changes in the measured quantity [3.48]
Dynamic error	Difference between the true value of a time-varying quantity and the value indicated by the measurement system if no static error (accuracy) is assumed [3.48]

mance characteristics (such as accuracy and precision) of the measurements that are needed to meet the objective should be defined. This provides extra flexibility when planning the measurement system—tradeoffs can be made among cost, required maintenance, and site access and arrangement while still meeting the project objective. Without this flexibility, it may not be possible to conduct the measurements at all.

Table 3.2 gives an overview of instrument characteristics that are applied to characterize and quantify the performance of a measurement system based on the concept of uncertainty (*technical realization perspective*).

The data requirements and instrument characteristics strongly influence the choice of the measurement technique and the specifics of its implementation. Other chapters of this handbook show that there are several options for classifying atmospheric measurement techniques:

- In-situ measurement (part B of this handbook) versus remote sensing (parts C and D)
- Mobile measurement platforms (Chaps. 37, 39, 48, 49, and 50) versus stationary measurement platforms (Chap. 6)
- Discontinuous versus continuous measurement
- Measurement of an individual quantity versus measurement of a sum quantity

- Measurement in the field versus measurement in the laboratory versus measurement in a simulation chamber (e.g., the European Photoreactor EUPHORE versus the SAPHIR (Simulation of Atmospheric PHotochemistry in a large Reaction Chamber) atmosphere simulation chamber; see [3.50, 51]).

Specific QA/QC considerations for the abovementioned categories are addressed in the corresponding chapters. It is assumed that the theory applied to transfer these signals into meteorological quantities is valid.

Plan the Measurement System

The final step in quality planning is to select the details of the measurement system according to the predefined requirements (both data requirements and instrument characteristics). To assure the quality of the final data, the entire data generation chain should be planned, all the way from measurement site selection to how the data are processed and provided to users.

Defining the spatial arrangement involves specifying the location of an individual measurement site or the density of multiple measurements sites within a given area. Defining the temporal measurement pattern involves designating the measurement time, duration, and frequency in a given investigation area. During the course of quality planning, the measurement

variables (measurands) must be determined. Measurement protocols are used to document the instruments deployed as well as the settings and installation (e.g., orientation) of the instrument. Maintenance schedules and tasks must be planned and personnel requirements for setting up, operating, and maintaining the sensor must be determined. How should the data be recorded, stored, and processed? Finally, it is also necessary to decide how the data should be evaluated and how the system will be monitored to check that it conforms to the requirements. This involves specifying the method used to evaluate adherence to data quality requirements as well as the method employed to quantify the measurement uncertainty.

A brief checklist for quality planning is given in Table 3.3. More details of the quality considerations involved in these selections are provided in subsequent sections.

3.3.2 Site and Instrument Selection and Configuration

Measurement planning can commence once the data product requirements have been defined for a given measurement objective (Sect. 3.3.1). Site and instrument selection and configuration are important components of the planning stage. This section addresses quality and practical considerations involved in those selections, and summarizes best practices.

Measurements are strongly influenced by the characteristics of the measurement site. It is therefore important to investigate whether a site is representative considering the measurement objective and data product requirements, i.e., the extent to which it reflects the actual conditions in the spatiotemporal domain of interest [3.41]. This is particularly important for highly derived data products that comprise multiple data streams

Table 3.4 Best practices for defining site selection requirements. This example of general recommendations (after [3.3, 11]) applies to a range of common measurement objectives from baseline meteorological observations to anchor forecasting. It may be necessary to adjust and consider the resulting uncertainty for specialized and new measurement objectives, such as the investigation of new measurement conditions

Characteristic	Description
Administration	<ul style="list-style-type: none"> Any necessary approvals and permits (e.g., from the building authority or the regulatory agency) should be available Planning for maintenance, care, repair, and exchange should consider vehicle access, access on foot, necessary aids Skilled staff should be available for monitoring, maintenance, care, repair, and exchange as well as for the inspection, storage, and further processing of data
Surface	<ul style="list-style-type: none"> The ground surface should be representative of the locality There should be no steep slopes in the vicinity, and the site should not be situated in a hollow or on a mound^a The site should be well away from obstructions such as tall vegetation, buildings, and walls^a
Exposure	<ul style="list-style-type: none"> Instruments should be exposed according to their operating requirements, preferably in close collocation to each other Tradeoffs should be evaluated per data product requirement, e.g., among open sites with unobstructed views of the horizon for radiation and cloud measurements, and sheltered sites suitable for precipitation measurements Night observations of cloud and visibility should be made from a site unaffected by extraneous lighting
Sustainability and provenance	<ul style="list-style-type: none"> The site should be surrounded by open fencing or palings to exclude unauthorized persons, and the open fencing or palings should be sufficiently far from the instruments that they do not disturb the measurements themselves Sites should be chosen to minimize the effects of changing characteristics over time, such as the growth of trees or the erection of buildings in the vicinity^a

^a Assuming that this is not the subject of the research or that it is not a relevant characteristic of the targeted locality.

that possibly originate from a range of instruments and measurement principles.

In Chap. 1, Sects. 1.3.2 and 1.3.3 provide a general discussion of spatial and temporal variability and representativeness. Here, we specifically address aspects of siting and exposure that should be addressed to avoid quality issues related to site selection. Possible influencing factors are large vertical or horizontal gradients of the investigated variables at the measurement site (e.g., they may be affected by heterogeneous surroundings, obstacles, etc.). It is therefore important during site selection to consider and document whether the physical effects of the surroundings permit joint analysis of the measured variables in support of the data product requirements [3.59].

A commonly made assumption is that variables measured at the same site represent a common *target area* or environment. While this remains a weak assumption in uniform settings, the individual source area and spatial representativeness of each variable should be considered in heterogeneous environments [3.60]. For example, measurements of the atmospheric state, thermodynamics, and composition are subject to dispersion: they represent a large ($\approx 10^4 \text{ m}^2$) upwind area that changes over time with diel and synoptic wind patterns, the local flow field and disturbances (obstructions), and

topography. Quantifying this variable area is the subject of footprint analysis (see Chap. 1; [3.61]). On the other hand, measurements of, say, surface optical properties typically represent a smaller ($\approx 10^2 \text{ m}^2$) area that is stationary. In addition, optical measurements are directly affected by the aspect, slope, and shading from obstructions. Measurements performed in the soil have an even smaller source area (on the order of 10^{-2} m^2), and often only represent their immediate surroundings. Hence, covering a spatial scale comparable to atmospheric or optical measurements can necessitate a multitude of distributed soil measurements.

Moreover, the observer effect (the effect of measurements on each other and their surroundings) must be taken into account. This introduces two contradictory requirements: that the measurements should be representative of the same target area while minimally impacting each other and their environment. Defining zones of mutual representativeness and exclusion can help to quantitatively optimize this collocation [3.62]: the zone of mutual representativeness identifies the joint target areas of the measurements, while placing each sensor outside the exclusion zones of the other sensors ensures that reciprocal and environmental impacts remain below the required threshold. Alternatively, it is possible to apply post-field corrections for environmental effects [3.3].

Table 3.5 Best practices for defining instrument requirements (after [3.3, 11])

Characteristic	Description
Instrument performance	<ul style="list-style-type: none"> • Uncertainty, including accuracy, precision, resolution, detection limit, range, speed of response, and cross-sensitivity • Reliability and long-term stability
Cost, durability, convenience of operation and maintenance	<ul style="list-style-type: none"> • Acceptable cost of instrument, consumables, and spare parts • Energy consumption and possibility of off-grid power supply • Robustness with respect to environmental conditions • Simplicity of design and maintainability
Safety	<ul style="list-style-type: none"> • Safe for staff and the environment

Table 3.6 Best practices for defining installation and configuration requirements (after [3.3, 11])

Scope	Description
Installation	<ul style="list-style-type: none"> • The quantity to be measured should not be falsified significantly by the instrument itself or by its structural parts, or by a cover to protect it • Support structures such as towers and boom arms should be designed with static requirements to withstand loads from (for example) thunderstorms and other site-specific phenomena • Additional devices that are required to operate the system (power supply, anti-theft device, lightning protection) should be available
Configuration	<ul style="list-style-type: none"> • The devices required for data acquisition should be implemented (data transport, transmission lines, operational requirements for acquisition systems)

Best practices for defining site selection requirements are provided in [3.3, 11] and are summarized in Table 3.4. In addition, [3.63] provides a detailed study of siting and exposure, and [3.64] provides a recent review of the topic in relation to setting up ICOS member sites. However, the measurement objective and requirements can necessitate deliberate deviations from these best practices. In this case, the usefulness of the measured variables remains specific to the measurement objective, and deviations from best practices should be thoroughly documented in the metadata.

All atmospheric variables change spatially and temporally under the influence of the characteristics of the measurement site. Consequently, the instrument response and sampling characteristics (see Table 3.2 and Chap. 2) must be able to resolve the spatial and temporal scales of the relevant atmospheric processes or the data quality may be significantly reduced. (For more on the scales of atmospheric processes and the relevant instrumentation, see Chap. 1.) Defining the instrument requirements provides a quantitative framework for acceptance testing and instrument selection and configuration in accordance with the measurement objective, data product requirements, and selected site. Inverting or numerically solving relevant equations permits instrument requirements to be derived from data product requirements. Such sensitivity analysis and uncertainty attribution is particularly useful for ensuring the quality of highly derived data products that encompass multiple data streams. Table 3.5 provides an overview of best practices for defining instrument requirements. Instrument selection should be based on the

degree to which these requirements are fulfilled, and the measurement objective should be considered when weighing the importance of individual requirements. For example, instrument stability is indispensable for long-term observations. However, it may be less important for short-term intensive measurement campaigns, where attaining spatial resolution through a batch of less expensive sensors may better address the objective. Where possible, instrument selection can be optimized through integrative design, i.e., interfacing the measurement objective and data product requirements not only with site and instrument requirements but also software developments. One example of this is provided by the adaptive calibration models that are used to improve instrument performance [3.65].

Once the instrument has been selected, it is important to ensure that its installation and the end-to-end data acquisition chain support the measurement objective and data product requirements. This can be accomplished by specifying installation and configuration requirements. Table 3.6 provides an overview of best practices. First and foremost, the sensor installation and configuration should permit the spatial and temporal scales of the relevant atmospheric processes to be resolved (see instrument requirements). Important considerations include measurement height above the ground and time of the day for optical measurements. Formal systems integration and verification should include installation and test plans and lead to an initial operations capability review. In addition to instrument deployment, considerations include digital versus analog signal processing, data logger versus

traditional computer versus single-board computer for data acquisition, polling, on-site (in-wire) application of calibration coefficients (traceability), and timestamping (Global Positioning System, the Network Time Protocol, the Precision Time Protocol, and quartz, e.g., in an offline personal computer). Particular attention should be paid to ring storage, where the oldest data are overwritten once capacity is reached, and to checking hashes during data transfer operations.

Documenting the site, instrument, installation, and configuration is paramount to ensuring the usefulness of the resulting data products. In the systems integration and verification process, machine-readable documentation for sensor configuration, the location hierarchy, and as-built drawings are used for this purpose. The geolocation should be recorded (e.g., geodetic system and model, height above mean sea level of the ground on which the supporting structure is erected, the locations of individual instruments relative to the reference point in a local coordinate system, consideration of true north versus magnetic north and declination). Any deviations from the above best practices should be recorded in the metadata, and the documentation for the site geography and its exposure should be regularly updated. When an instrument needs to be replaced, observations from the new instrument should be compared to those from the old instrument over an extended interval (at least one year; [3.66]) before the latter is taken out of service.

3.3.3 Calibration and Testing

Sensor calibration establishes the relationship between the values of quantities indicated by the sensor and the corresponding values realized by standards [3.67]. QA/QC should comprise initial calibration prior to a measurement series, final calibration after the completion of the measurement series, and regular assessment of the measurement data, so that failures are identified immediately. A long-term measurement campaign may require several measurement series so that calibrations are performed at designated intervals recommended by the manufacturer or as necessary to maintain the required measurement characteristics (e.g., accuracy and precision).

Typically, a sensor is calibrated in a sequence of operations under predefined measurement conditions by providing a known physical input to the instrument and recording the output. Thus, the purpose of calibration experiments is to determine the analytic function of a measurement method for a specified state variable [3.68]. Prior to determining the analytic function, it is necessary to specify the measurement range, the measurement conditions, the mathematical shape of the analytic function, and the number and distribu-

tion of reference states. The measurement conditions of the calibration experiment should correspond as far as possible to the conditions that may arise in the measurement task considered, and should be completely documented. The definitions used in this handbook are summarized in Table 3.7.

Calibration Practices

A calibration includes a calibration experiment and a mathematical evaluation of the experimental results. In the calibration experiment, the measured signal is measured at reference states. Subsequently, the observed relationship between the reference state and the measured signal is mathematically described by the analytic function for the corresponding range of values. The contribution of uncertainty to calibration is determined by statistically evaluating the results of the calibration experiment.

The characteristics of the measured signal as well as the characteristics of the corresponding reference values affect the choice of the calibration procedure (see Table 3.8) as well as the choice of the statistical evaluation method that is used to estimate the parameters of the analytic function (see Table 3.9). It is generally recommended that the calibration instructions provided by the sensor manufacturer should be consulted prior to defining the calibration conditions and the corresponding calibration strategy.

The input data for the estimation methods shown in Table 3.9 are the coordinates of the calibration points determined in the experiment (the reference value of the state variable and the corresponding value of the measured signal) as well as the uncertainties in one or both coordinates. The calculation is based on regression analysis, which takes the stated uncertainties into account. The results of the regression analysis are the parameters of the analytic function (see also Chap. 2).

The reference states should be chosen in accordance with the selected shape of the analytic function such that the reference values of the state variable appropriately represent the specified range of measured values. The reference states are generated with calibration devices. A good calibration device should always be combined with a proper measurement standard. Examples include feeding a certified test gas of known composition to gas sensors or operating a liquid bath temperature calibration chamber equipped with certified thermometers. The uncertainties in the reference values should be presented as standard deviations. Possible data sources include the uncertainty of the standard reference method and the uncertainty of the calibration device. Multiple independent replicate measurements should be taken at each reference state [3.68]. The average and the standard deviation should be calculated

Table 3.7 Terms and definitions used in the context of calibration (afetr [3.70])

Term	Definition	Remarks
Calibration function	Mathematical presentation of the measured signal as a function of the state variable for a specified range of values	Calibration function and analytic function are the inverse of each other.
Analytic function	Mathematical presentation of the state variable as a function of the measured signal for a specified range of values	The shape of the function is specified on the basis of preliminary information on the response of the measurement system
Reference state	State of the measuring object, where the value of the state variable is known with specified uncertainty	The generation of reference states is performed with calibration devices such as a reference material or a standard reference measurement method. The number of reference states required depends on the shape of the function. The minimum number is [3.68]: <ul style="list-style-type: none"> • Three reference states for a linear function • Five reference states for a second-order polynomial • Seven reference states for a third-order polynomial • Five reference states for a potential function • Five reference states for an exponential function (see Chap. 2)
Reference value	Value of the state variable in a reference state	Wherever possible, reference values and their uncertainties should be traceable to corresponding international or national standards
Measured signal	Quantity with values that are provided by the measurement system	The measured signal is the quantity that is generated by the measurement system as an image of the measurement object.
State variable	Quantitative characteristic describing the state of a system [3.69]	If the measured signal and the state variable are continuous quantities, then both functions increase or decrease monotonically across the range of values considered
Measurement range	Range of values of the state variable for the measurement task considered	See also Sect. 3.3.1
Measurement uncertainty	Parameter that is associated with the result of a measurement and characterizes the accuracy and precision of the values that could reasonably be attributed to the measurand	In this handbook, the measurand is the state variable, which is the objective of the measurement

Table 3.8 Selection of the calibration procedure according to the characteristics of the measured signal and the corresponding reference value

Characteristics of the measured signal	Characteristics of the corresponding reference value	Calibration procedure
Defective	Subject to a comparatively small stated uncertainty	Direct calibration [3.71, 72]
Uncertainty of the measured signal is smaller than the uncertainty of the reference value	Defective (comparatively large stated uncertainty)	Indirect calibration [3.71, 72]
Defective	Defective	Orthogonal calibration [3.71, 73, 74]

from the multiple replicate values for each reference state. These average values should be used as the values of the measured signal. The standard deviations of the averages are used as the corresponding uncertainties.

Finally, calibration is required to define the bias (or the average deviation from the standard), the random errors, the measurement thresholds, and the nonlinear response regions. Hysteresis should be identified by cycling the sensor across its operating range during cal-

ibration. Drift is identified by periodically performing calibrations over a longer time period.

In long-term measurement programs, it is especially important to quantify (and possibly correct for) instrument drift between calibrations and/or sensor changes to maintain quality and consistency in the data and associated uncertainty estimation. When a sensor is exchanged for a new one of the same type due to damage or wear or to perform calibration, it is vital to perform

Table 3.9 Overview of established estimation methods for the parameters of the analytic function (after [3.76, 77])

Method used to estimate the parameters of the analytic function	Description	Applications	Limitations
Least squares estimation (LSE)	The parameters of the analytic function are calculated by minimizing the sum of squares of the distances (along the dependent variable axis) between the measured values and the analytic function	The advantage of the LSE is that there is no need to assume a distribution type, only the relationship between the expected value and the unknown parameter. Thus, this estimation method is applicable to a wide range of problems. LSE is used when the uncertainties in the independent variable are insignificant	As LSE only uses information about the expected value but not information about the distribution (in contrast to the MLE method), the resulting estimators are not as good as those provided by MLE. If the expected value is not linearly related to the parameter, numerical approximation methods are generally employed to determine the minimum in LSE. Only residuals for dependent variables are considered
Total least squares estimation (TLSE)	The parameters of the analytic function are calculated by minimizing the sum of squares of the orthogonal distances between the measured values and the analytic function	TLSE accounts for observational errors in both the measurement signal and the reference value. It is a generalization of orthogonal regression, and can be applied to both linear and nonlinear models	Difficulties arise if the dependent and independent variables are not measured in the same units
Weighted least squares estimation (WLSE)	WLSE attaches nonnegative constants (weights) to the data points	It is particularly applicable to data of varying quality	WLSE requires that the weights are known. Weight estimation can have unpredictable results, especially when dealing with small samples. Therefore, the technique should only be used when the weight estimates are fairly precise
Minimum chi square estimation (MCSE)	MCSE is similar to LSE, but it is assumed that the random variables take discrete values (including categorized data)	MCSE is only applied to frequencies (such as the frequency of observations per class; e.g., photon counting). Observations are randomly sampled	It is difficult to find the minimum of the sum of squared errors because the minimization algorithm must take discontinuities into account
Maximum likelihood estimation (MLE)	In contrast to LSE, MLE requires that the type of distribution of the sample variable is known. The parameters of the distribution depend on the parameter sought. The estimated value of the parameter is the value that would most likely produce the observed sample	The advantage of MLE is the nature of the estimator: it is often consistent (i.e., increasing the number of observations improves the accuracy of the estimated value) and asymptotically efficient, and it is possible to formulate general significance tests for model comparisons	A major disadvantage of MLE is that the type of distribution of the sample variable must be known; choosing an inappropriate distribution type results in poor accuracy of the estimated value. Furthermore, in order to find the parameter, it is usually necessary to perform numerical maximization, which may end up in a local rather than a global maximum. However, if the precisions of the measured signals and the references are recorded, MLE will still provide superior performance [3.75]

pre- and post-deployment calibration of both sensors in order to account and/or correct for differences in readings that are simply due to the sensor change. So long as both sensors meet the measurement requirements (which should have been verified initially and throughout the program; see Sects. 3.3.2 and 3.3.7), changing the instrumentation should not diminish the ability of the measurement program to achieve the objective.

Nonetheless, such a change should be thoroughly documented to aid data interpretation (see Sects. 3.3.4 and 3.4.2). When a sensor is replaced with another of a different type (due to improvements in technology or because the model of the original sensor has been discontinued), it is necessary to perform and document a thorough instrument intercomparison (see below) that characterizes and accounts for differences in the in-

Table 3.10 Standards used for different meteorological parameters (after [3.11]) (for more details see Chaps. 7, 8, 9, and 10)

Level of standard	Description	Temperature	Humidity	Wind ^a	Pressure
Primary standard	Highest metrological quality; value accepted without reference to other standards	High-grade platinum resistance at an accredited calibration laboratory ^b	Gravimetric method, humidity generator at national standard laboratories	Wind tunnel according to ISO guidelines [3.78, 79]	Piston gauge with loaded piston
Secondary standard	Value assigned by comparison with a primary standard		Chilled mirror hygrometer ^c or WMO reference psychrometer [3.80]		Electric barometers, such as silicon diaphragm barometers with long-term stability
Reference standard	A standard that is generally of the highest metrological quality and is used in a given location or by a given organization to calibrate measurements	Well-calibrated reference thermometers or WMO reference psychrometer [3.80] ^d	Chilled mirror hygrometer ^c or WMO reference psychrometer [3.80]		Electric barometers, such as silicon diaphragm barometers with long-term stability
Working standard	Standard used to routinely calibrate or check measurement systems	Well-calibrated reference thermometers or WMO reference psychrometer [3.80] ^d	Chilled mirror hygrometer or Assmann psychrometer	Inspections	High-precision electric barometers
Traveling standard	A standard that is intended to be transported between different locations (and is therefore sometimes specially constructed to facilitate this)				High-precision digital barometer

^aThe WMO has not defined any standards
^bTermed a laboratory standard
^cHighly accurate instruments such as the Thygan (see Chap. 8) are recommended for use as secondary standards
^dTermed a field standard

struments across the range of expected measurement conditions.

Measurement Traceability

Sensor calibration is usually performed by comparing the output of the sensor to one or more measurement standards. These standards are classified according to their metrological quality [3.11]. Examples for the most important atmospheric parameters are summarized in Table 3.10. Unfortunately, the same levels of standards are not used for all meteorological parameters.

The primary standard is usually only available at a single institution (such as the World Radiation Center, Davos, Switzerland) or at authorized laboratories. Secondary standards are distributed to the regional centers of the WMO or even national centers. Reference standards should be available in all regions. Depending on the physical parameter considered or the instruments available, all of the sensors in a particular region should be calibrated against the appropriate reference standard for that region via working or traveling standards or traveling devices.

In addition to the list given in Table 3.10, there are also international standards that are authorized by inter-

national agreements for use in assigning values to other standards. Similarly, national standards for a particular country are authorized for use in assigning values to other standards in that country.

All equipment used for tests and/or calibrations—including equipment used for subsidiary measurements (e.g., of environmental conditions) that have a significant effect on the accuracy or validity of the test result, calibration, or sampling—should be calibrated before being put into service. The laboratory should have an established program and procedure for calibrating its equipment [3.81].

The equipment calibration program used in a calibration laboratory should be designed and operated so as to ensure that calibrations and measurements made by the laboratory are traceable to the International System of Units (SI) and recommended scales such as the International Temperature Scale (ITS-90; see Chap. 5). The measurement standards and sensors used by the calibration laboratory should be traceable to the SI through an unbroken chain of calibrations or comparisons linking them to the relevant primary standards for the SI units of measurement. This link to SI units may be achieved through reference to national measurement

standards. National measurement standards may be primary standards, which are primary realizations of the SI units or agreed representations of SI units based on fundamental physical constants, or they may be secondary standards, which are standards calibrated by another national metrology institute. When using external calibration services, measurement traceability should be assured through the use of calibration services from laboratories that can demonstrate competence, measuring ability, and traceability (see Sect. 3.3.8).

Instrument Intercomparison

Instrument intercomparisons complement the calibration process and can be performed in the laboratory (e.g., interlaboratory round robins), in the field (e.g., side-by-side field tests), or in environmental or emission test chambers (see [3.82–85]). Moreover, intercomparisons can be performed among different measurement platforms, techniques, and at the international, national, regional, multilateral, or bilateral level. In particular, intercomparisons should be performed before introducing new measurements and observation technologies.

Laboratory tests are essential for sensor calibration and for obtaining baseline information on the quality characteristics of the data from sensors. By extension, interlaboratory tests provide complementary information on the sensors and the laboratories involved. Those tests are temporally and spatially limited measurement comparisons that are used to demonstrate the competence and performance of the laboratories or to validate a measurement method (see [3.86]). The design of the interlaboratory test is intended to demonstrate how and the degree to which each measurement step affects the quality of the measurement result [3.87]. Interlaboratory testing schemes can be used to evaluate the performance of a laboratory when it carries out specific tests or measurements and to continuously monitor laboratory performance. Thus, interlaboratory tests allow the detection of problems with measurements performed by a particular laboratory, which should prompt corrective action. They can also be used to highlight interlaboratory differences. Overall, they reassure laboratory customers that the measurement methods used by that laboratory are effective and comparable. Furthermore, the outcomes of interlaboratory tests can be used by the participating laboratories to improve their own practices. Interlaboratory tests are also important for assigning values to reference materials and assessing their suitability for use in specific measurement procedures. Accordingly, claims regarding measurement uncertainty and the equivalence of measurements from national metrology institutes can be validated [3.88].

Aside from laboratory calibration and characterization, the atmospheric conditions (e.g., radiation and turbulence) can substantially alter the data quality properties of a sensor. For example, laboratory and field intercomparison tests can be performed to characterize measurement repeatability and reproducibility under controlled and varying environmental conditions, respectively. Field intercomparison tests are essential for determining the uncertainty bounds for sensor-based measurements that are substantially less reproducible than they are repeatable. Table 3.11 summarizes the complementarity of laboratory and field tests for some typical measurands.

Field intercomparisons must fulfill several requirements that go far beyond investigating sensor characteristics under laboratory conditions [3.92]. In general, field intercomparisons should be performed under measurement conditions that are reproducible and as close to ideal as possible. If the measurement conditions for a specific use case differ substantially from the ideal conditions, the instruments should be compared under the target conditions. First and foremost, a high-quality instrument—an *etalon*—should be applied for the comparison. This could be a primary- or secondary-standard sensor that shows long-term stability in laboratory calibrations and is probably less influenced than other instruments by radiation or flow distortion in the wind field. In general, the local topography of the measuring field can cause difficulties in field intercomparisons. For instance, the topography perturbs land–atmosphere interactions (including radiation), the air temperature, wind, and turbulence. Therefore, it is recommended that a horizontal and uniform measuring field with prevailing turbulence and negligible flow convergence and divergence should be selected. In addition, the measuring field should be free of obstacles in all wind directions. A measuring field in which the wind field does not change direction very often (e.g., in large valleys) may be useful. The mean radiation and mean wind speed should be identical in all parts of the measuring field, as should the turbulence statistics (standard deviations and normalized standard deviations; see Chap. 55). In addition, the measuring height should be identical for all sensors, and it should be high enough to ensure that the typically large gradients that occur near the surface do not influence the sensors (see Chap. 1). The distance between the sensors to be compared must be large enough that they do not influence each other or generate flow distortions; otherwise, the positions of the sensors should be changed several times during the intercomparison.

A notable variant of field intercomparisons utilizes traveling standards such as individual sensors or entire integrated measurement and data acquisition systems as *etalons*. This variant is commonly used in meteoro-

Table 3.11 Overview of intercomparisons performed in the laboratory or in the field

Measurand	Laboratory test	Field test
Temperature	<i>Thermometers</i> are calibrated with a very high degree of accuracy in thermostats with water or oil. However, they are used in temperature screens in which there is a significantly higher uncertainty attributed to heating of the sensors by shortwave radiation (see Chap. 7)	<i>Temperature screen</i> intercomparisons must be performed for different solar angles, wind velocities, and wind directions. The sensors should be rotated in a homogeneous wind field. One etalon that can be used in this context is the WMO reference psychrometer [3.80], and a possible experiment is described in [3.89] (see Chap. 7). Similar conditions are needed when comparing humidity sensors (see Chap. 8)
Wind speed	<i>Anemometers</i> are calibrated in a wind tunnel against an accurate hot-wire, <i>Prandtl</i> (pitot) tube, or laser anemometer. However, a wind tunnel has almost laminar flow and so the accuracy or flow distortion may differ from that associated with turbulent flow in the atmosphere	<i>Rotation anemometer and sonic anemometer</i> intercomparisons should be performed in a wind field with a dominant wind direction so that the anemometer installation does not have to be adjusted according to the wind direction to reduce flow distortion effects. It is important to know and restrict how turbulence parameters change across the measuring field. The distance between the sensors should be large enough to reduce flow distortion effects. Etalons for such comparisons are unavailable. A sensor type that is less affected by flow distortion and has undergone long-term calibration stability in a wind tunnel should be chosen as the etalon. One example of such a field experiment is given in [3.90] (see Chap. 9)
Precipitation	<i>Precipitation gauges</i> can be calibrated with simulated water inflows of different intensities. In the real atmosphere, the wind field, flow structures around the gauges, or evaporation can significantly reduce the accuracy	<i>Precipitation gauges</i> should be compared under changing wind (speed and direction) and evaporation conditions. To reduce any possible flow distortion effects, the positions of the sensors should be switched between the edge and the center of the sensor array. One possible etalon is a precipitation gauge which has the upper part at ground level and a small evaporating surface and shows stable calibration. A possible experiment is described in [3.91] (see Chap. 12)

logical measurement networks (Sect. 3.4.1) to ensure reproducibility across sites and time. One example is the AmeriFlux portable eddy covariance system, which consists not only of sensors but also mounting hardware, data acquisition, power options, software, and several optional components. The complete system can be requested by network member sites, where it is used to conduct side-by-side field intercomparisons of eddy-covariance, meteorological, and radiation measurements (see <http://ameriflux.lbl.gov/tech/pecs/>).

Intercomparisons can be performed among different measurement platforms—for example between remote sensing instruments (sodar, lidar, radar) and towers or radiosondes. Reports of such studies are available [3.93–95], but these studies have the disadvantage of comparing volume-averaged remote sensing data with point measurements, and the datasets that are compared probably utilize different time averaging [3.96]. Therefore, it is standard to apply post-field data quality control to the remote sensing data (see Sect. 3.3.6).

Satellite remote sensing is possible for levels ranging from the troposphere to the upper mesosphere. Relevant in-situ methods such as dropsondes launched with rockets are only rarely available. However, long-term stability is problematic below the upper stratosphere due to the difficulty of maintaining a stable instrumental spectral baseline. Thus, intercomparisons between satellite and ground-based instruments facilitate a com-

parison of their biases. Furthermore, the datasets can be used to assess the stability of the instruments (both satellite and ground-based) and the long-term trends in the variation of the measurand.

3.3.4 Inspection and Maintenance

Data quality issues are often irreversible, meaning they cannot be corrected after the fact. Therefore, the importance of regular inspection and maintenance cannot be overstated, as they can minimize or eliminate such issues entirely. Diligent inspection and maintenance of the site infrastructure and sensors will lead to higher data quality and fewer costly and time-consuming corrective maintenance bouts. Table 3.12 lists essential inspection and maintenance tasks that should be included in any long-term measurement program. Similar tables for measurement-specific maintenance frequencies are also provided in other chapters in this handbook.

The simplest yet most important routine task is frequent data inspection. This allows problems to be caught early, minimizing sensor downtime and improving overall quality. The frequency of data inspection and the method used to perform the inspection will depend on the scale of the project and the availability of remote communications. Meteorological services are increasingly using automatic unmanned systems that rely on remote data transmission and automated

Table 3.12 Essential inspection and preventative maintenance tasks. Note that the example frequencies given in the table would need to be adjusted to the site and sensor conditions and/or to manufacturers' recommendations

Activity	Example of frequency
Remote/on-site inspection of sensor readings	Daily or as frequently as possible
Document sensor status and environmental conditions, preferably including photographs	Every maintenance bout
Physical inspection of sensors, their configuration, and the measurement environment	Biweekly
Sensor cleaning	Biweekly or as needed
Vegetation, snow, and animal management (if applicable)	Biweekly or as needed during active season
Ensure site security	Biweekly
Physical inspection of infrastructure, including rust management	Monthly
Tighten nuts, bolts, and terminal connections	Quarterly
Service infrastructure and power systems; look for corrosion and solar degradation of physical components	Quarterly or as needed
Replace filters and/or desiccant packs, lubricate moving parts (sensors and infrastructure)	Semiannually or per manufacturers' recommendations
Field calibration/validation	Semiannually or per manufacturers' recommendations

checks [3.97]. Alerts are generated automatically for common problems (e.g., low battery, sensor error, out-of-range values) and sent via an email or text message to maintenance personnel. In the absence of automated checks, daily manual data inspection is relatively easy to accomplish if the project is small and data are communicated remotely in real time (or, more commonly, near real time). Otherwise, data inspection may have to wait until site visits are performed, but it should be done as frequently as possible. In addition to remote or on-site data inspection, routine physical inspection of sensors and infrastructure is vital to maintaining the safety of sensors and personnel and ensuring that the sensors are operating properly and measuring the intended environment. Many quality problems are difficult to detect from the data alone but are obvious upon physical inspection. For example, radiation sensors are often deployed on booms extending from a tower high above the ground. These are attractive perches for birds that consequently foul the sensors (Fig. 3.2). In such a scenario, sensor readings will likely remain within the expected range, but a routine site visit will quickly identify the problem. Without inspection, the data quality cannot be determined. Of course, it is also good practice to cross-compare data among replicate and related sensors in order to detect problems. However, replicate or related sensors are not always available, and routine physical inspection remains one of the best ways to assure data quality.

Regular preventative maintenance is required to keep infrastructure and sensors in good working order and ensure adequate measurement conditions. Dust, debris, and fouling must be removed; filters and desiccant packs must be changed; the appropriate sensor orientation and any specific operating conditions must

Fig. 3.2 Bird fouling on a radiation sensor at the NEON Lyndon B. Johnson National Grasslands site in Texas, USA (photo © Gary Henson, National Ecological Observatory Network, USA)

be maintained. Many atmospheric measurements are conducted in the natural environment, requiring regular animal and vegetation management to maintain measurement integrity. Frequent preventative maintenance allows many quality issues to be mitigated before they affect the data. For example, nuts, bolts, and terminal connections tend to unscrew or loosen over time due

to repeated (daily) thermal contraction and expansion cycles. Regularly tightening connections avoids data loss.

Maintenance bouts should periodically include instrument tests that can be performed on-site and may be a subset or modified versions of laboratory-based calibration and testing procedures (see Sect. 3.3.3). For example, tipping bucket rain gauges can be tested to ensure that the correct number of tips occur when a known amount of water is poured into the collector, and they can even be calibrated directly in the field. Tests may also include a roving reference to ensure calibration integrity between calibration intervals or to troubleshoot problematic readings. Field validation establishes a time point at which the readings were definitely valid (or invalid). Standardized thresholds for the maximum acceptable difference between the roving reference and the field-based sensor should be defined beforehand. In all cases, detailed records should be made of field-based testing and calibration, including pre- and post-calibration errors, to ensure that the information is correctly applied and evaluated during data processing.

Planning for Inspection and Maintenance

Every measurement program has unique maintenance needs that depend on the sensors or methods used and the environment in which the measurements are collected. It is important to identify the likeliest and greatest threats to quality and to then adjust maintenance schedules and activities to prioritize their mitigation. Thus, the frequency of preventative maintenance and the tasks involved will be program, environment, and sensor specific. For example, sensors deployed in a dusty environment will require more frequent cleaning and filter changes than those in a cold environment, where more important maintenance tasks may include clearing snow and ensuring that instrument heaters are operational. Table 3.13 provides a planning checklist for routine inspection and maintenance. The steps in this checklist should be periodically revisited as the measurement program progresses and experience and knowledge are gained.

Often, the desire for high preventative maintenance frequency must be balanced against the inherent limitations on the funds and personnel available. For example, preventative maintenance at the Oklahoma Mesonet (see Chap. 45) is limited to three site visits per year due to the costs incurred from salaries, travel, and vehicle use [3.98]. All of the materials required should be assembled and visits should be planned so that maintenance time and resources can be spent efficiently. Maintenance bouts should be evaluated afterward to clarify the amount of maintenance that can actually be

Table 3.13 Inspection and maintenance planning checklist

Activity	Notes
Create a maintenance schedule	Balance the desire for high maintenance frequency with available resources
Develop task lists and standard operating procedures (SOPs)	Prioritize the mitigation of common problems; develop SOPs for preventative and corrective maintenance
Create record templates/checklists	Preferably in electronic format
Assemble the materials required	Prepare a handy maintenance kit with commonly needed materials

accomplished in one visit. Standard operating procedures (SOPs) that provide step-by-step instructions for conducting routine preventative maintenance as well as common corrective maintenance tasks should be developed. Standardizing maintenance procedures through the application of SOPs helps to ensure that a consistent level of quality is achieved regardless of the time at which it was performed or the technician involved, and it increases efficiency because the workflow tasks are ingrained in the technician's memory. Where available, manufacturers' guidelines should be followed when creating SOPs. A training program should be developed for new technicians and procedures, and a mechanism permitting feedback on and adjustments to the SOPs based on practical experience should be incorporated.

It is also important to develop easy-to-use record templates or checklists (Fig. 3.3) that can serve as maintenance logs. Detailed logs of maintenance, measurement conditions, and other activities related to data collection are a valuable source of metadata, which can be used within the organization and can be provided to users to help them to interpret the corresponding data. Even if the same person sets up the measurement program, collects the data, maintains the sensors, and analyzes the data, it is very unlikely that they will remember all of the important details about the actions they performed and the conditions present on a particular day. This is particularly important given that the time delay between data collection and data analysis can be months or even years. Preferably electronic and machine-readable standardized logs that indicate the action performed and other relevant details facilitate data interpretation and analysis as well as improvements in long-term and system-wide patterns of sensor performance and data quality. Level shifts or other abrupt changes in data patterns are often associated with maintenance bouts in which a sensor was replaced with a freshly calibrated one or other maintenance (e.g., cleaning) was performed [3.99]. Maintenance logs tie

Table 3.14 Checks to complete during remote or on-site data inspection

Check	Notes and examples
Are data being recorded?	Check that all data streams are present and that the frequencies are correct
Are the sensor diagnostic codes reporting that the sensor is operating correctly?	Sensor manuals describe diagnostic codes and provide troubleshooting hints
Are the values plausible?	Also check ancillary data streams that are indicators of correct operation, such as flow rates for pump systems, the internal temperature and pressure of a sensor, the battery charge of a solar power system, etc.
Are values consistent between related sensors?	Identify sensors that should show correlated readings and ensure that they are consistent with each other

the change in the data to the (probable) cause. This knowledge can then be used to correct the data, exclude or flag erroneous data to prevent faulty interpretations, and/or make adjustments to the maintenance and calibration frequency and/or procedures in order to avoid subsequent data shifts. All of these actions improve quality. Even when the instruments are found to be in good order and are simply cleaned during a maintenance bout, the records containing this information verify that the maintenance frequency is adequate. Maintenance records indicating problem-free site and sensor conditions can be used to identify efficiencies, especially if the logs are standardized and digitized to facilitate analysis. Standardized logs can be implemented with simple spreadsheets or (mobile) applications that control the units and language used to describe activities, conditions, and problems. Fields for the date/time and technician should be included, and the serial numbers of the sensors should be recorded or verified, especially during sensor swaps. As measurement programs increase in size, complexity, and duration, it is becoming increasingly important for the metadata linked to inspection to be recorded in a digital, machine-readable format and hosted in a centrally accessible repository in near real time. This allows project operations to be efficiently coordinated and for quality-related metadata to remain organized and accessible to all project personnel, automated analyses, and ultimately to end users.

For large measurement programs, additional valuable tools include issue management and asset management systems. An issue management system is used to report, track, and record the resolution of problems. It facilitates communication and collaboration between the different roles in an organization and serves as a knowledge base for solving future problems (reducing downtime). Asset management systems track the locations and status of sensors and equipment, and are highly recommended for measurement programs with many sensors. The databases behind asset management systems can be leveraged during data processing to automatically apply the correct calibration coefficients or other required metadata for the date range and location of interest.

Performing Inspection and Maintenance

Prior to performing any maintenance, a remote or on-site inspection of data streams and sensor health should be carried out (Table 3.14). Remote data inspection prior to arriving on-site is highly preferable (especially if the travel time is significant), as it can be used to ensure that any materials needed for troubleshooting or repair are gathered ahead of time. This minimizes sensor downtime and reduces the need for follow-up visits. The automated generation of real-time graphs and statistics can speed up this task significantly, as can automated scripts that check important values and issue alerts for suspect data streams.

While performing any maintenance that may impact observations, it is important to either disconnect data collection, remove the data collected during the maintenance bout, or raise a quality control flag for the data that warns of potential measurement interference. Readings should be checked and recorded before and after cleaning/maintenance to quantify any change. The resulting data can be used to analyze the impact of cleaning/maintenance frequency on data quality, and potentially for data correction.

Digital photographs should be taken of the sensors, infrastructure, surroundings, and any identified concerns. Photos provide valuable context when interpreting measurements and quickly documenting the status of the sensors and measurement environment, especially across changes in personnel. A standardized, machine-readable file-naming system should be implemented to distinguish important characteristics such as location, date, time, and orientation or target view.

3.3.5 Data Processing and Management

Assuring the quality of atmospheric measurements does not stop at data collection. How the data are processed, stored, and made accessible to users are just as important as data collection. A data management plan specifies these details in advance to ensure that project resources are adequate to ensure data integrity, reproducibility, and access. In fact, most funding agencies (e.g., the US National Science Foundation since Jan-

Table 3.15 Characteristics of data standards

Type	Description	Examples
Variable notation	Reserved letters, words, or symbols that unambiguously denote measured quantities	<ul style="list-style-type: none"> • P = precipitation • Journal policies on notation (e.g., [3.100])
Naming convention	A set of rules for the character sequence that forms or combines identifiers	<ul style="list-style-type: none"> • ISO date format (YYYY-MM-DD) [3.101] • Filenames • Additional identifiers (e.g., position) appended to variable names
Unit of measurement	A definite magnitude of a quantity	<ul style="list-style-type: none"> • SI units • Imperial (English) units
File format	A standard way of encoding information for storage in digital media	<ul style="list-style-type: none"> • ASCII text, delimited (e.g., .csv, .txt) • Binary • XML • NetCDF, HDF
Coding systems	Shorthand descriptors of data values that are used to reduce data storage requirements	<ul style="list-style-type: none"> • Station names • Weather phenomena • Missing data designators • See the <i>WMO Manual on Codes</i> [3.18]

uary 2011 [3.102]) now require the inclusion of a data management plan in any research proposal. Regardless of whether it is required by a funding agency, a data management plan should be crafted during the planning process, and it should specify:

- The type(s) of data to be collected
- Products generated by the measurement program
- Standards to use for the format and content of the data and metadata
- How the data will be stored, processed, archived, and made accessible
- Policies for data reuse and redistribution.

The remainder of this section provides discussions of data and algorithm standards, metadata, processing considerations, and data archival from the perspective of data quality.

Data and Algorithm Standards

Data standards are the rules that must be followed when describing and recording data [3.103]. Standardizing the format and meaning of data ensures that the data will be interpreted consistently by users around the world. Table 3.15 provides common characteristics specified in data standards. There are organizations that devote considerable energy to crafting and promoting data standards, such as the WMO Information System [3.104] and DataOne [3.105].

Algorithm standards are accepted sequences of procedures that are implemented to statistically reduce data and derive data products from measured quantities. They also apply to the parameters and physical constants used within algorithms (see Chap. 5). Community standards for algorithms evolve as scientific

knowledge improves and new sensors that can measure the target quantity in different ways are developed. Many algorithms or portions of algorithms are well established, such as the basic sequence of mathematical operations that is applied to compute turbulent fluxes of mass and energy using eddy covariance instrumentation [3.106] (see Chap. 55). Others remain under active investigation, such as the use of particular corrections to account for instrument or computational bias. There are often multiple equally acceptable algorithms—all based on different theoretical approaches, applications, assumptions, or instrumentation—for a particular task. Each chapter in this handbook describes algorithm standards and areas of active investigation that are applicable to each measurement type. In all cases, it is important to justify and document algorithmic choices and to follow algorithm standards where available/applicable.

Metadata

Metadata is descriptive information about the collected data, including the origins of the data, the conditions and settings in which measurements were made, and any operations performed on the data. This information is invaluable, because data are practically useless without context. Scientific advances are made when studies are validated and repeated by others. This requires knowledge of the provenance of the data—a historical record of the data and their origins. The provenance of the data is provided as metadata. Metadata should provide traceability from the point of collection to the point of dissemination, and the information provided should be sufficiently detailed to enable the measurements to be reproduced or reprocessed. At a minimum, the metadata should describe:

Table 3.16 Metadata schemas

Name	Application	Description
ISO 19115	Geographic data	International standard for describing geographic information and services
ISO/IEC 11179	Data semantics and representation	International standard for describing data of any kind to promote a common understanding of data across organizations
DIF	Scientific datasets	Directory interchange format: a standard format for creating directory entries that describe scientific datasets
DOI	Resources on digital networks	Digital object identifier: a standard for registering and using persistent interoperable identifiers for resources (such as datasets) on digital networks

- Measurement methods, including sensor models and manufacturers
- Instrument settings and details of data logging
- Measurement location(s) and date ranges
- Calibration dates and methods
- Maintenance intervals and activities
- Significant events (and their dates) that may impact the data or its quality
- Processing steps and algorithm details
- The data format
- The version of the data and any software used to produce it.

Several schemas are available that can standardize metadata for specific applications so that the metadata can be easily shared and interpreted. These schemas specify the format and syntax of the metadata as well as the elements included and a controlled vocabulary for populating element values. Table 3.16 lists several metadata schemas that are relevant to atmospheric data.

Versioning and Testing

Scientific results are increasingly being obtained through the use of custom software tools created by scientists, even though scientists typically have no formal training in software engineering [3.107]. Software development practices are primarily learned by scientists from their peers or through self-study. As a result, scientific software and the results they yield vary greatly in quality [3.108, 109]. Two critical aspects of assuring the quality of scientific software and derived data products are versioning and testing. Implementing these methods can be a daunting task. Thankfully, several organizations provide resources that can help scientists to improve the quality of their scientific software. Examples include the Software Sustainability Institute [3.110], Software Carpentry [3.111], and the Kepler Project [3.112]. Furthermore, software can be made publicly available on, for instance, the Zenodo server [3.113] in order to make the application of the software clear to users.

Although the original data collected should never be modified, changes to derived data products and processing software are commonplace and must be

documented. This is accomplished through versioning. Versioning designates a unique identifier to progressive changes in data or processing code. An example of a versioning specification used for publically available scientific software is semantic versioning [3.114], which provides a set of rules for how version numbers should be assigned and incremented. Version numbers have the format

MAJOR . MINOR . PATCH,

where a MAJOR version makes non-backwards-compatible application programming interface (API) changes, a MINOR version adds functionality that is backwards compatible, and a PATCH makes backwards-compatible bug fixes. One of the main benefits of this specification is the automatic management of software dependencies. The version number explicitly identifies whether software that depends on another software package or is used by another software package will continue to work with subsequent versions. Versions of data and software should be annotated with *release notes* that provide a natural language summary of changes between the previous version and the current version. Both the version number and the release notes are important metadata and provide traceability between the data product and the software used to produce it.

Version control software facilitates the implementation of software versioning as well as collaboration in joint software development. Git and Apache Subversion (SVN) are two prominent open-source version control systems that are free, although there are many others. These systems regulate and track changes to code, documents, and other information so that a complete history is retained along with attribution. Learning about such systems is not a trivial task, but the benefits are well worth the investment.

A program of software testing should be implemented to routinely test code during development and upon progressive changes. Software testing verifies that the processing code and algorithms are fit for use, which typically involves finding errors and bugs during software execution. Testing assures the quality and integrity

Table 3.17 Testing methods commonly used in scientific software development

Testing method	Description	Examples of scientific applications
Unit testing	Verifies the functionality of a specific section or module of code tested independently of the rest of the software	[3.115–120]
System testing	Tests the entire integrated software system for the expected functionality and performance	[3.115, 117]
Regression testing	Compares previous output to new output to find unintended errors and bugs in existing software components after changes or additions have been made	[3.117, 119]

of the processing algorithms and derived data products, and minimizes the number of data and code versions that result from errors discovered after release. Table 3.17 lists three testing methods that are commonly used for scientific software [3.108].

Scientific software applications continue to increase in complexity and involve many developers and integrated computation modules. In response, software engineering philosophies that are developed specifically to address these complexities and improve software quality [3.121–123] are gaining traction in science. Two of the main philosophies are Agile development and DevOps. Agile software development [3.124] advocates continuous planning with short delivery cycles in which work is broken into small, demonstrable increments. Cross-functional teams work in close collaboration through daily communication, and working software is reviewed at the end of each short cycle (1–4 weeks). The advantages of this philosophy include adaptation to changing requirements and circumstances, minimizing risks through early and frequent feedback, and continuous improvement. DevOps is a related philosophy that builds off the Agile framework and focuses on collaboration between software developers and operators through the use of tools to continuously iterate the development, building, testing, packaging, and release of software and achieve a rapid turnaround [3.125, 126] (Fig. 3.4). DevOps promotes the recipe- or script-based generation of the computational environment, which then serves as explicit documentation of the dependencies and software components. This improves the accessibility, extensibility, and reproducibility of scientific software [3.122, 127]. The philosophies of Agile and DevOps rely on automated tools for continuous testing, integration, and versioning. Many of the example applications listed in Table 3.17 employ such tools within an Agile or DevOps framework.

Data Archival

Data archival is the preservation of data for future use. Most research funding agencies now require the inclusion of data archival in a proposal before they will award funding. Sufficient metadata must be included

**Fig. 3.4** The DevOps workflow

to ensure that the data are fully understood and can be used regardless of who produced the data [3.128]. The World Data Center (WDC) system is an international collective of data archive centers, each of which hosts data specific to a particular scientific discipline. Table 3.18 provides information on the WDCs that host atmospheric data products covered in this handbook. The International Science Council (ISC) World Data System [3.129] established in 2009 aims to transition from these existing standalone services to a common globally interoperable distributed data system that incorporates emerging technologies and new scientific data activities. Several of the WDCs mentioned in Table 3.18 are already members of the ISC World Data System.

3.3.6 Post-field Data Quality Control

The most important part of quality assurance is quality control (QC)—the use of operational techniques and activities to evaluate whether the quality requirements have been fulfilled. Applying these techniques leads to the quality-controlled dataset and corrective actions. Hence, QC should be performed in near real time, as this will minimize data loss by reducing the time taken to detect and solve problems [3.130]. This section provides an overview of post-field data QC approaches. Other aspects of QC are performed in-situ by the observer (Sect. 3.3.4) and as part of problem tracking and resolution (Sect. 3.4.1).

Data QC can be performed manually or automatically. Manual QC provides the foundations for data

Table 3.18 World Data Center archives of atmospheric measurements

Data archive	Summary of holdings	Web address, Accessed 10 Oct. 2021

QC [3.3, 130, 131]. For example, violations of requirements such as measurement obstructions or changes in the environment are often first identified by observers in the field. Similarly, atypical and suspicious data patterns are initially detected through post-field visual inspection by experts and data users. All QC procedures can be applied manually in principle, but the time required to do so is typically prohibitive. Additionally, while manual QC benefits from expert knowledge and human pattern recognition, it can suffer from human bias, operator-to-operator differences, and operator fatigue. Automated QC attempts to standardize the work done in manual QC and perform much of it programmatically. Parametric tests are generally used in automated QC, although adaptive tests based on machine learning are becoming increasingly popular [3.25]. The main advantages of automated QC are objectivity and repeatability, uniformity, practically unlimited test specifications, and efficient application to large datasets [3.1]. For this reason, automated QC has become the de facto standard for station networks (Sect. 3.4.1). Nevertheless, not all tests can be automated (examples of such tests include field observations and transfer standards); nor are automated tests infallible—they do not account for causation and multicollinearity, for instance. This underscores the importance of human supervision of automated QC procedures for ensuring that such procedures are effective at identifying suspicious data [3.130, 131].

In the following, QC tests for sample and observer data, time series data, and spatial data are summarized, followed by strategies for determining test thresholds. Sample and observer data collections are typically less uniform than instrument readings. For this reason, observer training is a particularly important element of any integrated quality management system [3.4]. QC of sample and observer data involves regular cross-validation, round robins, and blind tests, and focuses in particular on referential integrity, process quality, and data plausibility [3.132, 133]. Referential integrity refers to the absence of duplicate, orphaned, and/or *childless* records from datasets. Process quality corresponds to how much of the expected data and/or how many of the intended samples are obtained within a well-defined time interval. Data plausibility statements provide a qualitative assessment of whether data are *reasonable* or not. Standard operating procedures to examine the plausibility of the data should include a check that accepted abbreviations are used, an investigation of the consistency between variable statistics, pictorial representations, and diagrams, and simplified mathematical checks [3.1].

Table 3.19 provides an overview of characteristic tests of time series data as well as examples of their application. Initially, plausibility tests should be applied to constrain the data to electronically and atmospherically feasible values. Examples of such tests include those that examine the range of the recorded values,

Table 3.19 Overview of characteristic tests for time series data and examples of their application

Test	Purpose	Examples
Plausibility tests	Ensure only electronically and atmospherically feasible values are retained	Range test, sigma test, delta test, step test, null test, gap test [3.134]
Spike test	Outlier removal	Windowed tests [3.135, 136], filter-based tests [3.137, 138]
Higher-order moments of statistical distribution	Check the statistical plausibility of the values	Skewness, kurtosis [3.139, 140]
Application-specific tests	Check application-specific assumptions	Stationarity and mixing [3.141, 142], location bias [3.143]
Comparison with collocated/independent data	Check data consistency	Climatological and temporal checks [3.11], spatial consistency [3.131]

their variance structure, and step changes in those values [3.131, 134]. Once the data have been precleaned, spike tests can be used to remove any remaining outliers [3.135, 137]. It is important to note that several plausibility and spike tests require the time series to be equidistant, which can be achieved through regularization during preprocessing. The statistical plausibility of the values should then be evaluated further through the use of higher-level moments [3.139]. After that, application-specific tests should be performed to ensure that the methodological assumptions are fulfilled. Examples of such tests for eddy covariance measurements are stationarity and mixing tests [3.141, 142] as well as tests for location bias [3.143]. Lastly, the consistency of the data should be evaluated through comparison with collocated/independent data for instance. The *WMO Guide to Instruments and Methods of Observation* [3.11] provides detailed guidelines for climatological and temporal tests.

In principle, spatial data QC can utilize many of the time series tests listed in Table 3.19, some of which may require reduced dimensionality. Additional checks can also be made of the spatial coverage and correlation [3.144], cloud cover for optical measurements [3.145], and comparison of results among up/downscaled spatial resolutions and spatial aggregates [3.146].

Data quality control for remote sensing techniques such as radar and lidar is done as a post-field comparison with the results of weather prediction models. Two methods are applied. First, the vertical profile of the difference between the measured and modeled data and the root mean square (RMS) is determined. Such data can be averaged over periods of up to a month, and the resulting data products are available from several meteorological services. Bias and shifts in remote sensing data are clearly visible. Second, the forecast sensitivity to observation index (FSOI) [3.147]—a measure of how important the data are to the final model—is determined. If the data have little or even a negative influence on the model, the remote sensing systems should be checked.

All data QC relies on the use of thresholds—if a test result exceeds a predefined value, the corresponding observation is marked as suspicious. The challenge is then to determine suitable thresholds, because universal, absolute values do not necessarily apply across environments. One solution is to formulate either the test itself or the threshold value as a relationship that applies across a range of environmental conditions. Such an approach provides the consistency and uniformity gained from using a single relationship across a station network for example, and it also permits the necessary adaptivity to facilitate measurements across a variety of environments. One example of an adaptive test formulation with a universal, absolute threshold is that for integral turbulence characteristics (see Chap. 55; [3.141]). An example of an absolute test formulation with adaptive threshold values is the detection of the friction velocity change point in [3.142]. Alternatively, site-specific thresholds can be determined and tabulated automatically from sampling distributions of historic test results [3.134]. Gaussian statistics or robust statistics can be used for this purpose, as can a guided, semimanual approach combining sampling distributions with expert knowledge [3.148].

Post-field data QC aggregates over a test sequence, yielding a quality-controlled dataset and leading to corrective actions (Fig. 3.5). (i) Planning tests should be performed to determine whether site requirements are met. In addition, for sensor-based measurements, calibration, installation, and data acquisition requirements should be tested. For sample and observer data, the standard operating procedure should specify collection requirements. (ii) Next, in-situ tests should include sensor diagnostics and sample and observer data quality reports. (iii) During post-field tests, electronically and atmospherically feasible values, outliers, the statistical plausibility of the values, application-specific assumptions, and data consistency should be evaluated (Table 3.19). (iv) Both flat and hierarchical schemes can be used for quality aggregation. Flat schemes are often rank-based and provide a concise

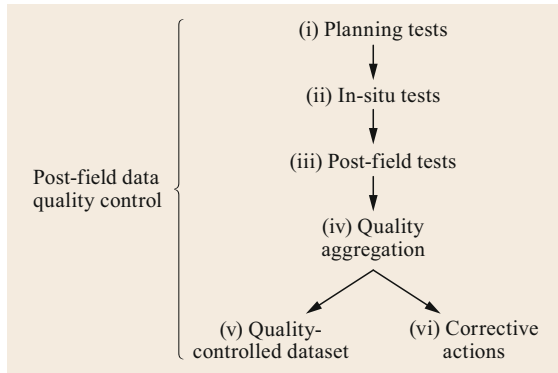

Fig. 3.5 Schematic of post-field data quality control: aggregating over a test sequence yields a quality-controlled dataset and leads to corrective actions (detailed explanations of items (i)–(vi) are given in Sect. 3.3.6)

depiction of overall data quality [3.149]. Because of their specificity to individual use cases, their extensibility (e.g., to different types of measurements and to sample and observer data) is typically limited. On the other hand, hierarchical aggregation schemes are by definition modularly extensible and permit the incorporation of visual data quality information for many data types [3.150]. They are most suitable for station networks because they allow quality information to be traced throughout the data generation chain. (v) Steps (i)–(iv) yield the quality-controlled dataset through the removal of suspect data points and/or by providing quality indications (*flags*) that should be documented as part of the metadata. (vi) If suspect quality conditions are identified, not only should the corresponding data points be marked but corrective actions should also be triggered. Two such corrective actions are issue management for tracking problems and how they are resolved (see Sects. 3.3.4 and 3.3.7) and data product adjustments for systematic deviations. Issue management informs the overall quality assurance workflow (Sect. 3.3) with the findings from post-field data quality control, and should include a formal communication process. Data product adjustments for systematic deviations are often use-case specific. For this reason, it is important to carefully evaluate (and document in the metadata) whether adjustments should be performed on the original data product or whether a subproduct should be created for this purpose. Examples include the conversion from station pressure to sea level pressure and from the measured wind speed to a reference height above ground, or the correction of measured precipitation for environmental effects [3.3].

3.3.7 Performance Monitoring

Performance monitoring facilitates continual improvement and evidence-based decision-making. Performance data should be collected and analyzed at every step in the data generation chain where this is possible/practical, as well as during other important processes carried out within the organization, to ensure that system requirements and quality objectives are being met. It is at this stage that we see the advantages of defining testable requirements during the planning stage and integrating monitoring into system design. The type of monitoring and the monitoring interval employed will depend on the requirement. Some monitored elements must be checked manually, while others can be evaluated continuously using automated methods.

It is also useful to periodically evaluate the requirements themselves. Because the planning stage is laborious, and requirements are sometimes constructed using incomplete information, some requirements may be found to be too lenient or too stringent to facilitate the objectives of the program. Continual improvement involves periodically evaluating the impact of the requirements on the final product or service and making adjustments where warranted to improve efficiency while maintaining quality. This allows valuable resources to be redirected toward areas in which quality is suffering.

Where possible, automated scripts and procedures should be used to monitor performance efficiently. Monitoring systems can be constructed in-house or using off-the-shelf analytics software. Reports should be generated, automatically if possible. These reports should be reviewed and used to identify and justify necessary improvements, and the reports and summaries should be distributed throughout the organization and the user community to improve awareness. A communication pathway to notify, track, and resolve problems identified by performance monitoring is required. A formal communication pathway is often included in off-the-shelf issue management systems.

Table 3.20 provides an overview of the performance monitoring that should be conducted for the various aspects of data generation. Monitoring site and instrument performance is a relatively straightforward task, as most of the requirements in this category are testable using the collected data. For visual observations and manual measurements, managers or dedicated staff should periodically audit sampling bouts to verify that measurement protocols are followed and performed consistently by different personnel.

Table 3.20 Performance monitoring conducted for various aspects of data generation

Performance category	Monitored elements	Examples of evaluations	Corrective actions
Site and instrument performance	<ul style="list-style-type: none"> • Measurement specifications • Instrument settings • Operational performance characteristics 	<ul style="list-style-type: none"> • Data frequency, resolution, coverage meets expectations • Appropriate instrument flow rates, internal temperature, etc. • Adequate power supply and system uptime (especially for remote installations) 	<ul style="list-style-type: none"> • Selection of a different sensor or manufacturer • Additional training • Addition or adjustment of resources
Calibration and testing performance	<ul style="list-style-type: none"> • Calibration frequency • Sensor accuracy and precision 	<ul style="list-style-type: none"> • Planned versus actual calibration frequency • Sensor degradation and lifetime • Calibration interval is adequate to keep the drift within the required range 	<ul style="list-style-type: none"> • Calibration interval adjustment • Sensor replacement • Additional training
Inspection and maintenance	<ul style="list-style-type: none"> • Maintenance frequency • Sensor and infrastructure conditions • Diagnostic data 	<ul style="list-style-type: none"> • Planned versus actual maintenance frequency • Maintenance interval is adequate to maintain proper operational status • Incident and failure analysis 	<ul style="list-style-type: none"> • Adjustment of maintenance frequency • Adjustment of maintenance tasks or equipment to reduce workload, increase efficiency, and prevent failure • Additional training
Data processing and management	<ul style="list-style-type: none"> • System resource load (memory, CPU, disk space) • Latency between raw data collection and end-user availability • Data products (including metadata) 	<ul style="list-style-type: none"> • Adequacy of system resources • Data product availability and completeness meet requirements 	<ul style="list-style-type: none"> • Addition or adjustment of system resources • Implementation of automated workflow and workload managers
Post-field data quality	<ul style="list-style-type: none"> • Quality flags • User satisfaction surveys 	<ul style="list-style-type: none"> • Proportion of data marked as suspect • Manual/expert evaluation of test thresholds [3.148, 151] • User satisfaction 	<ul style="list-style-type: none"> • Adjustment of data products (Sect. 3.3.6) • Adjustment of quality test thresholds • Addition or modification of quality tests • Adjustment of sensors and/or maintenance protocols

Calibration records and field testing data provide periodic status reports for sensor accuracy and precision, including calibration drift. Analyzing these statistics over time facilitates evidence-based adjustment of calibration intervals to improve efficiency and minimize the need to correct for calibration drift after it has occurred. Analyzing calibration records also helps to identify sensors that are degrading or do not meet expected performance requirements, and leads to a better understanding of sensor lifetimes.

Maintenance performance monitoring relies on accurate logs, and is aided in particular by the use of standardized and machine-readable language in maintenance records. Maintenance intervals should be adjusted according to the sensor conditions noted during inspection. If a sensor is found to be dirty or misaligned every maintenance bout, the return interval may need to be shortened or the infrastructure may need adjusting.

Alternatively, if sensors are found to be operating optimally over multiple maintenance bouts, a less frequent return interval could be justified, as this could free up resources for other areas in need of attention. Incident and failure analysis should be implemented by associating maintenance and calibration activities and other sensor diagnostic data with incident and failure statistics in order to find the root causes, which can then be corrected.

It is also relatively straightforward to monitor processing systems provided that system load data are retained. Workflow and workload managers are especially helpful for coordinating recurring processing tasks and computational system resources, respectively.

Real-time or near-real-time monitoring of data quality metrics should be performed to trigger corrective action when quality drops below acceptable levels. Issues identified at this stage can result from problems at

any point in the data generation chain, making traceability paramount. It is important to know not only that a data point was flagged but also why it was flagged, and to be able to trace the data point through all previous interactions to the point of origin. Finally, the user community should be leveraged to evaluate whether overall quality and usability goals are being met (customer focus). This should include sending out surveys and implementing mechanisms for user feedback.

3.3.8 Audits

An audit is a systematic, independent, and documented process for obtaining audit evidence (verifiable records or statements of fact) and evaluating it objectively to determine the extent to which the audit criteria (a set of policies, procedures, or requirements) are fulfilled [3.152]. An audit is therefore not an examination situation. It is a process in which the audited entity can expect great benefit in the sense of real added value—at least when the laboratory and the auditor actively support this idea. Typically, audits are distinguished according to the status of the auditor (the person with the competence to conduct an audit).

The procedures referred to as *first-party audits* are usually carried out by an internal auditor, who is usually (but not necessarily) a trained laboratory member. In this case, only one party—the laboratory itself—is involved. Nevertheless, internal audits can also be carried out by external auditors, but only on the condition that another certifier is utilized for a possible certification audit. *Second-party audits* are procedures involving two parties. Here, one organization is auditing another with which it has (or is going to have) a contract or agreement to supply goods or services. In this case, the auditor is often the quality management representative of a laboratory. Finally, *third-party audits* can only be carried out by external auditors (independent third parties) who are approved for the underlying regulatory framework. This is the scenario for certification audits. Certification is the procedure by which a third party gives written assurance that a product, process, or service conforms to specified requirements.

An audit that takes place in the course of certification according to an ISO standard is subject to the ISO audit criteria. The requirements for bodies that provide auditing and certification of management systems are laid down by ISO/IEC 17021 [3.153], and the guidelines for auditing management systems are given in ISO 19011 [3.154]. Detailed information on the requirements for bodies that certify products, processes, and services is provided by ISO/IEC 17065 [3.155]. Finally, the process of accreditation is also based on an international standard: ISO 17011 [3.156].

Certification and Accreditation

The difference between accreditation and certification is that accreditation is the validation and recognition of professional competence for certain tasks, while certification confirms that certain requirements are being met.

Accreditation is the independent evaluation of a conformity assessment body against recognized standards for carrying out specific activities [3.157, 158]. Such an evaluation is performed to ensure the impartiality and competence of the body. Applying national and international standards increases the confidence of governments, procurers, and consumers in the calibration and test results, inspection reports, and certifications provided. Accreditation bodies are established in many countries, and their main role is to ensure that conformity assessment bodies are subject to oversight by an authoritative body. Once they have been peer evaluated as competent, accreditation bodies sign regional and international arrangements to demonstrate their competence. These accreditation bodies then assess and accredit conformity assessment bodies to the relevant standards.

The Competence of Testing and Calibration Laboratories

The general requirements for the competence of testing and calibration laboratories include the establishment of a management system [3.81]. A management system is a set of interrelated or interacting elements of an organization that establish policies and objectives as well as processes to achieve those objectives [3.159]. A quality management system for a testing and calibration laboratory specifies procedures (e.g., standard operating procedures for instrument maintenance and calibration, the corresponding documentation, and training of personnel) to assure the quality of the test and/or the calibration results. Furthermore, the laboratory should periodically, and in accordance with a predetermined schedule and procedure, conduct internal audits of its activities to verify that its operations continue to comply with the requirements of the management system. The internal audit program should address all elements of the management system, including the testing and/or calibration activities. Such audits should be carried out by trained and qualified personnel who are independent of the activity to be audited. The laboratory should continually improve the effectiveness of its management system through auditing and by implementing corrective as well as preventive actions. The cycle for internal auditing, which is commonly known as the plan–do–check–act (PDCA) cycle, should normally be completed in one year.

ISO/IEC 17025 provides detailed technical requirements for assessing the correctness and reliability of testing and/or calibration laboratories. Table 3.21 gives an overview of factors used in such assessments.

Table 3.21 Factors for assessing the correctness and reliability of tests and/or calibrations performed by a laboratory according to ISO/IEC 17025

Assessment factor	Key criteria
Human factor	<ul style="list-style-type: none"> • Competence of personnel • Education, training, experience of personnel • Supervision of personnel
Accommodation and environmental conditions	<ul style="list-style-type: none"> • Energy sources • Lighting • Environmental conditions
Test and calibration methods and method validation	<ul style="list-style-type: none"> • Appropriate methods and procedures for the sampling, handling, transport, storage, and preparation of items to be tested and/or calibrated • Appropriate methods and procedures for estimating the measurement uncertainty as well as statistical techniques for analyzing test and/or calibration data • SOPs for the equipment • Up-to-date instructions, standards, manuals, and reference data • Deviations from test and calibration methods must be documented, technically justified, authorized, and accepted by the data user
Equipment	<ul style="list-style-type: none"> • Equipment and software used for testing, calibration, and sampling should be capable of achieving the required accuracy and should comply with relevant specifications • Calibration programs should be established for key quantities
Measurement traceability	<ul style="list-style-type: none"> • Equipment calibration should be designed and performed such that the traceability of calibrations and measurements to SI is ensured
Sampling	<ul style="list-style-type: none"> • A sampling plan and procedures for sampling should be established
Handling of test and calibration items	<ul style="list-style-type: none"> • Procedures for transportation, receipt, handling protection, and storage should be established • Quality control procedures for monitoring the validity of tests and calibrations

3.4 Application

This section presents real-world applications of QA/QC in atmospheric measurements. First, Sect. 3.4.1 gives an overview of QA/QC approaches for meteorological measurement networks. After that, Sect. 3.4.2 discusses common data problems, including their origins and mitigation.

3.4.1 QA/QC Systems of Meteorological Measurement Networks

QA/QC systems are commonplace in meteorological measurement networks ranging from regional to federal to global scales. Basic commonalities include the implementation of both manual and automated tests as well as the utilization of both in-situ testing and post-field testing at central data centers. QA/QC systems mainly differ in cross-site standardization and the connectivity of quality planning and in-situ tests, as well as in the method employed for a particular test.

In general, bottom-up network management structures allow for increased flexibility and optimization of QA/QC procedures at the site level. The quality program is implemented and managed individually by each site, allowing procedures to be tailored to site-specific concerns. However, this approach can mean

that communicating detailed quality information along the entire data generation chain becomes a challenge. Examples of such networks are the Aerosol Robotic Network (AERONET) [3.160], AmeriFlux [3.131, 161], FLUXNET [3.162], ICOS [3.26], the Cooperative Observer Program (COOP) of the National Weather Service (NWS) [3.163], and the WMO Global Observing System [3.1]. Conversely, top-down network management—as employed at the ARM [3.164], NEON [3.27], NOAA [3.165], NRCS [3.166], and USGS [3.167] station networks—enables end-to-end standardization across locations with a unified quality program (see Chaps. 63 and 64). Table 3.22 summarizes the unique characteristics of bottom-up and top-down quality management approaches.

As an example of a bottom-up management structure, AmeriFlux manages the network-level standardization, QA/QC, and distribution of data collected and submitted by network members (Fig. 3.6). AmeriFlux provides QA/QC resources to the network; however, training, preventative maintenance, sensor calibration, sensor health monitoring, data aggregation and site-level QC are performed by the network members according to their individual requirements. Problem tracking and resolution transcends the member level;

Table 3.22 Unique characteristics of bottom-up and top-down quality management approaches

Characteristic	Bottom-up quality management	Top-down quality management
Standardization	<ul style="list-style-type: none"> • Flexibility and optimization of QA/QC procedures at the site level • Site-specific choice of method for a particular test 	<ul style="list-style-type: none"> • End-to-end standardization across sites within a unified quality program • Adaption to site level through functional relationships
Quality planning and implementation	<ul style="list-style-type: none"> • Network provides QA/QC resources • Network members manage and implement individual quality programs 	<ul style="list-style-type: none"> • End-to-end science operations management framework • Standardized quality program across sites
Problem tracking and resolution	<ul style="list-style-type: none"> • Semiautomated reporting of quality information along the data generation chain • Iterative data quality assessment between network level and network members 	<ul style="list-style-type: none"> • Electronic sensor health reporting by field personnel and automated software • Direct integration with supervised alert, issue management, and data flagging systems

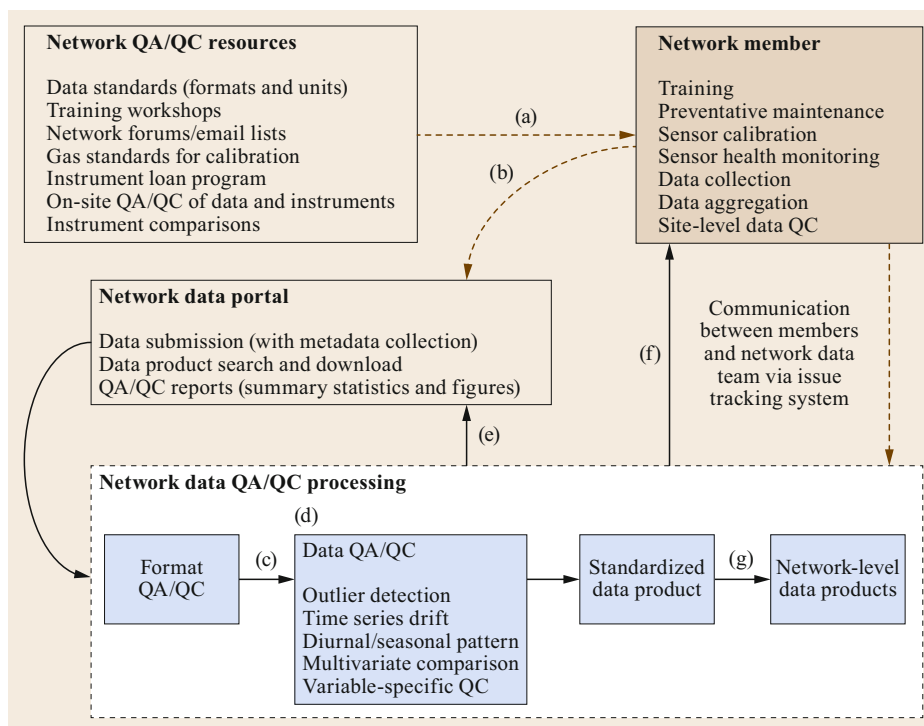

Fig. 3.6 Within the AmeriFlux data QA/QC framework, network members (a) voluntarily access network QA/QC resources and (b) upload data to the network in AmeriFlux standard data format. In the AmeriFlux data QA/QC processing pipeline, (c) automated format corrections are applied if necessary before (d) data QA/QC is applied to the entire data record. Results of QA/QC assessments are communicated to network members through (e) online summaries and reports as well as (f) via emails prompted by an issue tracking system. (g) Network-level data products are produced by applying standardized methods and QA/QC (e.g., data filtering and gap filling). Figure © Danielle Svehla Christianson, Lawrence Berkeley National Laboratory, with the support of the Office of Science, Office of Biological and Environmental Research of the US Department of Energy under contract no. DE-AC02-05CH11231 as part of the AmeriFlux Management Project

this requires semiautomated data processing at the network level that accommodates iterative solutions. Upon data submission, online results from data format checks are immediately available for network member review and correction. The data format assessment also in-

cludes an automated attempt to fix minor format errors. Next, automated network-level QA/QC is implemented to identify potentially erroneous data and communicate them online to members via easy-to-interpret graphics. Lastly, an issue-tracking system facilitates a problem

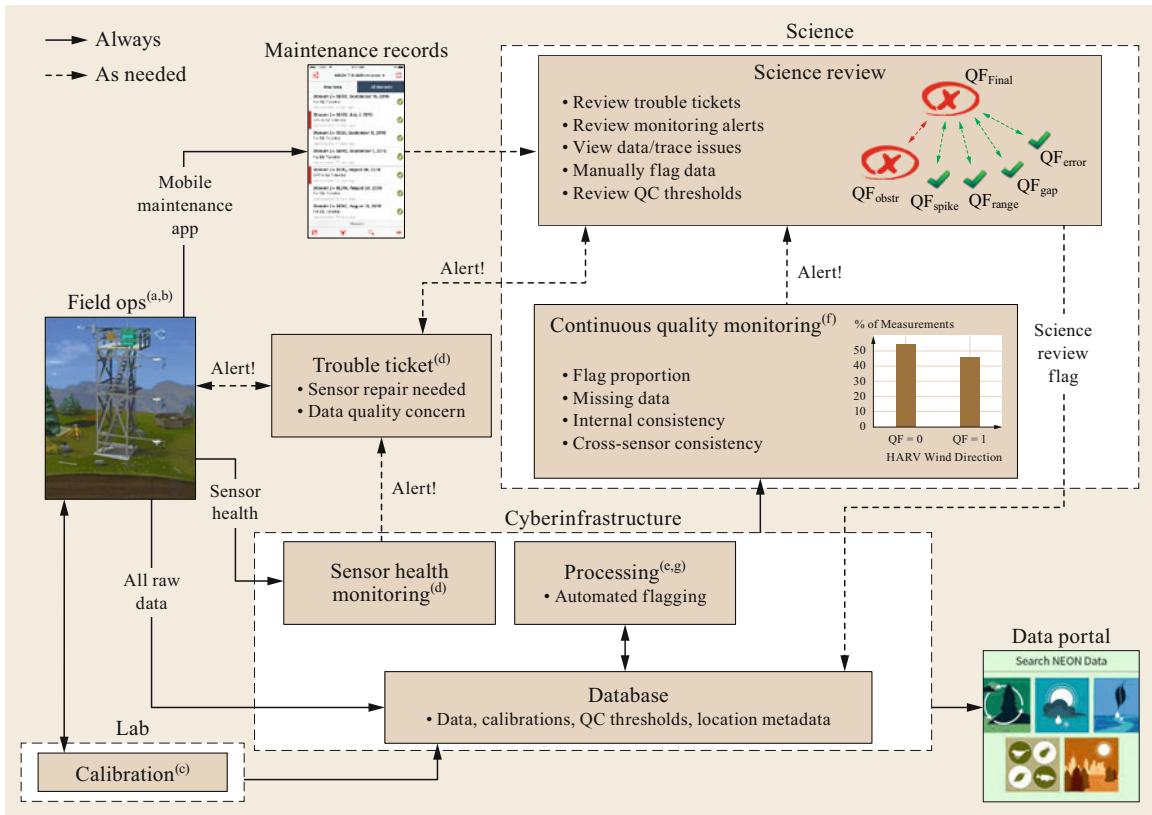

Fig. 3.7 The NEON science operations management framework for terrestrial instrument system quality assurance and quality control. The major components include (a) training, (b) preventive maintenance of sensors, (c) sensor calibration, (d) sensor health status monitoring, incident tracking and resolution, (e) data processing, (f) continuous data quality monitoring, and (g) data revising. Figure © National Ecological Observatory Network, Battelle

tracking and resolution process between the network-level data processing team and its individual members [3.168].

As an example of a top-down management structure, NEON's tight design integration and standardization enables an integrated, end-to-end science operations management framework for the QA/QC of terrestrial instrument systems (Fig. 3.7). This begins with sensor maintenance training, which is provided via curriculum lesson plans and hands-on demonstrations by qualified NEON staff. Preventative maintenance is then performed biweekly according to procedures developed by the NEON science and engineering departments; maintenance findings are recorded electronically on a mobile application. Most sensors are rotated out of the field at specified intervals and passed to the NEON Calibration and Validation Laboratory, where calibration is performed to traceable national and international standards (e.g., ITS-90 for temperature measurements). Sensor health is monitored by field personnel as well as re-

motely through software that interfaces directly with the data acquisition system at each site. An automated alert system monitors sensor health in near-real-time and issues are tracked in NEON's issue management system upon actual or impending sensor malfunction. Automated quality tests are applied during processing and are used to remove and/or flag suspect values. Continuous quality monitoring identifies potentially erroneous data patterns. Trouble tickets and data marked as suspect undergo scientific review for problem tracking and resolution and to ultimately accept or reject the data.

3.4.2 Common Data Problems

This section presents visual examples of common data problems, along with their causes and methods of avoiding or correcting them. In all cases, detecting these problems requires routine inspection of data and sensors, performance monitoring, and post-field quality control tests.

Fig. 3.8 Gaps in barometric pressure measurement due to datalogger failures (after [3.169])

Data Dropouts

Data dropouts (periods of missing data) are pervasive in atmospheric measurements since there are numerous potential causes of measurement failure, including a sensor malfunction, power failure, or the failure of a critical system component. Figure 3.8 presents an example of data loss due to datalogger failures. Data dropouts can also manifest as periods of constant sensor output, also known as a *stuck sensor*, which can be detected during postprocessing by testing for unusually low variation in data values [3.22].

Although it is difficult to completely eliminate data gaps, they can be minimized by performing near-real-time monitoring of data streams and regular preventative maintenance of sensors and infrastructure, as well as by planning for redundancy (of the power supply, instrumentation, and other critical system components). Correcting for data dropouts involves filling the data gap with suitable alternative measurements, such as those from a nearby or redundant sensor or values imputed from a statistical model. Thankfully, there are many general and measurement-specific gap-filling methods that can be applied to address this problem [3.171–175]. Any gap-filled values in the final dataset must be clearly marked.

Quantification Error

One type of error that is relevant to older instruments, mainly those in which the signal is measured in only a small part of the measuring range, is the quantification or digitization error [3.176]. Older instruments digitized the measuring range to only 12 bit, leading to $2^{12} = 4096$ possible values, whereas newer instruments digitize the measuring range to at least 16 bit ($2^{16} = 65\,536$). The use of 12 bit digitization can be problematic for temperature measurements and gas analyzers, where the measuring range is large and the range of the measured signal is small [3.139, 170], as demonstrated by the example shown in Fig. 3.9.

The deviation of the digitized data from the original data may be significant if the signal variation is small. Simulation tests should be made with an instrument with better resolution, to determine the impact of digitization on the intended data use and under which conditions the error may be significant. This is generally only an issue with some older datasets. Old instruments or data acquisition systems should therefore be replaced or the measurement range of the instrument should be reduced to the possible range of the signal.

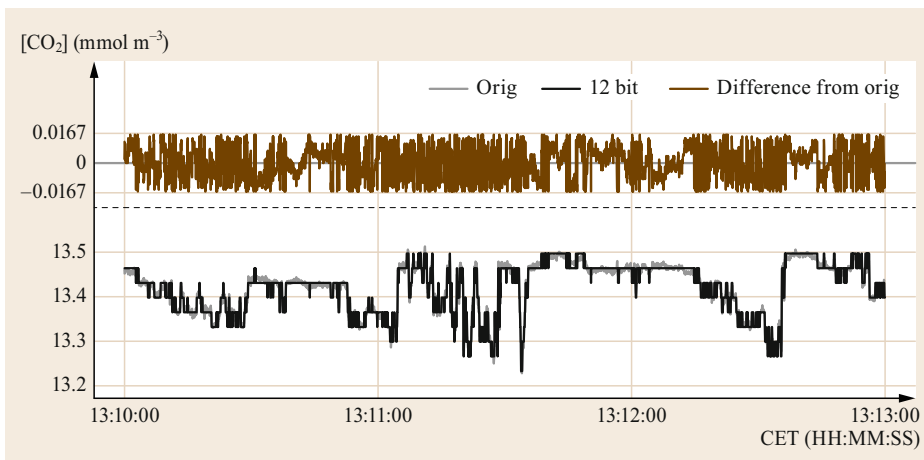

Fig. 3.9 Carbon dioxide concentration data obtained with a LI-COR 7500 instrument (orig) and then reduced to 12 bit resolution (after [3.170], © the authors)

Fig. 3.10 Spikes of no known cause recorded in 1 Hz measurements of wind speed (v -vector component) by a Gill Wind Observer II 2-D sonic anemometer. The raw sensor data were obtained from the National Ecological Observatory Network

Fig. 3.11 Level shift in global radiation measurements (outlined in red) caused by changes in sensor calibration (after [3.169])

Spikes

Spikes are sudden and excessive changes in data value. An example is shown in Fig. 3.10. Spikes can seem to occur at random with no known cause, although a poor electrical connection or momentary measurement interference from the environment is often to blame. Regular preventative maintenance and inspection of sensors and infrastructure can reduce the likelihood of spikes, as can implementing methods to deter known sources of interference from the environment, such as birds or insects. If deterrents are used, it is important to evaluate their impact on the measurements to ensure that measurement integrity is not compromised. Even so, spikes are hard to avoid, so they are commonly removed during postprocessing using despiking algorithms or other QC tests (see Sect. 3.3.6).

Data Shifts

One problem commonly encountered in long-term measurement programs is an abrupt change in the data value level. An example of this is provided in Fig. 3.11. Data shifts are usually due to changes in calibration or instrumentation that occur when sensors are recalibrated or replaced due to damage or wear. Data shifts can also arise from an unplanned sensor movement leading to measurements of a different target, or after the sensor has been cleaned following a long interval of missed maintenance when the sensor was fouled. Data shifts can also occur more gradually over time rather than abruptly, as in the case of calibration drift. This common problem highlights the benefits of regular preventative maintenance and cleaning of sensors as well as adhering to a calibration frequency that minimizes drift.

Fig. 3.12 Approximately one month of diel average global radiation measurements at Twitchell Island, CA, showing improper time zone application as well as shadowing of the sensor by site infrastructure in the afternoon. Error bars indicate standard deviations

Data shifts can be corrected for using statistical methods such as the pairwise comparison approach [3.99], by back-correcting for calibration drift [3.177], or by developing a regression based on a period of overlapping measurements for planned changes in instrumentation. In all cases, it is important to ascertain the reason for the data shift, as some may result from true changes in the measured quantity, such as the impact of a change in surface albedo on net radiation measurements [3.131]. For this reason, it is imperative to collect complete, accurate, and accessible records of sensor maintenance and calibration.

Time Shifts

An error that is common but easily corrected for in atmospheric measurements is a time shift, where data patterns are shifted in time with respect to theoretical expectations. It is easy to visualize this error by plotting radiation measurements according to time of day in local standard time, as in Fig. 3.12, where the long-term diel average should show a peak near noon. This error results from the incorrect application of a time zone offset during processing or incorrect time settings in internal instrument computers or dataloggers. However, it is more difficult to detect this error in measurements that do not have an expected temporal pattern. In this case, real-time checks of measurement timestamps should be performed during data collection. To correct for this error, the offset between the actual and the intended time zone of measurement must be determined and applied. Avoiding this error is a simple matter of

ensuring that the time settings of instrumentation and processing algorithms are correct.

Infrastructure Interference

Infrastructure interference is a pernicious error in atmospheric measurements; avoidance of this error requires careful site planning and configuration, and detection requires close scrutiny of the data. It is crucial to avoid this error as it is often impossible to correct for afterwards. Figure 3.12 shows an example of infrastructure interference with global radiation measurements in which the sensor was shadowed by infrastructure in the afternoon. This type of error can only be corrected for if the magnitude, pattern, and timing of the effect can be determined. Otherwise, the affected data must be removed or flagged as suspect. Better yet, proper site planning and configuration (see Sect. 3.3.2) should involve performing data collection tests before the experiment to ensure that measurements will not be significantly impacted by the measurement platform itself.

Internal/Theoretical Inconsistency

Data processing code and algorithms are often written specifically for the measurement program at hand and by the scientists who are also busy running the project. As such, errors in algorithms are common but can be identified and corrected through a program of software testing (see Sect. 3.3.5) that includes checks for violations of internal (including unit) consistency and mathematical and atmospheric theory. An example of this type of error is shown in Fig. 3.13, where a coding error

Fig. 3.13 Erroneously calculated wind direction data based on measured vector components of a 2-D sonic anemometer; note that some of the data values are beyond the theoretical limit of 360° N (after [3.169])

Fig. 3.14 Change in the relationship between two ground-based PAR sensors after sensor 2 was covered in dirt by fire-prevention activities on 18 January (after [3.169])

led to calculated wind directions outside the expected range of 0–360° N. Thankfully, processing errors can be mitigated by correcting the algorithm and reprocessing the data. The versions of the code and data should be incremented if the errors are discovered after release. Because computational errors of this nature are quite common, it is vitally important to retain the raw data in a form that is as close as possible to the original sensor readings.

Field Interference

Field interference includes a broad array of data problems resulting from the random interference of the natural environment or human factors with a measure-

ment. An example of this type of error is shown in Fig. 3.14, where fire prevention activities covered an understory photosynthetically active radiation (PAR) sensor with dirt, causing attenuation of the measurements. Such errors can be caused by any number of factors, are difficult to avoid, and are often difficult to detect with automated quality tests, making it imperative to frequently and diligently inspect the measurement conditions, as this can reduce the amount of data affected by field interference. Thorough maintenance records and photographs of the conditions at the site can help to narrow the time interval that must be considered when determining the data to remove or flag as suspect.

3.5 Future Developments

Some likely future developments in the area of QA/QC for atmospheric measurements include progress through the introduction of new technologies as well as the resolution of theoretical challenges associated with scientific software testing.

3.5.1 Machine Learning

The potential widespread use of machine learning techniques such as neural networks, Bayesian networks, random forests, and support vector machines in QA/QC of atmospheric and environmental sensor measurements shows considerable promise. These techniques are powerful because they require very little prior knowledge of sensor measurement theoretical basis and characteristics, and they do not require assumptions about functional relationships. Instead, they empirically identify patterns and dependencies based on the data alone. Examples of machine learning approaches in QA/QC include the quality control of sensor data, error analysis, and calibration. These are briefly described below.

Two main machine learning approaches have been used for the automated detection of outliers and/or the assignment of quality flags in environmental sensor data. The first approach constructs a model for the expected output and defines measurements that fall outside prediction bounds to be errors [3.178, 179]. The second approach directly classifies trustworthy or suspect data [3.180]. However, both approaches involve some challenges during application. Attention must be paid to the settings of the algorithm to avoid overfitting and thus maintain sufficient generalization for the algorithm to work well with new, previously unobserved data. In addition, data must be split into training and testing sets. For the latter approach (direct classification), this requires prior knowledge (and enough examples) of data anomalies to be successful. Though it is already recognized to be a powerful tool for quality control, addressing these issues would likely expand the use of machine learning in data QC.

Another area where machine learning is improving the quality of atmospheric measurements is in the quantification of systematic errors. Even when machine learning is not used, post-field corrections are commonly performed for some systematic effects, such as a height correction for measured wind speeds or a correction for wind-induced errors in data from precipitation gauges [3.3]. Treatments of other systematic observation effects are often more limited, such as linking measurements that represent different source areas with each other (Sect. 3.3.2) or with models [3.181].

Therefore, as an example, eddy-covariance flux observations are subject to transient location bias [3.41, 182] on the order of tens of percent—an order of magnitude larger than typical sensor errors. Here, machine learning concepts can improve our understanding of measurement techniques and environmental processes by extracting new information from joining observations. For example, through explicit point-to-area projections over heterogeneous surfaces, the environmental response function (ERF [3.60]) technique can combine the spatial coverages of different measurements into a joint target area. At the technical level, ERF complements existing mathematical descriptions of better-understood processes such as sensor functioning and atmospheric dispersion with observations from towers, aircraft, and satellites about less-understood phenomena. It then mines the joint information content, yielding the most complete solution possible based on the processes and observations provided.

Finally, one published example has shown the power of machine learning to resolve difficult calibration situations. The use of random forests has improved calibration models for low-cost air quality monitoring instrumentation, which was previously difficult to achieve using traditional laboratory procedures [3.65].

3.5.2 The Oracle Problem in Scientific Software Testing

A challenge specific to scientific software development is the lack of an *oracle* for testing. An oracle is an expected result that is used to verify the output of the software. Determining an oracle for scientific software is often difficult or impossible in applications in which (i) the software is developed in order to find as-yet unknown answers, (ii) the software tests a scientific theory and involves complex computations, (iii) uncertainty in the model prevents it from yielding a single answer for a specific set of inputs, (iv) the software is exploratory in nature, or (v) complex floating point operations are involved, making it difficult to select oracle tolerances [3.108]. As reviewed in [3.108], several studies have proposed methods to address this challenge, including the development of a *pseudo oracle*, which is independently developed software that produces the same output. Other techniques include comparing the output with analytically derived or experimental results, the use of simplified data, and the application of expert knowledge. However, more research is needed to thoroughly evaluate the efficacies of these and other emerging methods at detecting software errors without an oracle [3.108].

Cove Sturtevant

National Ecological Observatory Network (NEON); Battelle
Boulder, USA
csturtevant@battelleecology.org

Cove Sturtevant is a biometeorologist and data scientist at the National Ecological Observatory Network. His research activities focus on understanding the biophysical controls of greenhouse gas exchange between ecosystems and the atmosphere in relation to environmental change and land management. He holds a Master's degree in aerospace engineering from the University of Colorado and a PhD in ecology from San Diego State University.

Stefan Metzger

National Ecological Observatory Network (NEON); Battelle
Boulder, USA
smetzger@battelleecology.org

Stefan Metzger is a micrometeorologist and the Surface-Atmosphere Exchange Science Lead at the National Ecological Observatory Network, the largest single-provider flux tower network globally. His research activities include novel measurement techniques, community-extensible data processing, and data-mining approaches that reduce observational bias in boundary layer meteorology. He holds a Master's degree in geocology and a PhD in micrometeorology from the University of Bayreuth, Germany.

**Sascha Nehr**

European University of Applied Sciences
Brühl, Germany
s.nehr@eufh.de

Sascha Nehr is a chemical engineer and environmental management expert. His fields of expertise include process hazard analyses and quantitative risk assessment in the chemical industry as well as dispersion modelling of airborne pollutants. He holds a diploma in chemical engineering from the Niederrhein University of Applied Sciences and a PhD in physical chemistry from the University of Wuppertal. Since 2019, he is professor for management and engineering at the European University of Applied Sciences.

**Thomas Foken**

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

4. Standardization in Atmospheric Measurements

Simon Jäckel, Annette Borowiak, Brian Stacey

Standardization is a means to establish order. Standards are a collection of practical knowledge. They allow an action to be repeated, are a prerequisite for the application of uniform criteria, and prevent distortion of competition. Standards also facilitate trade and provide governments with technical support. Standards developing organizations provide a forum for cooperation and consensus utilizing expert knowledge. This chapter first broadly considers the principles, procedures, and products of standardization and then focuses on standardization in the field of atmospheric measurements including its benefits and possible shortcomings.

4.1	Background and Definitions	93
4.2	History	94
4.3	Principles and Procedures	96
4.3.1	Common Principles	96

4.5	Future Developments	103
4.6	Further Reading	104
	References	104

Standardization is a regulatory instrument of the technical world. It is an integral part of the existing economic, social, and legal system. Standards are an easily accessible source of information about the state of the art.

They represent an important tool in worldwide technology transfer and fulfill a number of protective functions, such as in environmental protection.

4.1 Background and Definitions

The need for standardization is undisputed. A smooth exchange of goods and knowledge presupposes uniformity of basic standards. Standardization usually produces significant positive economic effects [4.1]. Refer to, for example, [4.2–11] for details on the positive impact on the economy and other key drivers behind standards development.

The term standardization has a broad definition. It ranges from government regulatory activities (legal standards) and public standardization to industry standardization (from consortia and alliances to standardization within enterprises). Figure 4.1 depicts the different kinds of standards developed worldwide on

a company, industry, national, or international scale. This chapter deals exclusively with public standardization and its products, namely voluntary consensus standards and specifications, which are the results of work performed by standards development organizations (SDOs). Due to their negligible importance to standardization in atmospheric measurements, this chapter does not address company or de facto standards. State regulations, like parliamentary legitimated laws, are also not discussed.

As there is some confusion regarding the definitions of many of the terms used in this chapter, the following basic definitions are provided [4.12]:

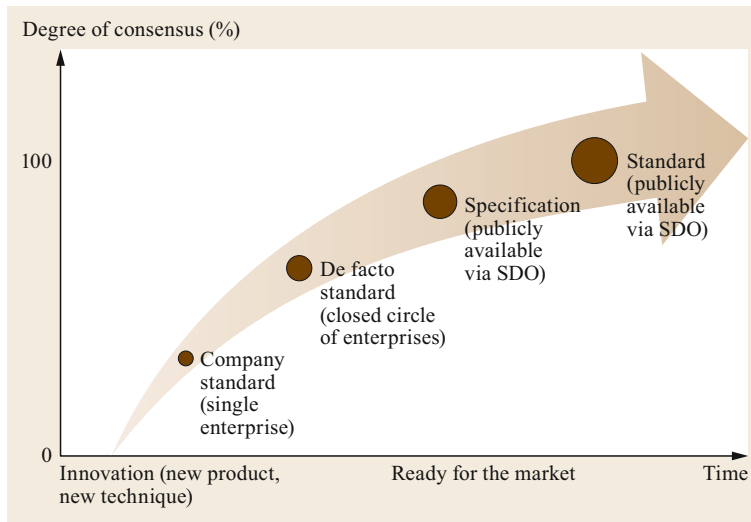

Fig. 4.1 Different kinds of standards shown with their respective degree of consensus and elaboration time

- *Standardization* is the activity of establishing, with regard to actual or potential problems, provisions for common and repeated use, aimed at the achievement of the optimum degree of order in a given context. In particular, the activity consists of the processes of formulating, issuing, and implementing standards.
 - *International standardization* is standardization in which involvement is open to relevant bodies from all countries.
 - *Regional standardization* is standardization in which involvement is open to relevant bodies from countries from only one geographical, political, or economic area of the world.
 - *National standardization* is standardization that takes place at the level of one specific country.
 - A *standard* is a document, established by consensus and approved by a recognized body, that provides, for common and repeated use, rules, guidelines or characteristics for activities or their results, aimed at the achievement of the optimum degree of order in a given context.
 - *Consensus* is a general agreement, characterized by the absence of sustained opposition to substantial issues by any important part of the concerned inter-
- ests and by a process that involves seeking to take into account the views of all parties concerned and to reconcile any conflicting arguments.
- *State of the art* is a developed stage of technical capability at a given time as regards products, processes, and services, based on the relevant consolidated findings of science, technology, and experience.

Standards are accessible to everyone. Whoever uses standards must ensure correct application in their individual case. Standards are not the one source of knowledge for technically correct behavior. They cannot cover all possible individual cases where further or restrictive measures may be required. Nevertheless, they are a benchmark for perfect technical performance. It should also be kept in mind that standards can only take account of the state of the art prevailing at the time of the respective publication. By applying standards, no one can escape responsibility for their own actions. The use of standards is generally voluntary. It is only when standards become the content of contracts or when the legislator refers to and requires compliance with them that standards become binding. SDOs do not have a mandate to require compliance.

4.2 History

The development of standards began in parallel with the need to measure [4.13]. Honest weighing became a factor in trade around 3000 BCE. At the same time, standardized building blocks made the construction of

the Egyptian pyramids possible [4.2]. As early as 2650 BCE, a closed system of measurement was established by *Shulgi*, King of Ur. Around 2000 BCE this system of measurement became the global standard. When in-

dustrialization began about 200 years ago, the need to unify the newly created objects was growing intensely. Several notable standards that were agreed upon by the nineteenth century were the metric system in Europe and the railway track gauge and screw threads in the English-speaking parts of the world [4.13]. Although a technical object can perform its task flawlessly in many variations, its industrial production is only meaningful if it can be used interchangeably in a particular design at different locations. The invention of the interchangeable system of manufacture by *Eli Whitney* (1765–1825) laid the foundation for mass production and higher productivity by means of simplification, modularization, and unification and made him the father of well-organized in-company standardization in the USA [4.14].

With the advent of a widespread division of labor and of industrial technology, the need to organize became more intense by the beginning of the twentieth century. It became more and more commanding to create special bodies, the national standards committees, which brought together the entire standardization work in their country. The organizational structure of standardization as we know it today started in 1901 with the founding of the British Standardization Institute (BSI), the first national standardization organization in the world [4.14, 15]. The initiative was copied by many countries in subsequent years and most followed the centralized UK model [4.15]. More information on the national standards bodies founded roughly in the first quarter of the twentieth century can be found in [4.14, 16].

The first international standardization organization was the International Electrotechnical Commission (IEC), which was founded in 1906 and focused on electronic and electrical engineering [4.14]. Another cooperation of the national standards committees led to the foundation of the International Federation of the National Standardization Associations (ISA) in 1928, which laid the foundation for international cooperation with a focus on mechanical engineering [4.14]. Participation in the ISA's activities was mainly limited to continental European countries [4.17]. The ISA distributed the detailed work to its members. In the technical committees, the management was transferred to the standards committee of a country. As a result, the general secretariat was able to limit itself to general matters, the preparation of meetings, and the monitoring of work in progress. The ISA did not publish international standards, but only recommendations in the form of ISA bulletins, which the individual national standards committees could use to shape their national standards. Whether members took these recommen-

dations into account or not was therefore completely voluntary. A total of 32 bulletins were issued and their content has been reflected in many national standards. Some have been introduced so extensively that they can rightfully be called world standards. These include, for example, the reference temperature of 20 °C and the standards for motion pictures (standard film 35 mm and substandard film 16 mm) [4.14]. In 1939, with the beginning of the Second World War, the work of the ISA came to a standstill, and the intergovernmental work remained restricted to direct trade between individual countries.

In 1944 the United Nations Standards Coordinating Committee (UNSCC) was set up with a time-limited statute [4.14, 17]. In 1946, after the end of the Second World War, the UNSCC, together with ISA representatives, met in London and decided to join forces and set up a new organization for international standardization [4.14, 17]. In 1947 the International Organization for Standardization (ISO) was launched, which was open to all countries of the world that wished to collaborate; each had equal duties and equal rights [4.17]. The ISO adopted most of the statutes and rules of procedure from the ISA, including the distribution of work to its members, and produced a list of the first 67 technical committees, roughly two thirds of which were previous ISA committees [4.17]. Thus, it is not surprising that a focus of the first years of the ISO's work was mechanical engineering. The initial strategy of the ISO was to evolve international standards from those already evolved nationally, and then to reimplement them nationally [4.17]. The IEC affiliated with ISO in 1947 and separated again in 1976 [4.14].

The impossibility of finding successful outcomes in certain technical areas mixed with many issues being relevant only to certain regions in the world and the urgent need for the elimination of trade barriers led to the foundation of regional standardization organizations, the first being the European Committee for Standardization (CEN) in 1961. Many others followed in the 1960s to 1990s, representing all major regions in the world (see Tab. 4.1).

On a national level, standardization in the field of atmospheric measurements started quite early, for example, in Germany with the foundation of the VDI (Association of German Engineers) Commission on Air Pollution Prevention in 1957, but on the international level it took almost 40 years longer before the first committee on standardization of atmospheric measurements – ISO/TC 146 Air quality – was founded in 1994. Standardization of meteorological measurements followed in 1994 with the foundation of ISO/TC 146/SC 5 Meteorology.

4.3 Principles and Procedures

This section states the common principles most SDOs share, shows how standards are developed, and defines the role of SDOs at the different levels (national/regional/international) of standardization.

4.3.1 Common Principles

Most SDOs share several features, regardless of their national, regional, or international level. The key features are clearly defined by a set of rules of procedure, which commonly include:

- Every stakeholder is allowed to submit a new work item proposal for the development of a standard and/or to have fair, reasonable, nondiscriminatory (FRAND), voluntary, and open access to contribute and share their expertise. Broad participation and transparency ensure acceptance of the resulting standard both in the public and in the market due to resulting social equity and fairness to all parties involved. The responsibility for the outcome of the standardization process lies with the world at large as it is assumed that everyone's interests have been taken into account when the standard was set [4.10].
- The solutions recorded in standards are not based on majority, but based on mutual consent, making the standard the outcome of a negotiation process between different interests. What is technically possible and economically feasible is negotiated.

In addition to the rules of procedure, some more general requirements are considered:

- Standardization works within the framework that scientific knowledge dictates and thus reflects the state of the art.
- The benefit of the general public stands above the advantage of individuals. Therefore, standards have to include societal goals.
- The aim of standardization is a world free of trade barriers. Therefore, the standardization work of international and regional SDOs takes precedence over purely national standardization.
- Standardization is not static but rather dynamic. Standards must be checked on a regular basis to see if they are still state of the art and thus have a typical review cycle of five years.

4.3.2 The Role of the Standards Developing Organization (SDO)

SDOs are usually nonprofit organizations [4.14] representing a formal and structured way of achieving consensus on things that impact millions of people around the globe and are service providers for standardization. Under their project lead, business experts, researchers, public authorities and consumers work together to develop standards. The SDOs ensure a smooth development process, to which the working group experts contribute their knowledge. Project managers plan and document meetings and ensure that the directives are followed. The resulting standards are published by the SDOs. In addition to that, SDOs:

- Coordinate national, regional, and international projects and ensure that all regulations are adhered to, which assures the acceptance of standards
- Provide the information as a public good and usually cover their administrative costs through membership fees and publication sales
- Inform the public about all standardization activities, starting with new work items and ending with the published standards
- Promote the application of standards

The SDOs usually use backwards planning to make sure that projects are published on time. The publication date of the finished standard, which is fixed at the very beginning of any project, is seen as the project end date. The time needed to reach each milestone along the path to a successfully published standard, for example, developing the content of the standard, consensus building, and public inquiry, is then calculated.

4.3.3 Levels of Standardization

This section defines the different levels of standardization, using the most important SDOs as examples.

National

The reason national standards differ between nations often lies in different ideas about what needs to be standardized. Unique national standards are most frequently prepared in conjunction with unique national legislation [4.18].

The majority of countries followed the BSI and decided to have a centralized approach on standardization [4.15]. In contrast, several countries followed a decentralized and thus sector-specific approach. The most diverse standardization system in the world is found in the USA [4.14], where at least 600 nongovernmental SDOs [4.19, 20] exist. Germany, with around 150 nongovernmental SDOs [4.21], is somewhere between diverse and centralized. More information on the different models can be found in [4.22].

Regional

There are several regional SDOs distributed all over the world (Table 4.1). Most of them deal with matters other than atmospheric measurements, such as promoting trade by the harmonization of standards in the given region.

One regional SDO – the European Committee for Standardization (CEN) – is engaged in air quality and atmospheric measurements. The CEN was founded in 1961 and is a nonprofit organization under Belgian law. Members of the CEN are the EU and European Free Trade Association (EFTA) countries. The main goal of European standardization can be defined as the unification of all standards that apply within Europe, which means harmonization of national standards. This results in the elaboration and subsequent adoption of European standards by all national SDOs that are members of CEN. In the CEN, each country is represented by one national SDO and the voting process is based on population of the countries of the CEN members, giving each member a specific weight in the voting process (cf. the ISO, where 1 nation = 1 vote).

Table 4.1 Examples of regional SDOs (after [4.14])

Region	Name
Association of Southeast Asian Nations (ASEAN)	ASEAN Consultative Committee on Standards and Quality (ACCSQ)
Arabian Peninsula and North Africa	Arab Industrial Development & Mining Organization (AIDMO)
Africa	African Organization for Standardization (ARSO)
Europe	European Committee for Standardization (CEN)
Europe	European Committee for Electrotechnical Standardization (CENELEC)
America	Pan American Standards Commission (COPANT)
Asia, Europe	Euro-Asian Council for Standardization, Metrology and Certification (EASC)
Europe	European Telecommunications Standards Institute (ETSI)
Pacific Rim	Pacific Area Standards Congress (PASC)

There are two specialties in the European standardization system worth mentioning. One is the process of *forced harmonization*, which means that every European standard must be adopted unchanged and by all members while at the same time withdrawing all conflicting national standards. The CEN standards are mandatory for EU member states. This is because of the strong political commitment to unification [4.20] and according to [4.23] is an effective harmonization tool in the case of markets with a stable variety, but at the same time is the more expensive solution because of, for example, the necessity of passing legislative procedures, the requirement of enforcement activities for sanctions, and distribution cost. The second specialty in the European standardization system is the use of standards as *policy tools*. The legal framework as set out in [4.24] allows the European Commission to request the CEN to draft a European standard by means of a standardization mandate leading to a so-called harmonized standard for the application of EU legislation. By using standardization as a policy tool [4.24], EU directives only need to determine the politically desired level of, for example, air quality. These basic requirements are then substantiated by harmonized European standards. This process is called the new approach [4.25] and has existed since 1985 [4.26]. Standards become regulatory when referenced in EU directives and they then cease to be voluntary. If additional scientific research is needed to be able to elaborate a harmonized European standard, the European Commission is willing to fund, for example, validation campaigns of measurement devices.

The technical work is performed in technical committees (CEN/TCs), consisting of representatives of the national SDOs. TCs usually build up several working groups to work on the different topics at hand. The CEN is comprised of more than 300 TCs with around 1500 working groups. Full-time secretaries who are paid by the individual national SDOs supervise all committees and working groups. The administrative work is therefore handled by the CEN member organizations. The national SDOs usually set up national mirror committees, which are open to all stakeholders on the national level. These national mirror committees build a national position on the standardization topic, which will then be represented on the international level.

When talking about atmospheric measurements, only CEN/TC 264 Air quality seems to be of relevance. Created in October 1990 as proposed by the VDI Commission on Air Pollution Prevention, CEN/TC 264 is responsible for elaborating standards of methods for air quality characterization of emissions, ambient air, indoor air, gases in and from the ground, and deposition, in particular measurement methods for air pollutants [4.27].

International

The International Organization for Standardization (ISO) is an independent, nongovernmental organization and a global network of national standards bodies from 162 countries. The ISO has published more than 22 000 ISO standards covering almost all aspects of technology and business; it is the world's largest developer and publisher of international standards.

The main goal of international standardization can be defined as the facilitation of the global exchange of goods and services and the promotion of international cooperation in technical, economic, scientific, and intellectual fields. The ISO standardizes topics of global relevance, which means that the international standard can be used as broadly as possible by affected industries and other stakeholders in markets around the world.

The ISO sets voluntary standards (cf. the CEN). According to [4.23], voluntary standards do not necessarily implement harmonization. Difficulties in the necessary harmonization may arise if the existing variety is stable and not everyone is willing to accept the voluntary standard. Following this assumption, voluntary standards are best suited for markets with unstable variety.

The technical work is performed in the same way as the CEN. There is a difference in the voting procedure; at the ISO level, each country has one vote.

In 1971, the ISO created its first technical committee in the environmental field: ISO/TC 146 Air quality. The objectives of standardization are related to tools for air quality characterization of emissions, workspace air, ambient air, and indoor air, in particular measurement methods for air pollutants (particles, gases, odors, and micro-organisms), meteorological parameters, measurement planning, procedures for quality assurance/quality control (QA/QC), and methods for

the evaluation of results including the determination of uncertainty [4.28].

The ISO committee ISO/TC 146/SC 5 Meteorology is responsible for the elaboration of meteorological ISO standards. The working group members of ISO/TC 146/SC 5 develop, build, sell, and use equipment covered by the standard practices, guides, and testing methods. Everybody involved in meteorological measurements should be aware of these ISO standards and consider using them as reference tools when procuring equipment and operating measurement programs. The focus of ISO/TC 146/SC 5 Meteorology lies on remote sensing techniques, such as lidar and radar, that are applied around the globe.

The World Meteorological Organization (WMO) has been accepted by the ISO as an international standardizing body. The WMO and the ISO also agreed on the development of common ISO–WMO standards. Thus, many standardization projects in the interest of WMO are developed in close cooperation, for example, through the WMO's Technical Commission on Instruments and Methods of Observation (CIMO). The CIMO's mission is to give advice on good practices for meteorological measurements and observations and to provide best practices, procedures, and basic capabilities of instruments and systems. The CIMO assists national meteorological and hydrological services, as well as other operators of observing systems, in the preparation of their manuals and procedures for meeting their specific measurement and observation needs by giving recommendations on the general features most common to various configurations of a given instrument or measurement system, thus enabling wide areas for further development [4.29]. More information on the WMO can be found in Chap. 1 Atmospheric Measurements, Sect. 1.2.3 Establishment of the World's Meteorological Organizations.

4.4 Standardization in the Field of Atmospheric Measurements

This section provides an in-depth overview of several atmospheric measurement topics, gives exemplary success stories clearly showing the effect standardization can have, and lists benefits and possible shortcomings.

4.4.1 General

Atmospheric measurements must be performed in a uniform way to make them comparable. Standards in this field produce methods for identifying instruments that facilitate comparable measurements, support users

both in planning and in execution of measurements, and are needed by manufacturers to communicate the performance characteristics of their equipment. Standards in atmospheric measurements usually provide:

- Terms and definitions
- Necessary basics
- Descriptions and/or definitions of the measurement targets (e.g., PM_{10})
- Specifications for measurements and measurement planning

- Methods of determining equipment characteristics and proper application of measuring equipment including:
 - Calibration
 - Monitoring
 - Maintenance
- Requirements for the selection and preparation of a measurement site
- Requirements on data collection, processing, and evaluation

Some standards go beyond that, specifying competencies and staff training, and discussing life-cycle management (ISO 19926-1 [4.30]).

Standards in atmospheric measurements are developed by those who apply them later. They give clear guidance to all stakeholders performing measurements and help prevent information asymmetry by providing all necessary information and sets of minimum admissible attributes, for example, for the measurement devices themselves. Standards even facilitate fair competition between vendors responding to calls for tender.

There are several different political, regulatory, and administrative approaches in the different countries of the world that tackle environmental problems and measurement tasks at various levels, such as local, regional, and national [4.31]. Standards provide a basis and a framework for consistent decision making at any level.

4.4.2 Measurement of Atmospheric Pollutants

The measurement of atmospheric pollutants is a major part of technical air pollution control and an important instrument for monitoring compliance with mandated values. Ambient air quality limit or target values set by administrations are used to report the frequency with which pollutant concentrations exceed harmful levels. It is advisable to link these values with measurement methods, sampling site locations, and the frequency of sampling, quality control measures, and statistical data analysis as defined by voluntary consensus standards [4.32]. Area-wide measurements according to measurement standards enable administrations to monitor the success of actions and abatement strategies.

Particulate matter has been monitored for a long time, mainly with filter-based techniques. The optical properties of particulate matter, such as black smoke, have also been monitored since the early 1960s. National legislation to protect human health has been in place since the London and Ruhr area smog episodes. As air pollution is a transboundary problem that does not respect national borders, European countries put

a directive in place with limit values and requirements to monitor suspended particulates in air in 1980. Driven mainly by health impact assessments, European legislation has been revised and reviewed on many occasions since 1980. Comparable air quality data and results from harmonized measurement methods are of major importance for the implementation and evaluation of legislation. Standard measurement methods are referred to in EU legislation to guarantee comparable assessments of air quality based on common criteria and the required accuracy of monitoring techniques. The development of European standards by the CEN goes hand in hand with advancing EU legislation.

For example, the air quality within the European Union has to be assessed by common methods within defined data quality objectives. Institutes and networks performing measurements need to employ standard measurement techniques and procedures. The CEN develops these harmonized methodologies, allowing for comparable assessment of air quality.

Exemplary Success Story: Gaseous Air Pollution

The measurement of NO_x, CO, O₃, and SO₂ in ambient air is important for monitoring air pollution levels, finding connections to health effects, and understanding the success or failure of emission abatement strategies. The measurement of these gases has been undertaken since the 1950s using a variety of different techniques, ranging from wet chemistry and diffusive samplers through to automatic point source analyzers and optical spectroscopic techniques.

Measurement of Gaseous Air Pollution. Up until 2005, the measurement of gases in the European Union followed a series of ISO standard methods, for example:

- ISO 7996 Nitrogen Dioxide [4.33]
- ISO 10498 Sulphur Dioxide [4.34]
- ISO 13964 Ozone [4.35]

In 2005, the CEN published a series of standard methods for gases:

- EN 14211 Oxides of Nitrogen [4.36]
- EN 14212 Sulphur Dioxide [4.37]
- EN 14625 Ozone [4.38]
- EN 14626 Carbon Monoxide [4.39]
- EN 14662 Parts 1–5 Benzene [4.40–44]

For the first time, these standards set out procedures for type testing in laboratory and field tests, ongoing quality control, and calculating measurement uncertainties at prescribed limit values. Like any standard, they are subject to review every five years and are updated to re-

flect improvements in test protocols and understanding of key components of the measurement processes.

The current EC Directive on Air Quality and Cleaner Air for Europe (2008/50/EC) [4.45] and its subsequent amendment (EU/2015/1480) [4.46] specify that measurements and associated measurement uncertainties shall be reported in accordance with procedures set out in the standard methods described above, using analyzers that have been tested using the standard methods. The data produced by the analyzers must conform to data quality objectives set out in 2008/50/EC; users are provided with all the details necessary to perform these assessments themselves.

Estimating the Benefits from Standardization of this Success Story. In 1992, the European Commission, led by the European Reference Laboratory for Air Pollution (ERLAP), initiated a campaign to evaluate the level of harmonization of air pollution measurements throughout Europe. It brought together national reference laboratories (NRLs) from many member states to demonstrate that they could measure standard test gas mixtures accurately, precisely, and comparably to each other. The benefit of such a test was manifold. It allowed testing under controlled conditions at a range of different concentrations for a large number of laboratories simultaneously. Each NRL was required to measure the test mixtures and report the concentration and measurement uncertainties, thus allowing for a comparison.

The ERLAP devised a series of test criteria to determine the performance of each NRL for the concentrations measured. These first tests, termed inter-comparison exercises (IEs), were conducted in Essen in May 1992 (under a WHO collaboration) and in Ispra in April 1993, and showed that 66.7% of the measurements reported by NRLs fell within the definition of *good* results (defined as a Z-score within ± 2).

These results identified that measurements across Europe in 1992/1993 were lacking in accuracy and harmonization. The ERLAP, working with the NRLs, began a campaign to promote best practice and develop standard procedures across all member states. Their work began by comparing calibration standards and certified reference materials and then moved to devising operating protocols for the calibration and testing of gas analyzers. The ERLAP and the WHO continued to develop and improve the testing program, which has continued since 1992 and has been arranged annually since at least 2007.

The activities of the key NRLs and ERLAP participants led to the formation of the Air Quality National Reference Laboratory Network (AQUILA) and participation in CEN working groups to develop formal standard methods for each of the pollutants. After many

years of preparation, this culminated in the publication of NO_x, CO, SO₂, and O₃ standard methods in 2005. These standards were adopted into the 2008/50/EC directive, and provided, for the first time, a legislative framework to evaluate analyzer performance and fitness for purpose. Users were able to specify that analyzers met a minimum performance standard, which ensured they fulfilled the required data quality objectives.

These tests, coupled with detailed procedures for operation, calibration, and ongoing quality assurance and quality control has had a dramatic effect on the performance of NRLs in subsequent IEs. Since 2005, over 95% of measurements in IEs have been *good*. In fact, with the exception of one exercise, 98% of IE measurements have been *good* since 2011.

This demonstrates that the work done since 1992 to devise and implement standard methods has had an overwhelmingly beneficial effect on the quality of measurements made by NRLs throughout Europe.

Exemplary Success Story: Measurement of Particulate Air Pollution

Particles can be characterized by a variety of parameters, such as mass concentration, number concentration, size, size distribution, surface area, radiation absorption, light reflection, or chemical analysis of compounds. The most common methods also reflected in the field of standardization are related to mass concentration measurement, particle size, and the chemical analysis of organic and metallic compounds of particulate matter. Several national SDOs, like the American Society for Testing and Materials (ASTM International), but also the international and regional SDOs ISO and CEN, have published standard methods to characterize air quality.

Whereas for gaseous pollutants several standard methods describe the preparation of standard atmospheres for calibration purposes (ISO 6141 through ISO 6145 on preparation of gas mixtures [4.47–51]), there is no such international equivalent for the preparation of particulate atmospheres. Most methods to characterize particulate air pollution are so-called methods by convention, but not necessarily traceable to SI units.

Physical Characterization. The most commonly used method to determine particulate pollution is a filter-based method, where ambient air enters a size-selective sampling head and further flows through a filter, where particles are deposited. A commonly used setup is described, for example, in the European standard EN 12341 [4.52], which is at the same time considered as the reference method for sampling and determination of the particulate matter (PM) size fractions PM_{2.5} and PM₁₀ with regard to EU air policy.

There are certain limitations to this reference method and it might not be the method with the highest metrological quality. This type of set up has been used for many years throughout the EU and the method has proven its suitability for practical use in air pollution monitoring.

Another important standard method developed by the CEN is EN 16450 [4.53], which describes performance requirements and procedures for automated PM measuring systems. Following this standard method, continuously working monitors are considered, for instance the oscillating microbalance mass sensor method, the beta-ray attenuation method, or optical methods such as light scattering.

While the traditional filter-(mass-)based ambient particle measurement biases the metric towards the measurement of large particles, the measurement of particle numbers shifts this emphasis to ultrafine particles (or nanoparticles). The European technical specification CEN/TS 16976 [4.54] describes the use and requirements for condensation particle counters. The ISO has published standards on the measurement of, for example, black smoke, asbestos fibers, and tire and road wear.

Chemical Characterization. The chemical characterization of particulate matter focuses on the content of ions, metals, polycyclic aromatic hydrocarbons, and elemental carbon/organic carbon in the PM matrix. There have been four EN standard methods developed by the CEN (EN 16913 [4.55], EN 16909 [4.56], EN 15549 [4.57], and EN 14902 [4.58]) to satisfy the measurement needs required by EU air policy. Further EN standard methods deal with the deposition of metals and polycyclic aromatic hydrocarbons. At the ISO level, standards exist to determine lead (ISO 9855 [4.59]) and polycyclic hydrocarbons (ISO 16362 [4.60]) in the particulate phase.

Estimating the Benefits from Standardization of this Success Story. At the European level, two international interlaboratory comparisons of standard reference methods were carried out between 2004 and 2006 [4.61] and then with a different setup in 2015 [4.62]. During the early exercises, a mobile laboratory visited monitoring stations and NRLs in 18 member states. The measurement results that did not match the data quality objectives of the EU directive [4.45] were 7.1% for PM₁₀ and 23.8% for PM_{2.5}. During the 2015 exercise, where 22 national samplers for each PM fraction were sampling at the same location, only 1.3% of the results did not match the data quality objective for PM₁₀ and 0.4% for PM_{2.5}. This strong improvement in performance can be partially explained by the different exercise setups, but certainly

the progress and wide acceptance of standard methods for PM_{2.5} and PM₁₀ have led to better quality and more harmonization in measurements as well.

4.4.3 Meteorological Measurements

Meteorological measurements are performed for a variety of reasons. They are used, for example, for the preparation of weather analyses, forecasts, severe weather warnings, the study of climate, local weather-dependent operations such as aerodrome flying operations, hydrology and agricultural meteorology, and for research in meteorology and climatology [4.29]. Usually the following meteorological parameters are measured and are thus the subject matter of standards [4.63]:

- Wind speed and direction
- Air temperature
- Air humidity
- Atmospheric pressure
- Precipitation
- Solar and terrestrial radiation
- Atmospheric turbidity

Meteorological measurements of these parameters are needed for measurement tasks such as [4.63]:

- General weather forecast and climatological applications
- Hydrological applications (e.g., flood warning, evaporation, water balance, and structural measurements)
- Wind and solar energy
- Source identification of air pollutants (e.g., depicting pollutant roses)
- Assessment of ambient air quality measurements (e.g., trend analyses, comparisons with other investigation areas, planning of industrial plants, and urban and regional planning)
- Input data for model calculations concerning the dispersion and transport of air pollutants (e.g., impact forecast, clean-air and precautionary plans, and smog situations) as well as for radiation protection, major accidents, disaster prevention, and environmental impact assessment
- Determination and assessment of the local climate and of its effects on humans, animals, plants, and materials (e.g., urban development planning, traffic planning, plant location planning, water management planning, urban climate, and climate of health resorts)
- Agrometeorological and forest meteorological assessment of plant populations and soils (e.g., vegetation management, pest control, and yield predictions)

Exemplary Success Story: Lidar Systems and the Definition of Conventional Range

Lidar systems have become commercially available instruments from many different vendors around the globe with applications like wind energy site assessment, wind turbine verification and control, operational meteorology, airport hazard detection, and air quality monitoring [4.64]. An ever-increasing number of commercial lidar systems is available and applied in lidar networks [4.65]. Accurate metrology is key to valuable measurements and every vendor promises, of course, that their respective lidar system shows good traceability of parameters and optimal performance. The international standards series ISO 28902 [4.66, 67], available since 2012 and with occasional additions, reduces the user's uncertainty about lidar characteristics and is thus increasing demand and confidence in the technology in the market. The series of standards is a good example of how standards eliminate information asymmetry between users and manufacturers, for example, by sharing scientific basics, methods that could be applied, and typical system characteristics.

Before standards were developed, lidar system owners simply had to trust the vendors and their research or had to perform their own research programs, for example, to compare different systems. Some vendors tended to report the maximum range of their lidar systems rather than the range that can be applied in practice. The maximum range varies significantly in different atmospheric conditions, such as precipitation, visibility, turbulence, aerosol types, and content [4.64]. The selection of the winning bid from a call for tender, for example, was quite difficult prior to standardization. One major step towards solving the issue of comparing different lidar systems is the so-called conventional range. Every vendor is asked to report this range, which is calculated for certain atmospheric characteristics, thus ensuring a uniform communication of this very important lidar characteristic. In addition, the standards series ISO 28902 gives companies a strategic tool to differentiate their products, creating market segmentation and a softening of competition.

4.4.4 Benefits and Shortcomings of Standardization in Atmospheric Measurements

The key benefits of standards in atmospheric measurements are:

- Prevention of information asymmetry: Standards reduce the degree of information asymmetry between the producer and consumer [4.68]. One group of stakeholders – public agencies – is particularly interested in the outcome of the standardization process,

as they are in need of the firm establishment of agreed-upon methods and the guidance to implement them. Public agencies have the most power to affect the future but at the same time have the least information about what would be the best choice. [4.69] therefore calls government agencies *blind giants*.

- Fair competition between vendors: Standards ensure better compliance with the rules of competition, by uncovering competitors who fail to comply.
- Reduction of transaction costs: Costs between producers and consumers can be reduced by reducing the amount of time consumers spend searching for the proper measurement device they want to buy, which generally also avoids customer dissatisfaction [4.10].
- Division of labor between administration and SDO: The job of public agencies is to set targets and timetables as well as to ensure the necessary implementation. The detailed technical work is performed by the SDOs. This way, administrations admit they cannot claim the required competence in this significant area of technical civilization. Administrations and SDOs are not in competition with each other, but there is a reciprocal relationship. The SDO provides the administration with expertise and a balance of interests, while the administration may offer the application of the law and other resources.
- Ensuring comparable data on air quality: The standardization of measurement and calibration methods combined with quality assurance programs, systems, and procedures has led to the availability of robust and comparable data on air quality in Europe, which are an important basis for impact assessments. By establishing international measurement standards, a worldwide comparability of air quality data will be reached.
- Boost economic growth: Standardization connects scientific developments with industry and regulations and is therefore an important boost to economic growth. The application of standard methods leads to confidence in measurements and a wide acceptance of results and data.
- Simplification of technical transfer: From the viewpoint of a developing country, international standards provide the transfer of technology from technological leaders to the developing country and thus lessen the dependence on imports [4.4, 70].

There are also several possible shortcomings:

- Amount of time for the development of a standard: Although SDOs are working on speeding up the standardization process, it takes an average of five

years to publish a standard [4.4, 71]. Although this is faster than it was in the 1970s and 1980s, when the average time to produce an international standard was seven years [4.17, 71], and in the 1990s when the average elapsed time was six years [4.71], it is still a frequent criticism of SDOs developing standards in sectors where technological advance is rapid [4.3]. The number of products with short product life cycles is growing, so there is an increasing need for standardization to be fast, although this may conflict with the wish to involve all interested parties in the process and to have consensus-based decision making [4.72]. To meet the demands of enterprises wanting faster results and sped up standardization processes in general, SDOs have launched faster standardization services like speci-

fications or reports for which participation and full consensus of all stakeholders are not necessarily required [4.71]. In addition, improved project management has proven to be successful at reducing delays.

- Underrepresentation of SME: Two groups of stakeholders, namely users and experts coming from small- and medium-sized enterprises, are often underrepresented due to their unwillingness or inability to spend substantial time and travel money for developing a standard. This is a known shortcoming not only in the field of atmospheric measurements [4.6]. Smaller enterprises usually get involved at the inquiry stage, where they can contribute by commenting on the draft standard.

4.5 Future Developments

Looking at standardization in general, we are still at a point in history where numerous countries are developing national standards at considerable cost. Then begins international standardization, which tries to use the knowledge of national standards and integrate it into a common international standard. As discussed earlier, standardization has the objective of harmonizing national standards to, for example, reduce trade barriers. If successful, the standards have to be changed in many countries. Industry, administration, users, etc., are faced with the need for conversion. The authors regard it as nonsensical to set national standards apart from each other at the national level, and then, when finished and introduced, laboriously coordinate them. It must therefore be achieved that international standardization starts as early as possible. It is a question of workload and efficiency. Why do the same work a dozen times in different countries when it can be done internationally for everyone? Cost also plays a role. Large countries can carry out extensive standardization work with numerous expert committees, whereas small or developing countries mostly cannot. This is because the sales of standard sheets do not cover the printing costs, and therefore cannot finance the standardization work.

Looking at standardization in the field of atmospheric measurements, numerous future challenges await us, including the following:

- Numerous studies have shown that air pollution is hazardous to human health (e.g., [4.21, 73, 74]) and was responsible for approximately seven million premature deaths worldwide in 2012 [4.75]. To tackle this problem, an important step would be the worldwide adoption of the WHO air quality guide-

lines into national air quality policies together with the prompt involvement of governments in monitoring their success [4.76, 77]. This is where standardization of atmospheric measurements comes into play. As of 2017, ISO/TC 146 Air quality offers a catalogue of 167 published and 34 international standards under preparation ranging from emission reduction and measurement of air pollutants to meteorological measurements [4.28]. The WHO guideline values and international standards are ready to be implemented and possibly updated, as the needs of developing countries may not yet be fully incorporated. The potential for the future is immense. It was shown that 27% of all countries in the world do not have any air quality policy and that there is no information available from an additional 12%, meaning that the implementation of air quality policy is pending in up to 39% of all countries in the world [4.77].

- In the case of changed preferences, or when new technologies become available inducing new questions, standards are introduced to find suitable solutions [4.78]. Recently, it has become more demanding to standardize atmospheric dispersion modeling approaches because citizens are interested in knowing the current air quality at their place of residence, which could be far away from a measurement station. Atmospheric dispersion modelling is used to establish a relationship between pollutant emissions and air quality in a given area [4.31]. Measurement data is needed to validate the model's output. In several regions of the world, for example in Europe, dispersion modelling is used as a tool to support air quality assessment, planning, and forecasting.

Simon Jäckel

VDI e.V. – The Association of German Engineers
Düsseldorf, Germany
jaeckel@vdi.de

Simon Jäckel is a DIN-certified standardization expert and project manager at the VDI Society on Automotive and Traffic Systems Technology and secretary of the VDI Society Technologies of Life Sciences. After his study of applied geosciences at Darmstadt University of Technology, he worked for several years at the VDI/DIN Commission on Air Pollution Prevention in the fields of meteorology and environmental measurements.

Annette Borowiak

Air and Climate Unit
Joint Research Centre
Ispra, Italy
annette.borowiak@ec.europa.eu

Annette Borowiak is a project leader at the European Commission's Joint Research Centre in Ispra, Italy. She has a chemical engineering background and has worked on ambient air monitoring for more than 25 years. Her areas of interest include the development, validation, and standardization of measurement techniques for gaseous and particulate air pollutants, the organization of quality assurance programs, and supporting the implementation and development of European air quality legislation.

Brian Stacey

Ricardo Energy and Environment
Didcot, UK
brian.stacey@ricardo.com

With 30 years' experience, Brian Stacey is Ricardo's air quality monitoring knowledge leader. He oversees ISO 17025 accredited quality assurance and quality control for UK air pollution measurements. He participates in collaborative programs on air quality monitoring techniques in the UK and Europe. As one half of the certification committee, Brian reviews and assesses the demonstration of equivalence tests under the UK government "MCERTS for PM in the UK" scheme.

Physical Quantities

5. Physical Quantities

Thomas Foken , Olaf Hellmuth , Bernd Huwe , Dietrich Sonntag

This chapter follows the tradition of classical textbooks on meteorology and presents relevant parameters for meteorology, including measurements in dry and moist air, water, and soil, as well as cloud physical quantities. Tables present the pressure, temperature, and humidity dependency of these parameters. Furthermore, soil physical quantities and calculation procedures are presented to calculate parameters of the solar and Earth system and of the time system.

Physical quantities and their dependencies on temperature, pressure, or humidity are essential for atmospheric measurements. Even when the accuracy of several measurements is much lower than the possible accuracy of physical quantities, in the following, the quantities are given in the highest possible accuracy on the basis of the newest scales, like the International Temperature Scale of 1990 (ITS-90). For several quantities of

metrological interest, their dependencies on temperature, pressure, and humidity are given in the typical meteorological range of application. The corresponding tables are presented here, even if the quantities can be easily calculated from the given equations, because the visual inspection of the quantities and its sensitivity to other influencing factors is very instructive for atmospheric measurements.

Electronic Supplementary Material The online version contains supplementary material available at https://doi.org/10.1007/978-3-030-52171-4_5.

5.1 Selection of Parameters

The basis for the measurement of all parameters is the International System of Units (SI). Only a few parameters are also given in other units, which are mainly used in some Anglo-American countries. The parameters were selected according to recent textbooks on meteorology or updated versions of former books with tables of atmospheric parameters. If possible, all data are given for the new temperature scale ITS-90.

The tables in this chapter provide the most relevant physical units and constants (Sect. 5.3), thermodynamic parameters of air, water vapor, water, and ice (Sect. 5.4), optical parameters of clouds (Sect. 5.5), absorption coefficients of selected absorber gases (Sect. 5.6), physical parameters of soil (Sect. 5.7), and the time and astronomical quantities required for many meteorological measurements (Sect. 5.8).

This chapter does not aim at a complete documentation of the relevant atmospheric parameters necessary for the execution and evaluation of atmospheric measurements. Instead, it is intended to facilitate the exploitation of this book in daily measurement practice. Already for some time now, books have lost their exclusive status as the primary media to transfer and communicate such data. Owing to their flexibility, storage capacity, and network capabilities, nowadays databases and/or software tools and even apps occupy the traditional place of book tables. In any case, a meaningful documentation and comprehensive references to the basic sources of the data are indispensable. Table 5.1 gives a list of such databases without claiming completeness.

5.2 History and Thermodynamic Standards

Tables or lists of properties of the dry and wet atmosphere are part of many textbooks of the nineteenth and early twentieth century. A complete list of these books is given by *Karl Schneider-Carius* (1896–1959) [5.3]. The first book of meteorological tables was published in 1852 by *Arnold Henry Guyot* (1807–1884) [5.4], a reprint of which was recently (2012) published. The first edition of the International Meteorological Tables was published in 1890 on the basis of a conclusion of the International Meteorological Congress held in Rome in 1879 (Chap. 1).

Franz Linke (1878–1944) edited a Handbook of Meteorology (*Meteorologisches Taschenbuch*) with five volumes [5.5], where volumes 1 and 2, published in 1931

and 1933, are the first edition, and volumes 3–5 from 1939 are the second edition. The book was edited after the Second World War by *Franz Baur* (1887–1977) and issued in three volumes [5.6–8], where volume II has a large part with tables with relevant parameters.

The World Meteorological Organization (WMO) decided in Toronto in 1953 to update the International Meteorological Tables from 1890. After the work of a panel of experts, S. Letestu edited the new tables in 1966, which were updated up to 1973 [5.9]. This material was the main reference for the tables in Landolt–Börnstein [5.1], see below.

A general handbook of parameters and tables from physics, chemistry, and materials science was published

in 1883 by *Hans Heinrich Landolt* (1831–1910) and *Richard Börnstein* (1852–1913) in one volume. Since then this book has been a standard work of natural science. The 6th edition (1951–1976) already comprised 15 volumes. Meteorology was first considered in this edition of the Landolt–Börnstein and published in 1952 [5.10]. In 1980, this series was finished with the title *Landolt–Börnstein: Zahlenwerte und Funktionen aus Physik, Chemie, Astronomie, Geophysik und Technik* (Numerical Data and Functional Relationships in Physics, Chemistry, Astronomy, Geophysics, and Techniques), and a new series started with the title *Landolt–Börnstein: Numerical Data and Functional Relationships in Science and Technology – New Series*. Up to the end of 2017 about 560 volumes were published. References should be made to the single chapters but not to volumes. The Landolt–Börnstein is now part of the online Springer Materials (<http://materials.springer.com/>). Meteorology is part of Group V *Geophysics and Space Research*; Volume 4 *Meteorology* edited by *G. Fischer* [5.1] was published in 1987 and is still part of Springer Materials. Of meteorological relevance are the volumes 4A *Meteorology · Thermodynamical and Dynamical Structures of the Global Atmosphere* and 4B *Meteorology · Physical and Chemical Properties of the Air*. This chapter is mainly based on volume 4A, while 4B with cloud physical parameters and radiation is more relevant for the remote sensing chapters (see Parts C and D). The tables can still be used, but they are based on the temperature scale IPTS-68 and not on the recently valid scale ITS-90, which is not relevant within

the accuracy of many applications. The most relevant tables for the present book are listed in Table 5.2.

5.2.1 ITS-90

The Committee on Data for Science and Technology (CODATA) of the International Council of Scientific Unions (ICSU) published a table of physical constants [5.11] in 1973. On this basis the International Temperature Scale 1968 (IPTS-68) was developed [5.12]. This temperature scale differs from the Thermodynamic Temperature Scale (TTS) from +0.013 to –0.026 K [5.13]. Following the new recommendations by CODATA for physical constants in 1986 [5.14, 15], overcoming shortcomings of IPTS-68, and realizing a recommendation of the Committee on Thermometry (CCT), the International Committee on Weight and Measures (CIPM) adapted the new temperature scale ITS-90 [5.16], which is identical with TTS [5.13]. Differences between IPTS-68 and ITS-90 are shown in Table 5.3.

5.2.2 TEOS-10

The emergence of highly accurate mathematical formulations of thermodynamic potentials for fluid water, air, ice, and seawater in the first decade of the new millennium stimulated the development of a new seawater standard by the Scientific Committee on Oceanic Research (SCOR) and the International Association for Physical Science of the Ocean (IAPSO) Working Group

Table 5.3 Differences of the temperature scales IPTS-68 (index 68) and ITS-90 (index 90) for temperature (T) and water vapor pressure of saturation with respect to water (E_w) and ice (E_i) [5.13, 16]

Temperature ITS-90 t_{90} (°C)	Water vapor pressure of saturation $E_w(t_{90})$ (hPa)	$E_w(t_{90}) - E_w(t_{68})$ (hPa)	$t_{90} - t_{68}$ (K)

127 (WG 127). This new standard is based on the realization of a very general algorithm to describe thermodynamic systems:

1. Formulation of the fundamental thermodynamic relation of the system of interest.
2. Determination of a suitable thermodynamic potential (containing by definition all information about the system) from experimental data or on the basis of microscopic theories within the framework of statistical thermodynamics.
3. Calculation of the thermodynamic properties, the thermic and caloric equations of state, and all other state variables of interest from the thermodynamic potential.

The joint efforts of WG 127 to realize this concept resulted in a new seawater standard for oceanological and meteorological applications, called the International Thermodynamic Equation Of Seawater 2010 (TEOS-10), which was adopted in June 2009 by the International Oceanographic Commission of the United Nations Educational, Scientific, and Cultural Organization (UNESCO/IOC) on its 25th General Assembly in Paris. To support the application of this standard, WG 127 developed a comprehensive source code library for

the thermodynamic properties of liquid water, water vapor, ice, seawater, and humid air, referred to as the sea-ice-air (SIA) library. The background information and equations (including references for the primary data sources) required for the determination of the properties of single phases and components, as well as of phase transitions and composite systems as implemented in the library, were presented in two key papers [5.17, 18], the TEOS-10 Manual [5.19], and the introductory and guidance papers [5.20, 21]. TEOS-10 is based on four independent thermodynamic functions defined in terms of the independent observables temperature, pressure, density, and salinity: a Helmholtz function of fluid water [5.22, 23], a Gibbs function of ice [5.24, 25], a Gibbs function of sea salt dissolved in water [5.26–28], and a Helmholtz function for dry air [5.29]. In combination with air-water cross-virial coefficients [5.30–32] this set of thermodynamic potentials is used as the primary standard for pure water (liquid, vapor, and solid), seawater, and humid air from which all other properties are derived by mathematical operations, i.e., without the need for additional empirical functions.

The IAPWS-95 fluid water formulation, which is of key importance for the description of atmospheric water within the framework of TEOS-10, is based on ITS-90 and on the evaluation of a comprehensive and consistent data set, which was assembled from a total of about 20 000 experimental data of water. The authors took into account all available information given in the scientific articles describing the data collection and critically reexamined the available data sets with respect to their internal consistency and their basic applicability for the development of a new equation of state for water [5.22, 23]. Only those data were incorporated into the final nonlinear fitting procedure that were judged to be of high quality. These selected data sets took into account experimental data that were available by the middle of the year 1994 [5.22]. A compilation of the experimental data used to develop IAPWS-95 can be downloaded from the official IAPWS website (see the reference in Table 5.1).

The availability of reliable experimental data on subcooled liquid water (i.e., metastable with respect to the solid) was restricted to a few data sets for several properties only along the isobar $p = 1013.25$ hPa, which set the lower limit of the temperature range of IAPWS-95 (and so of TEOS-10) to $T = 236$ K ($t = -37.15$ °C) [5.22]. This temperature is called the temperature of homogeneous ice nucleation (or homogeneous freezing temperature), T_H , which represents the lower limit below which it is very difficult to subcool water. Therefore, the TEOS-10 table values presented in Sect. 5.4 are restricted to temperatures $t \geq -37.15$ °C. The assessment of the accuracy of the IAPWS (Inter-

national Association for the Properties of Water and Steam) guideline IAPWS-95 in the temperature range of subcooled water ([5.22, Section 7.3.2]) revealed that TEOS-10 fully satisfies the meteorological needs with respect to accuracy down to this temperature.

Classical thermodynamic tables usually also contain data of subcooled water, which were extrapolated to temperatures below the homogeneous freezing temperature. While such low temperatures can occur in the upper troposphere, stratosphere, and mesosphere, the properties of liquid water in this range are not accessible by experiments, because even tiny water droplets will homogeneously freeze to ice. Upon hyperquenching of liquid water at extremely high cooling rates, water will be transformed at $T_{\text{VITR}} = 155 \text{ K}$ into an amorphous (vitreous) form, called amorphous ice [5.33]. While information on subcooled water in the temperature interval between T_{VITR} and T_{H} are experimentally not accessible (i.e., direct experimental proofs of the existence of water in that range are not available), different theories on the behavior of sub-

cooled water in this temperature range exist [5.33, 34]. Assuming the thermodynamic continuity between liquid water and amorphous ice at atmospheric pressure, the authors of [5.33] used experimental data on amorphous ice to constrain the thermodynamic functions of water at intermediate temperatures $T_{\text{VITR}} \leq T \leq T_{\text{H}}$. Employing experimental data on subcooled water and amorphous ice, those authors derived a user-friendly parameterization of the saturation water vapor pressure with respect to subcooled water in the extended temperature range of $123 \text{ K} \leq T \leq 332 \text{ K}$ [5.33, Eq. 10], which is recommended for application at atmospheric temperatures below the homogeneous freezing temperature. A list with typographical errors in the literature on vapor pressures for atmospheric applications (inclusive documents of WMO) is given in [5.33], which are highly relevant for any application of the incriminated expressions and table values and which were commented by those authors with the sentence “*no doubt there are additional errors awaiting discovery*”.

5.3 Units and Constants

In the present book, SI units are used (Table 5.4) for most of the quantities. However, in some Anglo-American countries non-SI units are still in use (Table 5.5). According to the recent definition of SI units, seven constants are chosen in such a way that any unit of the SI can be written either through a defining constant itself or through products or quotients of defining constants [5.35]: the unperturbed ground-state hyperfine transition frequency of the caesium 133 atom, the speed of light in vacuum, the Planck constant, the elementary charge, the Boltzmann constant, the Avogadro constant, and the luminous efficacy of monochromatic radiation of frequency $540 \times 10^{12} \text{ Hz}$ (Table 5.6).

Even though the accuracy of meteorological measurements is at most only three to five significant digits,

the following physical constants in Table 5.6 are given with errors expressed in ppm, because sometimes in the literature different values are reported. Temperature-dependent parameters are listed in Table 5.7.

In meteorology several standard parameters are given to simplify calculations or make calculations comparable (Table 5.8). They base partly on the ICAO-Standard Atmosphere [5.43], which gives a distribution of temperature, pressure, and density with height for air navigation (Table 5.9). This model atmosphere uses standard parameters at sea level (1013.25 hPa, 15.0 °C) and a lapse rates of -0.0065 K m^{-1} up to a height of 11 000 m, isothermal conditions up to 20 000 m and an increase of the temperature of 0.0010 K m^{-1} up to 32 000 m.

5.4 Parameters of Air, Water Vapor, Water, and Ice

All tables in this section were calculated on the basis of equations and software sources according to TEOS-10 [5.17, 18] and have not been published before.

5.4.1 Calculation of Data According to TEOS-10

Owing to its rigorous foundation on phenomenological and statistical thermodynamics, the employment of carefully selected experimental data and IAPWS guidelines, its quality assurance according to IAPWS certified protocols and procedures, and its adoption as an international seawater standard for oceanography by UNESCO/IOC, TEOS-10 provides the hitherto most advanced standard for the calculation of thermodynamic properties for meteorological applications. The disposability of the TEOS-10 SIA library in the program languages FORTRAN and Visual Basic allows a user-specific determination of any thermodynamic parameter from the generating thermodynamic potentials, which is defined within the framework of classical thermodynamics. However, for quick-look purposes, selected lookup tables of the atmospherically most important parameters and their dependence on temperature, pressure, humidity, etc., are presented here with a parameter resolution specified as a compromise between the table size and user needs.

In TEOS-10 the mass density of humid air, $\rho_a(m_d, T, p)$ is determined as a function of three independent observables: the mass fraction of dry air m_d , the temperature T , and the pressure p . The mass fraction of dry air is related to the specific humidity q and mole fraction of water vapor in humid air χ_w by

$$m_d = 1 - q = \frac{1 - \chi_w}{1 - (1 - \varepsilon)\chi_w}, \quad (5.1)$$

where

$$\varepsilon = \frac{M_w}{M_a} = 0.622 \quad (5.2)$$

denotes the ratio of the molar mass of water to that of dry air. Using the meteorological notion of virtual temperature T_v , the number of independent variables in a lookup-table of the humid air mass density can be reduced from three variables (m_d , T , p) to two variables (T_v , p). The virtual temperature is by definition the temperature at which dry air would have the same mass density as humid air at the given water vapor mole fraction, temperature, and pressure (Chap. 8). This definition of the virtual temperature allows the approximate determination of the mass density of humid air

ρ_a from lookup tables for the virtual temperature excess of saturated humid air and for the mass density of dry air only, both of which are well-defined thermodynamic functions of temperature and pressure. To ensure consistency with the TEOS-10 based formulation of ρ_a as a function of the mass fraction of dry air, temperature, and pressure, the expression for ρ_a was linearized with respect to temperature and humidity [5.47]. By this linearization the number of lookup tables for the calculation of ρ_a could be reduced to two, resulting in a user-friendly and sufficiently accurate form similar to Tables 13–15 already published in [5.1].

According to *William Henry* (1774–1836) [5.48], the amount of dissolved gas in an aqueous phase is proportional to the partial pressure of the dissolved species in the gas phase. This rule is known as Henry's law, and the proportionality factor is called Henry's constant. Henry's law is reconcilable with *Henry Louis Le Chatelier's* (1850–1936) principle, according to which a perturbation of a thermodynamic system at equilibrium by changing the concentration, temperature, volume, or pressure, will cause a readjustment of the system to a new equilibrium state to counteract the effect of the applied changes. Depending on the metrics used for the definition of the aqueous and gas phase concentrations of the dissolved species, there are different formulations of Henry's law, for example [5.49, Eqs. (4), (15)]

$$H_i = \frac{\chi_{aq,i}}{p_i|_{sat,h}} = \frac{1}{K_{H,i}}. \quad (5.3)$$

Here, H_i denotes the Henry's law solubility constant of species i (in Pa^{-1}), $K_{H,i}$ the corresponding volatility constant (in Pa), $p_i|_{sat,h}$ the partial vapor pressure of species i in humid air at saturation with respect to liquid water, and $\chi_{aq,i}$ is the molar mixing ratio of the dissolved species i in the aqueous phase at equilibrium vapor pressure $p_i|_{sat,h}$. In the present chapter, the volatility constant of dry air (composed of N_2 , O_2 , and Ar) is presented in Table 5.36.

The irreversible exchange of a substance between two different thermodynamic macrophases of a nonequilibrium system is described by the so-called Onsager force (*Lars Onsager*, 1903–1976), which represents the entropic driving force toward the thermodynamic equilibrium [5.50]. Subsaturated air in contact with liquid water or seawater is such a nonequilibrium system, in which the evaporation of liquid water into subsaturated air is an irreversible process [5.50, p. 116]. Owing to its pivotal role for the quantification of the hydrological cycle and the energy budget of the globe [5.51], in [5.52] a calculus for the determination of the evaporation flux of water from a seawater reser-

voir to a reservoir of humid air was proposed, which is based on a generalized definition of relative humidity in terms of relative activity and relative fugacity. The relative humidity according to the WMO definition [5.53] can be recovered from this generalized definition as the ideal-gas limit. The enhancement factor of water vapor in humid air is a humidity metric to describe real-gas effects of humid air. This factor is defined as the ratio of the partial water vapor pressure in saturated humid air to the saturation pressure of pure water vapor [5.54, 55]. More details can be found in Chap. 8.

According to the experimental data base underlying TEOS-10, all thermodynamic single-phase and equilibrium properties involving liquid water are restricted to temperatures above the homogeneous freezing temperature.

5.4.2 Water Vapor, Dry Air, and Humid Air

The Tables 5.10 to 5.35 presented in this section contain parameters of water vapor, dry air, and humid air according to TEOS-10 [5.17, 18].

Table 5.10 Saturation water vapor pressure above liquid water (in hPa) as a function of temperature calculated according to TEOS-10 [5.17, 18]. This table with an enhanced resolution of the temperature of 0.1 K between 40 °C and −30 °C is available as electric supplementary material (ESM) at https://doi.org/10.1007/978-3-030-52171-4_5

Table 5.17 Mass density of dry air (in kg m^{-3}) as a function of temperature and pressure (in the pressure range 1100–650 hPa) as calculated according to TEOS-10 [5.17, 18]. The mass density of humid air is approximately obtained by evaluating the mass density of dry air at the virtual temperature $T_v \approx T + RH\Delta T_{v,\text{sat}}$, where RH denotes the relative humidity according to the WMO definition (Chap. 8), and $\Delta T_{v,\text{sat}}(T, p)$ the virtual temperature increment of saturated humid air (Table 5.19) [5.47]. This table with an enhanced resolution of the temperature of 1 K is available as ESM at https://doi.org/10.1007/978-3-030-52171-4_5

Table 5.19 Virtual temperature excess of saturated humid air $\Delta T_{v,\text{sat}}(T, p)$ (in K) as a function of temperature and pressure (in the pressure range 1100–650 hPa), calculated by linearization of the TEOS-10-based expression of the mass density of humid air [5.17, 18] as a function of temperature, pressure, and mass fraction of dry air. The virtual temperature is given as a function of temperature, pressure, and relative humidity as $T_v \approx T + RH\Delta T_{v,\text{sat}}$, where RH denotes the relative humidity according to the WMO definition (Chap. 8) [5.47]. This table with an enhanced resolution of the temperature of 1 K is available as ESM at https://doi.org/10.1007/978-3-030-52171-4_5

Table 5.36 Henry’s volatility constant of dry air (N₂, O₂, and Ar) dissolved in liquid water (in GPa), $K_H = H^{-1}$ (where H denotes Henry’s solubility constant), as a function of temperature according to [5.56, 57], based on [5.30]

Temperature (°C)	Temperature increment (K)									
	0	1	2	3	4	5	6	7	8	9
50	9.194	9.258	9.321	9.381	9.440	9.497	9.552	9.606	9.657	9.707
40	8.453	8.535	8.615	8.693	8.770	8.845	8.918	8.990	9.059	9.127
30	7.557	7.653	7.747	7.840	7.932	8.023	8.112	8.200	8.286	8.370
20	6.542	6.648	6.752	6.856	6.959	7.062	7.163	7.263	7.362	7.460
10	5.459	5.569	5.678	5.788	5.897	6.005	6.114	6.222	6.329	6.436
0	4.367	4.475	4.583	4.692	4.801	4.910	5.020	5.129	5.239	5.349

In Table 5.37, the dynamic viscosity of dry air is calculated after [5.42, Eq. (38)]; superscript LJ2004 refers to [5.58],

$$\frac{\mu}{10^{-6} \text{ kg m}^{-1} \text{ s}^{-1}} = -9.8601 \times 10^{-1} + 9.080125 \times 10^{-2} T / \text{K} - 1.17635575 \times 10^{-4} T^2 / \text{K}^2 + 1.2349703 \times 10^{-7} T^3 / \text{K}^3 - 5.7971299 \times 10^{-11} T^4 / \text{K}^4, \quad 250 \text{ K} \leq T \leq 600 \text{ K}, \quad (5.4)$$

$|\mu - \mu^{\text{LJ2004}}| / \mu^{\text{LJ2004}} \leq 0.191\%$, in the subrange $250.15 \text{ K} \leq T \leq 335.15 \text{ K}$ at $p = 1013.25 \text{ hPa}$, and the thermal conductivity of dry air is calculated after [5.42, Eq. (39)]

$$\frac{k}{\text{W m}^{-1} \text{ K}^{-1}} = -2.276501 \times 10^{-3} + 1.2598485 \times 10^{-4} T / \text{K} - 1.4815235 \times 10^{-7} T^2 / \text{K}^2$$

$$+ 1.73550646 \times 10^{-10} T^3 / \text{K}^3 - 1.066657 \times 10^{-13} T^4 / \text{K}^4 + 2.47663035 \times 10^{-17} T^5 / \text{K}^5, \quad 250 \text{ K} \leq T \leq 1050 \text{ K}, \quad (5.5)$$

$|k - k^{\text{LJ2004}}| / k^{\text{LJ2004}} \leq 1.252\%$, in the subrange $250.15 \text{ K} \leq T \leq 335.15 \text{ K}$ at $p = 1013.25 \text{ hPa}$.

Unfortunately, there is an error in the original paper [5.42, p. 1103, left column above Eq. (39)]. The dimension of k on the left-hand side of the tailored Eq. (39) must be $\text{W m}^{-1} \text{ K}^{-1}$. Compare with [5.42, Fig. 3 therein] for correct order of magnitude. As the reference for the accuracy assessment of μ and k the highly accurate equations of state for viscosity and thermal conductivity as functions of temperature and air density proposed in [5.58] were used.

The other quantities were calculated accordingly. The kinematic viscosity (momentum diffusivity) in units $\text{m}^2 \text{ s}^{-1}$

$$\nu_m = \frac{\mu}{\rho}, \quad (5.6)$$

Table 5.37 Transport properties of dry air for 1000 hPa [5.42]

the thermal diffusivity in units $\text{m}^2 \text{s}^{-1}$

$$\nu_{\text{th}} = \frac{k}{\rho c_p}, \quad (5.7)$$

and the molecular Prandtl number

$$\text{Pr} = \frac{\nu_m}{\nu_{\text{th}}}, \quad (5.8)$$

5.4.3 Water, Seawater, and Ice

The tables presented in this section contain parameters of water, seawater, and ice according to TEOS-10 [5.17, 18]. The mass density of seawater and the boiling temperature of water are given in Tables 5.38 and 5.39.

For Table 5.40, the following approximations (derived by O. Hellmuth on the basis of [5.17, 18]) are valid for the vaporization enthalpy

$$\begin{aligned} \frac{\lambda_v}{\text{J kg}^{-1}} &= 0.7166 \times 10^7 - 0.6970 \times 10^4 \frac{T}{\text{K}} \\ &\quad - \frac{0.1166 \times 10^{10}}{T/\text{K}} + \frac{0.1126 \times 10^{12}}{(T/\text{K})^2} \end{aligned}$$

with $235 \text{ K} \leq T \leq 333 \text{ K}$:

$$\frac{|\lambda - \lambda^{\text{TEOS-10}}|}{\lambda^{\text{TEOS-10}}} \leq 1.3\%, \quad (5.9)$$

for the fusion (melting) enthalpy

$$\begin{aligned} \frac{\lambda_m}{\text{J kg}^{-1}} &= 0.23536 \times 10^8 - 0.27193 \times 10^6 \frac{T}{\text{K}} \\ &\quad + 1049.07 \left(\frac{T}{\text{K}}\right)^2 - 1.3345 \left(\frac{T}{\text{K}}\right)^3 \end{aligned}$$

with $234 \text{ K} \leq T \leq 273.15 \text{ K}$:

$$\frac{|\lambda_m - \lambda_m^{\text{TEOS-10}}|}{\lambda_m^{\text{TEOS-10}}} \leq 1.6\%, \quad (5.10)$$

Table 5.39 Boiling temperature of pure water as a function of pressure calculated according to TEOS-10 [5.17, 18]

Air pressure (hPa)	Boiling temperature (°C)
1100	102.292

5.5 Parameterization of Optical Properties of Clouds

Clouds can affect the atmospheric energy balance considerably through scattering and absorption of electromagnetic radiation at solar and infrared wavelengths. The ability of clouds to affect the radiative balance depends on their microphysical and optical properties. A key optical metric of a cloud with cloud base z_B and cloud top z_T is the dimensionless optical thickness τ

$$\tau = \int_{z_B}^{z_T} \beta_e(z) dz. \quad (5.12)$$

Here, $\beta_e(z)$ (in units of m^{-1}) denotes the height-dependent volumetric extinction coefficient of the cloud. This quantity depends essentially on cloud microphysical parameters, such as the cloud droplet size distribution and the geometrical shape of the cloud's constituent hydrometeors. Knowledge of the geometrical shape of an elementary *cloud particle* allows us to determine its optical parameters within the framework

of Mie theory (*Gustav Adolf Feodor Wilhelm Ludwig Mie*, 1868–1957) [5.59]. However, the latter is known to be computationally very expensive and to not be practicable for real-time applications such as cloud modeling and remote-sensing inversion. To overcome this difficulty, precalculated lookup tables are available for the most relevant optical parameters (extinction coefficient, single-scattering albedo, asymmetry factor of the phase function), on the basis of which user-friendly parameterizations in terms of easily accessible observables (and/or derivables) have been derived. In the following, the corresponding parameterizations of optical properties for warm and cold clouds that allow a quick calculation with a sufficiently high accuracy for most applications will be presented.

5.5.1 Warm Clouds

The total number concentration of a population of cloud particles, N (in m^{-3}), with radii in the interval $R_{\min} \leq$

$R \leq R_{\max}$ reads [5.60, Eq. (5.2.114)]

$$N = \int_{R_{\min}}^{R_{\max}} \frac{dN(R)}{dR} dR. \quad (5.13)$$

Here, $n(R) = dN(R)/dR$ denotes the particle size distribution (PSD) (in m^{-4}). The volumetric extinction and scattering coefficients of the cloud droplet population, β_e and β_s (in units of m^{-1}), are defined as follows [5.60, Eqs. (5.2.115) and (5.2.116)]

$$\beta_e = \int_{R_{\min}}^{R_{\max}} \sigma_e(R) n(R) dR, \quad (5.14)$$

$$\beta_s = \int_{R_{\min}}^{R_{\max}} \sigma_s(R) n(R) dR. \quad (5.15)$$

Here, $\sigma_e(R)$ and $\sigma_s(R)$ are the extinction and scattering cross sections (in units of m^2) [5.60, Eqs. (5.2.94) and (5.2.98)]

$$\sigma_e(R) = \pi R^2 Q_e(R), \quad (5.16)$$

$$\sigma_s(R) = \pi R^2 Q_s(R). \quad (5.17)$$

The quantities $Q_e(R)$ and $Q_s(R)$ are the dimensionless extinction and scattering efficiencies, respectively, which can be calculated within the framework of Mie theory as a function of the size parameter $x = 2\pi R/\lambda$, where λ denotes the wavelength [5.59]. The dimensionless single-scattering albedo, ω_s , and the dimensionless asymmetry factor, g , of an ensemble of cloud droplets are defined as follows [5.60, Eqs. (5.2.117) and (6.5.9a)]

$$\omega_s = \frac{\beta_s}{\beta_e}, \quad (5.18)$$

$$g = \frac{1}{2} \int_{-1}^1 P(\cos \Theta) \cos \Theta d \cos \Theta = \langle \cos \Theta \rangle. \quad (5.19)$$

In (5.19), $P(\cos \Theta)$ is the dimensionless phase function (or scattering indicatrix) as a function of the scattering angle Θ , as defined in [5.60, Fig. 6.1]. The asymmetry factor is the mean value of the cosine of the scattering angle, $\langle \cos \Theta \rangle$.

For a given PSD $n(R)$, the equivalent (or effective) radius R_e is defined as the ratio of the third to the second

moments of the PSD [5.61, Eq. (5)]

$$R_e = \frac{\int_0^{\infty} R^3 n(R) dR}{\int_0^{\infty} R^2 n(R) dR}. \quad (5.20)$$

For shortwave radiation, the droplet radius is large compared to the wavelength, $x \gg 1$, and the extinction efficiency asymptotically approaches the limit $Q_e = 2$. Therefore, and by virtue of (5.14) and (5.16), the volumetric extinction coefficients β_e reads

$$\beta_e \approx 2\pi \int_0^{\infty} R^2 n(R) dR. \quad (5.21)$$

The liquid water content (LWC) of a cloud, defined as the mass of condensed water per volume of air (in units of kg m^{-3}), is given by the following relation

$$\begin{aligned} \text{LWC} &= \rho_w \int_0^{\infty} V_w(R) n(R) dR \\ &= \frac{4}{3} \pi \rho_w \int_0^{\infty} R^3 n(R) dR. \end{aligned} \quad (5.22)$$

Here, ρ_w denotes the mass density of liquid water and $V_w(R) = 4\pi R^3/3$ the geometric volume of a single droplet. Inserting (5.21) and (5.22) into (5.20) yields an approximate expression for β_e in terms of LWC and R_e [5.61, Eq. (6), given therein in cgs units]

$$\beta_e \approx \frac{3 \text{LWC}/\rho_w}{2 R_e}. \quad (5.23)$$

Equation (5.23) provides the basis for the parameterization of cloud optical properties in terms of the effective radius and the liquid water content, which circumvents time-consuming Mie calculations. In [5.61, Eq. (7)], the corresponding lookup-tables were calculated using a generalized gamma distribution to represent the PSD

$$n(R) = \frac{N_0}{\Gamma(\gamma) R_m} \left(\frac{R}{R_m} \right)^{\gamma-1} \exp \left(-\frac{R}{R_m} \right). \quad (5.24)$$

Here, N_0 is the total number concentration of cloud droplets (in units of m^{-3}), and $\Gamma(\gamma)$ is the gamma function with γ denoting the dimensionless shape parameter determining the skewness of the PSD (large values correspond to broad distribution). The quantity R_m is a characteristic length scale, defined as the inverse of the frequently employed rate parameter of the

PSD. A bimodal gamma size distribution can be described as a superposition of two gamma distributions with the weighting factor $0 \leq c \leq 1$ [5.61, p. 729],

$$n(R) = (1 - c)n_1(R) + cn_2(R). \tag{5.25}$$

The following relation between the equivalent radius R_e and the characteristic radius R_m was derived from the insertion of $n(R)$ into (5.20) [5.61, Eq. (8a)]

$$R_e = \frac{\left[(1 - c)(\gamma_1 + 2)(\gamma_1 + 1)\gamma_1 R_{m,1}^3 + c(\gamma_2 + 2)(\gamma_2 + 1)\gamma_2 R_{m,2}^3 \right]}{\left[(1 - c)(\gamma_1 + 1)\gamma_1 R_{m,1}^2 + c(\gamma_2 + 1)\gamma_2 R_{m,2}^2 \right]} \tag{5.26}$$

For a single mode ($c = 0$ or $c = 1$), (5.26) reduces to [5.61, Eq. (8b)]

$$R_e = (\gamma + 2)R_m. \tag{5.27}$$

In [5.61, Eqs. (13)–(15)], a general functional dependence on the equivalent radius was adopted for the parameterization on the extinction coefficient β_e , the single-scattering co-albedo $1 - \omega_s$, and the asymmetry factor g for both solar and terrestrial wavelengths in the form of the following numerical value equations

$$\frac{\beta_e}{\text{m}^{-1}} = \frac{\text{LWC}}{10^{-3} \text{ kg m}^{-3}} \left[a_1 \left(\frac{R_e}{\mu\text{m}} \right)^{b_1} + c_1 \right], \tag{5.28}$$

$$1 - \omega_s = a_2 \left(\frac{R_e}{\mu\text{m}} \right)^{b_2} + c_2, \tag{5.29}$$

$$g = a_3 \left(\frac{R_e}{\mu\text{m}} \right)^{b_3} + c_3. \tag{5.30}$$

The parameter triples (a_i, b_i, c_i) for $i = 1, 2, 3$ are given in Tables 5.41–5.46.

Table 5.41 Fitting parameters a_1 , b_1 , and c_1 in the numerical value equation (5.28) for the volumetric extinction coefficient β_e as a function of equivalent radius $R_e = 2.5\text{--}60 \mu\text{m}$ (for small, medium, and large sizes) and electromagnetic wavelength λ (solar radiation $\lambda = 0.290\text{--}3.690 \mu\text{m}$) [5.61, Table 1]

5.5.2 Ice Clouds (Cold Clouds)

Ice crystals have a nonspherical shape, and ice crystal size distributions are usually expressed in terms of the maximum geometric dimension of crystals [5.62]. Analogously to the definition of the equivalent (or effective) radius of a population of warm cloud droplets, the mean effective size of a population of hexagonal ice crystals can be defined as follows [5.62, Eq. (2.1)]

$$D_e = \frac{\int_{L_{\min}}^{L_{\max}} [D(L)]^2 L n(L) dL}{\int_{L_{\min}}^{L_{\max}} D(L) L n(L) dL}. \quad (5.31)$$

Here, D denotes the width of an ice crystal and $n(L)$ denotes the ice crystal size distribution (ISD) (in m^{-4}) as the function of the length of the ice crystals, $L_{\min} \leq L \leq L_{\max}$, respectively. The geometric cross-sectional area for oriented hexagonal ice crystals generally deviates from the product DL . The ice water content (IWC) of an ice cloud is defined as the mass of frozen water per volume of air (in units of kg m^{-3}), given by the following relation [5.62, Eq. (2.2)]

$$\begin{aligned} \text{IWC} &= \rho_i \int_{L_{\min}}^{L_{\max}} V_i(L) n(L) dL \\ &= \frac{3\sqrt{3}}{8} \rho_i \int_{L_{\min}}^{L_{\max}} D^2 L n(L) dL. \end{aligned} \quad (5.32)$$

Here, ρ_i denotes the mass density of hexagonal ice, and $V_i = 3\sqrt{3}D^2L/8$ the volume of a hexagonal ice crystal. The volumetric extinction coefficient of a population of ice crystals reads [5.62, Eq. (2.3)]

$$\beta_e = \int_{L_{\min}}^{L_{\max}} \sigma_e(D, L) n(L) dL. \quad (5.33)$$

Here, $\sigma_e(L)$ is the extinction cross section (in units of m^2) [5.62, Eq. (2.4)]

$$\sigma_e(D, L) = \frac{3}{2} D \left(\frac{\sqrt{3}}{4} D + L \right). \quad (5.34)$$

Analogously, one can define the volumetric absorption coefficient

$$\beta_a = \int_{L_{\min}}^{L_{\max}} \sigma_a(D, L) n(L) dL. \quad (5.35)$$

Here, $\sigma_a(L)$ is the absorption cross section (in units of m^2), which is for small absorption proportional to the product of the imaginary part of the refractive index of ice and the ice crystal volume [5.62, Eq. (2.7)]

$$\sigma_a(D, L) \approx \frac{3\sqrt{3}\pi m_i(\lambda)}{2\lambda} D^2 L. \quad (5.36)$$

In (5.36), $m_i(\lambda)$ denotes the imaginary part of the refractive index of ice as function of wavelength λ . Inserting (5.34) into (5.33) and using the definition of D_e according to (5.31) and of IWC according to (5.32)

yields the following expression for β_e [5.62, Eqs. (2.5a) and (2.5b)]

$$\beta_e = \text{IWC} \left[\frac{1}{\rho_i} \frac{\int_{L_{\min}}^{L_{\max}} D^2 n(L) dL}{\int_{L_{\min}}^{L_{\max}} D^2 L n(L) dL} + \frac{4}{\sqrt{3} \rho_i} \frac{1}{D_c} \right] \approx \text{IWC} \left(a + \frac{b}{D_c} \right). \tag{5.37}$$

Here, a and b are physical constants. The approximate form of (5.37) is based on an analysis of the orders of magnitude of both summands in the brackets on the right-hand side of (5.37). By virtue of (5.33) and (5.35) and with consideration of $\beta_e = \beta_s + \beta_a$, the single-scattering co-albedo of a population of ice crystals, $1 - \omega_s$, is given by the following relation [5.62, Eq. (2.6)]

$$1 - \omega_s = \frac{\beta_e - \beta_s}{\beta_e} = \frac{\beta_a}{\beta_e} = \frac{\int_{L_{\min}}^{L_{\max}} \sigma_a(D, L) n(L) dL}{\int_{L_{\min}}^{L_{\max}} \sigma_e(D, L) n(L) dL} \approx c + d D_c. \tag{5.38}$$

Here, c and d are physical constants. With consideration of empirical findings from aircraft observations,

Table 5.48 Values of the regression coefficients a_n in (5.39) for the parameterization of the volumetric extinction coefficient β_e (in m^{-1}). The coefficients are determined for a reference ice mass density of $\rho_{i,0} = 916.7 \text{ kg m}^{-3}$ [5.62, Table 3]

17	– 1.741E-02	5.541	– 58.42
18	– 7.752E-03	4.624	– 42.01

in [5.62, Eqs. (2.9) and (2.10)], the following generalized parameterizations for $\beta_e(\text{IWC}, D_c)$ and $\omega(D_c)$ were postulated

$$\frac{\beta_e}{\text{m}^{-1}} = \frac{\text{IWC}}{10^{-3} \text{ kg m}^{-3}} \sum_{n=0}^N a_n \left(\frac{D_c}{\mu\text{m}} \right)^{-n}, \tag{5.39}$$

$$1 - \omega_s = \sum_{n=0}^N b_n \left(\frac{D_c}{\mu\text{m}} \right)^n. \tag{5.40}$$

The spectral division used in the parameterization and the regression coefficients a_n and b_n are given in Tables 5.47–5.49, respectively. The coefficients a_n in Table 5.48 are determined for a reference ice mass density of $\rho_{i,0} = 916.7 \text{ kg m}^{-3}$ yielding the reference volumetric extinction coefficient $\beta_{e,0}$. By virtue of (5.37) the volumetric extinction coefficient at the actual ice mass

density ρ_i reads

$$\beta_c = \left(\frac{\rho_{i,0}}{\rho_i} \right) \beta_{c,0}. \quad (5.41)$$

In [5.62], it was found that $N = 2$ is sufficient for the extinction coefficient expression to achieve an accuracy within 1%, and $N = 3$ for the single-scattering albedo.

For the representation of the phase function $P(\cos \Theta)$ and the asymmetry factor g of the ISD in the solar wavelengths in [5.62, Eqs. (2.11)–(2.13)], the following parameterizations were proposed

$$P(\cos \Theta) = \sum_{l=0}^M \tilde{\omega}_l P_l(\cos \Theta), \quad (5.42)$$

$$g = \frac{\tilde{\omega}_1}{3}, \quad (5.43)$$

$$\tilde{\omega}_0 = 1,$$

$$\tilde{\omega}_l = (1 - f_\delta) \tilde{\omega}_l^* + f_\delta (2l + 1), \quad (5.44)$$

$$l = 1, 2, 3, \dots,$$

$$\tilde{\omega}_l^* = \sum_{n=0}^N c_{n,l} \left(\frac{D_c}{\mu\text{m}} \right)^n, \quad (5.45)$$

$$f_\delta = \sum_{n=0}^N d_n \left(\frac{D_c}{\mu\text{m}} \right)^n. \quad (5.46)$$

Here, $P_l(\cos \Theta)$ denotes the Legendre polynomials (polynomial solutions to Legendre's differential equation), $\tilde{\omega}_l$ are the expansion coefficients of the four-stream approximation of the phase function, $\tilde{\omega}_l^*$ represents the expansion coefficient for the phase function in which the forward δ -function peak has been removed, and f_δ is the contribution from the forward δ -function peak. The quantity g is the asymmetry factor. The regression coefficients $c_{n,l}$ and d_n for the solar wavelengths are given in Tables 5.50 and 5.51. It was found in [5.62] that $N = 3$ is sufficient for the series expansions of $\tilde{\omega}_l$ and f_δ to achieve an accuracy within 1%.

For the parameterization of $\tilde{\omega}_l$ and g in the thermal infrared wavelengths, in [5.62, Eqs. (2.14) and (2.15)], the following expressions were proposed

$$\tilde{\omega}_l = (2l + 1)g^l, \quad (5.47)$$

$$g(\text{IR}) = \sum_{n=0}^N c'_n \left(\frac{D_c}{\mu\text{m}} \right)^n. \quad (5.48)$$

The regression coefficients c'_n for the infrared wavelengths are given in Table 5.52. In [5.62], it was found that $N = 3$ is sufficient for the series expansions of $\tilde{\omega}_l$ in the infrared region to achieve an accuracy within 1%.

5.6 Absorption Coefficients for Water Vapor, Ozone, and Carbon Dioxide

The incoming longwave atmospheric radiation flux (atmospheric back-radiation flux) impinging on the Earth's surface is a key quantity for climate monitoring and is largely controlled by the absorption of radiation due to different atmospheric gases in dependence on the atmospheric temperature and humidity distribution. Band-model calculations of the back-radiation flux require absorption data for different absorber gases in a large number of spectral lines. In the literature, different methods have been developed for the approximative calculation of this radiation flux on the basis of the radiative transfer equation (RTE), e.g., [5.63].

5.6.1 Effective Mass Absorption Coefficient for Water Vapor and Ozone

The effective mass absorption coefficients $\tilde{\kappa}_{\Delta\lambda}$ of water vapor (in the wavelength interval $5\ \mu\text{m} < \lambda < 44\ \mu\text{m}$) and ozone (in the wavelength interval $9\ \mu\text{m} < \lambda < 10\ \mu\text{m}$) are presented in Tables 5.53 and 5.54. In the wavelength interval $13\ \mu\text{m} < \lambda < 17\ \mu\text{m}$, the absorption of longwave radiation is significantly affected by carbon dioxide (absorption centered at $\lambda \approx 15\ \mu\text{m}$). The absorption effect of carbon dioxide is considered by appropriate adjustment of the effective mass absorp-

tion coefficients of water vapor in Table 5.53. Other atmospheric constituents, such as N_2O , CO , etc., have negligible effects on the absorption of longwave radiation [5.63].

5.6.2 Effective Molar Absorption Coefficient for Carbon Dioxide

The molecular absorption coefficients of carbon dioxide, K_a (in units of $\text{cm}^2 \text{molecule}^{-1}$), in the $15 \mu\text{m}$ absorption band (corresponding to the wavenumber interval $\nu = 582\text{--}752 \text{cm}^{-1}$) are presented in Table 5.55. The table values were calculated using the Information System Spectroscopy of Atmospheric Gases (SPECTRA, <http://spectra.iao.ru/home>) [5.2, 64]. The online databank SPECTRA enables user-friendly access to many spectroscopic parameters for a large variety of atmospheric gases. Depending on the application of interest the user is free in the specification of the gas isotopes, spectral range, spectral resolution, temperature, pressure, etc., considered.

Table 5.55 Molecular absorption coefficient of CO_2 , K_a in units of $\text{cm}^2 \text{molecule}^{-1}$, in the $15 \mu\text{m}$ absorption band as function of wavenumber ν ($\nu = 582\text{--}752 \text{cm}^{-1}$, $\Delta\nu = 1 \text{cm}^{-1}$, $T = 296 \text{K}$, $p = 1000 \text{hPa}$). The data are taken from the Information System Spectroscopy of Atmospheric Gases (SPECTRA, <http://spectra.iao.ru/home>) [5.2]. This table with an enhanced resolution of the wave number of 1cm^{-1} is available as ESM at https://doi.org/10.1007/978-3-030-52171-4_5 ►

The mass absorption coefficient of CO_2 κ_a (in $\text{m}^2 \text{kg}^{-1}$), is given by the following relation

$$\kappa_a = \frac{K_a N_A}{M_{\text{CO}_2}} \tag{5.49}$$

Here, N_A denotes the Avogadro number (Table 5.6) and $M_{\text{CO}_2} = 44.01 \text{g mol}^{-1}$ the molar mass of CO_2 .

5.7 Parameters of Soil

Soil temperature has a measurable impact on water properties relevant for heat storage, heat transport, water binding, and water transport. There is evidence from Table 5.56 that this influence is moderate for most parameters over a range of -5 to 50°C , except for dynamic viscosity, which has a direct impact on soil water

conductivity. For water density and specific heat, see Tables 5.38 and 5.39, respectively.

The bulk density, porosity, and void ratio in natural soil are given in Table 5.57. Loam soils have the highest compaction potential, while clay soils come up with the highest porosity (due to the *cardhouse* structure of the

primary platy clay minerals). However, water in clay pores is—to a high percentage—strongly bound in very fine pores and cannot be extracted by plant roots.

Particle size distribution is typically aggregated to soil texture classes, which are mostly represented in triangular diagrams as functions of clay, silt, and sand contents. Unfortunately, most nations have their own size classification and triangle diagrams. Figure 5.1 shows exemplary soil texture classes according to FAO/HYPRES (Food and Agriculture Organization of the United Nations, European Soil Bureau working group *Hydraulic Properties of European Soils*), USDA (United States Department of Agriculture), GEPPRA (Groupe d'Etude des Problèmes de Pédologie Appliquée, France), and the Soil Science Society of Germany (SSSG). According to SSSG particle size classes are defined by: clay (T): < 2 μm , silt (U): 2 μm to 63 μm ,

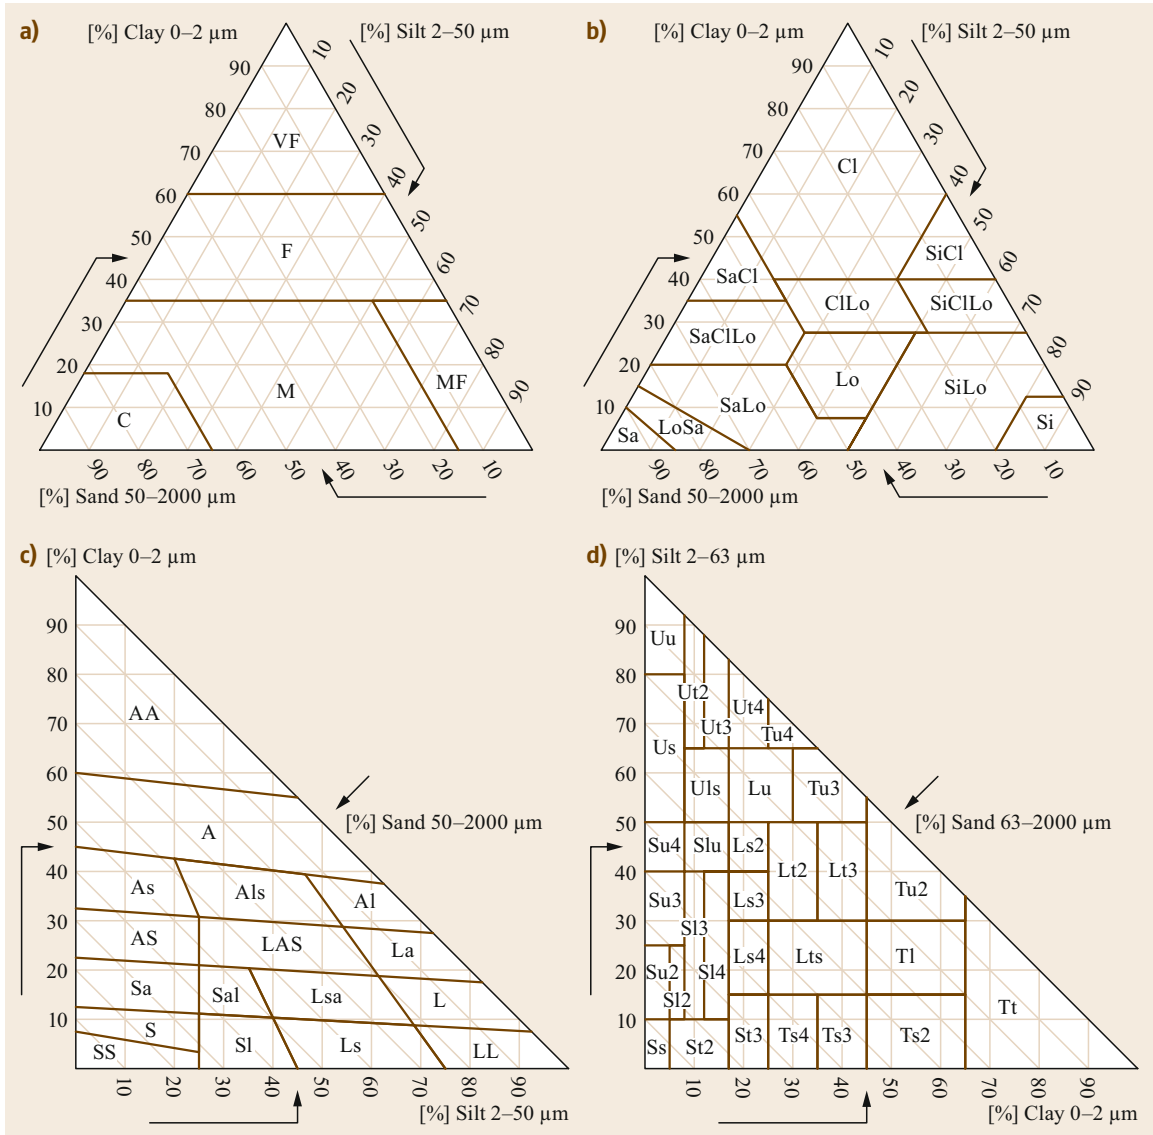

Fig. 5.1a–d Soil texture triangle according to (a) the Food and Agriculture Organization of the United Nations, the European Soil Bureau working group *Hydraulic Properties of European Soils*, (b) the United States Department of Agriculture, (c) the Groupe d’Etude des Problèmes de Pédologie Appliquée, France, and (d) the Soil Science Society of Germany, generated based on (after [5.68–70])

sand (S): 63 to 2000 μm (the same as FAO; the USDA classification differs only slightly, [5.65, 66]).

Soil texture is the aggregated equivalent particle size distribution of soil and conveys basic information about every soil (please note that texture is not the same as soil type, which means the entire soil body with its characteristic horizon pattern). The following tables relate soil texture, bulk density, porosity, and water content to important soil hydrological and

physical (thermal) properties. They provide rough estimates of water retention curves and derived ecological parameters (Tables 5.58–5.61), hydraulic conductivities (Table 5.60), thermal properties (Table 5.62), and parameters of a widely used parameterization of water retention curves and hydraulic conductivity curves [5.71]. However, in most cases, these tables give a first impression but cannot replace detailed measurements.

Table 5.61 Ecological characterization of pore space (%) with an average bulk density ($1.4 \times 10^3 \text{ kg m}^{-3}$ to $1.6 \times 10^3 \text{ kg m}^{-3}$) for different soil textural classes [5.67, simplified]; for more detailed tables see [5.67]

5.8 Time and Astronomical Quantities

The exact definition of time and several astronomical parameters are essential for the documentation of measurements in the atmosphere. For more details, see textbooks on astronomy, like [5.78].

5.8.1 Time Definitions

For time determination, the following definitions are used [5.79]:

Universal Time (UT) is the time scale of the mean solar time, which is related to the zero meridian (Greenwich Meridian), using the mean solar day as a base unit.

Universal Time coordinated (UTC) is the time scale—based on *International Atomic Time*—which, by definition of the zero point of the seconds count, is tied to Universal Time. This time is used in most countries as a basis for civil and scientific time.

Mean Local Time (MLT) is the same time (civil time)—based on the meridian of the place of observation—for all places at the same geographical longitude. It is the solar time measured from the time of the lower culmination of the mean sun by adding of 4 min to the universal time (UT) per degree of longitude in eastern direction.

Official Time is MLT mostly in steps of the 15th degree of longitude. For example, Central European Time (CET) corresponds to the mean local time of the 15th degree east of longitude and is UTC +1 hour.

Daylight Time is that time of the year when the clock is advanced by 1 h in relation to the official time observed to the rest of the year. In most of the countries that use daylight time, summer time begins at 1 a.m.

UTC on the last Sunday in March and ends at 1 a.m. on the last Sunday in October.

Time Equation indicates the periodically changing difference between the real time and the mean solar time due to Kepler’s laws. The time equation is positive if the real solar time culminates earlier than the mean solar time (day of sun). It varies between about −14 min 24 s (about mid-February) and 16 min 21 s (around the beginning of November), see [5.53]

True Local Time (TLT) is the same time (civil time) based on the meridian of the place of observation for all places at the same geographical longitude. The true local time is determined daily by the culmination of the sun. Therefore it varies with the variation of the time equation.

5.8.2 Calculation of Astronomical Quantities

In some applications, it is often necessary to determine the solar inclination angle as a function of time. The following approximations for some of these calculations must be applied in several steps [5.80]:

To determine the declination of the sun, δ , the latitude of the sun, φ_s , must first be calculated [5.81, 82]

$$\begin{aligned}\varphi_s &= x - 77.51^\circ + 1.92^\circ \sin x \\ x &= 0.9856^\circ \text{DOY} - 2.72^\circ, \end{aligned} \quad (5.50)$$

where DOY is the day of the year where the 1st of January has the number 1. Tables for DOY are available, e.g., [5.83].

The declination is given by

$$\sin \delta = 0.3978 \sin \varphi_S . \quad (5.51)$$

To determine the position of the sun, the hour angle ω

$$\omega = (LTST - 12 \text{ h}) \times 15^\circ \text{ in } ^\circ \quad (5.52)$$

must be calculated, which gives the angular difference between δ and the zenith of the sun [5.84]; thereby $LTST$ is the local true solar time. It is necessary to apply the equation of time Z [5.85], which gives the difference between the local true and the mean solar time (x , see (5.50))

$$\begin{aligned} Z = & -7.66 \sin x \\ & -9.87 \sin (2x + 24.99^\circ + 3.83^\circ \sin x) \text{ in min.} \end{aligned} \quad (5.53)$$

The time distance to culmination of the sun, t_H , (for Central European Time $\lambda = 15^\circ$) is given by

$$t_H = \left\{ t - \left[12 + Z + \frac{(15 - \lambda)4}{60} \right] \right\} 3600 , \quad (5.54)$$

where t is time in hours, and λ is longitude.

With the latitude φ in radians of a location, the angle of inclination of the sun can be determined for any time

$$\sin \gamma = \sin \delta \sin \varphi + \cos \delta \cos \varphi \cos \omega . \quad (5.55)$$

Table 5.64 Coefficients of (5.57) [5.86]

n	a_n	b_n
0	1.000110	
1	0.034221	0.001280
2	0.000719	0.000077

To determine the incoming extraterrestrial radiation at the upper border of the atmosphere from the solar constant S (Table 5.6) the variability of the distance between the sun and the Earth must be taken into account

$$K \downarrow_{\text{extraterr.}} = S \left(\frac{r_0}{r} \right)^2 \sin \varphi , \quad (5.56)$$

where r_0 is the mean distance of the Earth from the Sun (149 597 870.66 km) and r is the actual distance. The ratio of both can be determined as a Fourier series [5.86]

$$\left(\frac{r_0}{r} \right)^2 = \sum_{n=0}^2 a_n \cos(n\theta_d) + b_n \sin(n\theta_d) , \quad (5.57)$$

with

$$\theta_d = \frac{2\pi \text{DOY}}{365} , \quad (5.58)$$

where in the case of a leap year, the denominator is 366. The coefficients for (5.57) are given in Table 5.64.

5.9 Tables in Other Chapters

More specific tables are available in other chapters. These are listed in Table 5.65.

Table 5.65 Tables of parameters in other chapters

Table number	Content of the table
7.7	Resistance of thin platinum wires
7.9	Thermocouple output voltage for reference temperature 0 °C
8.7	Contraction of normal and rolled hair for hair hygrometers
8.10	Pressure dependence of the psychrometric coefficient
8.15	Saturated salt solution at 25 °C and their characteristic relative humidity
10.5	Correction factor for pressure on sea level

5.10 Future Developments

After the application of the new temperature scale ITS-90 many atmospheric parameters have an extremely high accuracy, which is not necessary for many practical issues. Therefore, it can be assumed that in the near future, no update of the tables given above will be necessary for atmospheric applications.

Recently, a number of metrological challenges for the measurement of the relative humidity was identified as a key climatological observable [5.52, 87, 88]. The corresponding studies deal, among others, with a generalized definition of relative humidity in terms of fundamental thermodynamic notions like *fugacity* and *activity*, which contain the *de-facto* standard relative humidity definitions as limiting cases. Of special in-

terest for atmospheric applications is the definition of relative humidity by the relative fugacity, which can be directly determined from the TEOS-10/SIA library or from analytical expressions as functions of water vapor mole fraction (or any other humidity measure), temperature, and pressure. The aim is to support the establishment of a SI-compatible standard for the definition of relative humidity for general use (see also Chap. 8).

Changes in the ITS-90 and TEOS-10, which will originate from the application of the new SI definition, are expected to remain safely within the confidence interval of atmospheric measurements of the table values presented here.

Thomas Foken

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

Olaf Hellmuth

Modeling Department
TROPOS Leibniz Institute for Tropospheric Research
Leipzig, Germany
olaf.hellmuth@tropos.de

Olaf Hellmuth is Senior Scientist in the Modeling Department of the TROPOS Leibniz Institute for Tropospheric Research Leipzig. In 1985, he received a diploma in meteorology and in 1988, he was awarded a Dr. rer. nat. His research activities comprise atmospheric sol formation, cloud microphysics with focus on hygroscopic growth and freezing processes, and theoretical aspects of hygrometry. He is member of the Leibniz Sozietät Berlin.

Bernd Huwe

Soil Physics
University of Bayreuth
Bayreuth, Germany
bernd.huwe@uni-bayreuth.de

Bernd Huwe received his Habilitation degree in 1991 in Soil Physics. From 1992 to 2017, he was Professor of Soil Physics at the University of Bayreuth. His research addressed theoretical and practical questions of water, heat, and nutrient and pollutant transport in soils. In this context, soil landscape modeling, regionalization of soil processes, effective modeling, and risk and parameter uncertainty analysis were important tools of his research group.

Dietrich Sonntag (deceased)

Dietrich Sonntag received his doctoral degree from the University of Leipzig in Meteorology in 1951 and his Habilitation degree from the Humboldt University Berlin in 1965. He developed several meteorological sensors mainly for humidity and radiation measurements. In 1988, he was one of the first scientists to be awarded the Professor Dr Vilho Väisälä Award of the WMO. He retired in 1992 and passed away in 2018.

Ground-Based

6. Ground-Based Platforms

Olaf Kolle , Norbert Kalthoff , Christoph Kottmeier , J. William Munger 

Ground-based platforms for atmospheric measurements are carriers for instruments, devices, or systems with the purpose of measuring meteorological variables, atmospheric composition, or more broadly the properties of the land or ocean surface. These platforms can be masts or towers with a wide range of heights and shapes; they can also be buoys and ships.

Starting in the nineteenth century, ground-based atmospheric measurement platforms were needed by national weather services while implementing networks of weather stations. Later, measurement masts and towers became an important tool for fundamental meteorological research. For example, wind data from tall towers in the vicinity of nuclear power plants can be used to help predict the direction of a radioactive plume after a hazardous incident. Tall towers are also built to address climate change questions. Furthermore, dense networks of weather stations are needed to improve weather forecasting and find suitable areas for wind farms. Each measurement platform must be planned and designed with regard to the specific measurement type, purpose, and desired instrumentation. Every platform impacts the measurements themselves and problems such as flow distortion or light reflections must be accounted for during the planning phase. Data from moving platforms like some buoys need to undergo special processing to eliminate artifacts as a result of movement. Most measurement platforms must comply with national and/or international rules and specifications, both structurally and in terms

of safety and regular maintenance. The chapter concludes with examples that illustrate the diverse applications of ground-based platforms for atmospheric measurements.

With most ground-based platforms, atmospheric measurements only take place within the atmospheric boundary layer (ABL, see Chap. 1). Energy conversion and circulation processes in this layer of the lower troposphere strongly influence the biosphere, weather patterns, the climate, and consequently the living conditions for all

plants and animals, in particular for us humans. For these reasons we want to understand all of the processes and feedback at the surface as well as within the atmospheric near-surface layer by trying to measure all relevant environmental variables. The following are advantages of ground-based measurement platforms:

- Simplest way to obtain atmospheric measurements and in many cases easy to install.
- Normally, a high spatial resolution of measurements can be obtained.
- Long-term measurements even at high temporal resolutions are possible (see Chap. 43).
- Various power supply systems can be deployed.
- Flexibility in power consumption and thus suitable for remote places.
- With tall towers, radio transmission masts, and other high buildings, heights of up to several hundred meters (currently more than 800 m) can be reached.

On land, ground-based measurement platforms are usually rigid, stable, and easy to implement. The higher

such structures become, the more complex they will be in terms of stability, safety, and regulations. Moreover, it is always necessary to find a compromise between the stability of a structure and the negative influence of the structure itself on the measurements.

On water, measurement platforms such as ships, floats, or buoys can either actively change their position, move with water currents, or be anchored. Besides horizontal movement, such platforms are exposed to irregular vertical movements and tilting effects due to waves. Therefore, some atmospheric measurements, for instance monitoring wind speed and direction, become more complex and additional postprocessing of the data is needed to correct for the effects of the unstable measurement platform.

6.1 Principles of Platforms

Ground-based measurement platforms are the oldest installations for carrying atmospheric measurement instruments. It is crucial to provide a structure that can carry instruments, sensors, or air inlets exposed to an undisturbed environment, where the meteorological conditions and atmospheric properties are representative for the vicinity. However, the influence of the local conditions on the measurements decreases while moving the sensor vertically upwards, and, at the same time, the area which contributes to the measured values (footprint) increases in size and in distance from the platform. This footprint area must be considered when choosing the position for an observation platform (see annotation in text). The corresponding footprint area can be quite large for tall towers (e.g., [6.1]).

Stationary ground-based measurement platforms must be stable and safe, including for the instrumen-

tion. It must also be technically feasible to attach, maintain, and exchange sensors and instruments without too much effort. Masts and towers can be made of different materials (such as steel, aluminum, or wood), the construction can be open or closed, the structures can be self-supporting or guyed, and they can be of fixed or adjustable height. As the kind of the construction has an effect on the measurements (flow distortion, shadowing, see Sect. 6.3.1) this must be considered in the planning of the observation platform.

Buoys drifting on the water surface or sea ice, or anchored at a fixed location, are made of buoyant bodies of stainless steel or plastic. Their diameters and lengths vary widely and are adapted for the load to be carried. They contain and carry sensors, cabling, electronics, and batteries. Buoys on sea ice need very solid hull material to withstand ice pressure and are shaped to

Table 6.1 Types of platforms

Type	Setup location	Purpose	Remark
Poles and tripods	Land	All types of meteorological and flux measurements	Heights up to 3 m
Small towers	Land	All types of meteorological, air pollution, and flux measurements	Heights up to 80 m or variable heights
Tall towers	Land		Heights up to 350 m
Radio transmission masts and high buildings	Land	Selected meteorological measurements	Heights up to 800 m
Moving platforms	Land	Selected meteorological and air pollution measurements	See Chaps. 37 and 50
Floats	Lakes (low wave height)	Selected meteorological, air pollution, and flux measurements	Additional measurements in the water or on ice
Buoys	Lakes, ocean, sea ice	Selected meteorological and air pollution measurements	
Ships	Rivers, lakes, ocean	Selected meteorological and air pollution measurements	

keep them at the surface. They are deployed either from ships via cranes or smaller systems can be mounted using helicopter transport or by parachute dropping from fixed-wing aircraft.

6.2 History

Weather vanes (or wind vanes) were the earliest sensors used for indicating the actual weather situation and making simple weather predictions. In the early first century BCE, the 13-m-high *Tower of Winds* (see Fig. 6.1) was built in Athens by the Greek architect *Andronikos of Kyrrhos* [6.2]. On top of this tower a weather vane shaped like a *Triton*, a daemon of the ocean, and made of bronze was spinning [6.3].

Such ancient weather vanes made of textile or metal arose and have been used where it was important to be able to predict the weather by reading wind direction

Fig. 6.1 An illustration of the *Tower of Winds*, which was built between 100 and 50 BCE in Athens, Greece. It is considered the world's first meteorological station (after [6.4], clipart courtesy FCIT)

Table 6.1 summarizes the major types of ground-based platforms. Airborne platforms and moving platforms are described in detail in Chaps. 37 and 50, respectively.

and wind velocity from the direction and rotary motion of the weather vane. The ground-based platforms for these early sensors were usually simple metal poles on high buildings such as steeples or lighthouses, on roof ridges, or on ship masts.

In 1780, the *Societas Meteorologica Palatina*, the Meteorological Society of Mannheim, Germany, was founded. This was the first society that organized transnational meteorological observations carried out at fixed reading times. Later, in the middle of the nineteenth century, the need for specific sensor platforms arose with the rise of continuously recording instruments. Early versions of recording instruments had paper charts and mechanical apparatus to record on the paper. This, and the need to measure from a standard height above ground, gave rise to the standardized louvered box that was typically deployed at weather stations. The installation had a roof overhead to protect the instruments from weather and shield them from direct sunlight, but had well-ventilated sides so the temperature inside the box would be the same as the outside air temperature away from the structure. To measure wind velocity and wind direction at the standard height of 10 m above ground, the wind instruments were mounted on the top of a self-supporting or guyed mast.

Nuclear fission research and the beginning of peaceful uses of nuclear energy with the world's first nuclear power plant in Obninsk in the former Soviet Union, which began delivering electrical energy on 26 June 1954, forced the erection of meteorological masts in the vicinity of such nuclear plants. In Obninsk, a 315-m-high cable-stayed steel-tube mast was constructed in 1958 with several measurement platforms carrying instruments to measure radioactivity and meteorological variables. The first nuclear research reactor in Germany was established in 1957 at Garching and in 1959 a 50-m-high measurement mast was completed and then replaced by the 62-m-high Oskar-von-Miller Tower in 2010. The building permit for any nuclear plant usually requires the erection of a measurement mast. In the case of a major plant failure with radioactive leakage, it is essential to have access to current meteorological data to be able to forecast the propagation of the radioactive plume.

When researchers started to experimentally investigate atmospheric turbulence, fluxes of momentum, and sensible and latent heat in the early 1960s, they used smaller masts and towers with heights of up to 16 or 32 m. During the first experiments (e.g., [6.5]), profiles of wind velocity, air temperature, and humidity were measured at several heights to utilize the data for analysis of the turbulent transfer processes for heat and water vapor. In 1968 and 1973, the well-known Kansas and Minnesota boundary-layer experiments were conducted and, besides profile measurements, eddy-covariance instrumentation was also deployed on the measurement masts [6.6].

During the first decade of the twentieth century, an international cooperation was initiated to establish a weather monitoring network based on merchant and postal ships as moving platforms, making use of radio transmission techniques to communicate the observations and data to the national weather services in real time. Starting in 1941, the allies established a network of eleven stationary weather ships in the North Atlantic, which was active for 30 years. Beginning in the 1960s, the weather ships were increasingly pushed aside as weather satellites, long range aircraft, and weather buoys became more and more common. The last weather ship, the *Polarfront*, was suspended from service by the Norwegian government in 2009. During the Second World War, the German Navy distributed approximately 15 weather buoys using radio transmis-

sion (WFS buoys) in the North Atlantic. In regular intervals, these buoys were able to automatically surface from their underwater standby position to take measurements and transmit data to the navy weather service.

With this progress in meteorology and atmospheric sciences, a huge development in atmospheric measurement techniques and instrumentation followed. Measurements ought to expand in space and should at the same time increase their spatial and temporal resolution. This leads to an enormous demand for a variety of measurement platforms carrying all kinds of instruments. Ground-based measurement platforms can be categorized as follows:

- Weather stations: Instrument shelter 2 m above ground and masts up to 10 m high
- Stations to measure meteorological variables and turbulent fluxes at a single height or as profiles: Tripods, small poles, and masts for bare soil and low vegetation; tall masts and towers up to 100 m above ground for high vegetation
- Stations to deliver data for modeling (back) trajectories above the boundary layer and to measure trace gas and aerosol concentrations in and above the boundary layer: Tall towers 200–400 m above ground
- Stations to measure meteorological variables, turbulent fluxes, trace gases, and aerosols above water (lakes and open sea): Buoys and ships

6.3 Theory

A number of partly obvious difficulties and problems that can occur when using ground-based measurement platforms must be addressed to avoid artifacts in the results of the measurements by misinterpretation of the collected data. Masts and towers can influence the variables that in fact ought to be unaffectedly measured by the instruments attached to the structure. The first subsection will address such problems and present some guidelines and recommendations on appropriate measurement setups. When using buoys or ships to perform atmospheric measurements it is particularly necessary to correct the wind data for the movement of the platform itself. All ground-based platforms may be affected by oscillations, vibrations, and resonance phenomena triggered by wind or motion of the sea, which must be accounted for, especially in case of turbulence measurements. Wind-induced oscillations, on the other hand, can endanger the structure itself and may result in the collapse of the mast or tower [6.7].

6.3.1 Flow Distortion

The support structure for meteorological instrumentation inevitably distorts the microclimate and wind field nearby. The goal when establishing a measurement site is to reach an optimal solution that minimizes measurement biases while still providing a safe and reliable platform. Extensive theory and observations made in wind tunnels and in the field provide ample guidance on the magnitude and extent of flow distortion and modification of microclimates around structures.

Wind flow is impacted on all sides of a structure [6.8,9]. Based on field observations and wind-tunnel experiments with a scale model, a substantial downwind tower shadow effect with up to 40% interference within two structure diameters was reported [6.10]. In this case, the tower was an open structure triangular radio-type tower and not a solid structure. Some results suggest that the magnitude and

size of structure wake effects depend on wind speed. Increased turbulence at higher wind speed may limit the persistence of downwind wake [6.11–13]. A stagnation point forms on the upwind side of a structure where wind is blocked and flow streamlines diverge around the obstacle. Field observations and wind-tunnel models find wind speed reductions of up to 30% extending out to one structure diameter upwind of the platform [6.10, 12, 13]. Mass conservation causes wind flow to accelerate as it passes around an obstacle [6.14]. Observed wind speed increases in the range of 10–20% extending out to two structure diameters are reported for towers in the field and wind-tunnel models [6.10, 12, 13]. Wind flow is distorted above a structure as well as to the side. Some of the diverted flow goes up and over the structure rather than around the side [6.12, 13, 15]. As much as 40% acceleration of wind in the vertical axis at the upwind face of a large box-like structure was reported [6.12, 13]. Where there is flow distortion or wake turbulence, wind direction will be influenced as well, contributing both mean offsets and increased variability. Apart from the reduction of the mean wind speed, the spectra and cospectra exhibit a strong anisotropy for such cases. The results from [6.16] demonstrate the significant influence of a tower on turbulence spectra in the wake region of a meteorological tower. A major source of wind measurement uncertainty is due to complex wind flow distortion caused by the lattice geometries of masts. In [6.17], computational fluid dynamics and wind-tunnel experiments were used to study those effects to quantify this uncertainty and suggest guidelines for mounting instruments. The *European Wind Atlas* [6.18] also formulates clear selection criteria for high-quality wind observation sites and claims to avoid selecting stations where flow distortion or sheltering by nearby obstacles is suspected at the anemometer location.

6.3.2 Impact on Other Measured Variables

Platform structures can affect other meteorological parameters as well. Shadows and reflections alter light measurements. Similarly, differences in heating or cooling of the platform structure compared to the surroundings can influence long-wave radiation measurements. Anomalous heating and cooling of the platform structure will alter the temperature of air close to or passing through the platform structure. Shifts in temperature cause shifts in relative humidity. Furthermore, temperature and wind can directly interact with each other. Temperature differences near the structure will induce convective flows that introduce a vertical component

to wind measurement as well as distorting the vertical wind profile. The vertical components of wind that are induced by diversion around the structure will distort the vertical temperature profile.

On account of physical affects from platform structures that bias meteorological parameters, the best advice is to make the structure as small and open as possible. Available evidence suggests that sensors should be placed a minimum distance of two structure diameters away from the platform face. Being outside the region of flow disturbance should be sufficient to ensure unbiased temperature measurements. For smaller, lighter structures the two-diameter limit will be easier to achieve without imposing serious engineering challenges. Horizontal booms oriented into the prevailing wind direction are usually sufficient. Alternatively, anemometers could be installed at two opposing sides of a tower to allow selecting the data from the windward exposed anemometer only [6.1] (see Fig. 6.1). Note that because structures may induce vertical flows (also referred to as the chimney effect), vertical posts extending directly above a structure are not an ideal solution. On the other hand, the top of the structure is an ideal location for measuring downwelling radiation because there is nothing above to cast shadows. Sensors for measuring upwelling radiation will need to be positioned as far from a structure as possible in order to minimize the area of structure that is in the sensor field of view. Many radiation sensors combine the upward and downward components. They should be placed on the equatorward side of structure so the sun stays in front of the sensor and the structure is behind.

Oscillation and vibration platforms, outriggers, and booms can directly have a negative influence on the performance or operation of specific instruments due to resonance phenomena. Some gas analyzers have built-in rotating chopper disks that might resonate with platform vibrations and provoke malfunction of the instrument [6.19]. Thermocouples with very fine wires are susceptible to vibrations and can be damaged at specific amplitudes and oscillation frequencies [6.20]. The same applies to the filament of the infrared source of some gas analyzers. If tipping bucket rain gauges are not installed stiff enough on a tower, tipping might be triggered by strong or gusty winds. Turbulence measurements with fast sonic anemometers or sphere anemometers can be distorted by oscillations or vibrations of the instrument's carrier [6.21]. Generally, sensors mounted on towers will be subjected to wind-induced vibration, so it is important to make sure that locking nuts are used to secure the equipment [6.22].

6.4 Platforms and Sensor Installations

In the following subsections, various ground-based measurement platforms and their application areas will be described in detail.

6.4.1 Small Towers

To be able to obtain worldwide comparable meteorological data that can be used for a synoptic overview and as input for weather forecast models, it is essential to measure and collect the data as similarly as possible at all observation stations. For this reason the World Meteorological Organization (WMO) developed regulations and guidelines for the setup of weather stations [6.23] (see Chap. 43). These guidelines were adapted by the national weather services and implemented whenever the networks for manual and automated weather stations were established and extended.

A commonly accepted weather station consists of at least three ground-based platforms:

- An instrument shelter housing sensors for air temperature and humidity that protects the instruments from rain and solar radiation (see Fig. 6.2)
- A short pole carrying the rain gauge so that the receiving surface is 1 m above ground level (AGL) (AGL))
- A mast on top with a height between 10 and 12 m carrying sensors for wind velocity and wind direction

Today we have tens of thousands official and private weather stations worldwide, most of them long-term or permanent installations. In addition, a large variety of small masts and towers (< 100 m high) are deployed for atmospheric measurements ranging from short-term experiments to long-term observations.

Small towers are normally used to measure profiles of meteorological and air chemical parameters in the surface layer. This is done over bare soil or over low vegetation as well as in and above forests. Additionally, small towers are used to determine the different components of the energy balance equation of the underlying Earth's surface. For this, profiles of either temperature, humidity, and wind speed are captured (profile method, e.g., [6.24]), the Bowen ratio (e.g., [6.25–27]) is applied (see Chap. 57), or the eddy-covariance method (e.g., [6.28]) is utilized (see Chap. 55). Typically such masts and towers are also used as platforms for various spectrographic measurements, for carrying cameras to follow the phenological development of the vegetation, or to support laser scanners investigating the structure of forests.

Fig. 6.2 Instrument shelter and mast for wind measurements at the Hohenpeißenberg Meteorological Observatory (photo (enlarged detail) © Christoph Radtke)

Masts and towers have a wide spectrum of structural shapes, geometries, and materials used for their construction.

Poles and Tripods

The simplest ground-based measurement platforms are short vertical poles with or without supporting guys

Fig. 6.3 A temporary weather station on a tripod with instruments for wind velocity, wind direction, air temperature, and humidity as well as a precipitation gauge on a simple pole (photo © Olaf Kolle, MPI-BGC)

Fig. 6.4 Erecting short (and flexible) masts by folding up with a winch

or tripods to carry single instruments, Bowen-ratio systems, subcanopy eddy-covariance measurements or small weather stations as shown in Fig. 6.3.

Flexible Tube-Type Masts

Short masts up to approximately 16 m can be constructed of tubing made of steel, aluminum, or glass-fiber reinforced plastic (GRP) material as a single piece or as pluggable segments; a single wooden pole is also conceivable. The great benefit of the metal and GRP types is their small diameter so that any disturbance by the structure itself is minimized. As a function of height, diameter, material, wall thickness, load, and tolerable oscillation, such masts can be self-supporting or guyed. A common method to erect such short masts is shown in Fig. 6.4. Using a supporting mast and a swivel joint at the structure base, the mast is lifted up from the horizontal ground position to the vertical position by a manual or electric winch.

The thin tube-type masts shown in Fig. 6.5 cannot be climbed, so the instrumentation must be mounted to the mast in the horizontal position before erecting the structure. In this case, the attachment, the correct orientation, and the fault-free functioning of the instruments must be examined accurately beforehand. At a later stage, the devices attached to the mast can only be accessed after folding down the mast again.

Masts and Towers of Special Material

More solid and higher masts and towers are fabricated from steel, aluminum, or in some special cases from wood. To avoid corrosion, steel structures are commonly galvanized or coated with anticorrosion paint; stainless steel can also be used (see Fig. 6.6).

Metal structures that are located close to a coastline are exposed to salt aerosols and salty sea spray, which usually results in near-term damage such that a mast or tower may become unstable and inoperable. An appropriate alternative for such environmental conditions is a mast constructed from timber. Figure 6.7 shows a 30-m-high tower close to the shore of the island São Vicente (Cape Verde Islands) as an atmospheric measurement platform for the *Cabo Verde observatorio atmosférico Humberto Duarte Fonseca*. Initially, a metal tower (galvanized scaffolding material) was built, but unfortunately the corrosion was so intense that safety

Fig. 6.5 A line of thin tube-type masts during the LOTREX 10E (Longitudinal Land-Surface Traverse Experiment 10 E)–HIBE 88 (Hildesheimer Börde Experiment 1988) experiment (see also Sect. 6.8.2) (photo © Olaf Kolle, MPI-BGC)

could not be guaranteed after only two years of operation. Subsequently a walk-up tower made of timber with connecting and clamping elements of stainless steel was erected, which has been a long-lasting solution.

The shape of masts and towers is usually rectangular (Figs. 6.6–6.9), triangular (Fig. 6.10), or round (less frequent). Self-supporting structures must have a tapered shape in the vertical direction so that the bending moments can be absorbed adequately and the forces can be transferred into the concrete foundation. For guyed masts, a ballast bed of at least 0.5 m depth is sufficient.

Fig. 6.9 Installation of a 45-m walk-up tower in a beech forest in Thuringia, Germany (photo © Martin Hertel, MPI-BGC)

The adjustable legs of the mast should stand on wooden planks, concrete slabs, or special aluminum frames. The shape and dimensions of guyed masts are predominantly identical over the entire height of the structure. Rectangular masts are anchored in four directions and triangular ones in three directions. The anchoring

heights along the tower, the angles and tension of the guy wires, and the type and dimensions of the anchors may be prescribed by the manufacturer of the tower material or must be calculated by a structural engineer. The angles of the guy wires with respect to the horizontal should range between 30 and 60°. Strong soil pegs or special bolts for soil, rocks, or big blocks of concrete

Fig. 6.10 A 36-m triangular mast near Tanguro, Brazil, during the installation of isolated lightning protection wire (photo © Martin Hertel, MPI-BGC)

can be used as anchors. For a short-term installation, masts in forests may also be guyed to the base of trees.

Walk-Up Towers

Among the climbable masts and towers, we distinguish between so-called walk-up towers (Figs. 6.7–6.9), which have an integrated staircase, and structures that can be accessed only by a vertical ladder or by using the structural elements themselves for climbing (Figs. 6.6, 6.10). Walk-up towers consist either of identical segments that are stacked one upon the other or they are assembled by many individual pieces of scaffolding material. The base area of such towers is approximately $2.0\text{ m} \times 1.5\text{ m}$ and the individual aluminum segments are between 1.8 and 2.0 m high. For transport, the connecting bars are released and the segments are folded flat. This kind of tower can reach maximum heights of approximately 80 m.

A group of technically skilled and physically trained people is able to erect a 50-m-high segmented walk-up tower within three days. The segments are lifted with a crane that is gradually raised so that it is always on the top segment. If the tower is built in a forest, a crossbow with a fishing line attached to the arrow

Fig. 6.11 A 10-m tower of box-type aluminum profile on a wooden platform in a swampy area in Central Siberia close to the Zotino Tall Tower Observatory (ZOTTO) (photo © Martin Hertel, MPI-BGC)

can be used to find the path for the guy wires through the crowns of the trees (see Fig. 6.9).

Masts for Vertical Climb

Masts for vertical climb have a smaller base area with an edge length between 30 and 60 cm. In most cases, these masts are of triangular or rectangular shape and consist of segments 3–6 m in length. The typical triangular mast material shown in Fig. 6.10 is normally used to carry antennas for the mobile network.

The rectangular box-type aluminum profile of the tower shown in Fig. 6.11 is assembled from many identical aluminum sheets of $1.2\text{ m} \times 0.3\text{ m}$, which are bent by 45° along both long sides so that the sheets can be bolted together. The sheets are vertically shifted, which gives more stability to the whole structure. This type of tower is very well suited for remote areas because all parts can be transported in easy-to-handle boxes that are no longer than 1.25 m. Some disadvantages are the higher wind resistance compared to an open mast,

Fig. 6.12 A telescopic mast on an agricultural field near Gebesee, Germany (photo © Martin Hertel, MPI-BGC)

the more pronounced wind field distortion, and the influence on radiation fluxes, which can be reduced to some extent by coloring the surface. Furthermore, special mounting material is needed to attach outriggers and sensors.

To make the vertical climb more convenient and safe, it is strongly recommended to equip such masts and towers with a combination of rungs and safety rails as shown in Figs. 6.10 and 6.11.

Special-Purpose Masts

For special purposes, mobile towers and telescopic masts are available. The telescopic mast shown in Fig. 6.12 was used to be able to adjust the measurement height of the eddy-covariance system to maintain the flux source area independent of the height of the vegetation. Following a simple model, the measurement height can be increased while the plant cover is growing.

Mobile masts as shown in Fig. 6.13 can easily be moved between different deployment locations and are operational within a few hours. These devices are also usually telescopic masts mounted on a trailer. The masts

Fig. 6.13 A mobile mast with a maximum height of 25 m in the Spanish Dehesa (photo © Olaf Kolle, MPI-BGC)

Fig. 6.14 A 10-m mast with rotatable arm on top (photo © Olaf Kolle, MPI-BGC)

are lifted up either by a winch and a complex steel cable system inside the box profiles of the segments or by a hydraulic system. On telescopic masts, it is not possible to attach outriggers or instruments at any freely selectable height.

Figure 6.14 shows a special mast installation with a rotatable arm at a height of 10 m that carries a net radiometer and sensors for radiation measurements in narrow spectral bands with a small field of view. By rotating the arm in regular intervals the radiative properties of the tree and the surrounding grassland can be compared using the same set of instruments. An antenna rotator is used to turn the horizontal arm to any desired direction.

6.4.2 Tall Towers

Tall towers, which reach 200–325 m AGL, are predestined for investigation of the nocturnal stable boundary layer (NSBL) because they cover the corresponding layer. For studies of the convective boundary layer, a combination with additional systems is necessary (e.g., see Chap. 47). Furthermore, tall towers are very well suited to investigate issues related to wind energy (as most tall towers cover the hub height of the wind turbines) and the environment of forests. Finally, the

Table 6.2 Selection of tall towers for meteorological observations

Name of tower	City/Region	Country	Height (m AGL)	Year built	Research field
Amazon Tall Tower Observatory (ATTO)	Vila de Balbina	Brazil	325	2015	Climate studies and exploration of the rainforest biosphere

Obninsk Meteorological Tower	Obninsk	Russia	310	1958	For meteorological and radioactivity measurements

towers are often used to test novel remote-sensing systems. Table 6.2 summarizes some of the tallest towers and their fields of research. Some of them are discussed in more detail below.

Amazon Tall Tower Observatory

The Amazon Tall Tower Observatory (ATTO) is a scientific research facility located in the Amazon rainforest of Brazil that has a 325-m-high lattice structure shown in Fig. 6.15 [6.29]. Also part of the research site are two smaller 80-m towers, one of which is a rectangular scaffolding walk-up tower and the other a triangular mast [6.30]. The official start of the project was in 2009, the foundation stone ceremony for the tall tower was in August 2014, and the structure was completed in August 2015. The ATTO tower, currently the highest structure in South America, it is located 150 km northeast of Manaus at 2.1458694° S, 59.0055889° W, and 80 m above main sea level (ASL). The major research goals of this observatory are:

- To collect data that improves our knowledge of the influence of the huge rainforest area on the climate (atmosphere–biosphere model validation)
- To locate and understand sources and sinks of greenhouse gases such as CO₂, CH₄, and N₂O
- To investigate aerosol formation, which is important for cloud formation

- To investigate transport processes of air masses over large distances of several hundred kilometers (atmospheric chemistry monitoring)
- To investigate smaller-scale transport processes within the turbulent boundary layer

The rectangular tall tower, with an edge length of 3 m, is guyed in four directions at six levels. Twelve measurement levels, each with a narrow balcony and a 4.5-m-long folding outrigger, are distributed along the tower at heights of 42, 81, 99, 126, 150, 171, 195, 222, 246, 273, 297, and 321 m AGL. The outriggers point in the northeast direction because this is the prevailing wind direction and in 80% of all cases the wind is coming from the sector ± 90 degrees relative to the outrigger direction. To also be able to catch the remaining 20% of weather situations, there is one additional measurement level at 192 m where the outrigger points in the opposite direction towards the southwest.

At all levels, temperature-humidity sensors and 3-D sonic anemometers are installed. Additional flux measurement systems for CO₂ and H₂O are available at 83 m AGL and on both outriggers at around 195 m AGL, where two net radiometers with short- and long-wave incoming and outgoing radiation components as well as sensors for photosynthetically active radiation are installed. Air inlets for instruments sitting inside containers at the tower base for measurements of aerosols (two

Fig. 6.15 The ATTO tall tower near Manaus, Brazil (photo © Martin Hertel, MPI-BGC)

lines), greenhouse gases (six lines), and reactive gases (three lines) are distributed along the tower at different levels. Due to the gap in the forest at the tower base it makes no sense to continue the profile measurements below the 44 m level. Therefore, more densely staggered profile recordings of meteorological variables, trace gas concentrations, and fluxes are continued on the 80-m scaffolding tower close by because there is virtually no disturbance of the forest structure. In the center of the tower, there is a lift shaft for a freight elevator that can carry up to 250 kg. A novel battery-powered personnel lift for operational work (HighStep Systems) can bring an individual to the top of the tower within 13 min.

Zotino Tall Tower Observatory

The Zotino Tall Tower Observatory (ZOTTO) is a climate research facility located in the Siberian Taiga close to the village Zotino, which is situated at the shore of the Jenissei river approximately 600 km north of Krasnojarsk [6.31]. The research station has been operational since October 2006. The coordinates of the facility are 60.7983920° N, 89.3535260° E and the

Fig. 6.16 The ZOTTO tall tower near Zotino, Central Siberia (photo © Michael Hielscher, MPI-BGC)

tower base is at 120 m ASL. The tall tower is a triangular guyed structure consisting of discrete segments, each 6.5-m long, with a total height of 301 m AGL (see Fig. 6.16). The edge length is 3 m, the segments are made of welded steel tubes, and they are connected to each other by bolted flanges. Vertical ladders lead to the top and every 13 m on a small platform the ladder segments are horizontally displaced; there is no elevator.

The major research goals of this observatory are similar to those of ATTO (see above), but in a very different climate zone and above a different ecosystem. Measurement platforms with a balcony are located at 4, 52, 92, 158, 227, and 301 m AGL. At these levels, continuous high-precision gas concentration measurements of CO_2 and CH_4 , as well as meteorological measurements (air temperature and humidity, 3-D turbulent wind field, and partly air pressure), are implemented. Air inlets for aerosol and CO measurements are installed at 301 and 52 m AGL, but only at 30 m for ozone and NO_x .

Ochsenkopf (Integrated Carbon Observation System Atmospheric Measurement Network)

The Ochsenkopf TV Tower shown in Fig. 6.17 is a reinforced concrete structure built in 1958 on top of the Ochsenkopf Mountain in the Fichtelgebirge at an elevation of 1024 m ASL and at 50.029888° N, 11.808337° E. The tower is 188 m high and in 2003 the Max Planck Institute for Biogeochemistry equipped it with instruments as part of the Tall Tower Atmospheric Gas Measurements framework.

Gas analyzers for continuous trace gas measurements and a flask-filling facility have been installed in a container at the tower base. Meteorological variables are measured continuously at a height of 163 m AGL. After a measurement technology upgrade, the site was integrated into the Integrated Carbon Observation System (ICOS) project (see Chap. 64).

Fig. 6.17 The Ochsenkopf TV Tower, where the German Meteorological Service (DWD) operates an ICOS atmospheric measurement facility (photo © Falk Hänsel, MPI-BGC)

Boulder Atmospheric Observatory

The 300-m-high Boulder Atmospheric Observatory (BAO) tower—an open lattice structure built in 1977—

was located on gently rolling terrain 25 km east of the foothills of the Colorado Rockies 1584 m ASL at 40.0500279° N, 105.0038355° W [6.32] (see Fig. 6.18). It was installed to serve as a research facility for studying the ABL and calibrating and testing meteorological sensors (e.g., [6.33]). It served the needs of a broad range of users. The tower was decommissioned in July 2016. On the tower, the instrumentation for measurements of mean and turbulent parameters was distributed at 10, 22, 50, 100, 150, 200, 250, and 300 m AGL [6.34]. Due to the tower's height, its top almost always extended above the nocturnal ABL, thus enabling observations of turbulence structure in stable layers [6.35]. Another research topic, also related to stable stratification, was the investigations of gravity waves and turbulence [6.36] and gravity wave climatology [6.37]. As the top of the tower nearly extended above 25% of the daytime convective boundary layer (CBL) [6.34], convective properties could be investigated as well like the diurnal behavior of boundary-layer winds [6.38]. A summary of the most important experiments conducted at BAO appears in [6.39].

Karlsruhe Institute for Technology Integrated Atmospheric Observation System (KITcube)

The Karlsruhe Institute for Technology (KIT) meteorological tower (see Fig. 6.19) was built in 1972 and is part of the KITcube observation system [6.40], which consists of a transportable [6.41] and fixed part. The measurements started in December 1972 and have been running to this day without any long breaks. With a height of 200 m AGL, this observation platform is among the largest meteorological towers in Europe. The

Fig. 6.18 (a) The Boulder Atmospheric Observatory with a 300-m triangular-segmented tower (photo © Shelby Frisch, NOAA Earth System Research Laboratory); (b) View from tower top to ground facilities (photo © Jon Kofler, NOAA/ESRL Global Monitoring Division)

Fig. 6.19 The Karlsruhe KITcube tower, where anemometers are installed at the two prevailing wind directions to minimize the effect of wind distortion on the measurements (photo © Stephan Kraut, KIT)

lattice tower is situated at 49.0925° N, 8.4258333° E, and 110.4 m ASL in the upper Rhine Valley in the southwestern part of Germany [6.1, 42]. The tower is equipped with sensors to monitor profiles of temperature, humidity, wind speed, and wind direction. Booms for the sensors are at 20, 30, 40, 50, 60, 80, 100, 130, 160, and 200 m AGL. Sonic anemometers at three heights (40, 100, and 200 m AGL) provide turbulence information. Additionally, air pressure, short- and long-wave radiation components, and precipitation are measured on a meadow close by. To avoid wind measurement disturbances due to the structure of the tower, the wind measurements at each level, except for those at the lowest and uppermost levels, are carried out on two different booms, one oriented to the west, the other to the east. Depending on the mean wind direction, the measurement from the respective windward direction is taken to calculate the mean wind speed.

The tower is used for climate studies [6.1], investigation of phenomena in the boundary layer, like counter currents in broad valleys [6.42], and for validation of remote-sensing instruments like sodar (sonic detection and ranging) or Doppler lidar (light detection and ranging) systems [6.43].

Koninklijk Nederlands Meteorologisch Instituut (KNMI) Cabauw Tower

The Cabauw Tower is part of the experimental site for atmospheric research (CESAR [6.44]) observatory, which is located in the western part of the Netherlands. The coordinates of the tower are 51.9711111° N, 4.9266667° E, and the foot of the tower is at 0.5 m below mean sea level. The surroundings are flat with surface elevation changes of at most a few meters within a radius of 20 km consisting of meadows and ditches, with scattered villages, orchards, and lines of trees. The tower was built in 1972 and was first described in [6.45]. Booms for temperature, humidity, or wind are at 0, 0.6, 2, 10, 20, 40, 60, 80, 140, 180, and 200 m AGL. Short-wave radiation is measured at the tower's top (214 m AGL). Additional information about the facilities can be found in [6.46]. Close to the tower, micrometeorological measurements of the energy balance components, including soil temperatures and various radiation measurements, complement the tower observations. The tower is operated to study relationships between land–surface properties, the state of the ABL, and general weather conditions. For example, in [6.47] the tower data were used for the validation of a model determining the growth of the ABL height. A comparison of resistance laws with observations for the height of the stationary boundary layer during stable lapse rate conditions from the Cabauw tower has been described in [6.48]. The tower also serves as a reference for the comparison of ABL diffusion schemes and air pollution models [6.49, 50]. Figure 1.9 shows the footprints of tall towers in Europe.

6.4.3 Buoys and Floats

A buoy is a buoyant floating device that can have many purposes. Buoys can be moored or they can drift on the ocean surface, sea ice floes, or icebergs. Drifting and moored data buoys are now generally accepted and getting widespread application as a very cost-effective means for obtaining meteorological and oceanographic data from remote ocean areas. Data buoys measure and transmit data automatically in near real time via satellite telecommunication systems such as Argos, ORBCOMM[®] (International company for Asset Tracking, Monitoring and Control), and Iridium. Observations with data buoys make significant contributions to our ability to understand, describe, model, and predict global weather, as well as to monitor surface weather and climate on all time and space scales. The data collected are used to validate data from other platforms, such as from ships or weather satellites. By transmitting data via the Global Telecommunications System (GTS), automatic buoys are used for data assimilation in forecast models.

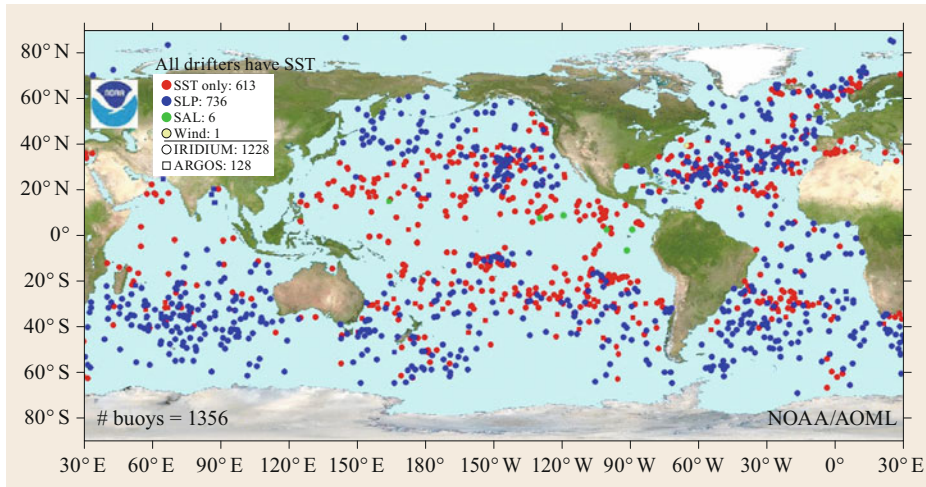

Fig. 6.20 A global composite of drifting buoy locations on an arbitrary day (13 May 2019). It covers the subset of drifters with meteorological sensors and documents the large international efforts in maintaining a global observation network with major gaps only in the polar regions and certain tropical parts of the oceans (adapted with permission from NOAA/AOML)

Many different types of drifting buoys and moored buoys (see Table 6.5) have been deployed and national activities are coordinated by various international organizations and working groups, such as the Data Buoy Cooperation Panel (DBCP), the International Arctic Buoy Program (IABP) and International Programme for Antarctic Buoys (IPAB) of the World Climate Research Programme (WCRP), the Global Drifter Program (GDP), and associated data centers. Figure 6.20 shows a typical example of the global composite of drifting buoy locations.

Drifting Buoys

Drifting buoys on the open ocean measure ocean surface and atmospheric conditions. Drogues or subsurface sails are attached to them to get a drift representative of the upper ocean current at a depth of about 10 m. Buoys that track surface currents are called Lagrangian drifters. They can be deployed easily, are cost-efficient, and easy to operate for an average lifetime of 18 months [6.51]. Buoys that track surface currents in this way track ocean currents at the depth corresponding to the length of their drogue while collecting surface and subsurface measurements. They have been used for a long time in oceanography and marine meteorology. There have also been many types of drifting buoys used for meteorological purposes since the First GARP (Global Atmospheric Research Program) Global Experiment (FGGE) in the 1970s. Lagrangian drifters were first designed and deployed in the world oceans in the context of the Surface Velocity Program (SVP) of the World Ocean Circulation Experiment (WOCE), which

became the GDP. The Data Buoy Cooperation (formerly Data Buoy Cooperation Panel DBCP) [6.51] was established decades ago to design standardized drifting buoys to fulfill observational requirements for meteorological and oceanographic applications. The SVP drifters were standardized in 1991, with small spherical hulls and floats, and a large drogue centered at 15 m below the surface. In 1993, drifters with barometer ports, called surface velocity program barometer (SVPB) drifters were tested in the high seas and proven reliable. The Lagrangian barometer drifter, designed by the GDP, is now commercially available at low cost and meets both oceanographic requirements (research: measurements of sea surface currents and sea temperature) and meteorological requirements (operational: sea surface temperature and air pressure).

Ice Buoys

Ice buoys, as shown in Fig. 6.21, have been used to some extent in Arctic and Antarctic regions to track sea ice or iceberg movement and are available commercially for deployment by ships or aircraft. Such buoys are equipped with low temperature electronics and lithium batteries that can operate at temperatures down to -50°C . In addition to the original locations from the Argos satellite system (accuracy ≈ 350 m), modern ice buoys are equipped with receivers for satellite navigation systems, which can compute the positions more accurately (better than 50 m). Buoy positions are determined from Doppler shifts of transmitter signals observed from different satellite positions (see Fig. 6.22). The accuracy of the position depends on transmitter sta-

Fig. 6.21 An antarctic sea ice buoy deployed during the 1989 Winter Weddell Gyre Study by Alfred Wegener Institute Bremerhaven/Univ. Hannover. It takes meteorological observations with a propeller/wind vane anemometer on a 3-m tripod, air pressure, air temperature, and ocean mixed-layer temperatures with a 200-m-long thermistor chain beneath the 2-m-thick ice flow, and sea ice temperature profiles with a thermistor rod (photo © D. Engelbart)

bility and satellite constellation geometry. Buoy data logging systems collect and average the sensor data, usually over 10 min, and transmit them to polar-orbiting satellites every 60 or 90 s. Depending on latitude and area of coverage during the satellite overpass, 16 to 22 independent data transmissions are available for each platform per day. Only the data set with the largest number of identical transmissions within a satellite pass is saved in preprocessing the data [6.53].

Atmospheric pressure is measured with various buoy devices, including aneroid cells, beam balance quartz crystal transducers, and piezoresistive transducers. The inlet or pressure port allows the ambient pressure to be transmitted freely into the sensing element. The error or pressure change is related to the shape and configuration of the inlet. In most cases, the pressure error is related to the square of the wind velocity. Atmospheric pressure measurements from a small drifting buoy in the open ocean are difficult to obtain due to natural atmospheric pressure variation, wind interaction with the sensor, sensor error, sensor calibration, long-term drift, telemetry bit errors, and other factors.

Air temperature measurements are typically conducted with a thermistor contained within a radiation-shielded housing about 1 m above the ocean surface. Thermistors also measure sea surface temperature. A source of error is the heating effect produced when solar and infrared radiation strike the air temperature transducer. This error can be significant during direct insolation and low winds, but can be reduced by improving radiation shields or, when battery capacity allows for it, by using forced ventilation during sunshine.

Moored Buoys and Wave Buoys

In contrast to drifting buoys, moored buoys are anchored at fixed locations and collect a larger variety of atmospheric and oceanographic variables (Fig. 6.23). Their data are used for data assimilation in numerical weather prediction and for maritime safety needs. Be-

Fig. 6.22 Locations of buoys drifting on Antarctic sea ice at quarter-year resolution, from 1986 to 2001. Symbols give the numbers of days a buoy was active within the three months (after [6.52])

Fig. 6.23 The meteorological/oceanographic station anchored offshore Hörnum/Sylt in the North Sea. Powered by a solar panel, it takes wind, temperature, radiation, turbidity, and salinity observations (photo © H. Garbe, Helmholtz-Center Geesthacht)

cause of their size and instrumentation, moored buoys are large and expensive. Their size can vary from a few meters in height and width, to over 12 m [6.51]. Variables being measured are surface variables (wind speed and direction, air and sea surface temperature, salinity, and air pressure), as well as subsurface temperatures down to a depth of suspended cables of up to several hundred meters. Data are usually collected through one of the Argos, Iridium, polar orbiting (ORBCOMM[®]), or geostationary satellites, transmitted in real time and shared on the GTS of the World Meteorological Organization (WMO). They have a typical maintenance interval of one year and their construction, in particular the tether line keeping the buoys at a constant location, must be very robust to withstand storms or high seas. Many different designs exist for moored buoys depending on the ocean application purposes and the environmental influences on operations.

Because of limited data transmission, the fixed buoys often store more data on board than they send in real time. When a moored buoy is recovered, the data are processed offline by the operators. A major part of the DBCP's moored buoy network is the Tropical Moored Buoy Implementation Panel array, which con-

Fig. 6.24 A Technical University of Dresden measurement float with eddy-covariance sensors on a reservoir during the project Greenhouse gas emissions from reservoirs (TREGATA) (photo © Dr. Uwe Spank)

sists of arrays of moorings in each ocean basin and is used to monitor large-scale phenomena such as El Niño and the Southern Oscillation, showing the importance in the annual variability of global climate [6.51].

Many types of wave buoys exist to capture and model information about ocean dynamics on the surface. These buoys measure the frequency and size of wave energy (known as the spectra) from which significant wave height, dominant wave period, and average wave period are derived. Even the direction of wave propagation is measured on many moored buoys. This information can be used to greatly improve the predictions of and warnings for dangerous storms.

Platforms and Floats

For measurements on shallow lakes with short fetches, platforms and floats (also called pontoons) are often deployed. The short fetch is necessary to reduce the wave height; however, the footprint of the measurements should be within the fetch. Platforms are fixed at the bottom of the lakes. Floats are airtight hollow structures assembled to rectangular or triangular structures (Fig. 6.24). The floats are fixed in the ground with at least one anchor. The movement of the floats due to waves and wind must be controlled and the measurements must be corrected if required. In the past, floats were often used for evaporation pans; more recently, they have been equipped with several instruments for measurements in air and water including eddy-covariance measurements. An overview of experiments with floats is given in [6.54].

6.4.4 Infrastructure

Before any ground-based measurement platform is installed, all relevant national and local regulations must be taken into consideration and all required approvals must be obtained from the competent authorities or any other relevant parties such as property owners. For masts and

towers, a building permit might be needed depending on the height of the structure and the planned duration of the installation. Tall towers and buoys must be equipped with appropriate beaconing following international and national regulations for aviation or shipping.

It is now necessary to define the power supply system(s) for an installation, which should be selected based on the availability of power sources and the energy demands of the measurement systems including all accompanying infrastructural elements. If line power is not directly available nearby but the power demand is high (> 1 kW), the cost–benefit ratio, environmental protection and aspects of sustainability should be arguments for the decision between a connection to the closest line power distribution or a self-sufficient power supply system. Installing an underground power line over a distance of four to five kilometers can cost up to 100 000 €; an overhead line would be cheaper but is more prone to damage. The following power supply systems are commonly used as energy sources for ground-based measurement platforms:

- Line power from public electricity supplier: from conventional power plants or renewable energy; up to many kW; maintenance-free.
- Local power generator based on petrol, diesel, or propane/butane engine: up to several kW; emission of exhaust gases might be an issue for the measurements; noise emissions; intensive care and maintenance required; regular costs for spare parts or complete replacement. In large installations, two or even three identical systems are needed to avoid power interruption.
- Solar energy based on photovoltaic modules: up to a few kW (increasing space requirements); shading should be avoided; strong gradient in yield rate from high latitudes to low latitudes; no emissions; maintenance-friendly (cleaning; replacement of broken/damaged modules); long lifetime. Batteries of sufficient capacity are needed to store surplus energy that will bridge the nights and cloudy phases.
- Fuel cells: preferably operated with methanol as liquid fuel, which is easy to handle and can be shipped worldwide inside approved canisters; up to 500 W; emission of CO_2 can potentially bias the measurements. Batteries of sufficient capacity continuously power the measurement system and are recharged by the fuel cell every time the batteries are discharged to a certain extent. Cell lifetime is limited to a few years.
- Small wind energy systems: up to 1 kW; only useful in areas with reliable wind and mostly used as additional support for other systems.
- Batteries only: must be manually replaced in regular intervals; recommended only for systems with very low power consumption (< 1 W) and where regular and easy access to the site is ensured.

Often it is necessary to combine different types of power supply systems to guarantee an energy supply as reliable as possible. It is common to combine a solar energy system (third bullet point in the left column of this page) with a power generator (second item) that automatically starts operation every time the batteries are discharged to a certain extent and no solar energy is available. Also, a system comprised of solar energy modules (third item) and a fuel cell (fourth item) is very efficient and reliable (see Fig. 6.13). To avoid measurement system shutdowns in the case of short power interruptions, uninterruptible power supply (UPS) systems are recommended, at least for the most sensitive instruments and to automatically and orderly power down computers. It is recommended to set up the measurement system in a way that all instruments, computers, and data acquisition restart properly without taking action manually.

To have full access to the instruments and data acquisition systems (computers or data loggers) the site must be connected to the Internet. This can be obtained by landline connection, mobile network, or satellite, which can be cost intensive if large data volumes must be transmitted. In very remote places, including the oceans, it might be appropriate to only set up a one-way connection to transmit the collected data to a base station following a fixed schedule. Besides the satellite systems already mentioned in Sect. 6.4.3, the geostationary satellites of the British Inmarsat communication company provide worldwide Internet access except in the very high latitudes; the US provider HugesNet offers high-speed Internet access covering the Americas.

To avoid damage to the instrumentation, data acquisition systems, and communication systems by thunderstorms, it is essential to install an appropriate lightning protection system. Such systems can be a simpler design with less protection or more complex, which requires the following levels and elements of protection:

- External lightning protection:
 - Lightning rods on top of the structure and potentially on outriggers to capture the lightning
 - Lightning conductor that can be the metal tower itself or an isolated conductor at some distance (≈ 1 m) from the structure
 - Proper grounding via deep earther, ring earther, or foundation earther depending on specific application
- Internal lightning protection (inside the building or inside the electrical cabinet):
 - Sufficient distance between conductors
 - Proper shielding and earthing of cables and electronic devices

- Surge protection for all wires that enter from outside

Any lightning protection always acts only as a reduction of the risk of severe damage; protection will never reach 100%.

All instruments and electronic devices are limited to an operational temperature range and the environmental temperature should not exceed this range to ensure proper functioning of the equipment. In many cases, it is sufficient to use fans and small heating or cooling devices for this purpose. High-precision gas analyzers or other temperature sensitive instruments may require highly stable ambient conditions that can only be achieved by using self-regulating air conditioning systems and adequate insulation. Underground installations of laboratory containers and the use of heat-exchanger tubes deep below the surface can significantly contribute to stabilizing the laboratory temperature and reducing the energy required to operate air conditioning systems.

For all towers that can be climbed, proper and correct safety measures for the personnel working on the structure must be implemented. The safety devices must at least meet the national safety regulations, but it is reasonable to deploy a safety setup that is compliant with the requirements of all nations from which people are accessing the mast or tower. Towers that are climbed vertically by a ladder should be equipped with a safety rail or safety rope with fall arresters. If not present, personal protective equipment with a Y-type shock absorber must be used while climbing the mast. Signs must indicate potential risks and point to basic procedural rules.

To protect the installations from damage by bigger animals such as cows, sheep, and elephants, it is very important to use fences that are strong enough or even electrified to prevent animals from entering the vulnerable area. A fence is also recommended to safeguard the installations against vandalism and to avoid self-endangerment of curious people. Any electrical or other control cabinets should be secured against smaller animals such as mice, termites, wasps, snakes, and spiders because they may damage cables and electronic devices and pose a potential risk for people accessing the cabinets due to toxicity.

At larger tall-tower installations in remote areas, it is necessary to establish facilities such as accommodation, laboratories, office containers, a kitchen, toilets, and showers. Internal communication devices between the tower and the camp or along the tower are needed as well as an external means of communication such as satellite telephones, especially to organize help in emergency situations. A rescue concept must be established as complete chains, e.g., starting from rescuing a person in trouble from the tower, followed by an ini-

tial treatment by trained personnel, and ending with the evacuation of the person if necessary.

6.4.5 Relevant Sensors for Different Platform Types

The selection of sensors for any ground-based measurement platform is, besides many other criteria, dependent on weather, climate, the environment in general, and thus on the location of the platform itself. The sensor specifications must meet the environmental conditions especially with regard to temperature and humidity ranges for operation of the sensor. In most cases, in particular for continuous long-term measurements, sensors must be optimized for outdoor use (complies with protection class IP65 (dust-tight and protected against water jets) or better [6.55]). Sensors and connectors must be waterproof against heavy rain and the instruments should provide valid measurements even in rainy conditions (important for sonic anemometers). If the weather conditions regularly stimulate the accretion of ice on the structure and sensors, then instruments with integrated heating should be chosen. It may also be an option to equip a sensor with homemade heating. In situations with ice formation, sensors and sensor mounts must be robust enough to take the additional loads [6.56]. Sensors and cables should be resistant to UV radiation, especially if the site is located in the tropics or subtropics. Sensors and connectors used on platforms close to the shoreline or on ships and buoys in seawater must be highly resistant to corrosion; often only custom-built sensors or special versions meet such requirements.

On masts and towers, not only in areas with a high thunderstorm frequency, it is recommended to mount the sensors isolated against the structure and connect the instrument body with a thick grounding cable to a common earthing point. Instruments and sensors with high-grade integrated surge protection are preferred over ones with less or no overvoltage protection.

At some sites, birds use the mast or tower and the sensors in particular to rest or look out. Sensors for downwelling radiation can't be protected against birds

Fig. 6.25 An automatic bird scarer for radiation instruments (photo © Nadine Hempel, MPI-BGC)

with fixed metal spikes because of shadowing effects. A useful installation is a thin metal stick attached to an enclosed electric wiper motor (see Fig. 6.25) that swings forth and back approximately 120° every minute during the daytime.

Small-sized vertically movable platforms automatically travelling up and down a tall tower, drifting buoys,

or any other moving platforms must be equipped with instruments and sensors with small time constants to ensure a measurement signal that represents the true conditions along the motion path as much as possible. Longer time constants lead to delayed signals and smoothed data series, which can numerically be traced back to the true signal only to a certain extent (see also Chap. 50).

6.5 Specification

Table 6.3 summarizes the most common types of small masts and towers, their approximate maximum heights, and further specific information. The first five types of masts, which are all cable-stayed, do not necessarily require a concrete foundation, but measures must be taken to ensure the stability of the mast or tower basis and to avoid subsidence effects. Any self-supporting structures will require a concrete foundation. For almost all masts

and towers, the use of personal protective equipment to prevent falls is mandatory while climbing, except for larger structures where an inside staircase exists. Nevertheless, the use of protective equipment is also strongly recommended in this case.

In Table 6.4 the most relevant types of tall towers including examples and further specifications are listed. Tall towers are sometimes equipped with an el-

Table 6.3 Small towers for meteorological and eddy-covariance measurements

Type of tower	Maximum height (m)	Guyed	Climbable	Secured climbing	Instrument installation
Pole and tripod	≈ 3	Yes/No	No	NA	At ground
Thin tube round closed	≈ 20	Yes	No	NA	At ground
Telescopic rectangular/round closed	≈ 30	Yes	No	NA	At ground
Segmented, small triangular/rectangular open	≈ 80	Yes	Ladder or structure	Yes	On mast
Segmented or single elements, small rectangular/round closed	≈ 50	Yes	Ladder	Yes	On mast
Segmented, large rectangular open	≈ 80	Yes	Stairs	No	On mast
Lattice structure or in one piece conical shape open	≈ 30	No	Ladder or structure	Yes	On mast

Table 6.4 Tall towers for meteorological, eddy-covariance, and trace gas measurements

Type of tower	Typical height (m)	Guyed	Climbable	Secured climbing
Segmented (e.g., ZOTTO) triangular/rectangular open	150–350	Yes	Ladder or stairs	Yes/No
Lattice structure (e.g., ATTO, KIT) triangular/rectangular open	150–350	Yes	Ladder or stairs	Yes/No
Tube type (e.g., Obninsk) round closed	150–350	Yes	Ladder	Yes
Concrete (e.g., Ochsenkopf) conical shape closed	150–350	No	Ladder	Yes

Table 6.5 Characteristics of different buoy types. In general there exists a wide range of different specifications and sensors

Type of buoy	Robustness needed against	Material	Typical dimensions (m)	Lifetime (y)	Maintenance visits (y ⁻¹)	Climbable
Drifting ocean buoys	Wave motion, sea spray	Steel	W: 1–2, H: 1–5	1–3	Not accessible	No
Drifting ice buoys	Ice pressure, low temperatures	Steel, plastic	W: 1, H: 1–3	0.5–3	Not accessible	No
Moored buoys	Waves and sea spray	Steel	W: 3–8, H: 1–10	5	1–2	Yes
Wave buoys	Waves and sea spray	Steel	W: 1–3, H: 1–3	5	1–2	Yes/No
Floats	Waves and sea spray	Steel, plastic, wood	W: 3–5, H: 1–3	10	Can be frequent	Yes/No

evator, which might only be a freight elevator or also suitable for transporting people; special lifts for transporting a single person also exist (see Sect. 6.4.2).

Table 6.5 summarizes the most common buoy types, which in many cases are deployed in harsh environ-

mental conditions. The buoy housings and instrument materials must be robust, especially against sea spray, but also against cold conditions. If accessible, regular and accurate maintenance can help extend the limited lifetime of this kind of measurement platform.

6.6 Quality Control and Safety

All relevant national and, in special cases, international safety regulations and quality requirements for setting up the particular structure must be met. During the planning phase for a mast or a tower, structural calculations may be needed to determine the overall stability of the construction and the admissible additional loads due to wind and weight. This defines the area and weight of instruments, devices, cables, tubing, etc., that can be installed on and attached to the mast or tower. The environmental conditions at the site where the structure will be built must also be considered. It might be necessary to select specific or special material and selective combinations of materials for the structure and various extensions because of high corrosion potential (for locations close to coastlines) or large differences between the possible temperature extremes such that diverging expansion coefficients of different materials would cause problems. Special measures must be taken if the site is located:

- In an area with high earthquake potential
- In a region where extremely high wind velocities may occur (tornadoes, hurricanes)
- Where the potential for inundations is high or where recurring flooding occurs
- In a region with high thunderstorm frequency (see Sects. 6.4.4 and 6.4.5)
- In a region with cold climatic conditions where severe ice buildup may occur [6.56]
- Where strong electromagnetic radiation may result in technical faults of the measurements, e.g., when instruments are installed on a transmission mast or close to other sources of electromagnetic fields [6.57]

6.7 Maintenance

All ground-based platforms must be maintained in regular intervals. Depending on the dimensions of the structure, the environmental conditions the platform is exposed to, the complexity of the installations, and the potential risk to life but also to valuable objects, maintenance ranges from a simple visual inspection to a time-consuming prescribed service procedure by ex-

A concept for a highly reliable power supply with almost 100% availability is, as part of the infrastructure (see Sect. 6.4.4), essential for the quality assurance of ground-based measurement platforms. All elements, devices, instruments, and other items that are attached to the tower must be thoroughly secured against falling to minimize the risk of serious injury to persons working on the ground or on the tower.

For the overall quality of a ground-based platform, a key criterion is also the scientific usability of the measurements obtained using the particular structure. The selection of the terrain, the climate zone, and the ecosystem, together with the footprint area [6.1] for the measurements, are the most important site factors. On one hand, these are determined by scientific issues, but on the other hand they determine the long-term perspective and usability of an installation.

When a tower or mast is in standard operation, retroactively installed extensions must exceed the admissible additional wind and/or weight loads. After natural events like storms, lightning strikes, or inundation, a thorough examination of the structure and all installations must be carried out for safety reasons. This must happen even if a standard maintenance and examination procedure has recently been conducted. In winter, subfreezing air temperatures associated with gale-force winds can cause severe ice accretion on the structures. When these get too heavy or as temperatures increase, blocks of ice can fall and cause damage and endanger life. Protection measures and a timely closure of the tower vicinity are part of the essential duties of the operator in such situations.

ternal experts from qualified authorities or companies. For small towers without any moving parts, visually inspecting the structure and testing all clamps and other mechanical connections for instruments, outriggers, and other attachment parts is sufficient. If the structure consists of hollow sections and ambient temperatures are around or below 0°C, freezing water inside hol-

low spaces may crack even metal tubes, which require particular attention during inspection. In the case of a guyed mast, all parts of the anchoring (clamps, guy-wires, anchors, etc.) must be checked and the tension of the guy ropes must be measured and adjusted if required. This procedure should be performed every four to six weeks. Falling trees in close vicinity of a tower can cause severe damage to the installation and may tear down masts of lower steadiness especially when hitting the guy wires. It is recommended to regularly check the health and stability of surrounding trees and to cut down the ones that pose a risk to the installations.

For tall towers, a typical test procedure that should be carried out in one- or two-year intervals consists of:

- Checking the vertical alignment of the structure and adjusting, if required
- Checking the tower foundation and guy wire anchor points
- Inspecting the status of the mast construction and outriggers by checking for:
 - Loose, missing, or fallen mechanical connections
 - Bent, twisted, or buckled parts
 - A defective tower base
 - Defective joints
- Controlling the guy ropes:
 - Check the tension and adjust, if required
 - Visual inspection of the wires (also by binoculars) and the connection points at the tower and anchor foundation
- Controlling stairs, ladders, and tread areas

- Checking for corrosion and controlling the status of protective coating
- Checking for ease of operation of any moving parts (e.g., outriggers) and greasing if required
- Inspecting and testing the aircraft warning light system

At intervals of several years, it is necessary to inspect the steel cables holding tall towers for inspection and maintenance (coating or greasing). In general, guy wires must be replaced as soon as they no longer meet the quality and safety requirements.

A detailed examination of any means of transport such as lifts or elevators either for freight or for passengers must be conducted one or two times per year. Also, all electrical components must be checked in regular intervals:

- Ground fault circuit interrupter every six months
- Portable electrical devices that can be connected to line voltage every two years
- Permanently installed electrical devices connected to line voltage every four years

Every personal protective equipment component must be annually reviewed and any defective or outdated parts must be taken out of service.

All inspections must only be conducted by qualified and/or authorized persons. Any identified shortcomings must be rectified as soon as possible. If danger to life is determined, permission to operate must be temporarily withdrawn.

6.8 Applications

The following subsections briefly describe some applications where the combination of different ground-based measurement platforms support diverse measurement strategies and enable the investigation of complex atmospheric processes and interactions between ecosystems and the atmosphere.

6.8.1 Vehicle-Induced Turbulence

In order to investigate the intensity and range of vehicle-induced turbulence in comparison to the natural atmospheric turbulence, a combination of small observation platforms (4–48 m high) has been installed adjacent to a motorway (see Fig. 6.26) [6.58]. The instrumental setup allowed for the measurement of the mean and turbulent wind field as well as the stratification. Most of the towers were installed on the downwind side of the

motorway to cover the spatial range of the turbulence anomaly.

6.8.2 Internal Boundary Layer

To investigate the growth of an internal boundary layer, a set of small towers (4.5–18 m high) was deployed over two adjacent fields with different vegetation (see Fig. 6.27) [6.59]. Two energy-balance stations provided information about the stratification.

6.8.3 Large-Scale Manipulation Experiment

MaNiP (Manipulation Nitrogen and Phosphorous) is a long-term experimental project that aims to help us understand the responses to different eddy-covariance sites from nutrient loading (primarily N and P) and wa-

Fig. 6.28 A measurement setup near Majadas, Spain with a subcanopy eddy-covariance system on tripod (*left*), a 15-m walk-up tower with eddy-covariance system and meteorological measurements (*center*), and a 10-m triangular mast with rotatable arm for spectral radiative measurements (*right*) (photo © Tiana Hammer, MPI-BGC)

ter availability on ecosystem-level carbon, water fluxes, and their interannual variability [6.60].

The two study areas in a Mediterranean savanna ecosystem are located in the Extremadura region in the southwest of Spain. The installations are in both cases situated in a *dehesa*, a multifunctional, agrosilvopastoral system. The distance between the sites is 165 km and the more southern site receives significantly less precipitation. Figures 6.28, 6.13 and 6.14 show the deployment of various platforms for a wide range of measurement methods and instrumentation: walk-up towers and a telescopic mast for eddy flux and profile measurements above the canopy, tripods for eddy flux measurements below the tree canopy, and masts with a rotatable arm for radiative measurements above different surfaces. Dendrometers, sap flow sensors, chambers for respiration, and photosynthesis measurements as well as lysimeters, soil moisture, and soil temperature profile probes are utilized.

6.8.4 Tall-Tower Observatories

The two tall-tower observatories ATTO and ZOTTO are both examples of multiplatform installations each consisting of three towers or masts. Besides the tall tower, one walk-up tower and one thin triangular mast, both 80 m high, are also part of ATTO (see Fig. 6.29). The walk-up tower is similarly equipped with instruments as the tall tower (see Sect. 6.4.2) and continues the flux and profile measurements into the undisturbed canopy and down to the trunk space. The triangular mast is used to carry a number of air inlets for trace gas concentration

Fig. 6.29 Two 80-m masts in proximity to the ATTO tall tower (photo © Martin Hertel, MPI-BGC)

measurements with gas analyzers located inside a container at the mast base. This mast needs to be climbed only occasionally. This setup is well suited to investigate, for instance, the flux gradient or the variance method to estimate fluxes over tall forests [6.61].

At ZOTTO, two small towers for eddy-covariance flux measurements are utilized in two different ecosystems (forest and bog) in addition to the tall tower (see Sect. 6.4.2). The combination of measurements of trace gas and aerosol concentrations, solar radiation, and CO_2 exchange allows investigating the effect of aerosol loading on solar radiation and the subsequent effect on photosynthesis as a relevant question for estimating climate feedback mechanisms [6.62]. High aerosol concentrations regularly result from smoke from wildfires.

6.9 Future Developments

An article in *Windpower Monthly* has the provocative title “Do we still need met masts?” [6.63], which in this case is related to weather monitoring within the scope of onshore and offshore wind farms. Met masts can in many cases be replaced by remote-sensing (RS) devices

like lidar [6.64] and sodar (light/sonic detection and ranging). Both traditional met masts and RS devices, which can be ground-based or mounted on the nacelle, have their strengths and weaknesses and are summarized in Table 6.6.

Table 6.6 Comparison of met masts and remote-sensing devices

Met masts	Remote-sensing devices
Strengths	
Measurements technically well understood	Are portable and relatively easy to deploy
Broad industry acceptance	Ideal for prospecting potential sites
Traceability back to a standard	Lower installation costs
Weaknesses	
Siting permits required	RS devices can get buried in deep snow
Mechanical failure and lightning strikes	Struggle in certain atmospheric conditions
Highly visible to competitors and opponents	Can't measure hub-height, temperature, pressure, or humidity
Measurements impacted by tower shadow	
Instruments may stop working in severe ice	More vulnerable to theft

All of this is, of course, mostly applicable to investigations and the infrastructure related to wind energy technologies. For weather services and science, masts and towers will remain of fundamental importance, but

remote-sensing technologies and devices will gain in importance, which holds true for ground-based instruments as well as for airborne and space-based systems. On the other hand, the enormous increase in the number of wind turbines in many countries results in an enhanced availability of meteorological data on the upper border of the surface layer because most windmills carry some sensors for atmospheric measurements on top of their nacelle.

Unmanned aircraft systems (UAS) like multicopters are becoming more and more common in many fields of science (see Chap. 49). With the miniaturization of sensors, instruments, computers, and other devices, UASs can be used for a large number of applications. Atmospheric measurements on masts and towers can be extended vertically and horizontally so that 2-D or 3-D datasets can be gained by deploying such platforms.

The unique HighStep system [6.65] is an innovative development to facilitate reaching elevated working positions, in particular on high masts or towers. Climbing and walking up is replaced with a technical climbing device driven by electric engines running on a vertical rail. Instruments with a total weight of up to 150 kg are able to fully automatically move up and down a tower in regular intervals.

Olaf E. E. Kolle

Field Experiments and Instrumentation
Max-Planck-Institute for Biogeochemistry
Jena, Germany
olaf.kolle@bgc-jena.mpg.de

Olaf Kolle, who received a meteorology diploma in 1986 from the University of Karlsruhe, heads the Service Facility for Field Experiments and Instrumentation at the Max Planck Institute for Biogeochemistry in Jena, Germany. He and his team provide service for experimental research and build, deploy, and maintain instruments, measurement systems, and field installations worldwide. His main interests are eddy-covariance measurements, software development, and data acquisition and process control systems.

Norbert Kalthoff

Institute of Meteorology and Climate
Research, Department Troposphere
Karlsruhe Institute of Technology (KIT)
Karlsruhe, Germany
no.kalthoff@web.de

Norbert Kalthoff leads the Land Surface and Boundary Layer research group at the Institute of Meteorology and Climate Research (Department Troposphere) at the Karlsruhe Institute of Technology in Germany until 2010. He received his PhD in meteorology in 1986 from the University of Bonn, Germany. His team contributes to field campaigns worldwide, investigating the impact of land-surface processes on the atmospheric boundary layer and the initiation of moist convection.

Christoph Kottmeier

Institute of Meteorology and Climate
Research, Department Troposphere
Karlsruhe Institute of Technology (KIT)
Karlsruhe, Germany
christoph.kottmeier@kit.edu

Christoph Kottmeier is professor of meteorology and headed the Institute of Meteorology and Climate Research (Department Troposphere) at the KIT until 2020. His team conducts tropospheric research by applying advanced observation techniques (aircraft, automatic buoys, lidar, and radar) as well as numerical modelling with COSMO and ICON model systems. He initiated the construction of the KITcube facility for integrated observation.

jwmunger@seas.harvard.edu

J. William Munger is a senior research fellow in atmospheric chemistry at the Harvard School of Engineering and Applied Sciences. He received an MS in ecology in 1981 from the University of Minnesota and a PhD in environmental engineering science from the California Institute of Technology in 1988. His research uses field observations to quantify biosphere-atmosphere exchange of carbon and air pollutants.

Temperature

7. Temperature Sensors

Thomas Foken , Jens Bange 

Techniques that are used to measure the temperature of the atmosphere include liquid-in-glass thermometers, electrical thermometers, bimetallic thermometers, and the most commonly used instruments: resistance thermometers. Radiation shields and ventilation are important for minimizing erroneous results. Fine-wire thermometers and sonic temperature measurement are important techniques for turbulence measurements. In addition to providing technical data, this chapter describes maintenance requirements and quality control and calibration methods for temperature sensors.

Air temperature is the most important atmospheric parameter in daily life. It provides a subjective measure of the weather and is used for climate classification and more recently to evaluate climate change. Temperature measurements have a long tradition but they still present a challenge when high accuracy is required. In particular, radiation and insufficient ventilation can significantly increase the temperatures of in-situ sensors. While the technical possibilities in this field are now greater than ever, errors in measurement are often significantly underestimated, as addressed by *Fritz Albrecht* (1896–1965) [7.1] nearly 100 years ago. These errors can be minimized by using special radiation shields and ventilation systems with temperature sensors. The main prin-

ciple of classical temperature measurement is the expansion of a liquid or solid material. The temperature dependence of resistance is the dominant measuring principle in currently available sensors. To overcome problems with radiation error, remote-sensing techniques (e.g., sonic anemometers; see also Chap. 9) are applied to measure the temperature (mainly for turbulence measurements). As well as the air temperature at a given time, extreme values such as the daily or annual minimum and maximum temperature are often of interest, with these values ranging from about +60 °C to below –90 °C near the Earth's surface. For more on the spatiotemporal distribution of temperature, see relevant meteorology and climatology textbooks [7.2, 3] and Chap. 1.

7.1 Measurement Principles and Parameters

This section reviews temperature measurement scales and principles and highlights the typical temperature measurements performed in meteorology.

7.1.1 Measured Parameters

Temperature is defined as the thermodynamic temperature, symbol T , and is measured in kelvin (symbol K), which is $1/273.16$ of the thermodynamic temperature of the triple point of water [7.4]. The zero point of this absolute thermodynamic scale is absolute zero (-273.15°C). Precise definitions of various temperature scales have been formulated, with the most recently accepted scale being the International Temperature Scale of 1990 (ITS-90), which was adopted by the International Committee of Weights and Measures at its meeting in 1989; for more on the history of temperature scales, see Chap. 5. Earlier temperature scales were defined based on the ice and boiling points of water under standard pressure conditions: 273.15 and 373.15 K, respectively. The thermodynamic temperature expressed in this way is known as the Celsius temperature, symbol t , with units of degrees Celsius (symbol $^\circ\text{C}$). It is calculated via

$$t [^\circ\text{C}] = T [\text{K}] - 273.15. \quad (7.1)$$

A difference in temperature is given in kelvin or degrees Celsius, although it is more common to refer to the difference in kelvin.

The International Temperature Scale of 1990 (ITS-90) defines both the International Kelvin Temperature (symbol: T_{90} , unit: kelvin) and the International Celsius Temperature (symbol: t_{90} , unit: degree Celsius). The relation between these is given by

$$t_{90} [^\circ\text{C}] = T_{90} [\text{K}] - 273.15. \quad (7.2)$$

The ITS-90 is constructed in such a way that the numerical value of T_{90} is a close approximation to the numerical value of T for any given temperature. This was achieved through a series expansion, with the relevant fixed points in the meteorological temperature range being the triple point of mercury (234.3156 K), the triple point of water (273.16 K), and the melting point of gallium (302.9146 K). For further details, see [7.4, 5] and Table 7.1; for more on the differences between this and other scales, see Chap. 5.

Besides the air temperature at a given time, extreme temperature values are also of interest in meteorology, climatology, and applied sciences, so special sensors to measure these parameters have been developed. An overview of temperatures of interest is given in Table 7.2.

Furthermore, special temperatures are calculated in atmospheric science to overcome physical effects that are related to the temperature, as outlined below.

The air density depends not only on the temperature but also on the humidity. A special temperature is used

Table 7.1 Recommended temperature scales (for other scales, such as those that were more popular in the past, see Sect. 7.2)

Scale	Lower fixed point	Upper fixed point	Difference
Kelvin scale	Absolute zero (-273.15°C)	Triple point of water (0.01°C)	$1 \text{ K} = 1^\circ\text{C}$
Celsius scale	Melting point of ice (0°C) at 1013.25 hPa	Boiling point of water (100°C) at 1013.25 hPa	$1^\circ\text{C} = 1/100$ of the difference between both fixed points

Table 7.2 Parameters measured by temperature sensors (LT: local time)

Parameter	Description	Unit	Symbol
Absolute temperature	Temperature with the absolute zero point as a reference	K	T
Celsius temperature	Temperature with the melting point of ice and boiling point of water as references (see Table 7.1); usually measured at 2 m height	$^\circ\text{C}$	t
Temperature difference	Difference between two temperature values	K ($^\circ\text{C}$)	$T_1 - T_2$ ($t_1 - t_2$)
Water temperature	Temperature measured at a certain depth in a water body (lake, ocean, etc.)	$^\circ\text{C}$	t_w
Soil temperature	Temperature measured at a certain depth in the soil (typically up to 1 m deep)—usually 5, 10, 20, 50, or 100 cm deep	$^\circ\text{C}$	t_s
Minimum temperature	Minimum temperature within a given time interval (typically 18:00 to 6:00 LT)	$^\circ\text{C}$	t_{\min}
Maximum temperature	Maximum temperature within a given time interval (typically 6:00 to 18:00 LT)	$^\circ\text{C}$	t_{\max}
Minimum temperature at 5 cm height	Minimum temperature at 5 cm height during the night	$^\circ\text{C}$	$t_{\min-5 \text{ cm}}$

only with the gas constant of dry air R_d and is applied in the law of ideal gases, where the pressure is the sum of the individual pressures of dry air and water vapor,

$$\begin{aligned} p &= T \sum_i \rho_i R_i = T(\rho_d R_d + \rho_w R_w) \\ &= TR_d \left[(\rho - \rho_w) + \rho_w \frac{R_w}{R_d} \right]. \end{aligned} \quad (7.3)$$

The parameters in this equation are the air pressure p , the density of moist air ρ , the density of dry air ρ_d , the density of water vapor ρ_w , and the gas constant of water vapor R_w . This equation for moist air can be transformed into an equation for the specific humidity using the gas equation for moist air

$$p = \rho R_d T_v, \quad (7.4)$$

where T_v is the *virtual temperature* (see [7.2, 6] and Chap. 8), given by

$$T_v = T \left(1 + q \frac{R_w - R_d}{R_d} \right) = T(1 + 0.608q). \quad (7.5)$$

Here, q is an approximation for the specific humidity that is calculated via

$$\begin{aligned} q &= \frac{M_w}{M_w + M_d} = \frac{M_w}{M_d} \frac{e}{p - \left(1 - \frac{M_w}{M_d}\right) e} \\ &= 0.622 \frac{e}{p - 0.378e} \approx 0.622 \frac{e}{p} \end{aligned} \quad (7.6)$$

(M_w : molecular weight of water, M_d : molecular weight of dry air, and e : water vapor pressure). Also, note that

$$T_v \approx T \left(1 + 0.38 \frac{e}{p} \right). \quad (7.7)$$

The temperature increases under compression and decreases under expansion. To compare temperatures obtained at different atmospheric pressures, the *potential temperature* is calculated for a pressure of 1000 hPa using the *Poisson* equation (see [7.2, 6] and Chap. 46) as

$$\theta = T \left(\frac{1000 \text{ hPa}}{p} \right)^{\frac{R_d}{c_p}} = T \left(\frac{1000 \text{ hPa}}{p} \right)^{\frac{2}{7}}, \quad (7.8)$$

where c_p is the specific heat at constant pressure and $2/7 \approx 0.286$. For some applications it is useful to replace 1000 hPa with the pressure at the ground (Chap. 1).

The potential temperature is a state variable for an adiabatic process in unsaturated air. A similar state variable is defined for saturated air: the *equivalent potential temperature* θ_e of a pseudo-adiabatic process, which is calculated via the thermodynamic law for saturated air [7.2] as

$$\theta_e = \theta \exp \left(\frac{\lambda r_c}{c_p T} \right), \quad (7.9)$$

where r_c is the saturation mixing ratio and λ is the latent heat of evaporation (Chap. 5). It is assumed that an air parcel is raised to $z = \infty$ and the temperature is increased by the latent heat of condensation as the condensate is removed. After the maximum temperature has been reached, the air parcel is moved dry adiabatically to the surface and adopts the equivalent potential temperature.

The dependence of the speed of sound c on the temperature and moisture can also be applied to measure the temperature via the *Laplace* equation

$$c = \sqrt{\gamma \frac{p}{\rho}} \quad [\text{m s}^{-1}]. \quad (7.10)$$

The coefficient γ for dry air is

$$\gamma_d = \frac{c_{pd}}{c_{vd}} = \frac{7}{5} = 1.4, \quad (7.11)$$

where c_{pd} and c_{vd} are the specific heats of dry air at constant pressure and constant volume. The coefficient of the specific heats of water vapor at 1013.25 hPa and 15 °C,

$$\gamma_v = \frac{c_{pv}}{c_{vv}} = \frac{4}{3} = 1.328, \quad (7.12)$$

differs from the coefficient for dry air. Both of these γ coefficients must be applied to determine the speed of sound in moist air via (7.10). The ratio p/ρ for moist air in this equation can be calculated in a similar way to (7.3). Like the gas constant, the coefficient γ must be split into values for dry air and water vapor. Consequently, with the application of $q = \rho_w/\rho$, we get

$$\begin{aligned} c &= \sqrt{TR_d \gamma_d \left[\left(1 - \frac{\rho_w}{\rho}\right) + \frac{\rho_w}{\rho} \frac{R_w}{R_d} \frac{\gamma_v}{\gamma_d} \right]} \\ &= \sqrt{TR_d \gamma_d \left(1 + q \frac{R_w \gamma_v - R_d \gamma_d}{R_d \gamma_d} \right)}. \end{aligned} \quad (7.13)$$

Table 7.3 Definitions of selected temperatures that are considered in the atmospheric sciences

Special Temperature	Definition	Unit	Symbol
Virtual temperature	Temperature of dry air if it had the same density as moist air	K	T_v
Potential temperature	Temperature of air compressed/expanded to 1000 hPa	K	θ
Virtual potential temperature	Temperature of dry air if it had the same density as moist air at 1000 hPa	K	θ_v
Equivalent potential temperature	Temperature of air compressed/expanded to 1000 hPa and increased/decreased by the temperature equivalent of the latent heat due to the condensation of water vapor in the column up to $z = \infty$	K	θ_e
Sonic temperature	Temperature relating to the speed of sound (nearly identical to the virtual temperature)	K	T_s
Wind-chill index	Effect of the wind speed on cold sensation and cooling	°C	$t_{\text{wind-chill}}$

Table 7.4 Temperature measurement principles and their applications [7.7]

Measuring device	Method			Application	
	Thermodynamic	Electric	Sound	Mean	Turbulence
Bimetallic thermometer	✓			✓	
Liquid-in-glass thermometer	✓			✓	
Electric resistance thermometer		✓		✓	✓
Thermistor		✓		✓	
Semiconductor thermometer		✓		✓	
Thermocouple		✓		✓	✓
Sonic thermometer			✓	(✓)	✓

Using the appropriate numerical values and the approximation for the specific humidity given in (7.6), we obtain

$$c = \sqrt{401.88T(1 + 0.531q)} \approx \sqrt{401.88T \left(1 + 0.33 \frac{e}{p} \right)}. \quad (7.14)$$

This equation can be used to define a *sonic temperature* [7.8, 9],

$$T_s = T(1 + 0.531q) \approx T \left(1 + 0.33 \frac{e}{p} \right), \quad (7.15)$$

where the numerical value 0.33 differs because of the application of ITS-90 (formerly 0.32).

Comparing (7.7) and (7.15), the difference between both temperatures is less than 1‰ under typical atmospheric conditions, so the sonic temperature can be replaced with the virtual temperature.

There are several temperatures that are used to describe the influence of weather and climate on people. The latest is the universal thermal climate index (UTCI) [7.10]. A parameter that is well established in daily life and weather forecasts is the *wind-chill temperature* or *index*, which reflects the sensation of the air feeling cooler than it actually is due to the wind. After several modifications over the years, the current equa-

tion for this temperature is [7.11]

$$t_{\text{wind-chill}} [^\circ\text{C}] = 13.12 + 0.621t - 11.37u^{0.16} + 0.3965tu^{0.16}, \quad (7.16)$$

where the temperature t is in °C and the wind speed u is in km h^{-1} and is measured at 10 m above ground level.

Table 7.3 defines various special temperatures that are considered in the atmospheric sciences.

7.1.2 Principles of Temperature Measurement

The measurement principle of temperature sensors is—in most cases directly—based on the temperature dependence of a particular property, such as the volume of a liquid or solid material, the resistance of a metallic or other material, or the speed of sound. Recently used thermometers and their measuring principles are listed in Table 7.4, together with their utilization for slow measurements (i.e., mean values for time intervals of seconds to many minutes), including measurements of extreme values, and turbulence (5–100 Hz).

7.1.3 Site Considerations

Temperature sensors are often used together with humidity sensors (Chap. 8), but in such a scenario the

sensors should not influence each other. If the temperature measurements are used for the correction or transformation of humidity measurements, both sensors should measure the same small air volume and should be as close as possible to each other (at most 1 m apart). Radiation protection is important, and ventilation is necessary. The sensors should therefore be installed within meteorological shelters (Sect. 7.4.5 and Chap. 42). The standard installation height above

the ground is 2 m. Strong vertical temperature gradients (Chap. 1 and Sect. 7.3.10) mean that accurate leveling is essential. Temperature sensors should be protected against rain and moisture because moist sensors measure the wet temperature (Chap. 8), which can be several degrees lower than the actual temperature. Temperature sensors may be installed in different arrangements for specific purposes as long as the sensors are properly exposed (Chap. 6).

7.2 History

An excellent account of the history of thermometers in meteorology, written by *William Edgar Knowles Middleton* (1902–1998) [7.12], has provided the basis for many other historical studies [7.13, 13, 14]. The history of thermometers and temperature measurements is closely connected with the history of temperature scales. Here is a brief overview.

7.2.1 History of Temperature Measurements

The phenomenon of the expansion of air with increasing heat and the opposite phenomenon in cold conditions have been known since ancient times. *Philon of Byzantium* (about 250 BCE) and *Heron of Alexandria* (about 62 BCE) constructed thermoscopes. A description of a thermoscope as a heated or cooled globe connected by a tube to a bottle of water was published in 1575 in Italy, in Latin. But the first use of a thermoscope to measure the air temperature is attributed to *Galileo Galilei* (1564–1642), who used an air thermoscope that is thought to have been similar to that in Fig. 7.1a in his lessons during 1592–1593 at the University of Padua. Another instrument is often linked to Galileo: the Galileo thermometer, which was available in Florence at the beginning of the seventeenth century. In this sensor, several glass balls of different densities drift in a water-filled glass vessel. Depending on the temperature, the balls rise or drop (Fig. 7.1b). Decorative forms of this thermometer are still available.

There is no doubt that by the year 1613 Galileo had claimed to be the inventor of the air thermometer, this is evident from series of letters written to him ... [7.15]

Initial publications on the use of thermoscopes originate from *Santorio Santorio* (1561–1636), a professor of medicine at Padua, who used the device in 1612 to measure the body temperature in the mouth, and from *Giuseppe Biancani* or *Blancanus* (in 1617).

Giovafrancesco Sagredo (1561–1620) was the first to use snow as a fixed point, according to a letter to Galileo. North of the Alps, the Welsh musician *Robert*

Fig. 7.1 (a) Reconstruction of Galileo's thermoscope (photo © Deutsches Thermometermuseum Geraberg, Germany; the original is on display at the Museo Galileo in Florence). (b) Galileo thermometer (photo courtesy of TFA Dostmann, Wertheim, Germany)

Fludd and *Cornelius Drebbel* from the Netherlands constructed similar thermoscopes. *Otto von Guericke* (1602–1686) built an instrument that was combined with a barometer and had a scale showing the coldest and warmest days of the year. Around 1640, he found that the height of the air column of the thermoscope is a function of not only the temperature but also the pressure (Chap. 10).

The liquid-in-glass thermometer solved the problem of the pressure dependence of the temperature. Its development was supported by the Grand Duke of Tuscany, *Ferdinando II de' Medici* (1610–1670) and the *Accademia des Cimento* [7.16], and was probably available from 1641. Several instruments were constructed with 50- and 100-degree scales (among other scales), using alcohol as the liquid (Fig. 7.2). The resulting instrument with a scale was termed a *thermometer*. Thermometers were sent to many monasteries in Italy and north of the Alps to facilitate the first meteorological observations (Chap. 1). In 1828 in Florence, a comparison experiment was performed, and those involved were astonished to find that the 50-degree thermometers were extremely stable. Their zero point of the Florence small °Gk scale corresponded to -18.75°C and their 50-degree point to 55°C . At the Royal Society, *Robert Hooke* (1635–1703) built a similar thermometer as well as other instruments, and for the first time used the freezing point of water as a fixed point. He also had a calibration instrument that remained forgotten until the following century, when it was developed separately by Réaumur. Many thermometers dating from the end of the seventeenth century and the eighteenth century are shown in [7.14].

With the beginning of the eighteenth century, serious attempts were made to produce accurate thermometers with well-defined fixed points. The first, by *Daniel Gabriel Fahrenheit* (1686–1736), was probably significantly influenced by earlier works of the Danish astronomer *Ole Rømer* (1644–1710), with whom he was in contact. The lower fixed point on his scale was the freezing point of a mixture of water and sea salt ($0^{\circ}\text{F} \approx -20^{\circ}\text{C}$), which was not very accurate. It is also reported that this was the coldest temperature experienced in a winter in Gdansk. The upper fixed point was the body temperature of humans ($96^{\circ}\text{F} \approx 37^{\circ}\text{C}$). Until recently, the ice point of water was defined as 32°F and its boiling point as 212°F . Around the year 1716, Fahrenheit also used mercury as a liquid.

René-Antoine Ferchault de Réaumur (1690–1757) followed Hooke's idea of using just one fixed point: the freezing point of water. He made a special effort to use salt-free water, because he found that the freezing point depended on the salinity. Therefore, 0°R is 0°C . But

Fig. 7.2 Reconstruction of a liquid-in-glass thermometer of the *Accademia des Cimento* (photo © Deutsches Thermometermuseum Geraberg, Germany; original is on display at the Museo Galileo at Florence)

the other point, 80°R , corresponded to the boiling point of a specific dilution of alcohol. After 1730, 80°R was taken to be the boiling point of water, 100°C . A similar scale was devised by *Joseph Nicolas Delisle* (1688–1768), a French astronomer working in St. Petersburg.

Fig. 7.3 Six's thermometer (photo © Daniel Kobrle, Mělník, Czech Republic, <http://danyk.cz>)

On his scale, 0°D was the boiling point of water, and the other fixed point was the near-constant temperature of the water of the Neva River below the ice (149.5°D), so the freezing point of water was set to 150°D .

In Uppsala, the Swedish astronomer *Anders Celsius* (1701–1744) performed experiments with the thermometers devised by Réaumur and Delisle. In 1741, he created a scale for a mercury thermometer in which the boiling point of water was 0°C and the freezing point was 100°C . In 1750, after his death, the successor to his professorship, *Mårten Strömer* (1707–1770), inverted his scale, yielding the Celsius scale that is still in use today.

Of special interest was the measurement of maximum and minimum temperatures. Overflow thermometers were first described by both *Daniel Bernoulli* (1700–1782) and (mainly) *Lord Charles Cavendish* (1704–1783) in 1754. The minimum–maximum thermometer devised by *James Six* (1731–1793) is still in use (Fig. 7.3), but it is not in meteorological service due to its low accuracy. The fluid used in this thermometer is alcohol (in the bulb on the minimum side), and mercury is only used for indication.

In 1790, *Daniel Rutherford* (1749–1819) described the construction of independent maximum and minimum thermometers; his minimum thermometer design is still used by meteorological services today (Sect. 7.4.1).

The beginning of the eighteenth century saw the creation of deformation thermometers. An example is the metallic thermometer constructed by *Samuel Frothingham* in 1748. In this, a brass bar was screwed to an iron bar. The first published report of a bimetallic thermometer, originated by *Johann Heinrich Lambert* (1728–1777), dates from 1779.

7.2.2 Temperature Scales

As already discussed in Sect. 7.2.1, the development of thermometers was closely connected to the development of temperature scales. The scales of Réaumur and Delisle were used for a period in France or Russia. Many other scales were not used for extended periods or were only employed in a particular small region. The 50-degree scale of the Accademia des Cimento has special historical relevance, as it is associated with the first regular meteorological measurements.

In 1848, *William Thomson* (1824–1907; *Lord Kelvin of Largs* from 1892) pinpointed the lowest possible temperature, the temperature at which the molecules in a material have zero energy. He proposed an absolute temperature scale with $0\text{ K} = -273.15^{\circ}\text{C}$ and where an increment of 1 K was equal to an increment of one degree on the Celsius scale.

Besides the Kelvin and Celsius scales that are now defined by the ITC-90, the Fahrenheit scale is still in use in some Anglo-American countries. These scales are linked such that

$$T_{\text{F}} [^{\circ}\text{F}] = 1.8t [^{\circ}\text{C}] + 32 = 1.8T [\text{K}] - 459.67 [\text{K}]. \quad (7.17)$$

Transformations between the different scales mentioned in this section are defined in Table 7.5.

Table 7.5 Transforming between temperature scales [7.14]

Unit	Kelvin K	Celsius °C	Fahrenheit °F	Réaumur °R	Delisle °D	Florence small °Gk
K	1	$K - 273.15$	$1.8 \times K - 495.7$	$0.8 \times K - 218.52$	$\frac{K}{-0.667} + 559.73$	$0.68143 K - 172.6$
°C	$°C + 273.15$	1	$1.8 \times °C + 32$	$0.8 \times °C$	$\frac{°C}{-0.667} + 150$	$0.68143 \times °C + 13.5$
°F	$0.556 \times °F + 255.4$	$0.556 \times °F - 17.78$	1	$0.444 \times °F - 14.22$	$\frac{°F}{-1.2} + 176.67$	$0.37857 \times °F + 1.39$
°R	$1.25 \times °R + 273.15$	$1.25 \times °R$	$2.25 \times °R$			
°D	$\frac{°D}{-1.5} + 373.15$	$\frac{°D}{-1.5} + 100$	$\frac{°D}{-0.83} + 212$			
Florence small °Gk	$1.4675 \times °Gk + 253$	$1.4675 \times °Gk - 19.8$	$2.6415 \times °Gk - 3.66$			

7.3 Theory

This section describes the theory behind three physical principles of temperature measurement: those based on thermal expansion, changes in electrical resistance, and variations in the speed of sound. It also discusses typical errors in temperature measurements and thermometer screens.

7.3.1 Liquid-in-Glass Thermometers

Liquid-in-glass thermometers are widely used for general temperature measurements. They make use of the cubic (volumetric) thermal expansion of a liquid in a glass bore with a constant circular cross-section (Fig. 7.4). The volumetric expansion of the liquid due to a change in the temperature T (which is close to neither the boiling nor the freezing point of the liquid) is given by [7.17, 18]

$$\Delta V = \alpha V_0(T - T_0), \quad (7.18)$$

where ΔV is the change in liquid volume due to the change in temperature, α is the cubic thermal expansion coefficient, and V_0 is the volume of the liquid at temperature T_0 . The change in the length of the liquid column Δh in the cylindrical glass bore of radius r upon a change in temperature ΔT is calculated via

$$\Delta h = \frac{\alpha V_0(T - T_0)}{\pi r^2}. \quad (7.19)$$

Typically, ethanol, with a cubic thermal expansion coefficient of $\alpha = 109 \times 10^{-5} \text{ K}^{-1}$, is the liquid used in modern liquid-in-glass thermometers. Historically, mercury ($\alpha = 18 \times 10^{-5} \text{ K}^{-1}$) was commonly employed, but applications of this toxic liquid are now restricted due to the regulation of toxic substances [7.19, 20].

Besides the expansion of the liquid, the expansion of the glass and the scale must also be taken into account (Chap. 10), but both are small, so they are included in the measurement error (Sect. 7.4.1).

7.3.2 Bimetallic Thermometers

A bimetallic thermometer consists of a strip of one metal bonded to a strip of another metal with a different metallic expansion coefficient. The bimetallic strip is fixed at one end. When the temperature changes, the strip bends in a circular arc (Fig. 7.5). The reference temperature is taken to be the temperature when the strip is planar. The passive part of the strip typically has an expansion coefficient of $< 5 \times 10^{-6} \text{ K}^{-1}$; e.g., the nickel-iron alloy Invar (FeNi36) has a very low expansion coefficient of $1.2 \times 10^{-6} \text{ K}^{-1}$. The active component typically has a thermal expansion coefficient of $15 \times 10^{-6} \text{ K}^{-1}$ and is made from an alloy of iron, nickel, manganese, and chrome. For small temperature changes, the deflection of the free end of the strip is given by [7.17]

$$y = \frac{K \Delta T L^2}{D}, \quad (7.20)$$

where K is a constant that depends on the material, L is the length of the strip, and D is the thickness of the strip.

7.3.3 Metal Resistance Thermometers

Platinum wires have come to dominate temperature measurement because of their stable temperature–

Fig. 7.4 Liquid-in-glass thermometer (after [7.17], with the permission of Oxford University Press)

Fig. 7.5 Schematic of a bimetallic thermometer (after [7.17], with the permission of Oxford University Press)

resistance relationship. The temperature dependence of the resistance R is given by the equation [7.5, 17, 18]

$$R(T) = R_0[1 + \alpha(T - T_0)], \quad (7.21)$$

or, with $T_0 = 273.15$ K,

$$R(t) = R(0^\circ\text{C})[1 + \alpha t], \quad (7.22)$$

where α is the temperature coefficient of resistance in the vicinity of T_0 , which ranges from 0.00385 to 0.00392 K^{-1} depending on the purity of the platinum. By adding iridium, the brittleness of the wire can be reduced, which typically leads to lower temperature coefficients than for pure platinum. In the meteorological measurement range of -50 to 50°C , an almost linear temperature dependence is obtained. For larger temperature ranges, a modified version of (7.21),

$$R(T) = R_0[1 + \alpha(T - T_0) + \beta(T - T_0)^2], \quad (7.23)$$

where β is about $-5.85 \times 10^{-7}\text{ K}^{-2}$, is more accurate. Typical platinum thermometers have a resistance $R(0^\circ\text{C}) = 100\ \Omega$ ($1000\ \Omega$ is also available) and are standardized [7.21, 22]. $100\ \Omega$ platinum resistance thermometers (Pt100) are categorized into accuracy classes

(Table 7.6) according to the linear approximation (7.22). Class AA is the most common Pt100 class used in atmospheric measurements. Even more accurate are those that comply with Standard 1/10 DIN class B (DIN: Deutsches Institut für Normung; the German Institute for Standardization).

Thin-Wire Thermometers

Very thin wires with diameters of $< 20\ \mu\text{m}$ are used for turbulence measurements. The diameters of these wires are on the order of the wavelength of an electron in a platinum wire with contaminated surface [7.23] (about $\lambda = 1.62\ \mu\text{m}$). Therefore, the specific resistance ρ_d is greater than that of an infinitely thick wire ($\rho_\infty = 9.8 \times 10^{-8}\ \Omega\ \text{m}$) and can be approximated by the equation [7.23]

$$\rho_d = \rho_\infty \left(1 + \alpha \frac{\lambda}{d} \right), \quad (7.24)$$

where d is the thickness of the wire and the coefficient $\alpha = 3/8$ [7.24]. Specific resistances of wires with various diameters are given in Table 7.7. The time constant of a $20\ \mu\text{m}$ thick platinum wire is about $0.01\ \text{s}$ [7.25, 26]. The maximum currents without self-heating for 2, 5, and $25\ \mu\text{m}$ thick platinum wires are 2, 5, and $50\ \text{mA}$, respectively [7.27].

Table 7.6 Maximal tolerance for $100\ \Omega$ platinum resistance thermometers [7.21, 22]

Temperature °C	Maximal tolerance		Class B		Class AA ^a	
	Class A K	Ω	K	Ω	K	Ω
-100	±0.35	±0.14	±0.8	±0.32	±0.27	±0.11
0	±0.15	±0.06	±0.3	±0.12	±0.10	±0.04
100	±0.35	±0.13	±0.8	±0.30	±0.27	±0.11

^a Formerly 1/3 DIN class B.

Table 7.7 Specific resistances of very thin platinum wires [7.27]

Diameter of the wire (μm)	Specific resistance ($\times 10^{-8} \Omega \text{ m}$)	Resistance of 1 m length of the wire ($\Omega \text{ m}^{-1}$)
1	15.8	201 200
2	12.8	50 300
5	11.0	5600
10	10.4	1320

20	10.1	321
30	10.0	141
50	9.9	50

Electronic Circuits for Resistance Thermometers

A bridge circuit is used to perform electrical measurements in a resistance thermometer. The classical *Wheatstone* bridge is seldom used with two- and three-wire circuits because of nonlinearity and poor compensation for wire resistances. For the circuits given in Fig. 7.6a, with a temperature-sensitive resistance $R_1 + \Delta R$ and a reference resistance R_2 , it follows that if $R_1 + \Delta R \neq R_2$, the output voltage (source voltage of the bridge U) is [7.28]

$$U_{\text{out}} = U \frac{\Delta R R_4}{(R_1 + \Delta R + R_2)(R_3 + R_4)}. \quad (7.25)$$

The error in the output voltage is only lower than 1% if ΔR refers to a temperature difference of less than 5 K. Therefore, different linearization methods have been developed [7.28]. A second problem arises from the cables between the sensor and the bridge, because all metallic cables exhibit temperature sensitivity. The two-wire circuit (Fig. 7.6a) was replaced with a three-wire circuit in which two cables were attached to one side of $R_1 + \Delta R$, with one of the cables connected to R_2 and the other linked to the galvanometer. More effective is the Thomson bridge with four cables. In recent

years, most of these bridges have been replaced with constant-current circuits in which the temperature sensor is connected to four cables. These circuits are linear and unaffected by the temperature sensitivity of the cables (Fig. 7.6b).

7.3.4 Thermistors

Thermistors are resistors with larger temperature coefficients than standard resistors. They are grouped into those with a positive temperature coefficient (PTC) and those with a negative temperature coefficient (NTC). Thermistors used in the atmospheric sciences are typically of the latter type, which are made from sintered metal oxides.

Resistance-measuring devices with integrated electronic circuits have largely replaced thermistors [7.29, 30] as measurement sensors, because even though thermistors have tenfold greater temperature sensitivity, they also exhibit nonlinear characteristics. Thermistors must undergo heat and cold aging before use, and frequent recalibrations are often necessary during operation. Modern thermistors are as stable as platinum wires [7.31]. The temperature dependence is given by the β equation

$$R(T) = R(0^\circ \text{C}) e^{\left(\frac{\alpha}{T} + \frac{\beta}{T^3}\right)}, \quad (7.26)$$

where, typically, $\alpha \approx 4500 \text{ K}$ and $\beta \approx -1.5 \times 10^7 \text{ K}^3$ [7.17]. The most important areas of application are in radiosondes and for measurements of body and dome temperatures in radiation sensors. Thermistors have been used in bridge circuits with a logarithmic approximation for possible linearization of the output signal [7.30]. Another approximation is the *Steinhart–Hart* equation [7.32]

$$T = \frac{1}{A + B \ln(R) + C [\ln(R)]^3}, \quad (7.27)$$

Fig. 7.6a,b Electronic circuits used in resistance thermometers: (a) classical Wheatstone bridge and (b) constant-current difference amplifier (I_c : constant current source)

which is often used for linearization in microcomputers.

Thermistors are more affected by self-heating than the platinum wires usually used in resistance thermometers. The highest input power to a thermistor is 0.06 mW, which guarantees self-heating of below 0.1 K [7.31].

7.3.5 Semiconductors

Semiconductor temperature sensors are not very common in atmospheric science. These sensors make use of the temperature dependence of the voltage across a semiconductor *pn* junction such as a diode. The simplest silicon diodes have a temperature sensitivity of about -2 mV K^{-1} [7.18]. The benefit of using a semiconductor is that it is simple to include the sensor in an electronic circuit.

7.3.6 Thermocouple

A thermocouple consists of two junctions of dissimilar metals [7.17, 18] with different *Seebeck coefficients*. If the temperatures of the two junctions are different, the thermocouple produces a temperature-dependent voltage called the Seebeck or thermoelectric effect. If one junction is kept at a constant temperature (the reference temperature), the thermocouple voltage is a measure of the temperature difference between the two junctions. A vessel with a water–ice mixture (0°C) or a metallic block at a constant temperature as regulated using an

Fig. 7.7 Schematic of a thermocouple (after [7.18], with the permission of Wiley and Sons)

other temperature measurement can be used to obtain the reference temperature. A schematic of the electric circuit of a thermocouple is shown in Fig. 7.7.

The two metals (and thus the electrical properties of the metals) used in a thermocouple can vary. Thermocouples used for meteorological temperatures are listed in Table 7.8.

The characteristics of thermocouples are given by the equation [7.33, 34]

$$U [\mu\text{V}] = \sum_{i=0}^n c_i t^i, \quad (7.28)$$

where the temperature t is in $^\circ\text{C}$. The first four coefficients for the most common copper–constantan thermocouple according to ITS-90 are $c_0 = 0.0 \mu\text{V K}^{-1}$, $c_1 = 3.874811 \times 10^1 \mu\text{V K}^{-1}$, $c_2 = 4.419443 \times 10^{-2} \mu\text{V K}^{-2}$ (-270 to 0°C), $c_3 = 3.329223 \times 10^{-2} \mu\text{V K}^{-2}$ (0 to 400°C); for further coefficients see [7.33, 34]. It is obvious that only the coefficient c_1 (Table 7.8) is relevant given the typical accuracy of the measurements. Relevant thermoelectric voltages are given in Table 7.9.

7.3.7 Sonic Anemometers

Modern sonic anemometers (Chap. 9) use the travel time principle and direct time determination [7.35]. In this method, a sonic signal (about 100 kHz) is transmitted from each side of a measurement path and received at the opposite side. The wind velocity u causes one signal to be faster than the other. The exact travel times of the sonic signals from each side ($t_{1,2}$) are used to determine the wind velocity via

$$t_{1,2} = \frac{\sqrt{c^2 - u_n^2} \pm u_d}{c^2 - u^2} d, \quad (7.29)$$

where d is the path length, u_d is the wind component along the path, u_n is the normal component of the wind, and c is the speed of sound. The sum of the reciprocal

Table 7.8 Thermocouple type definitions [7.33, 34] along with values of the coefficient c_1 according to (7.17) ($c_0 = 0.0 \mu\text{V K}^{-1}$ if no other value is given)

Type	Composition	Temperature range ($^\circ\text{C}$)	Coefficient c_1 ($\mu\text{V K}^{-1}$)

travel times gives the speed of sound through the equation

$$\frac{1}{t_1} + \frac{1}{t_2} = \frac{2}{d}c\sqrt{1 - \frac{u_n^2}{c^2}} \approx \frac{2}{d}c, \quad (7.30)$$

which is a function of the temperature and the moisture according to (7.15) (e : water vapor pressure, p : pressure), similar to the virtual temperature (Sect. 7.1.1),

$$T_s = \frac{d^2}{1607.52} \left(\frac{1}{t_1} + \frac{1}{t_2} \right)^2. \quad (7.31)$$

Recalculation of the true temperature is possible by applying the geometric parameters of the sonic anemometer (Chap. 55).

7.3.8 Radiation Error

The influence of radiation on temperature measurement is called the radiation error, which can be estimated as the additional heating caused by the absorption of radiation by the sensor. As well as the shortwave radiation and the properties of the sensor, the heating depends on three other parameters: the Prandtl number [7.7, 27],

$$\text{Pr} = \frac{\nu}{a_T}, \quad (7.32)$$

which is the ratio of the kinematic viscosity ν to the molecular thermal conductivity ($a_T = 0.71$ for air); the Reynolds number

$$\text{Re} = \frac{LV}{\nu}, \quad (7.33)$$

which is the ratio of inertial forces to frictional forces at the characteristic length scale L and the characteristic

velocity scale V ; and the Nusselt number

$$\text{Nu} = f(\text{Re}, \text{Pr}), \quad (7.34)$$

which is a function of the heat conductance and the flow characteristics. For forced convection ($0.01 < \text{Re} < 10000$) of air [7.36],

$$\text{Nu} = 0.39 + 0.51\sqrt{\text{Re}}. \quad (7.35)$$

The radiation error ΔT , the difference between the true and measured temperatures, is therefore a function of the radiation balance at the sensor surface Q_s , the sensor surface area F , and the heat transfer properties α , such that

$$\Delta T = \frac{Q_s}{\alpha F}, \quad (7.36)$$

where

$$\alpha = \text{Nu} \frac{\lambda}{d}, \quad (7.37)$$

$$Q_s = aK_{\downarrow}F_R. \quad (7.38)$$

Here, a is the absorption capacity of the surface, λ is the molecular heat transfer number, d is the sensor length, K_{\downarrow} is the downwelling shortwave radiation, and F_R is the area affected directly by the radiation.

On this basis, the radiation error of a cylindrical sensor with the dimensionless constant $c = 0.62$ can be calculated as [7.17, 18]

$$\Delta T = \frac{K_{\downarrow}(1-a)}{c\lambda} \sqrt{\frac{\nu d}{V}}. \quad (7.39)$$

Therefore, the radiation error is proportional to the shortwave radiation at the sensor surface and the square

Fig. 7.8 Radiation errors for thin platinum wires with $K_{\downarrow} = 800 \text{ Wm}^{-2}$ and $a = 0.5$ in the presence of various wind velocities u (after [7.27] with permission from Wiley-VCH)

root of the sensor diameter and inversely proportional to the square root of the characteristic velocity.

Extensive investigations of the use of resistance wires for turbulence measurements have been performed [7.26, 27, 37]. Radiation errors for the absorption capacity of platinum ($a = 0.5$) are given in Fig. 7.8. Thus, radiation errors of $< 0.1 \text{ K}$ are only realized for wire diameters of $< 20 \mu\text{m}$.

Given the difficulties involved in measuring the temperature increase due to radiation error, the measurement accuracy outside of closed rooms is typically about 0.1 K (ventilated radiation shield; see Sect. 7.3.9), although the accuracy can reach 0.05 K for very well-maintained devices. Therefore, the radiation error is much greater than the errors of a well calibrated platinum wire sensor ($< 0.001 \text{ K}$).

7.3.9 Radiation Screens

To reduce the radiation error, *static (passive) radiation screens* have long been used in climate observations. A temperature shelter [7.18, 39] should protect the sensor from direct radiation, suppress any radiation-induced warming of the thermometer, prevent reflected radiation from the thermometer, exclude external sources of heat, allow air to flow freely around the thermometer, and protect it from precipitation. The utilization of various double-louvered screens (Venetian blinds) is well established in this context (Sect. 7.4.5). Several comparison experiments are available, but a theory that could inform guidelines for optimal construction is still missing. Multiple sensors can be housed in a shelter with Stevenson-type wooden screens, while a single sensor can be protected by a Gill multiplate shield, which is optimized to minimize errors [7.38]. Figure 7.9 shows the overall structure of such a shield (see also Fig. 7.15) along with a modeled flow distribution. Natural ventilation helps to reduce the error caused by housing the sensor in a confined space (the hut error) [7.40] to $1\text{--}2 \text{ K}$.

Besides the hut error, large static radiation screens have a lag time of up to 30 min in near-calm conditions [7.41]. This lag time is given by the approximation [7.42]

$$L = 2.5u^{-0.7} [\text{min}] . \quad (7.40)$$

To overcome the radiation error, the screen can be ventilated. Such a screen is known as an *active screen*. The hut error is reduced to below 1 K [7.31] when active screens are used, and can be even removed completely by adopting a system involving sufficient forced venti-

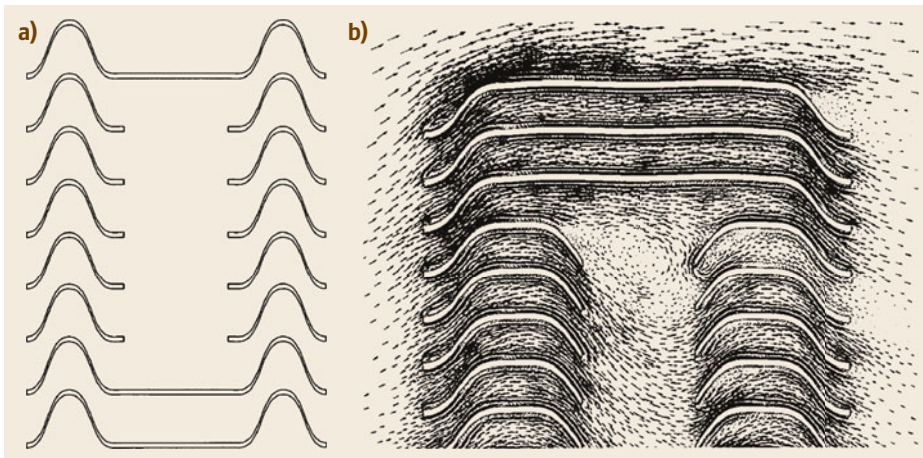

Fig. 7.9a,b The Gill multiplate shield. (a) Schematic showing a cross-section. (b) Velocity vectors calculated with a numerical model. Flow enters from the left at 1.0 m s^{-1} ; the speed is proportional to the length of the vector. The largest velocity, 1.6 m s^{-1} , occurs at the top leading edge of the shield (after [7.38] with permission from the American Meteorological Society)

Table 7.10 Classification of temperature and humidity measurement sites based on site characteristics [7.5]

lation of double-tube radiation shields, similar to those of the *Assmann psychrometer* (Chap. 8).

7.3.10 Influence of the Surrounding Area on Temperature Measurements

The siting recommendation for temperature measurements is based on the structure of the temperature field near the surface and the vertical gradients (Chap. 1). The recommendation is also valid for humidity measurements (Chap. 8). Sensors should be installed inside a radiation screen at a height of between 1.25 and 2 m [7.5].

The main factors that influence temperature and humidity measurements are the presence of obstacles close to the screen (leading to a shadow effect and reduced nighttime cooling) and artificial surfaces, which may affect wind conditions, reflections, etc. Shadow effects due to the natural relief are not taken into account. The vegetation should be lower than the height of the screen. The World Meteorological Organization has developed a clear schema for the classification of temperature and humidity measurement sites based on site characteristics [7.5], as shown in Table 7.10 (see also Chap. 43).

7.4 Devices and Systems

Several previously popular measurement methods have either been supplanted in the last few decades or are now used only for special applications. These include thermocouples, semiconductors, and thermistors. Very fine thermocouples are still used for turbulence measurements (Chap. 55). Due to restrictions on the application of mercury (which is toxic) and the trend for automating measurements, liquid-in-glass sensors are also increasingly being sidelined. Therefore, this chapter only describes sensors that are still in use. For more on sonic thermometers, see the discussion of sonic anemometers in Chap. 9.

7.4.1 Liquid-in-Glass Thermometers

Liquid-in-glass thermometers are still commonly used for routine air temperature observations, including maximum, minimum, and wet-bulb temperatures [7.5]. In such a sensor, the expansion of the liquid as the temperature increases should be much larger than the expansion of the glass container. The stem is a fine bore of

constant circular cross-section that is only partly filled with the liquid and is connected to the main liquid-filled bulb. The inside surface of the bore should be coated to reduce adhesion forces. Thermal expansion of the liquid causes the length of the liquid column to change, allowing the change in temperature to be gauged. Usually the stem is sheathed and the temperature scale is engraved on the stem or on a glass strip attached to the stem. Nowadays, alcohol is generally used as the liquid rather than the previously popular mercury due to the toxicity of the latter material [7.19, 20]. A liquid with properties similar to mercury has recently become available. This eutectic alloy of gallium, indium, and tin, marketed as Gallistan® [7.43], has a melting point of -19°C and gives stable results above -2°C . This liquid is used in maximum thermometers intended for medical purposes. It could also be applied for meteorological observations in areas that are always above freezing. In this case, the bore is coated with gallium oxide to increase adhesion forces so that it is not necessary to narrow the bore in the maximum thermometer (Fig. 7.10c).

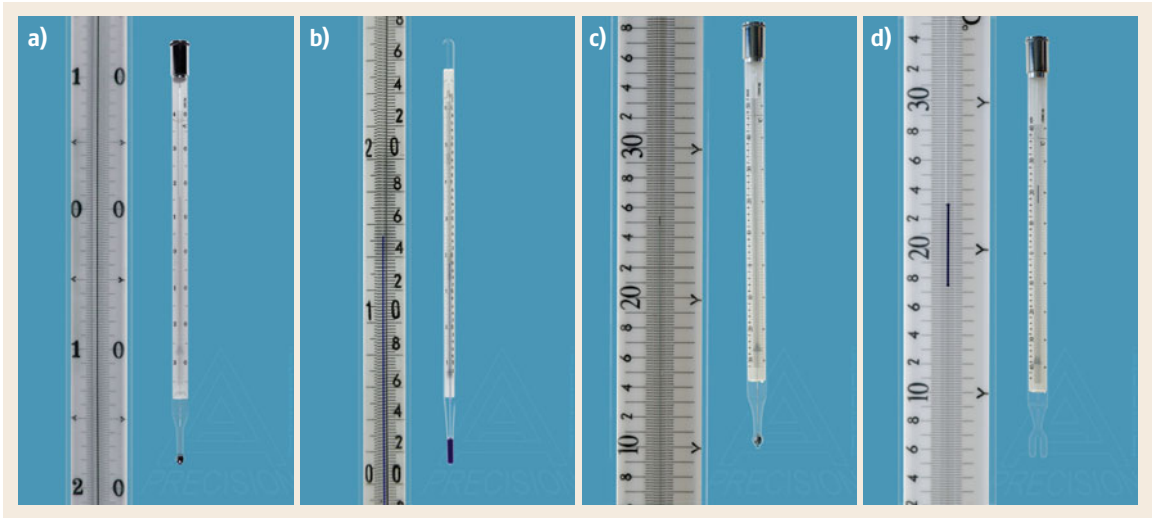

Fig. 7.10a–d Liquid-in-glass thermometers: (a) station thermometer (August psychrometer), (b) station thermometer (Assmann psychrometer), (c) maximum thermometer, (d) minimum thermometer (photos © Amarell GmbH & Co. KG, Kreuzwertheim, Germany)

Different types of liquid thermometers are available (Fig. 7.10) for meteorological applications according to the British standard [7.44] or German standards [7.45]. These thermometer types are only used in classical thermometer screens. The ordinary station thermometer has a scale increment of 0.2 K, or occasionally 0.5 K, and is available in a larger form for use in the August psychrometer (Chap. 8) or in a smaller form for use in the Assmann psychrometer (Chap. 8). Minimum and maximum thermometers are also available. The minimum thermometer has a dark glass index (Fig. 7.11), about 2 cm long, that is immersed in the spirit. This thermometer should be orientated in a near-horizontal position. The maximum thermometer is a mercury-in-glass thermometer with a reduced diameter and a constriction in the bore between the bulb and the beginning of the scale (Fig. 7.11). This constriction prevents the mercury column from receding with falling temperatures. The observer can reset the thermometer by holding it bulb end downwards and swinging their arm until the mercury column is reunited. The maximum thermometer should be mounted at an angle of about 2° from the horizontal position. Soil thermometers have an inclined stem that permits measurements down to a depth of 20 cm. To probe greater depths, an ordinary thermometer is mounted on a wooden or plastic tube and sunk into the ground to the required depth (Chap. 61). For a discussion of the application of liquid-in-glass thermometers to climatological observations, see Sect. 7.8.1.

Thermometers should be read as rapidly as possible in order to avoid changes in temperature caused by the

Fig. 7.11 Schematic showing cross-sections of maximum and minimum thermometers with a reduced bore and constriction and a dark index, respectively (after [7.17] with permission from Oxford University Press)

observer's presence [7.5]. The liquid meniscus (or index) and the thermometer scale should be in the same plane to avoid parallax errors. Readings should be made to tenths of a degree (important in psychrometry; see Chap. 8), even when the scale is divided into fifths or even halves of a degree. Corrections for scale errors that are given in the calibration certificate should be applied to the readings.

The following errors may be applicable to measurements made using liquid-in-glass thermometers [7.5]:

- The *reversible elastic error* is important when the thermometer is exposed to a large range of temperatures in a short time interval, and depends on the quality of the glass (it ranges from 0.03 to 1 K for a temperature range of 0 and 100°C). This type of

Fig. 7.12 (a) Schematic of a bimetallic thermograph (after [7.45] with permission of VDI e. V., Düsseldorf, Germany) and (b) a recently produced device (photo courtesy of Feingerätebau K. Fischer GmbH, Drebach, Germany, 2018)

error is relatively unimportant for most of meteorological measurements.

- *Irreversible elastic error* occurs when the bulb slowly contracts over a period of years. Even for high-quality glass, this error will be about 0.01 K during the first year of use.
- *Error due to an emergent stem* occurs if the thermometer is not completely surrounded by air at a uniform temperature. This error may be relevant during calibrations.
- *Parallax error* occurs if the viewing angle is not perpendicular to the stem of the thermometer.
- *The gross reading error* is usually 1°, 5°, or 10°. Therefore, the observer should read to the nearest tenth of a degree.
- *The error due to the different cubical expansion coefficients of the alcohol and the glass* necessitates careful calibration. This error is more relevant for mercury thermometers than alcohol thermometers, which have a much higher expansion coefficient.
- Thermometers with organic liquids have some special errors, such as *errors due to liquid adhesion to the glass or liquid polymerization with age*. The liquid column may be broken, mainly due to transport, or drops of liquid may form in the upper part of the thermometer stem due to evaporation and condensation (see also Sect. 7.7).

7.4.2 Bimetallic Thermometers

Bimetallic thermometers are mainly used in thermographs for atmospheric measurements. They are often employed in combined thermo-hygrographs (Chap. 8) but not as single temperature sensors. Furthermore, bimetallic thermometers are used for temperature compensation in hair hygrometers (Chap. 8) and in aneroid barometers (Chap. 10).

A bimetallic thermograph for measurements in large temperature screens or for indoor measurements is shown in Fig. 7.12 [7.5]. The movement of the recording pen is controlled by the change in curvature of the bimetallic strip, which has one fixed end. The arm with the pen should be adjustable so that the zero of the instrument can be changed if necessary. Instrument errors are related to the mechanics of the instrument, mainly the lever, the recording drum, and the strip chart, as well as possible corrosion of the bimetallic strip. Sometimes the strip is replaced with a *Bourdon tube* (a curved metal tube filled with alcohol), which has a faster response time but is less sensitive.

7.4.3 Resistance Thermometers

Resistance thermometers can only be used in thermometer screens or in specially constructed instruments. Typical resistances are 100 Ω (Pt100) or 1000 Ω (Pt1000). AA class resistance thermometers [7.21, 22] that utilize four-wire sensors (two cables on each side of the resistance; see Sect. 7.3.3) are mainly used for atmospheric measurements. A simple resistance thermometer construction is shown in Fig. 7.13. Often the sensor is combined with a capacitive humidity sensor,

Fig. 7.13 A resistance thermometer (photo © Adolf Thies GmbH & Co. KG, Göttingen, Germany, 2018)

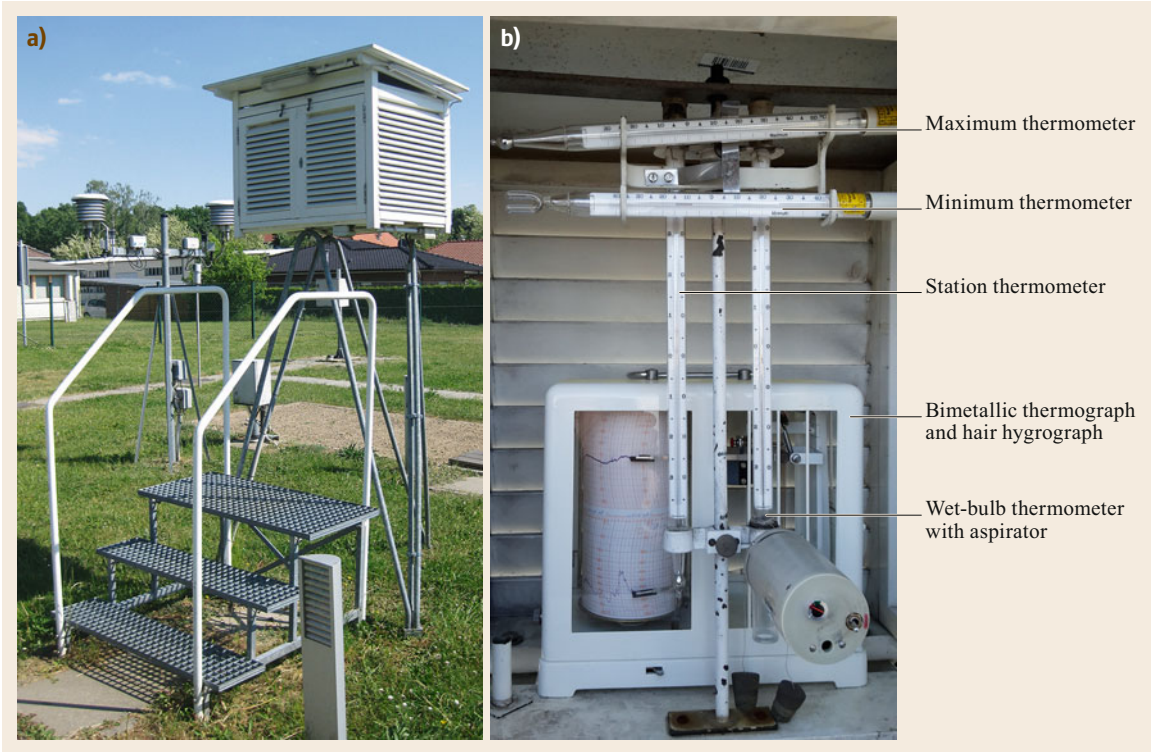

Fig. 7.14 (a) Stevenson temperature screen (photo © T. Foken). (b) View inside a temperature screen showing the classical instrumentation setup; the station thermometer and the wet-bulb thermometer together comprise an August psychrometer (see Fig. 9.17) (photo © T. Foken)

as shown in Fig. 8.17b, while the sensitive measuring element is shown in Fig. 8.17a.

Typical error sources for resistance thermometers include [7.5]:

- *Self-heating of the measurement element.* Depending on the diameter of the wire, the current should be less than 2 mA so that the self-heating is significantly lower than 0.1 K [7.46].
- *Inadequate compensation for the lead error.* A four-wire circuit is thus recommended.
- *Inadequate compensation for nonlinearities.* The sensor should be selected according to the possible range of temperatures that will be encountered (excessively large range should be avoided). The resulting error due to nonlinearities will depend on the resistance class (see Table 7.6).
- *Sudden changes in switch contact properties,* which can occur as the switch ages.

Fine-wire fast response thermometers are no longer commercially available. Some institutionally made sensors are described in the literature [7.27, 47]. Because fine wires are difficult to handle, *Wollaston wire*, which

is a very fine (< 0.01 mm diameter) platinum wire clad in silver, can be used. After fixing the wire in place, the silver can be eliminated using an electrolytic method in which potassium cyanide is used as the electrolyte [7.48].

7.4.4 Radiation Screens

Any radiation or temperature shield or screen should be designed such that it provides an enclosure with an internal temperature that is both uniform and the same as that of the outside air [7.5]. Temperature screens for meteorological and climatological sensors vary widely between countries [7.39]. The most common temperature screen is that of Stevenson (see Fig. 7.14a).

The rising popularity of automatic weather stations has led to a significant increase in the number of screen designs. The screen should completely surround the thermometer and exclude radiant heat, precipitation, and other phenomena that might influence the measurements. To ensure that the shelter (hut) effect is comparable between shelters, the comparison procedure as well as the main construction details are standardized [7.49]. To avoid biases due to differ-

Fig. 7.15a–e A selection of nonventilated (**a,b**) and ventilated (**c–e**) temperature screens: (**a**) screen developed by Gill (model 41003; photo © R. M. Young/GWU Umwelttechnik GmbH, Erfstadt, Germany); (**b**) naturally aspirated helical radiation screen (photo © baranidesign, Bratislava, Slovakia); (**c**) ventilated screen of the German Meteorological Service with four sensors (photo © Eigenbrodt GmbH & Co. KG, Königsmoor, Germany); (**d**) aspirated screen (photo © Apogee Instruments, Logan, UT, USA); (**e**) ventilated temperature screen (model 43502; photo © R. M. Young/GWU Umwelttechnik GmbH, Erfstadt, Germany)

ences between the microclimate inside the screen and properties of the surrounding air, screens with forced ventilation are often used. When artificial ventilation is used, the sensors should not be affected by water droplets, etc., and the ventilation motor should not heat up the air inside the screen. The shield material should be highly reflective and have low heat absorption. Naturally ventilated thermometer screens permit accurate air temperature measurements, to ± 0.1 K in most circumstances, but occasionally differ by more than 0.5 K in light winds or because of a slow response. Furthermore, during low wind conditions maximum temperatures are underestimated and minimum temperatures are overestimated [7.50]. Some comparison experiments of temperature shields have been reported,

but mainly only as internal reports of various meteorological services [7.5, 51].

Figure 7.15 shows a selection of small nonventilated and ventilated temperature screens. Only the classical screen developed by Gill (Fig. 7.15a) is well described [7.38]. The helical radiation screen provides natural aspiration [7.51] (Fig. 7.15b). Figure 7.15c shows the ventilated radiation screen design used by the German Meteorological Service. The ventilated radiation screen in Fig. 7.15d is a double tube filled with insulating material. The sensor can be mounted from the side. Figure 7.15e shows a ventilated double tube with the sensor in the middle. Comparison experiments show that the radiation error for nonventilated screens drops significantly with increasing wind speed, but for

Table 7.11 Advantages and disadvantages of different temperature sensors

Devices	Advantages	Disadvantages
Liquid-in-glass instrument	Easy to handle	Not suitable for registration, only for use in radiation screens
Bimetallic thermometer	Easy to use for mechanical registration systems	No electrical output signal, only for use inside radiation screens or for indoor measurements
Resistance thermometer with Pt100/Pt1000 sensor	Accurate and almost linear signal	Only for use inside radiation screens
Resistance thermometer with thin wire < 20 μm diameter	Temperature measurements (turbulence) with no radiation error	Very sensitive and difficult to handle
Thermistor	Tenfold higher temperature coefficient than resistance thermometers	Highly nonlinear characteristic, self-heating possible
Thermocouple	Very thin thermocouples can be used for turbulence measurements	Reference temperature required, not as accurate as resistance thermometers

Fig. 7.16 Assmann aspirated psychrometer with one sensor (a resistance thermometer), ventilation, and a double-tube radiation shield (photo © Theodor Friedrichs & Co., Schenefeld, Germany, 2018)

mann's guidelines for the dimensions of the double radiation shield are followed and the ventilation velocity is larger than 2.5 m s^{-1} [7.52] (Chap. 8, Fig. 8.20). A version of this instrument with just one temperature sensor (a resistance thermometer) is shown in Fig. 7.16.

Several small temperature screens are available for the combination of a resistance thermometer with a capacitive humidity sensor (see Fig. 8.17b), some of which are partly ventilated (Sect. 7.4.5).

7.4.5 Sensor Comparison

The number of methods used for atmospheric measurements has decreased over the last few decades because of the trend away from visual measurements with liquid-in-glass thermometers, the restrictions on mercury thermometers, and the increasing popularity of electronic sensors that can be used in automatic stations. Even the bimetallic thermograph has been largely replaced; nowadays, it is only applied for climatological and indoor measurements. The resistance thermometer has the most advantages of any electronic sensor, including high accuracy, the nearly linear output signal of a constant-current circuit, and easy handling. Because of the availability of good amplifiers, its relatively low temperature coefficient is no longer a restriction. Resistance thermometers can be made very small, leading to a fast response time. They have therefore even replaced thermistors in radiosondes (Chap. 46). An overview of the advantages and disadvantages of different temperature sensors is given in Table 7.11.

low wind speeds ($< 2 \text{ m s}^{-1}$) it is still several degrees (1–2 K), although it varies significantly depending on the type of screen used. The radiation error for ventilated screens is always below 1 K [7.31].

The requirements of a radiation screen—excellent radiation protection and sufficient ventilation—are best realized with an Assmann aspirated psychrometer (Chap. 8 and Fig. 8.19). This device consists of two thermometers that are ventilated at $> 2.5 \text{ m s}^{-1}$ and equipped with a double radiation shield. Liquid-in-glass thermometers are generally used (Fig. 7.11b), although electrical sensors are also relatively accurate if Ass-

7.5 Specifications

Typical uncertainties in the measurements obtained using various temperature sensors are given in Table 7.12, and typical response times are provided in Table 7.13.

For turbulence measurements, only sonic thermometers, fine-wire resistance thermometers, or thermocouples with a diameter of $< 20 \mu\text{m}$ can be used. When a

Table 7.12 Specifications of various temperature sensors [7.5, 45]

Method	Typical total uncertainty (K)	Typical temperature range (°C)	Remark
Liquid-in-glass	≤ 0.2	−40 to 50	Mercury should not be used below −38.9 °C
Liquid-in-glass (maximum and minimum thermometers)	≤ 0.5	−30 to 50, −40 to 40	
Bimetallic thermograph	≤ 1	−40 to 50	Flow rate ≥ 2.5 m s ^{−1}
Resistance thermometer	≤ 0.1	−40 to 50	
Thermistor	≤ 0.2	−40 to 50	
Thermocouple	≤ 0.5	−40 to 50	

Table 7.13 Time constants of temperature sensors

Measurement device	Time constant (s)
Sonic thermometer	< 0.01
Thin resistance wire (< 20 μm diameter)	< 0.01
Thermocouple	1–2, < 0.01 (< 20 μm diameter)
Thermistor	0.1–1
Liquid-in-glass and resistance thermometers (3–5 mm diameter)	10–30
Bimetallic thermograph	25 s (ventilation 5 m s ^{−1})
Required response time [7.5]	20 s

liquid-in-glass or resistance thermometer is used in a psychrometer (Chap. 8), the uncertainty should be 0.1 K

or less. Well-calibrated resistance thermometers can be used as a reference standard.

7.6 Quality Control

After calibrating a temperature sensor with a reference standard, corrections are required for at least each 10 K interval. The characteristics given in Table 7.14 should be fulfilled for these corrections.

7.6.1 Reference Standards

The World Meteorological Organization has developed some standards for data quality control [7.5], which are separated into laboratory standards and field standards.

Laboratory Standards

Primary-standard high-grade platinum resistance thermometers should be held and maintained at national standards laboratories, which may be national meteorological or other accredited calibration laboratories. Because the triple point of water is known precisely,

these thermometers should be checked periodically in a water triple-point cell with an uncertainty of 1×10^{-4} K.

Field Standards

Well-calibrated reference thermometers should be used for comparisons in the field. While the World Meteorological Organization recommends the WMO reference psychrometer [7.53], which is a free-standing instrument with radiation shield and ventilation (Sect. 8.4.4) and an uncertainty of 0.04 K, this instrument is only rarely available. However, the working standard of humidity measurements—the Assmann aspiration psychrometer—can also be used (Sect. 8.6.1).

Several calibration points can easily be generated in a Dewar flask, such as 0 °C (using a mixture of ice pieces and water) or −20 °C (with one part ice and three parts sodium chloride).

Table 7.14 Required thermometer characteristics for different types of thermometers [7.5]

Characteristic	Ordinary	Maximum	Minimum
Scale range (°C)	−30 to 45	−30 to 50	−40 to 40
Calibration range (°C)	−30 to 40	−25 to 40	−30 to 30
Maximum error (K)	< 0.2	0.3	0.2
Maximum difference between maximum and minimum corrections within the range (K)	0.2	0.5	0.3
Maximum variation in the correction within any 10 K interval (K)	0.1	0.1	0.1

Table 7.15 Typical test criteria for temperature measurements

Method	Error	Reason
All sensors	Temperature too low in comparison to other nearby temperature measurements Temperature too high (> 1–2 K) in comparison to other nearby temperature measurements Temperature is constant for more than 3–6 h	Sensor element is wet and provides a temperature close to the wet-bulb temperature Sensor is influenced by shortwave radiation; check the radiation shield and the ventilation Functionality of the sensor and/or the circuit is impaired; replacement required
Liquid-in-glass thermometer	Temperature too low in comparison to other temperature measurements Temperature too high in comparison to other temperature measurements	The liquid has partly evaporated and is seen in the upper part of the glass bore; maintenance or replacement required The liquid has partly evaporated and air is present in the middle of the liquid column in the glass bore; maintenance or replacement required
Electrical thermometer	Temperature out of the measurement range Temperature is a few degrees too high or low in comparison to other temperature measurements	Broken wire or defective measurement circuit; replacement required Contact problem; maintenance of all connectors required

7.6.2 Temperature Calibration

Temperature sensors should be calibrated against the reference sensor in a vessel of water. The calibration should be performed indoors to exclude the effects of radiation. The sensors should be separated by a distance of around 1 cm or less. For liquid-in-glass thermometers, the temperature difference between the water and the temperature of the room should be smaller than 5 K to ensure that the liquid and the glass have nearly the same temperature.

According to the ITS-90, resistance thermometers should be calibrated using the *Callendar–Van Dusen* equation [7.5, 22], which is the interpolation

$$R_t = R_0 [1 + A t + B t^2 + C (t - 100)t^3], \quad (7.41)$$

where R_0 is the resistance at 0 °C and A , B , and C are constants ($C = 0$ when $t > 0$ °C).

7.6.3 Specific Quality Control Methods

When performing quality control of temperature measurements, it is useful to compare the data with other temperature measurements obtained with temperature sensors in other devices such as net radiometers in the surrounding area or with sensors at other measurement heights. It should be taken into account that typical variations are also possible within the daily cycle (Chap. 1). For temperatures at different heights, a linear or (better) logarithmic approximation should be derived according to the profile equations (1.8) and (1.10). Sensors that do not follow this approximation during the daytime should be checked. Possible reasons for over- or underestimating the temperature are listed in Table 7.15.

7.7 Maintenance

The thermometer should be installed in a manner that guarantees that the measuring element is always dry, otherwise the (lower) wet-bulb temperature will be measured. Furthermore, visual checks of liquid-in-glass thermometers are very important because evaporation of the liquid in the glass bore will interrupt the liquid column, meaning that higher temperatures will be simulated.

Maintenance activities should be scheduled at regular intervals, as shown in Table 7.16. Inspections should include all electrical cables and their connections. The result of the inspections should be documented in the metadata.

Table 7.16 Maintenance of temperature measurement systems [7.45]

Maximum interval	Liquid-in-glass thermometer	Bimetallic thermograph	Resistance thermometer
1 week	Visual check and cleaning if necessary (dirt and cobwebs)		
	Comparison with a ventilated thermometer	Comparison with the station thermometer	
6 months		Compare measurements with a calibrated reference thermometer	
		Check mechanical functions	
2 years	Calibration of the sensor in the laboratory		
			Replace the fan

7.8 Applications

Temperature sensors are widely used in atmospheric measurements because a reference temperature is needed to perform corrections to various measurements or to carry out additional calculations, such as the determination of the air density (Chap. 5). The most prominent application of temperature sensors is, of course, to measure the temperatures used for weather prediction and climatology.

7.8.1 Temperature Measurements for Meteorology and Climatology

The most important measurements are listed in Table 7.2. Because of the horizontal heterogeneity of the temperature field and strong vertical gradients (Chap. 1), several requirements must be fulfilled to ensure that temperature measurements are comparable. For general meteorological work, the observed air temperature should be representative of the free-air conditions surrounding the station at a height of between 1.25 and 2 m above ground level and over an area as large as possible [7.5]. Liquid-in-glass or (more recently) resistance thermometers are used, all within a temperature screen, and ventilated if possible. Specific instructions for meteorological stations are given in Chap. 43. Besides the temperature at a particular time, the minimum (measured from 18:00 to 6:00 LT) and maximum (measured from 6:00 to 18:00 LT) temperatures should also be measured at the same height. The minimum at 5 cm above ground should be measured too. Because the sensor is used without a radiation screen, the measured value can only be used for the minimum, which occurs around sunrise. The soil temperature is usually measured at depths of 5, 10, 20, 50, and 100 cm (Chap. 61).

Calculation of Mean Values

Modern data acquisition technologies allow sampling rates of 0.1 to 10 s. The typical averaging interval for temperature is 10 min, but intervals of 30 or 60 min are also used. For standard meteorological measurements in Central Europe, the daily mean temperature is calculated from 24 temperatures t_i recorded at one-hour intervals between 23:50 UTC of the previous day and 22:50 UTC of the current day [7.45], i.e.,

$$\bar{t}_{\text{day}} = \frac{1}{24} \sum_{i=0}^{23} t_i. \quad (7.42)$$

For other time zones, the averaging times must be adjusted accordingly. The climatological daily mean is

calculated according to (7.42). If more than four successive hourly values are not available, the daily mean is calculated from the arithmetic mean of the measurements at 00:00, 06:00, 12:00, and 18:00. At climate reference stations, the daily mean is derived by averaging the temperatures measured at 6:30, 13:30, and 20:30 UTC [7.54], i.e.,

$$\bar{t}_{\text{day}} = \frac{t_{6:30} + t_{13:30} + 2 t_{20:30}}{4}. \quad (7.43)$$

Furthermore, days are assigned to climatological classes based on the minimum and/or maximum temperature during the day; see Table 7.17.

Effect of Changing the Sensor on Climatological Data

The temperature is an important indicator of climate change. The effect of changing the temperature scale on the bias of the measured temperature is small, as illustrated by Fig. 7.17. The bias is only significant for very low and very high temperatures before 1968, but even then it is still $< |0.05 \text{ K}|$ [7.46].

However, changes in instrumentation—mainly from liquid-in-glass thermometers housed in large thermometer screens to resistance thermometers protected by ventilated or nonventilated small thermometer screens—have had a much greater influence on the bias. That said, extensive investigations of this effect are still lacking. Based on data from an analysis by the German Meteorological Service [7.55], changing from using a liquid-in-glass thermometer to a resistance thermometer decreases the measured temperature by $-0.03 \pm 0.16 \text{ K}$. Also, changing the equation used to calculate the daily mean from (7.43) to (7.42) leads to a drop in temperature of $-0.08 \pm 0.52 \text{ K}$. Therefore, changes in the measurement sensors and calculation procedure used cannot explain the increase in atmospheric temperatures observed in recent decades, as together they would be expected to decrease measured temperatures by about -0.1 K .

Table 7.17 Climatological classification of days based on the minimum and/or maximum temperature

Type of day	Minimum temperature (°C)	Maximum temperature (°C)
Ice day		$t_{\text{max}} < 0$
Frost day	$t_{\text{min}} < 0$	$t_{\text{max}} > 0$
Ground frost day	$t_{\text{min}-5 \text{ cm}} < 0$	
Summer day		$t_{\text{max}} \geq 25$
Hot day		$t_{\text{max}} \geq 30$
Tropical day	$t_{\text{min}} \geq 20$	

Fig. 7.17 Plot showing the correction that must be made to historical temperature data measured before the application of the ITS-90 in 1990 as a function of temperature (after [7.46] with permission from Wiley & Sons)

Climate Diagrams

Temperature data are an important part of climate diagrams, which are calculated for thirty-year climate periods. The reference period for these diagrams is generally 1961–1990, before the strong recent increase in atmospheric temperatures, although the period 1981–2010 is sometimes used. Climate diagrams are often combined with precipitation sum data for the same

7.9 Future Developments

Measuring principles that allow digital data recording and have a near-linear response characteristic dominate. These criteria are fulfilled in particular by resistance thermometers, as well as—for turbulence measurements—sonic thermometers and, on occasion, thin platinum wires. Liquid-in-glass or bimetallic sensors are still popular as visual display in private areas or for classical reference measurements. Because platinum sensors can be integrated into chips and miniaturized, they can have low response times, and have therefore replaced thermistors for aerological measurements. The number of measurement principles in use has significantly decreased in the last few decades, and this trend will continue. A eutectic alloy of gallium, indium, and tin that is marketed under the tradename Gallistan® [7.43] can be used as the liquid in maximum

Fig. 7.18 Climate diagram for Bayreuth, Germany during 1961–1990, plotting both precipitation and temperature (after [7.56], © the authors)

period; an example is shown in Fig. 7.18. For other climatologically relevant illustrations, see Chap. 1.

7.8.2 Further Applications

Besides their application in meteorology, temperature measurements in the atmosphere are necessary for many technical processes. Radiation shields and ventilation are necessary for accurate measurements. The influence of shortwave radiation and heat sources can be excluded from indoor measurements.

thermometers for warm areas and in thermometers employed in Assmann psychrometers, because the accuracy of this psychrometer is too low below 0 °C.

Temperature sensors are included in many devices used in daily life, such as smartphones and cars. Because many sensors can now be accessed online, the number of temperature sensors in the atmosphere has increased dramatically. Of course, these sensors are not being applied in accordance with the recommendations given above, but the extremely large number of sensors available offers the possibility of filtering the data with mathematical models to make this information usable. This method is called crowdsourcing thermometry (Chap. 44). It can be assumed that a very detailed description of the horizontal temperature distribution will become available in the near future.

Thomas Foken

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

Jens Bange

Centre for Applied Geo-Science
University of Tübingen
Tübingen, Germany
jens.bange@uni-tuebingen.de

Jens Bange is a Professor for Environmental Physics at the University of Tübingen since 2010. He received a PhD in meteorology in 1998 and a diploma in physics in 1992 at the University of Hannover. His research interests include atmospheric turbulence, boundary-layer meteorology, wind-energy research, airborne meteorology, and environmental measurement technology. He is a founding member of the research networks ISARRA and WindForS.

Humidity Sensors

Dietrich Sonntag, Thomas Foken , Holger Vömel , Olaf Hellmuth 

For measurements of atmospheric humidity, a variety of different techniques has been used in the past, such as hair hygrometers, polymer sensors, optical instruments, and also those based on thermodynamic properties of moist air. Current sensor technology is mostly based on the psychrometric method, dewpoint measurements, and optical measurements, as well as capacitive sensors. Of special interest are the psychrometric theory and the theory of optical measurements. Technical specifications, exposure recommendations, necessary maintenance associated with different methods, as well as methods of quality control and calibration are presented.

Water occupies a special place among the constituents of air because it exists in the solid, liquid, or gaseous phase. Furthermore, it exhibits the strongest contribution to the natural greenhouse effect. Due to precipitation, evaporation, and long-range transport, the water-vapor content of air varies considerably throughout the atmosphere. Depending on the temperature, concentrations of wa-

ter vapor near the surface are on the order of $0.1\text{--}30 \times 10^{-3} \text{ kg m}^{-3}$. The water vapor is mostly concentrated in the lowest kilometer of the atmosphere (atmospheric boundary layer), whereas less than $0.3 \times 10^{-6} \text{ kg m}^{-3}$ of it is present in the stratosphere. Comprehensive descriptions of water vapor in the atmosphere are contained in textbooks of meteorology and climatology [8.1, 2].

8.1 Measurement Principles and Parameters

The humidity of air is measured as several parameters, such as the degree of saturation or the water-vapor pressure. Some of these parameters are measured but others must be calculated. The following section gives an overview of the different parameters and measurement principles.

8.1.1 Measured Parameters

Most humidity sensors measure relative humidity, which is the ratio of water-vapor pressure in the atmosphere in relation to the water-vapor pressure at saturation for a given temperature. Relative humidity is a temperature-sensitive parameter, which must be taken into account when calculating other humidity parameters. Therefore, a temperature measurement (Chap. 7) is essential. Some instruments measure absolute humidity or mixing ratio directly. Other measured parameters are dewpoint or frostpoint temperature and psychrometric difference – the temperature difference between a dry-bulb and wet-bulb thermometer – used for psychrometric methods. Table 8.1 gives an overview of parameters and their units measured by humidity sensors.

For many applications other humidity parameters are used. These are mainly water-vapor partial pressure, specific humidity, absolute humidity, or saturation vapor pressure that are given in Table 8.2 and possible calculations between humidity units are given in Table 8.3.

Of high importance is the maximum possible amount of water vapor in the air for a given temperature,

known as the water-vapor pressure of saturation. This relationship is given on the basis of the thermodynamic laws by the Clausius–Clapeyron equation [8.1, 2]

$$\frac{dE_w}{dT} = \frac{\lambda}{T\Delta v}, \quad (8.1)$$

where E_w is the saturation vapor pressure, T is the absolute temperature, λ is the specific heat of evaporation (λ_v) or sublimation (λ_i), and Δv is the difference between the specific volumes of water and water vapor. Assuming $\lambda = \text{const.}$, neglecting the volume of liquid water compared to that of water vapor, and adopting ideality of the gas mixture, it follows with the gas constant of water $R_w = 461.525 \text{ J kg}^{-1} \text{ K}^{-1}$

$$\frac{dE_w}{E_w} = \frac{\lambda}{R_w} \frac{dT}{T^2}. \quad (8.2)$$

After integration the saturation vapor pressure can be written as

$$E_w = E_{w0} \exp\left(\frac{\lambda}{R_w T_0} \frac{T - T_0}{T}\right) \quad (8.3)$$

with $E_{w0} = 6.112 \text{ hPa}$ and $T_0 = 273.15 \text{ K}$. From (8.3) it follows that with the specific latent heat of evaporation

$$\lambda = \lambda_v = 2.50 \times 10^6 \text{ J kg}^{-1},$$

the water-vapor pressure over water, and with the latent heat of sublimation

$$\lambda = \lambda_i = 2.83 \times 10^6 \text{ J kg}^{-1}$$

Table 8.1 Measured parameters of humidity sensors

Parameter	Description	Unit	Symbol
Relative humidity	Ratio of water-vapor pressure to saturation water-vapor pressure	%	RH
Absolute humidity	Mass of water vapor per volume of moist air	kg m^{-3}	a
Psychrometric difference	Difference between the dry-bulb and wet-bulb (or ice-bulb) temperature	K	$t - t_w$
Dewpoint	Temperature at which the saturation vapor pressure over water is reached	$^{\circ}\text{C}$	t_d
Frostpoint ^a	Temperature at which the saturation vapor pressure over ice is reached	$^{\circ}\text{C}$	t_f
Mixing ratio ^b	Mass of water vapor per mass of dry air	kg kg^{-1}	r

^a Below 0°C the dewpoint temperature is lower than the frostpoint temperature at a constant partial water-vapor pressure. Above 0°C the frostpoint temperature is not defined.

^b The mixing ratio can be replaced with sufficient accuracy by the specific humidity (see Table 8.2) or vice versa.

Table 8.2 Other relevant parameters for humidity measurements

Parameter	Description	Unit	Symbol
Vapor pressure	Partial pressure of water vapor in air	hPa	e
Specific humidity	Mass of water vapor per mass of moist air	kg kg^{-1}	q
Saturation vapor pressure over water	Vapor pressures in air in equilibrium with pure bulk water at a flat interface	hPa	E_w
Saturation vapor pressure over ice	Vapor pressures in air in equilibrium with pure bulk ice at a flat interface	hPa	E_i
Virtual temperature	Temperature of dry air if it had the same density as moist air at the same pressure	K	T_v

(both values for 0 °C, see Chap. 5) follows the water-vapor pressure over ice. This widely used analytical form is the Magnus equation, which is recommended [8.4] in the form given in Table 8.3. In some English speaking countries the Tetens equation is often used (Table 8.3).

In the ideal-gas approximation the density of moist air is a function of temperature, pressure, and specific humidity [8.1, 2]

$$\rho_a = \frac{p}{R_d T (1 + 0.608q)}, \quad (8.4)$$

with the gas constant of dry air

$$R_d = 287.0586 \text{ J kg}^{-1} \text{ K}^{-1},$$

the pressure p . Thereby,

$$T_v = T(1 + 0.608q) \quad (8.5)$$

is the virtual temperature (Table 8.3), which can be used in the gas equation together with the gas constant of dry

air instead of that for moist air. An approximation of the virtual temperature with the water-vapor pressure is given in Chap. 7. This parameter is also used as a parameter for humidity measurements.

The specific heat of evaporation and sublimation is a function of temperature (Chap. 5); for the heat of evaporation the following temperature dependence can be used

$$\lambda_v = 2500827 - 2360(T - 273.15\text{K}) [\text{J kg}^{-1}]. \quad (8.6)$$

The expressions for the dewpoint and frostpoint temperatures in Table 8.3 follow directly from the Magnus equation in the same table, neglecting the temperature dependency in $f(p, T)$ [8.4, 13] (see footnote in Table 8.3).

8.1.2 Principles of Measurements

Historically many physical and chemical principles have been used to measure atmospheric humidity. Dif-

Table 8.3 Relationship between water-vapor pressure and different humidity units (after [8.4–8]), based on the new ITS-90 temperature scale [8.5, 9]. For dimensions and symbols see Tables 8.1 and 8.2; p : air pressure in hPa, e : water-vapor pressure in hPa, T : absolute temperature in K, t : temperature in °C. Note: For the often used calculation according to *Wexler* [8.10–12] a transformation on the ITS-90 scale is recently available [8.9]

Humidity unit	Equation
Relative humidity	$RH = 100 \frac{e}{E_{w,i}}$
Water-vapor pressure for saturation with Tetens's equation over water [8.3], only of historical relevance	$E_w = 6.11 \exp\left(\frac{17.2694(T-273.16\text{K})}{T-35.86\text{K}}\right)$
Water-vapor pressure for saturation with Magnus's equation (−45 to +60 °C over water, pure phase) [8.4, 5] For moist air	$E_w(t) = 6.112 \exp\left(\frac{17.62t}{243.12+t}\right)$ $E'_w(t, p) = f_w(p)E_w(t)$ ^{a,b}
Water-vapor pressure for saturation with Magnus's equation (−65 to +0.01 °C over ice, pure phase) [8.4, 5] For moist air	$E_i(t) = 6.112 \exp\left(\frac{22.46t}{272.62+t}\right)$ $E'_i(t, p) = f_i(p)E_i(t)$ ^{a,b}
Dewpoint temperature for water (−45 to +60 °C)	$t_d = \frac{243.12 \ln\{e/[6.112f_w(p)]\}}{17.62 - \ln\{e/[6.112f_w(p)]\}}$ ^{a,c}
Frostpoint temperature for ice (−65 to +0.01 °C)	$t_f = \frac{272.62 \ln\{e/[6.112f_i(p)]\}}{22.46 - \ln\{e/[6.112f_i(p)]\}}$ ^{a,c}
Psychrometric formula for water	$e = E'_w(p, t_w) - 6.53 \times 10^{-4} p (1 + 9.44 \times 10^{-4} t_w) (t - t_w)$
Psychrometric formula for ice	$e = E'_i(p, t_i) - 5.75 \times 10^{-4} p (t - t_i)$
Absolute humidity	$a = \frac{0.21667e}{T}$ ^d
Specific humidity	$q = 0.62198 \frac{e}{p-0.378e}$ ^e
Mixing ratio	$r = 0.62198 \frac{e}{p-e}$ ^e
Virtual temperature	$T_v = T(1 + 0.608q)$

^a $f(p) = 1.0016 + 3.15 \times 10^{-6} p - 0.074 p^{-1}$, $f(p)$ is the enhancement factor (Sect. 8.3.1) and a function of both pressure and temperature, i.e., $f = f(p, t)$ [8.13]. In practice, the temperature dependency ($\pm 0.1\%$) is much weaker than the pressure dependency (0.0 to +0.6%). Therefore, the temperature dependency has been omitted in the formula above. This formula, however, should be used only for pressure around 1000 hPa (i.e., surface measurements) and not for upper-air measurements, for which Table 4.10 in [8.13] should be used.

^b For lower temperatures, see [8.8, 10].

^c For dewpoint and frostpoint temperatures outside this range, inversions should be used.

^d e in hPa and T in K.

^e e and p in hPa.

Table 8.4 Properties of humidity measurements and applications for mean values and turbulence measurements [8.6, updated]

Type of sensor	Properties			Application	
	Thermodynamic	Absorption of radiation	Material	Mean	Turbulent
Hair hygrometer			✓	✓	
Lithium chloride sensor			✓	✓	
Capacity hygrometer			✓	✓	
Psychrometer	✓			✓	
Dewpoint and frostpoint hygrometer	✓			✓	
Ultraviolet hygrometer		✓		(✓)	✓
Infrared hygrometer		✓		(✓)	✓

ferent sensor types and methods, listed in Table 8.4, are used for slow (mean values, seconds to many minutes) and fast response (turbulence measurements, 5–100 Hz) humidity measurements. This chapter concentrates on these methods, and only in Sect. 8.2 are historically relevant methods described.

8.1.3 Siting Considerations

Humidity measurements can be interpreted only in connection with temperature, and are generally measured together [8.4, 7]. The distance between the humidity and temperature sensor should be as short as possible (at most 1 m); however, the sensors should not

influence each other, yet measure the same small air volume. Depending on the sensor, radiation protection and ventilation may be necessary. The standard height above ground for humidity measurements is 2.0 m. Except in the case of UV hygrometers or IR hygrometers, sufficient radiation protection may be achieved by installing the sensor inside a meteorological shelter [8.4] (Chaps. 7 and 43). For specific purposes humidity instruments may also be installed in different arrangements as long as the sensor is properly exposed (Chap. 6). Moisture sensors should not be exposed to atmospheric contaminants, rain, or wind. Furthermore, the material of the housing should neither adsorb nor desorb water vapor.

8.2 History

Many methods are available for measuring atmospheric humidity. A comprehensive review of methods available up to the 1960s was given by *Sonntag* [8.14] and *Wexler* [8.15]. Only the most important methods and instruments, which are based on the principles still in use, are reviewed here.

8.2.1 Hygrosopes

Moisture in the air and its effect of increasing the weight of some materials, mainly wood, has been known since antiquity, e.g., in the Western Han dynasty in ancient China between 200 BCE and 10 CE [8.16] from East Asia. The first hygroscope, dated to about 1450, was developed by the German *Nicholas of Cusa* (*Nikolaus von Kues*, lat. *Cusanus*) (1401–1464) [8.17, 18], who used a weight scale and an unspecific hygroscopic material. A more accurate description is from the architect *Leon Battista Alberti* (1404–1472), who used a sponge and a scale to measure the “heaviness

and dryness of the wind and air” [8.18]. *Leonardo da Vinci* (1452–1519) made several drawings showing such a system, for instance a scale with a sponge [8.19] in a sketch made for his famous painting *The Last Supper*.

In the seventeenth and eighteenth century, several humidity-dependent materials from animals, plants (Table 8.5), and minerals were tested, but all instruments using these were still classified as hygrosopes because they were only indicators of the humidity. The hygrometer from *Johann Heinrich Lambert* (1728–1777), who used catgut string, dates from this time (Fig. 8.1). The torsion of the material was used to rotate a hand about 360° from low to high humidities [8.20]. At the end of the eighteenth century, the use of terms like saturation or relative amount of water (*Ludwig Achim von Arnim*, 1781–1831) marked the beginning of quantitative hygrometry. A further often-used instrument was built by *Jean-André de Luc* (1727–1817) in 1772 using ivory as a measuring element.

Table 8.5 Hygroscopic material used for hygrometers (after [8.18])

Source	Material	Hygroscopic properties
Animal and human	Catgut string	Torsion
	Amnion	Expansion
	Ivory	Expansion
	Whalebone	Expansion
	Horn	Expansion
	Leather	Expansion
	Human hair	Expansion
	Sponge	Weight
	Skin	Expansion
Herbal	Cotton	Expansion, weight
	Oat beard	Torsion, flexion
	Hemp, twisted	Torsion, expansion
	Paper	Expansion, weight

**Fig. 8.1** Lambert's hygrometer from about 1772 (after [8.18]), using the torsion of catgut string. Translation of the German engraving: two graduations are 3 degrees of humidity within a cubic foot of air (photo © Freunde alter Wetterinstrumente, Riedlingen, Germany)

8.2.2 Hair Hygrometer

The philosopher *Horace Bénédicte de Saussure* (1740–1799) experimented with human hair and found that untreated thin and soft hair from men and women – the latter was more usable because of its length – could be used after some preparation [8.18]. This was mainly degreasing by cooking, and treatment with cold water and soda solution. The tension on the hair and hand was exerted by a small weight. A hair hygrometer similar to the prototype of 1781 is shown in Fig. 8.2. From the beginning the scales of the hygrometers were linear, but the extension of the human hair was found to be nonlinear. *Wilhelm Klinkerfues* (1827–1884) devel-

**Fig. 8.2** Hair hygrometer according to the prototype of 1781 by Horace Bénédicte de Saussure [8.18] (photo © Freunde alter Wetterinstrumente, Riedlingen, Germany)

oped a system to linearize the scale in 1882. Some years earlier he had developed the bifilar hygrometer with a second nonhygroscopic hair to reset the hand. This instrument was produced at Göttingen in 1875 by *Wilhelm Lambrecht* (1834–1904). In 1880 Lambrecht developed the *Polymer*, which combined a hair hygrometer and a thermometer, both of which had two scales. The thermometer had an additional scale indicating the water-vapor pressure at saturation, and the hygrometer a scale for the calculation of the dewpoint, which is the difference between the temperature and its value at this scale. He also developed a thermo-hygroscope in 1881. The mechanical connection of a hygrometer with a bimetal-thermometer made it possible to determine the increase or decrease of the absolute humidity. The round form of the hygrometer similar to Lambert's hygrometer (Fig. 8.1) has been prevalent since approximately 1850, and not much has changed in this respect up to now.

The theory of the hair hygrometer is based on *Sresnevsky* 1895 [8.21], who assumed that a hair is a capillary tube. If the hair is immersed in water the hair is filled with water up to the capillary rise. The curvature of the meniscus in the pores of the hair determines the maximum water-vapor pressure in the pores. This was set proportional to the absolute value of the logarithm of the relative humidity. The largest extension of the hair occurs at 100% relative humidity and the largest

contraction was assumed for 7.8%, with no further contraction below this value. For the contraction δL (range 0.0–1.0) follows [8.14, 22]

$$1.104\delta L = -\log\left(\frac{RH}{100}\right). \quad (8.7)$$

The theory was updated by *Whipple* in 1921 [8.23]. He found that for very narrow capillaries the hydrostatic pressure is larger than the barometric pressure in the upper part of the capillary, where negative pressures of 0.012 hPa for 99% relative humidity and 2.1 hPa for 20% humidity occur. This still forms the basis of the recent theories presented in Sect. 8.3.2.

8.2.3 Other Absorption and Adsorption Hygrometers

The metal-paper coil hygrometers are based on early works with two strips, where one is humidity dependent. The first was made in 1867 by *Robert Wolf* with the bark of a fir tree [8.24]. Several constructions have been reported since that time. The method is still in use with a metallic spiral covered on one side with a hygroscopic material. The principle is similar to a bimetal thermometer.

The first proposals to use goldbeater's skin, a treated outer membrane of the intestine of an animal, which was normally used to produce gold leaf, was already reported by *Vincenzo Chiminello* (1741–1815) in 1783 [8.14] – the so-called goldbeater's skin hygrometer. Because of its faster response time for lower temperatures in comparison to human hair, it remained in use for a long time.

With the invention of radiosondes at the beginning of the 1930s, intensive research started to develop electric and faster sensors. Experiments were done with many chemical solutions and salts. The most successful salt was lithium chloride (LiCl). *Dunmore* [8.25] used copper wire electrodes wound around a glass tube. He found the best results with a 5% aqueous LiCl solution that had a time constant of about 4.5 s. The disadvantage of the sensor was the high resistance and a cross sensitivity to temperature. Tests were made with several materials [8.14, 15], and some progress was achieved by *Jones* in 1960 [8.26] using glass plates coated with a film of barium fluoride (BaF₂) over a metallic electrode. A minimized version of such a sensor (3.0 × 4.5 mm²) could reach time constants of down to 0.1 s [8.27].

A problem with these sensors is the temperature dependence and the low calibration stability, so that these sensors were mainly used for radio sounding or similar applications. At the end of the 1950s, the LiCl sensor was modified to a heated dewpoint sensor [8.28],

Fig. 8.3 A basic view of a heated lithium chloride sensor (after [8.29])

which is shown in Fig. 8.3. The method is based on the equilibrium between the water-vapor pressure of the heated aqueous LiCl solution and the water-vapor pressure in the air (Sect. 8.3.3). The temperature sensor measures the dewpoint. This type of sensor is still currently in use.

Another class of sensors uses solid materials. Since the 1930s it has been known that graphite changes its resistance with humidity. Mainly through industrial research, carbon humidity elements, also called carbon hygrometers, were constructed for radio soundings [8.14, 15]. Polymers were another material found in industrial research that adsorbed water at the surface, changing the resistance. These materials are used as a dielectric of a capacitor [8.30–32]. The benefit is a nearly linear response of capacitance to the change of humidity. The frequency output of a resonant circuit is transformed into a voltage or current. Today, these capacitive polymer sensors are widely used as humidity sensors [8.33, 34], for example the Humicap[®] technology developed by the company Vaisala Oyj (Sect. 8.3.4).

8.2.4 Psychrometer

Before 1792, *James Hutton* (1726–1797) in Edinburgh found a cooling effect on thermometers with a wet bulb, and *John Leslie* (1766–1832), who found that this resulted from the drying quality of the atmosphere, constructed a differential thermometer in 1790 – called the Leslie hygrometer – which was the prototype of a psychrometer [8.35] (Fig. 8.4). In 1802 *M.A.F. Lüdicke* proposed separation of the U-form of the differential thermometer into two discrete thermometers. In a comparison of the Leslie hygrometer with the devices by de Saussure and de Luc, *Böckmann* found in 1803 [8.36] that the measurements depended on temperature, pressure and, to a large extent, on wind. The first equation describing the behavior of a psychrometer was presented in 1822 by *Joseph Louis Gay-Lussac* (1778–1850).

The theory of the psychrometer [8.37] is based on *James Clerk Maxwell's* (1831–1879) diffusion theory of 1877 [8.38], the convection theory of *J. Ivory*

Fig. 8.4 Schematic view of the Leslie differential thermometer with a wet and dry bulb filled with sulfuric acid (with permission from Educational Technology Clearinghouse – University of South Florida)

1822 [8.35] and *Ernst Ferdinand August* (1795–1870) in 1825 [8.39, 40], and the theory of influence of the wind [8.41], which was for a long time the limiting factor in the application of the method. *Richard Assmann* (1845–1918) developed a psychrometer in the 1880s where both thermometers were ventilated in parallel [8.42, 43], while the earlier type by *August* [8.44] used a nonventilated thermometer (later the wet-bulb thermometer was ventilated), Fig. 8.5. The aspirated psychrometer of *Assmann*, finally described in 1892 [8.45], is still in use and one of the best instruments for measuring humidity (Sect. 8.4.4). *Assmann* also made the sling or whirling hygrometer more popular [8.46], which has two parallel thermometers – one with a wet bulb, one with a dry bulb, which the user whirls in open air. This instrument is still available.

About 50 years ago, when no fast response hygrometers were available, tests with thin cold wire thermometers, where one was covered with a thin cotton thread, were tested with partial success [8.47].

Because of the complexity of the calculation of psychrometric data, psychrometric charts were developed, the first in 1904 by *Willis H. Carrier*

Fig. 8.5 Historical psychrometer according to August A. Greiner, Munich, 1850 (photo © Prof. Jürgen Baumüller)

(1876–1950) [8.48] (Fig. 8.6). Several such charts were developed in the previous century, and psychrometric slide rules were used as well. Nowadays smartphone apps are available, but unfortunately the user cannot be sure that the right equations are used.

8.2.5 Dewpoint and Frostpoint Sensor

The knowledge of obtaining moisture measurements using a cool material that becomes covered with dew if the temperature of the material is lower than the dewpoint has been well known since the Roman Empire. The effect has been applied since the beginning of the nineteenth century to construct several types of dewpoint hygrometers. One of the most impressive is the instrument by *John Frederic Daniell* (1790–1845) from 1820 [8.50, 51] (Fig. 8.7). He used two evacuated and connected glass balloons. The balloon with the thermometer was filled up to 2/3 of its volume with ether.

Fig. 8.6 Psychrometric chart according to Carrier 1904 (after [8.48]), temperatures in °F. *Left ordinate:* absolute humidity in grain per cubic foot ($\approx 1/4 \text{ g m}^{-3}$). *Right ordinate:* relative humidity, pressure 30 inch (approximately 1015.9 hPa) (after [8.48] with permission from the American Society of Heating, Refrigerating and Air-Conditioning Engineers, Inc., Atlanta GA, USA)

Fig. 8.7 Dewpoint hygrometer according to Daniell (photo © Prof. Jürgen Baumüller)

Fig. 8.8 Dewpoint hygrometer according to Thornthwaite (after [8.49] with permission from National Oceanic and Atmospheric Administration, Central Library)

The other balloon was covered with a gauze bandage and was wetted with ether that evaporated. Therefore it cooled down and the ether in the other balloon evaporated too and cooled the balloon. At the dewpoint in the air a dew film covered the balloon and the dewpoint temperature could be measured with the thermometer. This type of hygrometer – also called visual dewpoint hygrometer – was used up to the twentieth century.

The prototype of the currently used photoelectric chilled-mirror dewpoint hygrometers is the device by Charles Warren Thornthwaite (1899–1963) from 1939 [8.49] (Fig. 8.8). It is a photoelectric system with a mirror of chromium-plated copper. The mirror is con-

Table 8.6 First developments of fast response hygrometers (for an overview see [8.63])

^a Including measurement of carbon dioxide

ected by a copper rod with a cooling liquid and is heated. The dew on the mirror can be detected with a lamp and a photocell. Heater and photocell are parts of an electric circuit.

Besides visual and photoelectric dewpoint hygrometers, other electrical sensors, such as radiometric and crystal oscillator dewpoint hygrometers were constructed [8.14, 64].

8.2.6 Fast Response Hygrometers – Optical Sensors

Progress in the use of the eddy-covariance method (Chap. 55) at the beginning of the 1960s required the development of fast response sensors for water-vapor flux measurements (latent heat flux). The first versions of fast response psychrometers or adsorption hygrometers were not successful for general use [8.47]. Only the optical systems following Bouguer–Lambert–Beer’s law incorporated a change that allowed practical use of (8.21). The first infrared sensors were less practical due to the low sensitivity and long path lengths necessary [8.57]. At the end of the 1960s, sensors for measuring the UV light in the Lyman-alpha line of 121.56 nm were developed for satellite applications. Used together with a hydrogen

lamp, the Lyman-alpha hygrometer was developed at the beginning of the 1970s almost in parallel in the USA, the Soviet Union, and the former GDR [8.52–54], but only the American device was commercially produced for many years, by AIR Inc., Boulder, CO. About ten years later a second type of UV hygrometer was developed using a krypton lamp [8.56]. The benefits of this device were a longer lifetime and easier production. But the absorption band is not directly located in the Lyman-alpha band and has a cross sensitivity to oxygen. Fast response hygrometers are nowadays an important part of all measuring complexes for turbulent energy fluxes. There has been a significant change in measuring systems within the last 15–20 years. While sensors that were commercially available in the 1990s mainly used UV absorption lines, at present there is almost exclusive use of sensors working with the IR absorption lines. This is because the hydrogen lamp for hygrometers working at the Lyman-alpha line is not very stable, and the lamps were mainly handmade. Lyman-alpha hygrometers are only in use today for aircraft applications. At the same time, the sensitivity of IR sensors has been increased and these sensors have been the only commercially available sensors since the end of the 1990s. The pioneering work in the development of fast-response hygrometers is shown in Table 8.6.

8.3 Theory

This section gives a short introduction to the theory of the exact definition of relative humidity. Furthermore, the theories of the different measurement methods are briefly described.

8.3.1 Fundamental Equations of Relative Humidity

Relative humidity is a key observable quantity in atmospheric science, especially in climate monitoring,

the SI compatible definition and measurement of which poses a great metrological challenge. In the climate system, heat and matter fluxes of water are essentially controlled by the differences of chemical potentials of water between the ocean, sea ice, and humid air at their mutual interfaces. These chemical potential differences can be exactly expressed in terms of the relative fugacity of atmospheric water vapor [8.65]. The relative humidity according to the World Meteorological Organization (WMO) definition can be recovered from the

relative fugacity as its ideal-gas limit. Considering humid air to be a nonideal binary gaseous mixture of water vapor and dry air, relative humidity, in its most general and physically rigorous form, is defined by the relative fugacity RF [8.65–68]

$$RF(\chi_w^{(g)}, T, p) = \frac{f_w^{(g)}(\chi_w^{(g)}, T, p)}{f_w^{(g)}(\tilde{\chi}_w^{(g)}(T, p), T, p)},$$

$$f_w^{(g)}(\chi_w^{(g)}, T, p) = \chi_w^{(g)} p \varphi_w^{(g)}(\chi_w^{(g)}, T, p). \quad (8.8)$$

The relative fugacity is a function of three independent variables, namely the mole fraction of water (subscript w) in humid air (superscript (g) for the gas phase), $\chi_w^{(g)}$, the temperature T , and the pressure p . The functions $f_w^{(g)}(\chi_w^{(g)}, T, p)$ and $\varphi_w^{(g)}(\chi_w^{(g)}, T, p)$ denote the fugacity and the fugacity coefficient of water in humid air, where the latter is given in analytical form by its virial approximation [8.67]. The quantity $\tilde{\chi}_w^{(g)}(T, p)$ is the water-vapor mole fraction of saturated humid air (term with $\tilde{}$), i.e., of humid air in thermodynamic equilibrium with the condensed phase of water, which can either be pure or air-saturated water (i.e., an ideal mixture of water (solvent) and dry air (solute)) or pure hexagonal ice. The definition of relative humidity in terms of relative fugacity is motivated by the fact that the relative fugacity is the generating observable quantity for the thermodynamic driving force, the so-called Onsager force [8.66, 69], controlling the exchange of water between the vapor and condensed phases of humid air [8.66].

The standard WMO definition of relative humidity RH is obtained as the ideal-gas limit of the relative fugacity [8.70]

$$\lim_{p \rightarrow 0} \varphi_w^{(g)}(\chi_w^{(g)}, T, p) = 1$$

$$\rightarrow RH(\chi_w^{(g)}, T, p) = \lim_{p \rightarrow 0} RF(\chi_w^{(g)}, T, p) = \frac{\chi_w^{(g)}}{\tilde{\chi}_w^{(g)}}. \quad (8.9)$$

The fugacity coefficient,

$$\varphi_w^{(g)}(\chi_w^{(g)}, T, p) = \frac{f_w^{(g)}(\chi_w^{(g)}, T, p)}{\chi_w^{(g)} p}, \quad (8.10)$$

is closely related to the so-called enhancement factor (subscript E) of humid air [8.67, 71] with respect to the condensed water phase (c)

$$f_{E,w}^{(c)}(T, p) = \frac{\tilde{\chi}_w^{(g)}(T, p)p}{e_w^{(c)}(T)}$$

$$\approx \frac{\varphi_w^{(g)}(1, T, e_w^{(c)})}{\varphi_w^{(g)}(\tilde{\chi}_w^{(g)}, T, p)} \Pi^{(c)}(T, p) \geq 1. \quad (8.11)$$

The enhancement factor describes the effect of air on the saturated partial pressure of water vapor,

$$\tilde{p}_w = \tilde{\chi}_w^{(g)} p. \quad (8.12)$$

The approximation sign in (8.11) results from the neglect of the solubility of air in liquid water. The quantity $\Pi^{(c)}(T, p)$ denotes the dimensionless Poynting correction factor for liquid water [8.71]

$$\Pi^{(c)}(T, p) = \exp \left\{ \frac{1}{R_w T} \int_{e_w^{(c)}(T)}^p v_w^{(c)}(T, p') dp' \right\}$$

$$\approx \exp \left\{ \frac{[p - e_w^{(c)}(T)] v_w^{(c)}}{R_w T} \right\}. \quad (8.13)$$

Here, $e_w^{(c)}(T)$ is the saturation vapor pressure of pure water vapor with respect to the condensed water phase, which can be stable liquid water, supercooled liquid water, or hexagonal ice. The quantity $v_w^{(c)}(T, p)$ is the specific volume of the condensed phase, and R_w is the specific gas constant of water. The enhancement factor is fully determined by the thermodynamic functions $\tilde{\chi}_w^{(g)}(T, p)$, $e_w^{(c)}(T)$, and $v_w^{(c)}(T, p)$, which are provided by TEOS-10 (Thermodynamic Equation Of Seawater – 2010) [8.72] on the basis of the corresponding IAPWS (International Association for the Properties of Water and Steam) formulations for fluid water, supercooled water, and hexagonal ice (Chap. 5).

Fig. 8.9 Differences between the standard definition of relative humidity according to WMO (Table 8.3) and four nonstandard definitions at 40 °C and 1000 hPa. The nonstandard definitions are of the form where the relative humidity is quantified by the mixing ratio ($RF = (m/m_{\text{sat}}) \times 100\%$, squares), the specific humidity (triangles), the fugacity (diamonds), and the IUPAC (International Union of Pure and Applied Chemistry) definition (circles) (after [8.70] with permission from IOP Publishing)

Table 8.7 Contraction of normal and rolled hair on the basis of a simplified theory [8.73] and on the basis of validation measurements [8.14]

Relative humidity (%)	Normal hair		Rolled hair	
	$\bar{m}\%$	$\frac{\Delta L_0}{\Delta L_{0s}}$	$\bar{m}\%$	$\frac{\Delta L_0}{\Delta L_{0s}}$
100	100	1.000	100	1.000
90	75	0.939	72	0.927
80	65	0.877	62	0.854
70	57.5	0.813	55	0.782
60	51	0.746	49	0.709
50	45.5	0.676	43.5	0.636
40	40	0.604	38	0.564
30	35	0.514	33	0.477
20	29	0.392	27.5	0.357
10	20	0.218	20	0.210
5	13.5	0.120	13.5	0.115
1	5.3	0.025	5.3	0.025
0	0	0.000	0	0.000

The mole fraction of water vapor, $\chi_w^{(g)}$, can be easily transformed into any other meteorological humidity metrics such as the water-vapor mass-mixing ratio and the specific humidity [8.65, 70] (Fig. 8.9). The differences between the real-gas and ideal-gas formulations of relative humidity are quantified in [8.70].

8.3.2 Hair Hygrometer

The first steps toward a theory of hair hygrometers were already described in Sect. 8.2.2 [8.21–23], and these still form the basis for the recent theory. The contraction of the hair is given by [8.74]

$$\frac{\Delta L}{L} = \frac{\rho_v R^* T}{Y M_w} \ln \frac{100}{RH}, \quad (8.14)$$

with the mass density of water vapor ρ_v , the universal gas constant R^* , the modulus of elasticity of the hair Y (in units of Pa), the molecular weight of water M_w , and length of the saturated hair L .

In a simple model [8.73] it was assumed that between the cells of the hair are flexible chains of molecules that can absorb the moisture. The distance between the cells is L and the contraction in the moist state is ΔL_s , and in the dry state ΔL_0 with $\Delta L_{0s} = L_s - L_0$. From this theory follows a linear relationship between the logarithm of the scale of the hygrometer $(\Delta L_{0s}/\Delta L_0) - 1$ and the ratio $(m_s - m)/m$, with m the absorbed mass of water (index s in the case of saturation)

$$\log \xi + \zeta \log \frac{m_s - m}{m} = \log \left(\frac{\Delta L_{0s}}{\Delta L_0} - 1 \right). \quad (8.15)$$

The results of the theory [8.73] were validated for normal and rolled hair with the coefficients $\xi = 1.612$ and $\zeta = 0.3733$ [8.14]. The results are given in Table 8.7.

8.3.3 Lithium Chloride Heated Condensation Hygrometer (Dew Cell)

The basis of this method [8.4, 29, 75] is the physical circumstance (Raoult's law) that the equilibrium vapor pressure at the surface of a saturated salt solution is less than that for a similar surface of pure water at the same temperature, and that lithium chloride has a very low equilibrium vapor pressure (Sect. 8.2.3). If the aqueous salt solution is heated, the vapor equilibrates with the vapor pressure of the ambient air. At this point, the balance will shift from condensation to evaporation, and eventually, there will be a phase transition from the liquid solution to a solid hydrate (crystalline) form (efflorescence). The transition point may be detected through a characteristic decrease in the electrical conductivity of the solution as it crystallizes. The temperature of the solution at which the ambient vapor pressure is reached provides a measure of the ambient vapor pressure. Due to the underlying physical principle, the hygrometer does not work below 15% relative humidity at 0 °C [8.4]. The ambient dewpoint can be determined by empirical relationships.

8.3.4 Capacitive Hygrometer

In capacitive humidity sensors the dielectric material can either be a sandwiched structure with two electrode surfaces on each side or it can be placed between two interleaved comb electrodes. The ceramic aluminum oxide or, more recently, dielectric poly-

Fig. 8.10 Schematic configuration of the capacitive hygrometer (source: Vaisala Oyj, Finland)

mer film is positioned between these electrodes [8.32, 75], where atmospheric water-vapor molecules are deposited. A capacitive-type thin film humidity sensor called Humicap[®] was developed by Vaisala Oyj in Finland and is now widely used. The schematic of a polymer humidity sensor is shown in Fig. 8.10. It consists of two electrodes that are attached to a glass or ceramic highly insulating substrate. A thin film sensing layer of cellulose acetate is applied on top of one of the two bottom electrodes. Finally, a water-permeable layer of gold is deposited as the upper electrode on top of the polymer layer and electrically connected to other of the two bottom electrodes. The thickness of the gold layer is around 10–20 nm and porous enough to allow water-vapor transport through it. Due to the significant difference in the relative permittivity (dielectric constant) of $\epsilon_r = 80.1$ for water and $\epsilon_r = 1.00059$ for air at 18 °C and 50 Hz, the capacity changes dramatically, and the output signal is proportional to the relative humidity [8.8]. The sensor capacitance changes from 45 to about 70 pF for a relative humidity range of 0–100%, and it shows a rapid response time of approximately 1 s to reach 90% of the output value [8.32].

8.3.5 Psychrometric Method

The first theoretical derivation of the psychrometric method was proposed in 1822 by *Ivory* [8.35], later called convection or mixing theory [8.14]. It was assumed that the air in contact with the wet bulb is always saturated and the heat of evaporation originates from the same air. This method does not consider different ventilation velocities and applies for a well-

Fig. 8.11 Comparison of the factor $(K/D)^n$ for the three psychrometer theories for different liquids (1: water, 2: methyl alcohol, 3: propyl alcohol, 4: toluene, 5: ethyl propionate) (after [8.37])

ventilated psychrometer. The theory of nonventilated air is called diffusion theory [8.14] and was developed by Maxwell [8.38]. In both theories the heat transfer is not exactly determined, leading to a third theory – the similarity theory (following Reynolds similarity theory).

The basis of all theories is the psychrometric equation

$$e = E(t_w) - \frac{c_p p}{\gamma \lambda_v} \left(\frac{K}{D} \right)^n (t - t_w), \quad (8.16)$$

with the water-vapor pressure e , the dry-bulb temperature t in °C, the wet-bulb temperature t_w in °C, the water-vapor pressure for saturation E , the specific heat capacity for constant pressure c_p , the pressure p , the ratio of the molecular masses of water vapor and dry air $\gamma = 0.62198$, the specific heat of evaporation λ_v , the diffusion coefficient for heat K , the diffusion coefficient for water vapor D , and the exponent n , which is the ratio of the wind speed at the boundary layer u_h and the ventilation speed u . For the convection theory with $u = \infty$ follows $n = 0$ and for the diffusion theory $n = 1$. For the similarity theory, n is in the interval from 0 to 1 and depends on the construction of the psychrometer. The three theories are illustrated in Fig. 8.11.

It is obvious that water is the preferential liquid for psychrometers, because for all three theories K/D and $(K/D)^n$ are approximately 1, which reduces the parameters in (8.15), and the generally used psychrometer equation (Sect. 8.4.2) follows. Further theories were developed to investigate special effects of psychrometer construction like laminar flow, heat conduction, etc. [8.14].

8.3.6 Dewpoint and Frostpoint Hygrometers

The basic principle of most dewpoint and frostpoint hygrometers lies in the temperature of the liquid or solid condensate layer that is in equilibrium with the vapor phase in the air above. From the measured dewpoint or frostpoint [8.4]

$$t_d = \frac{243.12 \ln \{e / [6.112f_w(p)]\}}{17.62 - \ln \{e / [6.112f_w(p)]\}} \quad (8.17)$$

$$t_f = \frac{272.62 \ln \{e / [6.112f_i(p)]\}}{22.46 - \ln \{e / [6.112f_i(p)]\}}, \quad (8.18)$$

the water-vapor pressure for saturation can be calculated over water or ice using the enhancement factor (8.11) $f_{w,i}(p) = 1.0016 + 3.15 \times 10^{-6}p - 0.074p^{-1}$, which describes the deviation of the equilibrium vapor pressure in presence of another gas at higher pressure. The relative humidity can be calculated as

$$RH_w = 100 \frac{e}{E_w(t)} = 100 \frac{E_w(t_d)}{E_w(t)}, \quad (8.19)$$

$$RH_i = 100 \frac{e}{E_i(t)} = 100 \frac{E_i(t_f)}{E_i(t)}. \quad (8.20)$$

The definition of the dewpoint is related to a plane surface covered with a film of water. But water droplets have a curved surface over which the saturation vapor pressure is higher due to the Kelvin effect. Contaminants in the condensate layer may lower the dewpoint or frostpoint (Raoult effect), but can be minimized with careful maintenance of the hygrometer. Both effects can together raise or lower the dewpoint, but they are minimized if the critical droplet size is large, which reduces the curvature effect and lowers the concentration of the soluble contaminant [8.4].

8.3.7 Optical Method

All optical hygrometers make use of Bouguer–Lambert–Beer's law

$$I = I_0 \exp(-\rho_v kx), \quad (8.21)$$

where I is the light intensity at the detector, I_0 the light intensity of the lamp, ρ_v the absolute humidity, k the mass absorption coefficient, and x the path length between lamp and receiver. Emission and detection efficiencies as well as any absorption do not affect I_0 . For absolute humidity measurements, the lamp intensity must be known. For turbulence measurements only the relative fluctuations need to be determined. However, knowledge of k and x is required for proper scaling of fluctuations in ρ_v . The physical principle of optical instruments is shown in Fig. 8.12. Water-vapor concentrations can be measured at specific absorption lines in the ultraviolet and infrared band wavelengths.

The absorption coefficient for water vapor used in the UV range with a spectral resolution of 0.05 nm [8.76, 77] and for oxygen in the same spectral range with a spectral resolution of about 0.1 nm [8.77, 78] are shown in Fig. 8.13.

Of practical relevance are the wavelengths shown in Table 8.8. The advantage of the Lyman-alpha band is the negligible absorption by oxygen. Unfortunately, the emission of atomic hydrogen lamps is not very stable. Therefore krypton lamps are often used, which are more stable, but emit at two wavelengths, which are absorbed both by water vapor and oxygen. The absorption by ozone is negligible. Because of the oxygen cross sensitivity, the sensor can only be used under constant pressure conditions and is not well suited for absolute measurements.

In the IR range, different wavelengths are used, some with cross sensitivities between water vapor and carbon dioxide.

Fig. 8.12 Schematic representation of an absorption hygrometer (after [8.6])

Table 8.8 Selected spectral lines of the water-vapor absorption

Range	Wavelength (μm)	Radiation source	Measuring path	Absorber
UV	0.12156	Atomic hydrogen (Lyman-alpha)	(3–10) mm	H ₂ O
	0.12358 0.11647	Krypton	(5–15) mm	H ₂ O, (O ₂ , O ₃)
IR-A,B	Different wavelengths	Stable light bulbs	(0.125–1) m	H ₂ O, CO ₂

8.4 Devices and Systems

In addition to Sect. 8.2, this section describes humidity sensors that are still in use and can be applied for measurements with different accuracy and response characteristics.

8.4.1 Hair Hygrometer

Hair hygrometers [8.4, 7, 31] are still in widespread use as single instruments for room climate. These instruments appeal due to their simplicity, and for applications with relaxed requirements, they are often preferred over electronic sensors (Fig. 8.14).

The basic design of these instruments and the preparation of the hairs has not changed much since the original work of de Saussure. They typically use a bundle of specially prepared hair, which has been degreased and specially aged for durability. It is important that the hair has not been chemically treated. Often longer hairs of women are preferred. After being degreased, the hair must undergo a special aging procedure with low and high temperatures applied. Details are often a trade se-

cret of the producer. For low temperatures, hair treated by rolling is preferred. Besides hair, synthetic or textile fibers may also be used. Similar instruments are also available as metal-paper coil or bispiral hygrometers. One side of a metallic spiral is covered with a hygroscopic material. Such instruments, however, should not be used for very high or low humidities and are not as accurate as hair hygrometers, but they have a good long-term stability [8.81].

The change of the length of the hair with the humidity is a nonlinear function. At high humidity, the change in length is smaller than at low humidity, which can be compensated for by using linkages and levers to provide a nonlinear amplification. However, chemical treatments with barium or sodium sulfite may increase the linearity. Temperature effects can be compensated for by the insertion of a bimetallic strip into the sensor support. However, hair hygrometers have a hysteresis for increasing and decreasing humidity.

Hair hygrometers are rarely used for atmospheric measurements. But they do have certain advantages for

Fig. 8.14 Hair hygrometer (photo © Feingerätebau K. Fischer GmbH, Drebach, Germany)

Fig. 8.15 Hair hygrograph (after [8.7] with permission of VDI e. V., Düsseldorf, Germany)

measurements at low temperatures, when psychrometers, for example, can no longer be used. Still in use for climatological measurements in meteorological screens (Chap. 7) is the drum recorder with a spring mechanism (hygrograph, Fig. 8.15). The change in length of the sensing hair can be converted into an analog electrical signal, e.g., by an inductive displacement transducer [8.82]. Figure 8.16 shows an electric hair hygrometer using a bimetal temperature compensation.

Hair hygrometers should be employed in moderate climates that are neither very dry nor very wet. Good

Fig. 8.16 Example of a hair hygrometer with analog voltage output (after [8.7, 82] with permission of VDI e. V., Düsseldorf, Germany)

instruments have an accuracy of $\pm 3\%$. The response time strongly depends on temperature, ranging from half a minute for high temperatures to several minutes for low temperatures. High humidities of nearly 100% relative humidity regenerate the hair. If this is not the case, such as in a dry climate or for indoor measurements, the regeneration should be made by covering the instrument with a sheet – wetted with warm water – for about 30 min. If a hygrometer is not regenerated, the indicated humidity increases for most of the instruments over a period of several years before it stays constant [8.81].

In polluted air, the hair should be cleaned by washing with water. In ammonia-polluted air hair hygrometers should not be used. Besides the regeneration, a zero-offset occurs due to changes of the tension of the hair. This can be corrected during regeneration by turning the adjustment screw. Regular comparison with an

Assmann aspiration hygrometer or another higher quality hygrometer are essential (Sect. 8.4.4).

Hysteresis in the hair sensing element is a short-term effect and not a cause for significant errors [8.4]; however, hysteresis in the mechanism may be significant, in particular if it is polluted. Therefore, the hygrometer should be tipped lightly to reduce any tension in the mechanical system before the measurement. It should be noted that the hair hygrometer measures the humidity above liquid water even at temperatures below 0 °C.

8.4.2 Lithium Chloride Heated Condensation Hygrometer (Dew Cell)

Because of the progress of the capacitive hygrometers and the effort required for maintenance, this sensor type is no longer produced.

8.4.3 Capacitive Hygrometer

Over a period of the last forty years capacitive sensors using thin polymer films as dielectric material have become the most widely used humidity sensors because of their small size, low maintenance, and nearly linear response [8.33]. These sensors were at first developed by Vaisala Oyj for radiosondes under the trademark Humicap®, but are now used for all types of humidity measurements from meteorological to industrial applications [8.34]. Due to the dependence of relative humidity on temperature, these sensors are often combined with temperature sensors in the same housing.

The basic design of the capacitive polymer humidity sensors consists of an upper electrode, a polymer film, and a lower electrode on a glass substrate as shown

in Fig. 8.10. For surface-based measurements, the sensor element and its electronics are typically mounted in a tube, sometimes combined with a Pt100 platinum thermometer. To minimize particulate contamination, the sensor is shielded by a filter cap. The filter cap is part of the sensor and technical parameters like response time need to consider the effect of the protective cap. The sensor shown in Fig. 8.17 is typical for most producers of meteorological instruments. Capacitive sensors are considered stable in arid conditions, but may experience nonnegligible drift at higher humidities [8.83].

To address problems, which may occur at high relative humidities, several manufacturers have introduced heated polymer humidity sensors. By heating the sensor, the immediate sensor environment is at lower relative humidity than the surrounding air. An integrated measurement of the humidity sensor temperature allows calculating the ambient relative humidity using

$$RH_{\text{ambient}} = RH_{\text{sensor}} \frac{E_w(t_{\text{sensor}})}{E_w(t_{\text{ambient}})}, \quad (8.22)$$

where RH_{ambient} is the relative humidity of the surrounding air, RH_{sensor} is the relative humidity by the heated sensor at its elevated temperature t_{sensor} , and t_{ambient} is the ambient air temperature, which must be measured nearby, but outside the air parcel impacted by the heated humidity sensor. This technique requires an additional measurement of the sensor temperature, which must be calibrated to the same level or better than the corresponding air temperature measurement.

Capacitive sensors for low absolute humidities used in radiosondes are described in Chap. 46.

40	2.2	0.4
50	1.8	0.3

8.4.4 Psychrometer

The psychrometer measures the psychrometric difference between a dry-bulb and wet-bulb thermometer while both thermometers are radiation shielded and ventilated with at least 3.5 m s^{-1} , because at lower ventilation rates, there is a sensitivity to the ventilation speed. Furthermore, the atmospheric pressure at the level of the station must be measured with sufficient accuracy. The wet bulb has a wick fitting closely around the sensing element (well-washed cotton, without synthetic fibers).

The formula currently used to calculate water-vapor partial pressure in hPa [8.8, 84] over water at standard atmospheric pressure of 1013.25 hPa is

$$e = E'_w(p, t_w) - 6.53 \times 10^{-4} \times p (1 + 9.44 \times 10^{-4} t_w) (t - t_w). \quad (8.23)$$

For temperatures above 30°C the following equation should be applied

$$e = E'_w(p, t_w) - 6.53 \times 10^{-4} (p - E_w(p, t_w)) \times (1 + 9.44 \times 10^{-4} t_w) (t - t_w). \quad (8.24)$$

The water-vapor partial pressure over ice (ice-covered wet-bulb thermometer, t_i) is

$$e = E'_i(p, t_i) - 5.75 \times 10^{-4} p (t - t_i). \quad (8.25)$$

The factors (numerical value and pressure and temperature-dependent parts) in the summand with the psychrometer difference is called the psychrometer coefficient with the dimension hPa K^{-1} – sometimes also called the psychrometer constant – and a function of temperature and pressure. These formulae are tabulated in more recent psychrometer charts [8.85] and can

be used for calculation, using the measured dry-bulb and wet-bulb temperatures as a basis. The uncertainty of the psychrometer coefficient per 0.1 K error of the wet-bulb temperature is $0.15 \times 10^{-4} p \text{ K}^{-1}$ [8.86] (Table 8.9). A pressure difference of 10 hPa in comparison to the standard air pressure causes an error of the psychrometer difference of about 1%. The resulting error of the relative humidity is temperature-dependent (Table 8.10). Therefore, near sea level the calculation can be made using the standard pressure if no extreme low pressure system passes the station. For stations above sea level the partial pressure of water vapor should be calculated with the local pressure. Because psychrometer charts and diagrams are often no longer in use, apps to calculate relative humidity from psychrometer readings should only be used if they are well documented and use pressure as an input parameter.

Below 0°C , the psychrometer difference is small and can cause large errors in relative humidity as shown in Table 8.9. The error in wet-bulb temperature under these conditions can be large, because the cotton wick must be fully covered by ice. This can be realized for single measurements but is a problem for continuously running electric psychrometers. In principle, water can be replaced by an ammonia solution, but only for psychrometers without metallic parts. Because of these problems, in winter psychrometers are replaced by hair hygrometers or, more recently, by capacitive hygrometers.

For all types of psychrometers, several requirements must be fulfilled [8.4]:

- At sea level the ventilation speed should not be lower than 2.5 m s^{-1} (better 3.5 m s^{-1}) and not larger than 10 m s^{-1} . At lower pressure the speed limits should be adjusted inversely proportional to the density of the atmosphere. Typically, a ventilation speed of 3.5 m s^{-1} is used, which does not need a correction for height above sea level.
- The ventilation speed should not be impacted by the wind field if the instrument is not in a meteorological screen, otherwise the ventilation speed has a dependency on the wind direction and speed. A vertical orientation of the flow around the thermometer is preferred.
- The wet bulb and dry bulb must be protected from radiation using a ventilated double shield, which should be polished, unpainted, and thermally isolated from other parts of the psychrometer.
- Both thermometers should be separately ventilated with an inflow of ambient air close to the thermometers.
- Great care should be taken to prevent transfer of heat from an aspirating motor or from the outer shields to the thermometers. Also recirculation of

Table 8.10 Psychrometer coefficient in hPa K^{-1} as a function of the pressure and the wet-bulb temperature (only for water) for water or ice on the cotton wick; difference to the standard values of 0.667 hPa K^{-1} (water) or 0.575 hPa K^{-1} (ice): bold ($< 1\%$) and bold-italic ($< 5\%$), for equations see Table 8.3

air must be prevented. This may be a problem inside screens or in low winds and stable stratification.

- The water reservoir and wick should be arranged such that the distilled water reaches the wet-bulb thermometer, but not affect the temperature of the dry bulb. Furthermore, the level in the water reservoir should be nearly constant.
- The cotton wick of the wet bulb should fit tightly around the sensing element and extend at least 2 cm up the stem of the thermometer. Before installation, it should be washed thoroughly in an aqueous solution of sodium bicarbonate at a dilution of 5 g per liter, and rinsed several times in distilled water. Alternatively, a solution of pure detergent in water may be used.
- The response time of both thermometers should be similar. For the same bulb dimension, the wet-bulb thermometer will be faster.

Several systematic errors may occur, which depend partly on the construction of the psychrometer [8.4]:

- The index error of the thermometers should be corrected. The effects of the index error and all other temperature errors are presented in Table 8.9.
- The space between the sensors and the radiation shield should not be bridged by water droplets or

ice, as this would enable heat conduction from the shield to the sensor.

- At temperatures below 0°C , it must be determined whether the bulb is covered with ice (completely) or with supercooled water.
- Errors due to contamination of the wet-bulb wick or to water impurities.
- Errors due to heat conduction from the thermometer stem to the wet-bulb system if the stem is insufficiently covered.

Common types of psychrometers are the August psychrometer for use in meteorological screens, the Assmann aspiration psychrometer, and electrical psychrometers based on the Assmann principle. Mercury thermometers, which are used in older instruments, have been replaced by alcohol liquid-in-glass thermometers. The Assmann aspiration psychrometer is considered a reference psychrometer for comparison experiments. There is a large number of electrical instruments available, most of which were developed at research institutions, with only a few being commercially available. Those based on the Assmann principle are the most common. In accordance to a proposal of the World Meteorological Organization, a WMO reference psychrometer was developed and is used as a WMO primary standard.

Fig. 8.18 Psychrometer according to August, with forced ventilation of the wet-bulb thermometer (after [8.7] with permission from VDI e. V., Düsseldorf, Germany)

Psychrometer According to August

The psychrometer according to August [8.39, 40] for measurements in meteorological screens (Figs. 8.5, 8.18) using liquid-in-glass thermometers is still in widespread use at climate stations (Chap. 43). These instruments have two vertically oriented thermometers, but only the wet-bulb thermometer is ventilated. The wetting of the bulb must be done by hand before each measurement. The aspirator is driven by a spring or, more recently, an electrical motor. Ventilation should be started approximately 5 min before the measurement.

Psychrometer According to Assmann

The Assmann aspirated psychrometer [8.4, 7, 14, 45] uses liquid-in-glass thermometers, originally filled with mercury and more recently with alcohol. This instrument is not suitable for continuous measurements, but rather the Assmann aspirated psychrometer is still among the most accurate humidity measuring instruments. Besides the original version, many similar constructions are currently in use. In 1987 the World Meteorological Organization compared a large number of these psychrometers against the WMO reference psychrometer. This study found that psychrometers with the original dimensions were the most accurate instruments [8.84].

The dry and wet thermometers are protected against radiation by a double radiation shield and are ventilated.

The distance between both bulbs and the radiation shield is large enough that water droplets or ice cannot bridge this gap, which would otherwise lead to heat conduction. Both thermometers are ventilated separately. The ventilation speed should be about 3.5 m s^{-1} so that it is not reduced significantly by the larger wet bulb. Normally a spring driven aspirator is used. The speed may be controlled by the number of rotations made by the casing box of the spring within a certain time interval. The spring may also be replaced by an electric motor. Details of the construction are illustrated in Fig. 8.19.

The measurements should be made following the standard operating procedures listed below. During the measurements, the instrument should be vertically oriented so that the influence of the wind speed is minimized. The instrument should not be oriented towards the sun and should be placed sufficiently far from the body of the observer. Installation on a separate boom is helpful. The typical height of measurement is 1.25–2.0 m. Before taking measurements the instrument should be in equilibrium with the air, which can be tested by taking several readings of the dry temperature. Outdoor psychrometric measurements should be repeated at least three times and averaged because of the fast changing air temperature. The order of the steps is [8.4]:

- Moisten the wet bulb.
- Wind the spring drive (or start the electric motor).
- Wait 2–3 min or until the wet bulb reading has stabilized.
- Read the dry-bulb thermometer.
- Read the wet-bulb thermometer.
- Check the reading of the dry-bulb thermometer again.

Electrical Psychrometer

Many types of electrical psychrometers, where the liquid in glass thermometers are replaced by Pt100 resistance thermometers (Chap. 7), are available, often built by research institutes. Of the commercially produced psychrometers, the types that best fulfill any given requirement are constructed similarly to the Assmann aspiration psychrometer. One such instrument is the psychrometer according to *Ernst Frankenberger* (1899–1985) [8.87], with resistance thermometers (Pt100) and a double screen radiation shield in the same dimension as the original instrument. Figure 8.20 shows this instrument, which is suitable for continuous measurements above 0°C .

A disadvantage of this instrument is the nonvertical orientation of the tubes of the thermometers, which can generate a slight dependence of the ventilation speed on the wind speed and direction. Furthermore, the length of the cotton wick between the sensor and the water

Fig. 8.19 (a) Schematic view of an Assmann aspirated psychrometer (after [8.7] with permission from VDI e. V., Düsseldorf, Germany). (b) A production model (photo © Theodor Friedrichs & Co., Schenefeld, Germany)

Fig. 8.20 (a) Schematic view of the psychrometer according to Frankenberger (after [8.7] with permission from VDI e. V., Düsseldorf, Germany), and (b) a recently produced type (photo © Theodor Friedrichs & Co., Schenefeld, Germany)

level can change, and the water flow can be interrupted at high evaporation or if the water level in the reservoir is allowed to drop too low. The water level should be checked every few days, especially during summer. To reduce possible re-circulation under conditions of weak winds or stable stratification, sensor and aspirator

should be separated, which can be easily realized. The tubes of the thermometers should be oriented towards north (northern hemisphere).

Below $0\text{ }^{\circ}\text{C}$, water in the wet-bulb wick may freeze, leading to measurement ambiguity. To avoid this problem and since the water-vapor pressure does not depend

Fig. 8.21 Construction details of the proposal for a WMO reference psychrometer (after [8.88] with permission from World Meteorological Organization, Geneva, Switzerland). *Upper: top view. Lower: side view*

on temperature, a heated psychrometer was used. The heated psychrometer has a dry-bulb thermometer for ambient temperature and a heated and ventilated chamber ($\approx 10^\circ\text{C}$) with wet-bulb and dry-bulb thermometers according to the psychrometric principle [8.4]. The relative humidity at ambient temperature can then be calculated based on these measurements.

The WMO Reference Psychrometer

In 1957, the second session of the WMO Commission for Instruments and Methods of Observation (CI MO) at Paris recommended building a reference psychrometer, which was directed by the Working Group on Hygrometry (lead by *Russell G. Wylie*, Australia). A final report was given at the sixth session in Helsinki in 1973. First, four types were constructed in the USA, Australia, the UK, and Japan. The main recommendations were to achieve a psychrometer coefficient close to the theoretical value of $6.53 \times 10^{-1} \text{ hPa K}^{-1}$ at 20°C , 1000 hPa and 50% relative humidity. The construction sketch is shown in Fig. 8.21. In this design, evaporation at the wet-bulb thermometer should be very efficient, and an external heating or heat conduction from the mounting should be excluded. Both thermometers should be double shielded, well-ventilated, and horizontally oriented. The water level should be constant, which can be im-

plemented using an airtight reservoir above the sensors (not shown in Fig. 8.21), a downpipe, and a reservoir below the wet-bulb sensor having a constant water level.

According to these recommendations, finally two WMO reference psychrometers were constructed in Germany (former GDR) [8.89] and Australia [8.88]. The comparison of both reference psychrometers with the standard Assmann psychrometer showed good agreement within the given accuracy [8.84].

The WMO reference psychrometer is a primary standard for meteorology, because its performance is very predictable with few external influences only. This instrument can be used inside a screen together with other instruments. Special attention needs to be given to the aspiration and the cleanliness of the wet-bulb thermometer. Comparison experiments should be conducted by experienced personnel following WMO recommendations [8.88].

8.4.5 Dewpoint and Frostpoint Hygrometers

Dewpoint and frostpoint hygrometers are among the most stable and accurate instruments [8.8], since they measure dewpoint or frostpoint temperature directly. For that reason, they are often used as reference instruments [8.4]. Most dewpoint and frostpoint hygrometers are based on the chilled mirror principle [8.90]. In these instruments, a small mirror is cooled until water condenses on its surface, either as liquid water or ice. An electronic detector senses the reflectivity of this condensate and regulates the mirror temperature such that the measured reflectivity remains constant. Under this condition, the condensate is in equilibrium with the gas phase of water in the air above the mirror, and the temperature of the condensate is a direct measurement of the equilibrium temperature. This temperature represents the dewpoint temperature, if the condensate on the mirror is liquid, or the frostpoint temperature, if the condensate is ice.

Cooling of the mirror may be done using electronic Peltier coolers, through cryogenic cooling or a combination of both. Some research instruments have also used Stirling coolers. Some systems have an automatic mirror-cleaning heating cycle, in which volatile contaminants are evaporated, or use a mechanical wiper to clean the mirror.

A dewpoint or frostpoint hygrometer requires a minimum flow rate of approximately $0.25\text{--}1 \text{ L min}^{-1}$ to achieve an acceptable response time and stable operations [8.4]. For temperatures below 0°C the phase of the condensate on the mirror must be known to distinguish between supercooled water, i.e., the mirror

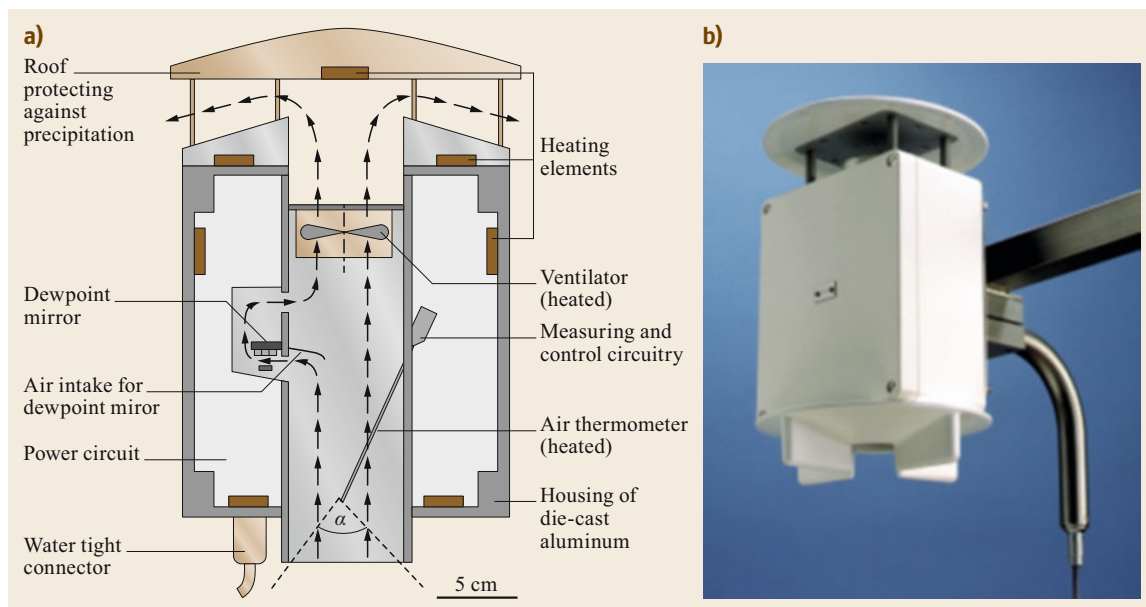

Fig. 8.22a,b Dewpoint hygrometer Thygan VTP6: (a) Schematic view (after [8.91] with permission from Meteolabor AG, Wetzikon, Switzerland); (b) sensor (photo © Meteolabor AG, Wetzikon, Switzerland)

temperature corresponds to dewpoint temperature, and ice, i.e., the mirror temperature corresponds to frost-point temperature.

One dewpoint hygrometer, used occasionally as reference instrument for atmospheric water-vapor concentrations, is made by Meteolabor AG [8.91,92] (Fig. 8.22). Less complicated but still highly accurate instruments are available from other manufacturers. But dewpoint hygrometers are seldom used as in-situ sensors because of possible contamination. They are the standard instrument in dewpoint generators for humidity calibration. Dewpoint hygrometers are also used in balloon borne and aircraft observations for measurements of upper air humidity (Chap. 46).

8.4.6 Optical Hygrometers

Optical instruments are the only instruments suitable for measuring humidity fluctuations at frequencies up to about 100 Hz. These instruments are mainly used for turbulence and flux measurements (Chap. 55), less frequently for measurements of humidity (absolute humidity, mixing ratio) due to possible drifts and long-term stability issues. IR hygrometers dominate the market despite their lower sensitivity and have almost completely replaced the more sensitive but less stable UV hygrometers. Infrared hygrometers are available as either an open-path instrument for measurements near the wind sensor, or as a closed-path instrument, where

an inlet near the anemometer is connected to the analyzer through a tube. Some trace-gas analyzers may also measure water vapor, usually based on the principles discussed here (Chap. 16).

UV Hygrometers

The Lyman-alpha hygrometer was the first instrument used for humidity flux measurements. Due to the high light absorption of water vapor in the Lyman-alpha band (Fig. 8.13), the instrument – composed of a hydrogen lamp and a detector – is very sensitive, even for path lengths as short as 10–20 mm and low absolute humidities. Because of the low stability of the lamp, this system is mainly used on aircrafts (Chaps. 48 and 49).

The more stable krypton hygrometer KH20 produced by Campbell Sci. Inc. (Fig. 8.23) uses a low-pressure krypton glow tube as a light source and is still in use. The krypton lamp emits a minor band at 116.49 nm (band 1) and a major band at 123.58 nm (band 2). Radiation at 123.58 nm is strongly attenuated by water vapor, whereas absorption by other gases is relatively weak (Fig. 8.13). Radiation at the shorter wavelength (116.49 nm) is attenuated by water vapor as well as oxygen molecules, but the intensity of the transmitted beam is considerably attenuated by magnesium fluoride windows used at the lamp and detector tubes [8.56]. The measured signal I (I_{01} and I_{02} are the intensities of the source at both wavelengths) depends

Fig. 8.23 Krypton hygrometers (image © Campbell Scientific, Inc., Logan UT, USA, 2017). The design of Lyman-alpha hygrometers was similar, but with a slightly larger lamp

on the path length x , the mass absorption coefficients k , and the densities ρ of both absorbers: water vapor (index w) and oxygen (index O) [8.56, 93]

$$I = I_{01} \exp[-x(k_{v1}\rho_v + k_{O1}\rho_O)] + I_{02} \exp[-x(k_{v2}\rho_v + k_{O2}\rho_O)], \quad (8.26)$$

where the indices 1 and 2 refer to the two wavelengths at 116.49 nm and 123.58 nm, respectively.

The absorption coefficient at the short wavelength is half of that at the longer wavelength [8.94]. Since only the signal of these two wavelengths is measured, it is possible to extract the water-vapor absorption signal from the combined measurement with a combined value k_v . The fraction of the oxygen absorption of band 1 is f and of band 2 is $(1 - f)$. The simplified (8.26) is

$$I = I_0 \exp(-xk_v\rho_v) \times [f \exp(-xk_{O1}\rho_O) + (1 - f) \exp(-xk_{O2}\rho_O)]. \quad (8.27)$$

For most applications, the additional oxygen absorption can be ignored and the basic equation for the calculation of krypton hygrometer KH20 is

$$\ln(V) = \ln(V0) - \rho_v x K_v, \quad (8.28)$$

with the intercept $\ln V0$ in $\ln(\text{mV})$, $\approx 8 - 10 \ln(\text{mV})$, the calibration coefficient (effective absorption coefficient for water vapor) K_v in $\ln(\text{mV}) \text{ m}^3 \text{ g}^{-1} \text{ cm}^{-1}$, the coefficient xK_v in $\ln(\text{mV}) \text{ m}^3 \text{ g}^{-1}$ for a given path length x in cm and the absolute humidity ρ_v in g m^{-3} . This simplification is possible because only fluctuations of absolute humidity are of interest (see Chap. 55) and the oxygen concentration is assumed not to change (for nearly constant air pressure, therefore no application on

aircrafts possible). Nevertheless, small corrections are recommended [8.95, 96].

Equation (8.26) can also be used for calibration: assuming a constant absolute humidity, the path length can be changed to determine the calibration coefficient. This method was already developed for Lyman-alpha hygrometers because of the low source stability but can also be applied for krypton hygrometers [8.97]. But here the calibration is against oxygen and assumes a similar contamination of the windows or the source for both gases – oxygen and water vapor [8.98].

IR Hygrometers

The absorption of infrared radiation by water vapor is not as strong as that of ultraviolet radiation. Therefore, the absorption is often measured at two nearby wavelengths, where one is strongly absorbed by water vapor, the other not. Alternatively, in closed-path systems, two measurements may be taken, where one measurement is that of the air sample, the other that of dry reference gas. From the difference of both signals the concentration can be calculated. The devices often measure not only water vapor but also carbon dioxide. Because the sensitivity is much lower than for UV devices, the path length of approximately 15 cm is about tenfold that of the UV devices. To increase the path length, mirror systems are designed that reflect the light beam multiple times. A chopper system measures the different spec-

Fig. 8.24 Open-path $\text{H}_2\text{O-CO}_2$ -gas analyzer (LI-7500-DS) (image: ©, LI-COR, Inc., Lincoln NE, USA)

Fig. 8.25 Closed-path gas analyzer (LI-7000), for details see text (image: ©, LI-COR, Inc., Lincoln NE, USA). One cell measures the air sample, while the other measures the dry reference gas

tral lines separately. Due to the fast response time the systems can measure at a sampling rate up to 20 Hz. The frequency of measurement is currently limited by the sensitivity of the electronics and not by any physical principle.

IR-hygrometers are available as open-path (Fig. 8.24) and closed-path systems (Fig. 8.25). While open-path systems measure the air volume of interest directly, i.e., near the sonic anemometer for eddy-covariance measurements (Chap. 55), the closed-path instrument extract air from a volume of interest using a tube and measure the water-vapor concentration in a closed cell nearby. Both systems detect the concentration as mass density (mass unit per volume) with some differences [8.99]. In the open-path system the concentration is affected by ambient temperature, requiring a specific density correction for water vapor – the WPL-correction according to *Webb, Pearman, and Leuning* [8.100] –, which is only a few percent for water vapor but may be large for trace gases. The advantage of open-path systems is a good frequency response, which is only limited by the path length. In closed-path systems, the optical cell has a uniform temperature and pressure, so that the mass density can be easily converted into the mass-mixing ratio

$$r_{\text{wm}} = \frac{R^*T}{M_d(p-e)} \rho_v, \quad (8.29)$$

(where R^* is the universal gas constant and M_d the dry air molar mass, ρ_v the density of water vapor), or into the mol fraction

$$\chi_w = \frac{R^*T}{M_v(p-e)} \rho_v, \quad (8.30)$$

with M_v the molar mass of water vapor. For more details see Chap. 55 and Table 55.3. The frequency response of closed-path systems is significantly slower than open-path systems due to the extractive sampling and transport of the air sample to the optical cell through the sampling tube. For turbulent flows the Reynolds number in the tube should always be larger than the critical Reynolds number of about 2500.

Manufacturers have recently attempted to combine the benefits of both systems, building closed-path systems that have very short sampling lines (about 1 m), or open-path systems with high-frequency temperature and pressure measurements. The direct measurement of the mixing ratio does not require the WPL-correction (Chap. 55).

8.4.7 Comparison of the Methods

The number of sensor principles and sensor types has significantly decreased in the last 20 years. One reason is that the capacitive polymer sensor, which has a nearly linear output signal, has been significantly improved and is now considered sufficiently stable. In contrast, lithium chloride dew cells are nearly out of use. Similarly for fast hygrometers, UV hygrometers have been replaced by IR hygrometers, which are more stable and have recently expanded their sensitivity range to low absolute humidities. The classical hair hygrometer has been used for a long time and continues to be used, mainly for indoor measurements or for instruments with mechanical registration. Psychrometers and dewpoint hygrometers continue to be used as reference instruments and for special applications, mainly in research. A brief description of advantages and disadvantages of each method is given in Table 8.11.

Table 8.11 Advantages and disadvantages of the different methods

Devices	Advantages	Disadvantages
Hair hygrometer	Simple mechanical instrument	Long time drift, regeneration necessary
Lithium chloride hygrometer	First electrical sensor to replace hair hygrometers	Handling of lithium chloride solution difficult, rarely used anymore
Capacitive hygrometer	Simple and stable electrical sensor	Screen may be necessary
Assmann psychrometer	High accuracy, reference instrument	No electrical output, difficult measurements < 0 °C
Electrical psychrometer	Electrical instrument, accurate	Not suitable for temperatures < 0 °C
Dewpoint and frostpoint sensor	Often very accurate, reference instrument	High level of maintenance required for accurate measurements
UV hygrometer	Fast response hygrometer, very sensitive at low absolute humidities	Unstable light source, rarely used anymore
IR hygrometer	Fast response hygrometer, sensitive over a large range of humidities, open-path and closed-path instruments	Density and other corrections necessary, especially for flux applications

8.5 Specifications

Typical uncertainties of different humidity sensors are given in Table 8.12. Most of the available dewpoint and capacitive sensors may be considered WMO working standards or even as reference standards (Sect. 8.6.1 and Table 8.14). In many applications the limiting factor is the housing of the sensor, not the sensor itself, in particular in low-cost installations. Details of the possible

influences of sensor enclosures on the measurements are described in Chap. 7.

Typical response times are given in Table 8.13. For turbulence measurements, optical sensors are generally used; for moving platforms, such as balloons and aircrafts capacitive polymer sensors and dewpoint and frostpoint hygrometers may also be found (Chaps. 46, 48, and 49).

Table 8.12 Typical characteristics for humidity sensing methods [8.7]. Some high quality sensors may have better characteristics than listed here

Method	Typical total uncertainty	Temperature range	Humidity range
Hair hygrometer	± 5% RH	−10 to 50 °C	> 40% RH
Capacitive hygrometer	± 3% RH ± 5% RH	0 to 45 °C −10 to 0 °C	5–100% RH 5–95% RH
Psychrometer	± 2% RH	0 to 50 °C wet-bulb temperature	> 5% RH
Dewpoint and frostpoint hygrometer	± 0.2 K	−100 to 50 °C dewpoint or frostpoint temperature	
Optical hygrometer	± 5–10% of absolute humidity	−10 to 50 °C	

Table 8.13 Typical time constant (63%) in seconds at 85% relative humidity for humidity sensing methods [8.4, updated]

Method	20 °C	0 °C	−20 °C
Hair hygrometer			
Ordinary human hair	32	75	440
Rolled hair	10	10	12
Goldbeater's skin	10	16	140

Psychrometer	30–50	30–50	30–50
Dewpoint and frostpoint hygrometer	1–50	1–50	1–50
Optical hygrometer	< 0.01	< 0.01	< 0.01

8.6 Quality Control

The section dealing with quality control for humidity sensors includes the definition of standards, calibration procedures, and the detection of typical errors.

8.6.1 Reference Standards

The WMO has developed a system of standards and instruments for calibration [8.4]. The requirements for these standards are given in Table 8.14. The primary standards (Sect. 8.6.2) should be available at the national standards and calibration laboratories. Secondary standards are required for national or regional calibration laboratories of meteorological services, etc. These standards must be compared against a primary standard every year. Reference standards for indoor calibration have almost a similar accuracy as secondary standards. Chilled-mirror dewpoint hygrometers or the WMO reference psychrometer [8.88] may be used as secondary or reference standards. Outdoor comparisons of humidity measurements may be done against working standards. These standards are chilled-mirror dewpoint hygrometers or the Assmann aspiration psychrometer

and must be compared against a reference standard at least annually. For an easy verification of the calibration of an instrument, salt solutions (Sect. 8.6.3) may be used. Ultraviolet hygrometers may also be calibrated in-situ by changing the path length (Sect. 8.4.6).

8.6.2 Primary Standards

Primary standards are maintained at the national metrology laboratories, where three different methods are in use [8.4]. The gravimetric method is based on an exact determination of the mass-mixing ratio. This is obtained by removing the water vapor from an air sample with a drying agent like phosphorous pentoxide (P_2O_5) or magnesium perchlorate ($Mg(ClO_4)_2$). The mass of the agent is determined by weighing before and after absorption of the vapor. Therefore a complex apparatus is required to accurately control the measurement conditions to determine the density of the sample.

The dynamic two-temperature standard humidity generator saturates air at one temperature. The saturated

Table 8.14 Typical measurement range for humidity standard instruments [8.4]

Standard instruments	Dewpoint temperature		Relative humidity	
	Range (°C)	Uncertainty (K)	Range (%)	Uncertainty (%)
Primary standard				
Requirement	−60 to −15	0.3	5–100	0.2
	−15 to +40	0.1	5–100	0.2
Gravimetric humidity generators	−60 to −35	0.25		
	−35 to +35	0.03		
	+35 to +60	0.25		
Standard two-temperature humidity generator	−75 to −15	0.25		
	−15 to +30	0.1		
	+30 to +80	0.2		
Standard two-pressure humidity generator	−75 to +30	0.2		
Secondary standard				
Requirement	−80 to −15	0.75	5–100	0.5
	−15 to +40	0.25	5–100	0.5
Chilled-mirror hygrometer	−60 to +40	0.15		
WMO reference psychrometer			5–100	0.6
Reference standard				
Requirement	−80 to −15	1.0	5–100	1.5
	−15 to +40	0.3	5–100	1.5
Chilled-mirror hygrometer	−60 to +40	0.3		
WMO reference psychrometer			5–100	0.6
Working standard				
Requirement	−15 to +40	0.5	5–100	2
Chilled-mirror hygrometer	−10 to +30	0.5		
Assmann psychrometer	−10 to +25		40–90	1
Electrical capacitive hygrometer	−20 to +40		5–90	2
	+15 to +30		5–90	1

Table 8.15 Saturated salt solution at 25 °C and their characteristic relative humidity [8.4, 101, updated]

Salt	Chemical symbol	Relative humidity (%)	Solubility (g/100 mL)
Potassium sulfate	K ₂ SO ₄	97.3	23
Barium chloride	BaCl ₂	90.3	37
Potassium chloride	KCl	84.3	34
Sodium chloride	NaCl	75.3	36
Potassium iodide	KI	68.9	144
Sodium bromide	NaBr	57.6	91
Magnesium nitrate	Mg(NO ₃) ₂	52.9	71
Potassium carbonate	K ₂ CO ₃	43.2	112
Magnesium chloride	MgCl ₂	32.8	54
Calcium chloride	CaCl ₂	29.0	135
Potassium acetate	KCH ₃ COO	22.5	228
Lithium chloride	LiCl	11.3 [8.101]	83
Lithium bromide	LiBr	6.4	160

air is then heated up to a second temperature for which the relative humidity can be calculated on the basis of the water-vapor pressure for saturation at the first temperature.

The dynamic two-pressure standard humidity generator has two chambers, one filled with air saturated over liquid water at the pressure p_0 . The air is expanded isothermally into a second chamber at a lower pressure p . Both chambers must have the same temperature. The relative humidity in the second chamber is defined by the ratio of the pressures in each of the two chambers through Dalton's law [8.4, 14]

$$RH = 100 \frac{e}{E_w} = 100 \frac{p}{p_0} \quad \text{in } \% . \quad (8.31)$$

Relative humidity with respect to saturation over ice is defined analogously to the procedure given above if the air at high pressure has been saturated over ice.

Most humidity generators use dewpoint hygrometer as a reference instrument. Recently, well-calibrated capacitive hygrometers have also been used as a reference sensor.

8.6.3 Salt Solutions

Air above the surface of a saturated salt solution equilibrates at a characteristic value of relative humidity (Table 8.15), which may depend slightly on temperature. This effect can be used for the calibration of small humidity sensors. Great care needs to be taken that the salt solution is properly saturated and that the entire system is thermally well equilibrated when a sensor calibration or calibration check is performed. Using an array of different salt solutions allows calibration over a large range of relative humidities. This method is very practical for checks of individual small sensors,

but does not supersede the comparison with reference hygrometers [8.4].

8.6.4 Quality Control Procedures

The quality control of humidity measurements must be part of the quality control procedures of all sensors at a meteorological station (Chaps. 3 and 43). A typical range of relative humidity is between 10 and 100%, with maximal changes within 1 min (10 min, 1 h) of 10% (30%, 50%). Nearly constant values within 6 h are questionable and constant values within 12 h are to be considered erroneous [8.102]. The upper limit of humidity is 100%, corresponding to saturation water-vapor pressure over water at a given temperature. Small values of supersaturation over water may be possible for a short amount of time (minutes), while supersaturation over ice may last significantly longer (up to hours). Table 8.16 gives some sensor-specific criteria that may be applied in quality control procedures. If the cause for invalid data cannot be determined and rectified, then a specialist should check the sensor and measurement setup.

Humidity sensors should be installed in meteorological screens or in a ventilated double shield for protection against radiation and rain. For open installations such as for optical instruments, a radiation error correction may be necessary and the instrument may fail all together under rainy conditions. If the sensor does not provide internal error coding, parallel rain detection may be necessary. Significant air pollution may lead to contamination of dry-bulb and wet-bulb wicks, mirrors or sensor windows. Wind may affect the ventilation rate leading to a dependence of the measurements on the wind direction in many instruments. Ventilation rates greater than 2.5 m s⁻¹ should be guaranteed for all wind directions and wind speeds.

Table 8.16 Typical tests criteria for humidity measurements

Method	Error	Reason
All instruments	$RH < \text{minimum for climate zone}$	Humidity too low for the method, new calibration necessary
Hair hygrometer	$RH > 100\%$ for more than 1 h $RH = \text{const.}$ for more than 3–6 h	New calibration necessary Mechanics must be cleaned
Capacitive hygrometer	$RH > 100\%$ for more than 1 h Low sensitivity	New calibration necessary Filter cap may be contaminated
Psychrometer	$RH \geq 100\%$ for more than 1–3 h Unusually small differences between dry-bulb and wet-bulb temperature	Dry-bulb thermometer is wet or wet-bulb thermometer is dry No or low aspiration or contamination of the wick of the wet-bulb thermometer
Dewpoint and frostpoint hygrometer	Measured dewpoint temperature larger than ambient temperature for more than 1–3 h, or reduced sensitivity	Mirror contaminated or detector dirty; most instruments give an error code
Optical hygrometer	Measured absolute humidity larger than saturation absolute humidity for the ambient temperature for more than 1–3 h, or reduced sensitivity	Windows contaminated or reduced signal of the light source

8.6.5 Calibration of Optical Hygrometers

Optical hygrometers can be calibrated with gases with a given humidity. For this, a calibration tunnel is installed in the optical path and the calibration gas flows through at a controlled and not too large flow rate. The zero-point must first be calibrated normally with dry nitrogen gas. Next, for the span calibration, a certain water-vapor concentration can be generated with dewpoint generators. The dewpoint can be easily recalculated as absolute humidities. Optical systems for water vapor that are applied for other trace gases like carbon dioxide can be calibrated in a similar way with a zero-gas and one or more calibration gases with a given concentration (see also Chap. 55). In any case, the calibration instructions of the manufacturer should be carefully applied.

8.6.6 Documentation and Metadata

Sensors have significantly changed over the last 20–30 years. Sensors such as lithium chloride dew cell have been almost completely replaced by the capacitive polymer sensors in automatic weather stations. For the maintenance of atmospheric climate records as well as for operational observations it is vital that all sensor changes, updates, replacements, and other measures impacting the observations are meticulously documented [8.83]. This includes documentation of parallel observations with old and new sensors during periods of transition and overlap and other comparison experiments. However, calibration updates and comparisons with working or reference standards must be documented. These efforts are of utmost importance and constrain the impact that sensor changes may have on long-term climate records or input observations for short-term weather forecasting.

8.7 Maintenance

Some general rules for maintenance should be followed for all instruments [8.4]: Sensors and housings should be kept clean, as well as the meteorological screen if necessary. This is very important for radiation shields, but particularly for those of psychrometers. Some sensors, for example chilled-mirror, optical hygrometers, and hair hygrometers, may be regularly cleaned with distilled water. Where available, instructions by the manufacturer should be consulted.

Monthly comparisons with a working reference hygrometer, such as an Assmann aspiration psychrometer,

are essential. For sensors relying on air temperature measurements, such as psychrometers and dewpoint hygrometers, that temperature sensor should be checked as well, which may easily be done with the Assmann psychrometer. Calibration against a reference standard in the laboratory should be done at regular intervals, such as annual or biannual and should include checks of the electronic data acquisition system.

Table 8.17 gives an overview of required maintenance for the most commonly used sensor types. Further information is given in Sect. 8.4.

Table 8.17 Maintenance of humidity measurement systems [8.7, updated]

Maximum interval	Hair hygrometer	Capacitive hygrometer	Psychrometer	Dewpoint and frost-point hygrometer	Optical hygrometer
1 week	Regeneration of hair and readjustment, if necessary		Refill water	Clean mirror, if not done automatically	Clean window with methanol or ethanol
1 month	Function and plausibility check, comparison with working reference such as Assmann psychrometer				
3 month	Check the mechanical function	Check and replace the filter cap, if necessary	Replacement of the cotton wick; may be required more frequently in areas with high levels of air pollution; inspection of the aspirator		Calibration in a climate test chamber, for IR hygrometers after 6–12 months, if necessary
2 year	Calibration of the instrument				
If a check indicates a possible malfunction, an instrument is to be replaced					

8.8 Application

Humidity is a standard meteorological parameter measured at nearly all meteorological stations (Chaps. 43 and 45) and is an important parameter for determining evapotranspiration (Chap. 57) and latent heat flux (Chap. 55). Many physical and chemical processes in the atmosphere involve water vapor. Absolute humidity and water-vapor pressure are sufficient to characterize an air mass; however, but the relative humidity must always be recorded together with air temperature.

8.8.1 Climatology of Humidity

Modern data acquisition technologies allow sampling rates of 1–10 s. Typical averaging intervals for humidity are 10 min, but intervals of 30 min or 60 min are also used. For standard meteorological measurements in Central Europe the daily mean is calculated from 24 values a_i , which may be relative humidity, absolute humidity or water-vapor pressure, recorded at one-hour intervals between 23:50 UTC of the previous day and 23:50 UTC of the current day [8.7]

$$\overline{a_{\text{day}}} = \frac{1}{24} \sum_{i=0}^{23} a_i. \quad (8.32)$$

For other time zones the averaging times must be adjusted accordingly. The climatological daily mean is calculated according to (8.32). If more than four continuous hourly values are not available, the daily mean is calculated from the arithmetic mean measured at 00:00 UTC, 06:00 UTC, 12:00 UTC and 18:00 UTC. At climate reference stations, the mean of the humidity values obtained at 6:30 UTC, 13:30 UTC and 20:30 UTC is calculated from only these three readings.

8.8.2 Daily and Annual Cycles

Long-term averages of humidity carry only a limited significance. The frequency distributions of hourly averages are of higher significance. Instead of monthly means of relative humidity, the mean value at a fixed time, e.g., at 3 p.m., may be a better indicator for characterizing humidity at a station.

The daily cycle may be more instructive because high temperatures are related to low relative humidity and vice versa; for example, during a fine summer day the absolute humidity or the water-vapor pressure may not show significant changes or a daily cycle, whereas temperature and relative humidity do show a significant daily cycle (Fig. 8.26).

Fig. 8.26 Daily cycle of relative humidity and temperature during an arbitrary summer day (Bayreuth, Germany, Aug. 28, 2017)

8.9 Future Developments

The last review of hygrometry, including new developments in thermodynamics and devices, was made more than 20 years ago [8.8] and is a main reference in this field of research and measurements [8.4]. Since that time, the number of commercially used measurement principles has significantly decreased. Significant progress has been made to reduce drift in capacitive sensors particularly in humid environments. Dewpoint

hygrometers (except Thygan) are rarely used as in-situ instruments but they remain important laboratory reference instruments and essential instruments in humidity generators. The development of the capacitive polymer technology continues with an expanding use of heated polymer sensors. A significant extension of the use of well-calibrated capacitive polymer hygrometers seems likely in the near future.

8.10 Further Readings

A comprehensive review of the diverse sensors, applications and maintenance of hygrometry is given by:

Dietrich Sonntag (deceased)

Dietrich Sonntag received his doctoral degree from the University of Leipzig in Meteorology in 1951 and his Habilitation degree from the Humboldt University Berlin in 1965. He developed several meteorological sensors mainly for humidity and radiation measurements. In 1988, he was one of the first scientists to be awarded the Professor Dr Vilho Väisälä Award of the WMO. He retired in 1992 and passed away in 2018.

Thomas Foken

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

Holger Vömel

Earth Observing Laboratory
National Center for Atmospheric Research
Boulder, USA
voemel@ucar.edu

Holger Vömel is a scientist at the National Center for Atmospheric Research at Boulder, CO, USA. He graduated in Physics from the University Heidelberg, Germany in 1990 and received a PhD in Chemical Physics from the University of Colorado at Boulder in 1996. His research interests focus around high-quality observations of atmospheric parameters such as water vapor, ozone, temperature, pressure, and winds, to provide reliable data for studies of climate change and atmospheric processes.

Olaf Hellmuth

Modeling Department
TROPOS Leibniz Institute for Tropospheric Research
Leipzig, Germany
olaf.hellmuth@tropos.de

Olaf Hellmuth is Senior Scientist in the Modeling Department of the TROPOS Leibniz Institute for Tropospheric Research Leipzig. In 1985, he received a diploma in meteorology and in 1988, he was awarded a Dr. rer. nat. His research activities comprise atmospheric sol formation, cloud microphysics with focus on hygroscopic growth and freezing processes, and theoretical aspects of hygrometry. He is member of the Leibniz Sozietät Berlin.

Wind Sensors

9. Wind Sensors

Thomas Foken , Jens Bange 

Various techniques are used to measure the wind speed in the atmosphere, including cup, propeller, and sonic anemometers; the latter can also be used to measure the wind vector. Wind direction measurements are also performed using wind vanes. Sonic anemometers are the devices most commonly used for turbulence measurements. Hot-wire anemometers are employed for special measurements, and Pitot tubes are utilized for aircraft-based measurements. It is also important to note that the conditions at the measuring site can strongly influence the accuracy of wind measurements.

This chapter discusses the variables measured by all of the above devices as well as the corresponding measurement principles and their theoretical foundations. The technical data that each technique provides is presented, the maintenance that must be carried out when using each technique is described, and relevant quality control and calibration methods are introduced. The history of the development of wind sensors is also briefly summarized, and some examples of the application of wind measurements are presented.

The airflow in the atmosphere—the wind field—is crucial to the transport of air masses caused by the pressure field. Wind measurements are therefore necessary at all levels of the atmosphere to support weather forecasting

and to improve our understanding of global circulation and climate systems (see Chap. 1). Furthermore, fluctuations in the wind velocity (mainly its vertical component) are responsible for fluxes of momentum, heat, and

matter. The wind essentially determines the dispersion, transport, residence times, and changes in the mixing and concentrations of gases and particles. The high vari-

ability and significant vertical gradients in the wind field as well as the effects of heterogeneous landscapes on this field make measuring the wind a challenging task.

9.1 Measurement Principles and Parameters

The wind velocity is a vector with three components. For nonturbulent problems, usually only the horizontal wind speed and the direction of the mean wind are relevant, which are measured with separate sensors. This increases the number of wind parameters measured and sensor principles employed.

9.1.1 Measured Parameters

For the wind vector \mathbf{u} , it is assumed that

$$\mathbf{u} = f(U, \alpha), \tag{9.1}$$

where U is the magnitude (modulus) of the wind vector and α is the direction of the wind vector from north via east. For the horizontal wind components u (east–west direction) and v (north–south direction), it follows that

$$u = U \sin \alpha \tag{9.2}$$

$$v = U \cos \alpha, \tag{9.3}$$

and the vertical wind component

$$w = U \sin \beta, \tag{9.4}$$

where β is the inclination of the wind field.

The fluctuations in the components

$$\begin{aligned} u &= \bar{u} + u' \\ v &= \bar{v} + v' \\ w &= \bar{w} + w' \end{aligned} \tag{9.5}$$

describe the turbulence (from Reynolds decomposition) [9.1]. Here, an overbar indicates an average and a prime symbol indicates a fluctuation. Typical averaging periods range from 10 to 30 min, with 10 min being a particularly common averaging period for operational wind observations. The sampling rate required to get an adequate description of the turbulent part is typically ≥ 10 Hz. The parameters that are measured are listed in Table 9.1. In the SI system (see Chap. 5), speeds are measured in meters per second (m s^{-1}). However, other units are also used for speed in some Anglo-American countries and in particular fields, for example in aviation and in nautical applications (Table 9.2).

9.1.2 Measurement Principles

Many of the various techniques used to measure wind speeds were devised centuries ago, but anemometers based on them are still available commercially today and have their own fields of application. However, one of the more recently invented devices, the sonic anemometer, is becoming increasingly dominant (see Sect. 9.9) due to its ability to measure not just the mean wind speed but the whole three-dimensional wind vector (and therefore the wind direction). It is also able to measure the wind velocity with high resolution at frequencies of several tenths of a Hz. Instruments that can also be applied for turbulence measurements, such as hot-wire or laser anemometers, are less useful for performing measurements in the atmosphere and are therefore used mainly for calibration purposes. An overview of the various wind measurement principles is given in Table 9.3.

Table 9.1 Parameters measured by wind sensors

Parameter	Description	Unit	Symbol
Windway	Distance that an air parcel covers within a certain time interval (older instruments)	m	
Wind speed	Horizontal wind velocity (mean value of both horizontal components)	m s^{-1}	u_h
Wind gust	A burst of high-velocity wind	m s^{-1}	g_u
Wind components, see (9.2)–(9.4)	Components of the wind vector in the Cartesian coordinate system: u, v are the horizontal components and w is the vertical component	m s^{-1}	u, v, w
Fluctuations in the wind components	Fluctuations in the components of the wind vector in the Cartesian coordinate system: u', v' are the horizontal components and w' is the vertical component	m s^{-1}	u', v', w'
Wind direction	Direction that the wind comes from	°	

Table 9.2 Units of wind speed

Unit	Transformation	Application
Beaufort	See Chap. 22	Nautical applications, partly in weather forecasting
Meter per second (m s^{-1})	$1 \text{ m s}^{-1} = 2.236 \text{ mph} = 3.6 \text{ km h}^{-1}$	Widely used in meteorology and science
Kilometer per hour (km h^{-1})	$1 \text{ km h}^{-1} = 0.62 \text{ mph} = 0.278 \text{ m s}^{-1}$	Traffic, partly in weather forecasting
Mile per hour (mph)	$1 \text{ mph} = 1.609334 \text{ km h}^{-1} = 0.44704 \text{ m s}^{-1}$	Meteorology (in some countries)
Knot (kn)	$1 \text{ kn} = 1.852 \text{ km h}^{-1} = 0.514 \text{ m s}^{-1}$	Nautical applications

Table 9.3 Wind measurement techniques and their applicability to mean wind speed or turbulence measurements according to (9.5) [9.2]

Measuring device	Properties used to measure the wind				Applicability	
	Mechanical	Thermodynamic	Sound	Other	Mean	Turbulence
Cup anemometer	x				x	
Propeller anemometer	x				x	(x)
Thermal anemometer		x			x	
Hot-wire anemometer		x			x	x
Sonic anemometer			x		x	x
Laser anemometer				x	x	x
Pitot tube				x	x	x

9.1.3 Siting Considerations

Wind measurements can be strongly influenced by the measurement site. To obtain a representative wind field for a large region, the surroundings of the measurement site should be flat and free of obstacles; if this is not the case, the influence of the obstacles must be taken into account (see Sect. 9.3.9). These requirements are very important for measurements of the vertical gradient of the wind speed near the ground (see Chap. 54). Furthermore, when instruments such as cup anemometers and wind vanes are positioned relatively close, they should not disturb each other (ideally, the cup anemometer should be positioned about 0.1 m above the vane, and

the two instruments should be separated by about 1 m horizontally [9.3]).

According to the international guidelines [9.4], the standard measuring height in obstacle-free terrain is 10 m above the ground. The distance to the nearest obstacle should be ten times the obstacle height. In any case, the instrument must be installed 6–10 m above the mean height of buildings or the height of the surrounding vegetation.

Lightning strikes and other electric discharges pose a risk to wind-measuring instruments, as they can interfere with the measurements or destroy the equipment. The presence of lightning conductors can only remedy this situation to a limited extent.

9.2 History

The wind has been observed since ancient times; indeed, both Homer and the Bible speak poetically of four winds [9.5]. It is also known that the *Tower of Winds* in Athens (50 BCE) had an eight-point wind rose. During the Greek and Roman periods and right up to the sixteenth century in Italy, the wind direction was categorized into twelve winds: four groups of three centered on the four principal directions. The initials N, NNE, NE, ... were first used on a compass card in 1536 [9.6]. In addition, the history of wind measurements goes back about 2000 years.

9.2.1 Wind Vanes

Wind vanes have been in use since ancient times; for instance, the Tower of Winds had a wind vane. Wind vanes in the shapes of animals (such as snakes and dragons) or flags of kings were often used. Vanes in the shape of a rooster have been used on Christian churches ever since *Pope Nicholas I* (pontificate: 858–867) decreed that all churches must display this bird as an emblem [9.8]. The history of scientific instruments for measuring the wind started when the wind vane was

Fig. 9.1a,b Typical types of wind vanes: (a) the English R.A.E. pattern vane, (b) the German vane produced by Fuess (after [9.7], reproduced with permission from Springer, Berlin)

combined with a hand to show (and, later on, to register) the wind direction. In Florence in 1578, *Egnatio Danti* (1536–1586), a professor of mathematics at Bologna, built a wind vane with a single hand on a vertical dial, which was positioned on a 17 m high tower to ensure that wind measurements were not influenced by surrounding buildings [9.9]. A significant improvement in wind vane design was made by *Georges-Frédéric Parrot* (1767–1852) [9.6], the first rector of the Imperial University of Dorpat (now Tartu, Estonia). His design—a splayed vane—was a combination of two plates that diverged from the axis of the vane. His vane was relatively small; it was only about 19 cm in length and had a counterweight that was 11 cm long. This type of vane was used up to the twentieth century. However, in 1918, *Sir Geoffrey Ingram Taylor* (1886–1975) proposed a vane with an airfoil profile that became known in England as the *R.A.E. pattern vane* [9.10]. This vane precisely measures wind direction fluctuations with periods larger than 5 s [9.7]. In Germany, the wind vane produced by Fuess became popular (Fig. 9.1).

In 1788, *Franz Carl Achard* (1753–1821) developed an inclined wind vane to measure the vertical orientation of the wind field [9.6]. This system was used by micrometeorologists in combination with a propeller anemometer to measure the vertical wind velocity right up to the second half of the twentieth century, before sonic anemometers became available.

Weather vanes have long been employed to determine the wind direction; more recently, they have also been used in combination with anemometers [9.6]. Such vanes were included in the first meteographs (weather clocks, combinations of several instruments, including clocks), such as those constructed by *Robert Hooke* (1635–1703) in about 1678 and *Sir Christopher Wren* (1632–1723) in 1689. In 1789, the pastor *Christian Gotthold Herrmann* (1730–1792) of Cämmerswal-

de in Saxony constructed a machine with a twelve-point wind rose [9.11]. In this machine, a wheel was rotated by a wind vane carrying twelve radial compartments, and a hammer ejected a numbered cube from a magazine into the appropriate compartment of the relevant wind direction once every hour.

A professor of experimental physics in Milan, *Marsilio Landriani* (1751–1815), constructed a wind vane with eight pencils that marked the wind direction on a horizontal plate rotated by a clock. The professor of mathematics *James Henry Coffin* (1806–1873) at Easton (PA, USA) constructed a sand wind vane that used the same principle as Herrmann's instrument and distributed sand into 32 reservoirs. This instrument is currently being exhibited in the Museum of History and Technology in Washington, DC. In 1850, *Karl Kreil* (1789–1862), director of the observatory at Prague and the first director of the *Central Meteorological and Magnetic Bureau* at Vienna (from 1851), constructed another a wind vane using a pencil [9.12]. Several other instruments, including electrical recorders, have been constructed since then.

9.2.2 Mechanical Anemometers

Mechanical anemometers, which use the dynamic pressure of the wind field (see Chap. 12), can be grouped into swinging plate anemometers and rotation anemometers, while the latter can be further categorized into propeller and cup anemometers.

Swinging Plate Anemometers

Around 1450, the Italian humanist and scientist *Leon Battista Alberti* (1404–1472) constructed the first swinging plate anemometer, where a plate moves along a scale under the influence of dynamic pressure (Fig. 9.2). Later, *Leonardo da Vinci* (1452–1519)

Fig. 9.2 Swinging plate anemometer (*upper part*) made by von Wild (reprinted with permission from Dr. Alfred Müller, Meteorologische Instrumente KG, R. Fuess, Königs Wusterhausen, Germany)

painted the design of an instrument that looked similar to the one made by *Robert Hooke* (1635–1703) in 1684. Hooke’s construction—which was used by the Swiss meteorologist *Heinrich von Wild* (1833–1902), who was also the director of the St. Petersburg Observatory—can still be found in some stations and is available commercially (Fig. 9.2). Several more constructions, some of which form parts of more complex meteographs, are illustrated in [9.6].

Rotation Anemometers

The principle of a rotation anemometer is similar to that used by windmills, which have been employed in Europe since the twelfth century. Around 1678, *Robert Hooke* used this system for his weather clock. This principle was also used by the famous Russian scientist *Mikhail Vasilyevich Lomonosov* (1711–1765) for his anemometer, but he replaced the windmill with an overshoot water wheel [9.6]. In the first half of the nineteenth century, it was discovered that the rotation speed of this type of anemometer is dependent on the wind direction. This problem was overcome by combining the propeller with a wind vane (see Sect. 9.4.3) or through the precise application of the cosine dependency (see Sect. 9.4.1) of a propeller in helicoidal form. The first helicoid anemometer was built by the British meteorologist *William Henry Dines* (1855–1927) [9.13].

Fig. 9.3 Robinson’s cup anemometer from 1846 [9.15] (courtesy of the NOAA Photo Library, National Oceanic and Atmospheric Administration, Department of Commerce)

The earliest known windmills with a vertical axis occurred in Persia in the seventh century CE; such windmills were not used in Europe, except in Poland. Those anemometers looked like present-day wind power generators with a vertical axis. The most famous vertical-axis windmill was built in 1734 by the postmaster of Louis XIV, *Louis-Léon Pajot, comte d’Ons-en-Bray* (1678–1754), and can be viewed in the exhibition of the Conservatoire National des Arts et Métiers in Paris. A similar device was built by the English scientist *William Whewell* (1794–1866) in 1838 [9.6].

Anemometers similar to the cup anemometer have probably been available since the end of the eighteenth century, as reported by the physician *Georg Wilhelm Munke* (1772–1747). The first cup anemometer dates back to 1846 and was constructed by the Irish astronomer *Thomas Romney Robinson* (1792–1882) [9.6, 14] (see Fig. 9.3), who modified Whewell’s anemometer and postulated a theory for the forces on the sensor. He got the idea for this novel design from the writer and engineer *Richard Lowell Edgeworth* (1744–1817), who constructed a windmill with a counter in 1793.

There is a long list of instruments that combine a wind vane with a rotation anemometer and a registration method [9.6, 7]. A modified version of one such instrument developed in the factory of R. Fuess in Berlin (*Heinrich Ludwig Rudolf Fuess*, 1838–1917) at the end

Fig. 9.4a–c Wind registration system invented by R. Fuess: **(a)** schematic view, **(b)** gust recorder, and **(c)** wind recorder unit (*upper part*: wind direction separated into N-E-S and S-W-N, *middle*: windway, *lower part*: gusts). Reprinted with permission from Dr. Alfred Müller, Meteorologische Instrumente KG, R. Fuess, Königs Wusterhausen, Germany

of the nineteenth century was used right up to the second half of the twentieth century, and is still commercially available. It combines a wind vane with a cup anemometer, measures the wind speed as the windway, and uses a Pitot tube (see Sect. 9.2.4) combined with a hydraulic system to measure gusts (this was termed a pressure-tube anemometer by *William Henry Dines* (1855–1927) in 1892 [9.6]; see Sect. 9.2.4 and Fig. 9.4).

9.2.3 Sonic Anemometers

The development of the eddy covariance method (see Chap. 55) required anemometers that responded rapidly. The basic equations for such anemometers were published in 1955 [9.16]. Following the development of the first sonic thermometer [9.17], a vertical sonic anemometer with a path length of 1 m was developed by *Verner Edward Suomi* (1915–1995) [9.18] and was used during the O’Neill experiment in 1953 [9.19]. Mod-

ern sonic anemometer designs are based on a system developed in 1960 by *Viktor Markovich Bovscheverov* (1905–1995) [9.20], which used the phase shift between sonic signals transmitted in different directions to calculate the wind vector. Subsequently, *Jagdish Chandran Kaimal* (1930–2021) and *Jost A. Businger* [9.21] (in 1963) and *Y. Mitsuta* [9.22] (in 1966) used the travel time of the sound in two directions to determine the velocity. The anemometer design used by the latter (Fig. 9.18a) is still employed today. Another sensor design that is still in use is the K-probe [9.23], so named because the sensor configuration is K-shaped.

However, the wind velocity measured using these instruments is temperature and humidity dependent. An approach that provided velocity measurements which were not subject to those influences was first realized in 1982 by *T. Hanafusa et al.* [9.27], who calculated the velocity components from the reciprocal travel times. This has become the dominant method in use

Table 9.4 Milestones in sonic anemometer development (for further details, see [9.30])

Type of sonic anemometer	Institution	Year and reference
Phase shift	Institute of Physics of the Atmosphere, Moscow, Russia	1960 [9.20], 1973 [9.24]
	School of Agriculture, University of Nottingham, Loughborough, UK	1979 [9.25]
Travel time	University of Washington, Seattle, WA, USA	1963 [9.21]
	Disaster Prevention Research Institute, Kyoto University, Kyoto, Japan	1966 [9.22]
	Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra, Australia	1983 [9.26]
	National Oceanic and Atmospheric Administration, Earth System Research Laboratories (NOAA/ESRL) Wave Propagation Laboratory, Boulder, CO, USA	1990 [9.23]
Reciprocal travel time	Meteorological Research Institute, University of Kyoto, Kyoto, Japan	1982 [9.27]
	University of Washington, Seattle, WA, USA	1986 [9.28, 29]

today. To reduce flow distortion effects and increase the accuracy of the vertical wind component, *John C. Wyngaard* and coworkers [9.28, 29] developed the University of Washington anemometer design, which is now widely used (Fig. 9.18b) and forms the basis of all omnidirectional anemometers.

9.2.4 Pressure Tube Anemometers

In 1675, the Paris-based instrument maker *Hubin* was intrigued to hear that Hooke could measure the wind without seeing it. Therefore, developing an idea proposed by *Pierre Daniel Huet* (1630–1721), Bishop von Soissons, France, he built an instrument consisting of a mercury-

filled U-tube with one open limb that was oriented towards the wind. Under the influence of the wind, the mercury in the U-tube moved into the other limb; the distance moved by the mercury was dependent on the wind speed. Unfortunately, however, the measured signal was very small [9.6]. In 1732, this concept was used by the French engineer *Henri Pitot* (1695–1771) to measure water flow [9.31], and the instrument was modified into its present form—the so-called Pitot tube—by the French scientist *Henry Darcy* (1803–1858) [9.32] in the middle of the nineteenth century. In the 1890s, *William Henry Dines* (1855–1927) modified the instrument to measure gusts in a similar manner to the device built by R. Fuess in Berlin (see Sect. 9.2.2).

9.3 Theory

Mechanical anemometers and wind vanes are classic examples of first- and second-order dynamical systems. A general description of these systems is given in Chap. 2. In the following section, relevant characteristics of these instruments and other anemometers are listed together with factors that influence them and the theory behind these measurement principles.

9.3.1 Cup and Propeller Anemometers

Classical wind measuring devices such as cup and propeller anemometers (see Figs. 9.12 and 9.13) are based on a mechanical principle whereby the dynamic pressure of the airflow is transformed into rotational movement. The horizontal wind speed u can be calculated directly from the geometry of the cup anemometer when the drag coefficients C_D of the cups are known. According to Bernoulli's law (see Chap. 10), the force F on any fixed surface with an area A perpendicular to the wind is given by [9.33]

$$F = C_D A \frac{\rho}{2} u^2, \quad (9.6)$$

where ρ is the air density. Without any loss of generality, we can assume that the cup anemometer consists of only two cups. If there is no acceleration (i.e., assuming stationarity), the forces on both cups are the same. Now consider the instant that the lever arm connecting the cups is perpendicular to the flow. At this point, one cup exposes its convex (closed) side to the flow. This cup is moving towards the flow with a rotational speed u_{rot} . Its surface experiences a wind speed of $u + u_{\text{rot}}$. The other cup shows its concave (open) side to the flow and is moving away from it. The balance of forces is therefore

$$C_D^{\text{closed}} A \frac{\rho}{2} (u + u_{\text{rot}})^2 = C_D^{\text{open}} A \frac{\rho}{2} (u - u_{\text{rot}})^2. \quad (9.7)$$

This quadratic equation leads to two solutions, but only one is physically meaningful,

$$u = u_{\text{rot}} \frac{\sqrt{C_D^{\text{open}}} + \sqrt{C_D^{\text{closed}}}}{\sqrt{C_D^{\text{open}}} - \sqrt{C_D^{\text{closed}}}} > u_{\text{rot}}. \quad (9.8)$$

Fig. 9.5 Transfer function of a cup anemometer; n is the number of revolutions of the anemometer, u is the wind speed, and a , b , c , and d are constants (after [9.3], reproduced with permission from VDI e.V., Düsseldorf, Germany)

For spherical cups, $C_D^{\text{open}} \approx 1.33$ and $C_D^{\text{closed}} \approx 0.33$ are good approximations.

In order to calibrate mechanical anemometers, it is very important to know the transfer function between the speed in a wind tunnel and the speed measured with the anemometer. This is the linear relationship between the wind speed and the rotation speed of the anemometer within a defined working range, which must be determined in a wind tunnel [9.34–36]. It takes the form

$$u = a + bn, \quad (9.9)$$

where u is the wind speed, n is the number of rotations, a is the extrapolation of the transfer function to zero revolutions, and b is a constant: the sensitivity of the instrument. This relationship is linear over a wide range of speeds, but at low speeds ($< 2\text{--}4 \text{ m s}^{-1}$) it is necessary to use the exponential approximation

$$u = c \exp(dn) \quad (9.10)$$

because a rotating anemometer has a threshold speed c (about $0.1\text{--}0.3 \text{ m s}^{-1}$), which is the lowest wind speed that causes the rotating anemometer to move continuously (this should not be confused with a in the linear transfer function). This is illustrated in Fig. 9.5.

The time constant (see Chap. 2) of a rotation anemometer depends on the wind velocity. Therefore, the velocity-independent distance constant [9.34–36]

$$L = u_\infty \tau, \quad (9.11)$$

where u_∞ is the final velocity and τ is the time constant, is a measure of the inertia of the anemometer and gives the wind path (the passage of the air within a certain time interval or the exact product of wind

speed and time) required for an anemometer to register 63% of a wind speed difference. The distance constant is an important parameter of the inertia of mechanical anemometers; it is about 1 m for sensitive propeller anemometers, about 2–3 m for small cup anemometers, and about 5 m for larger anemometers. This constant should be used instead of the threshold speed to assess the measurement quality because the starting speed is generally below $0.5\text{--}1.0 \text{ m s}^{-1}$, and the turbulent wind field is not fully developed at these speeds. Low values for the response characteristics are required for gust measurements (see Sect. 9.8.3), where the usual averaging interval is 3 s and the sampling rate $\leq 4 \text{ Hz}$ [9.4].

As the distance constant increases, overestimation of the wind speed starts to occur due to torque on the cup rotor (overspeeding [9.36]). This overestimation of the measured wind speed relative to the true wind speed is induced by turbulence. Wind gusts will cause a mechanical anemometer to rapidly rotate due to a high torque. However, after the gust, the anemometer will require some time to adjust to the moderate wind speeds. There is no compensation for these additional rotations when the wind speed is low. Overspeeding can be as large as 10% of the wind velocity and is particularly large for low wind speeds and high distance constants. The overspeeding is proportional to $(\sigma_u/u)^2$, where σ_u is the standard deviation of the wind speed (u is the horizontal wind speed here). If overspeeding in measurements near the ground is not accounted for, wind gradients will be inaccurate.

A cosine response cannot be assumed for cup anemometers. If there is only a moderate inclination of the flow, the measured wind speed will always be roughly the same. This means that cup anemometers overestimate the wind speed for an inclined flow [9.35].

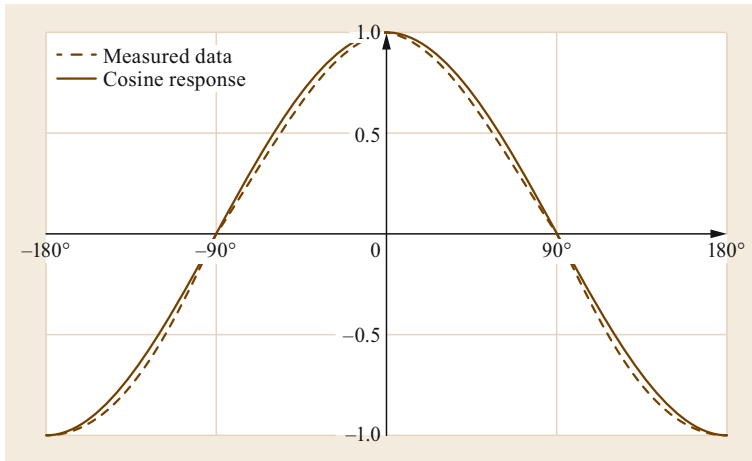

Fig. 9.6 Cosine response of a propeller anemometer (after [9.2])

For propeller anemometers (see Sect. 9.4.1), the cosine response is defined as the ratio of the measured wind speed for a certain angle of incidence α to the wind speed of the horizontal wind field $u(\alpha = 0)$ multiplied by the cosine of the angle, i.e.,

$$F(\alpha) = \frac{u(\alpha)}{u(0) \cos \alpha} \quad (9.12)$$

An ideal cosine response is $F(\alpha) = 1$. For propeller anemometers, deviations of up to 15% occur for incidence angles of about 45° (Fig. 9.6). For the light helicoidal propellers that tend to be used in three-dimensional propeller anemometers, these deviations can be relatively simply corrected using the relation

$$u_{\text{corr}}(\alpha) = u_{\text{meas}}(\alpha) [\cos \alpha - a \sin(2\alpha)], \quad (9.13)$$

where $a = 0.085$ [9.37] or $a = 0.140 - 0.009u$ [9.38]. For crosswinds ($\pm 90^\circ$, see Fig. 9.6), there is a dead zone of approximately $\pm 2^\circ$ where the propeller does not rotate. In measurements of the vertical wind, the dead zone is eliminated by employing two inclined sensors. It is recommended that a shank extension should be used for flow from the front [9.39] so that the dynamic conditions of the propeller are nearly identical for flow from the front and flow from behind.

9.3.2 Sonic Anemometers

Modern sonic anemometers use the travel time principle and direct time determination [9.27]. In this method, a sonic signal (about 100 kHz) is transmitted from both sides of the measurement path and received on the opposite sides (Fig. 9.7). Due to the wind velocity, one signal is faster than the other. The wind velocity is de-

termined from the exact travel times of the sonic signals

$$t_{1,2} = \frac{\sqrt{c^2 - u_n^2} \pm u_d}{c^2 - u^2} d, \quad (9.14)$$

where d is the path length, u_d is the wind component along the path, u_n is the normal component of the wind, and c is the speed of sound. This relation is based on the assumption that the flow in the sonic anemometer is slightly shifted by an angle γ from the measurement path, and the travel times are given by [9.35, 40]

$$t_{1,2} = \frac{d}{c \cos \gamma \pm u_d}. \quad (9.15)$$

The difference in reciprocal travel times gives the wind velocity along the measurement path, i.e.,

$$\frac{1}{t_1} - \frac{1}{t_2} = \frac{2}{d} u_d, \quad (9.16)$$

Fig. 9.7 Vector graph of the sound paths of a sonic anemometer (after [9.2])

and the sum of the reciprocal travel times eliminates the speed of sound, from which the so-called sonic temperature can be calculated (see Chap. 7). This equation also gives the computational detection limit for the wind speed based on the resolution of the runtime measurement $t_{1,2}$ and the error in the measuring path length. In practice, the detection limit is often given by the zero-point drift of the speed measurement, which can be verified in a null wind chamber [9.41] (see Sect. 9.6.2). The transducers and the mounting rods deform the wind field. These effects can be determined through wind tunnel calibrations. However, this shadow error is usually lower in the turbulent wind field. This is discussed in detail in Chap. 55.

9.3.3 Thermal Anemometers

Thermal anemometers use a protected cylinder at $\Delta T = 50\text{ K}$ higher than the air temperature T as a measuring element. Temperature sensors are arranged over the cylinder's surface. The heater voltage U to keep the temperature difference constant in time at $\Delta T = 50\text{ K}$ (using a loop control system) is used to measure the wind speed u via [9.3]

$$u = c_t \frac{T}{p} (U^2 - U_0^2)^2, \quad (9.17)$$

where c_t is a sensor-specific constant, p is the air pressure, and U_0 is the reference voltage at $u = 0\text{ m s}^{-1}$. The wind direction is obtained from the measured temperature distribution on the cylinder's surface using a compensating curve.

9.3.4 Hot-Wire Anemometers

Depending on the measurement electronics employed, a hot-wire anemometer can be utilized as a constant-voltage anemometer (CVA), constant-current anemometer (CCA), or constant-temperature anemometer (CTA). The latter requires a constant electrical resistance R and is a very common instrument in atmospheric physics. A number of variables determine the voltage that is required to keep the resistance $R(T)$ of the wire, and thus its temperature T , constant: the voltage U applied to the wire, the electrical current I through the wire, the Reynolds number Re of the flow across the wire (expressed by an exponent $n \approx 2$ for most atmospheric flows, see below), the temperature difference $T_{\text{wire}} - T_{\text{air}}$ between the wire and the ambient, the air density ρ , the heat capacity and conductivity of the wire (expressed by two material constants, c_1 and c_2), the heat H transferred from the wire to the ambient through convection, the heat radiated, by the wire and heat conducted from the wire to the mounting.

Above a certain wind speed u , the heat transfer H to the ambience is governed by forced convection, so radiation and heat conduction to the mounting can be neglected, implying that

$$H \approx [c_1 + c_2(\rho u)^{\frac{1}{n}}](T_{\text{wire}} - T_{\text{air}}). \quad (9.18)$$

This means that a CTA only works correctly for significant wind speed (typically above 0.2 m s^{-1}).

The heat Q stored in the wire changes over time t according to *King's law* of convective heat transfer,

$$\frac{dQ}{dt} = I^2 R - H = \frac{U^2}{R} - H, \quad (9.19)$$

after applying Ohm's law. In the quasi-stationary state $dQ/dt = 0$, the electrical heating equals the loss of H , and *King's law* becomes

$$U^2 = [c_1 + c_2(\rho u)^{\frac{1}{n}}](T_{\text{wire}} - T_{\text{air}})R(T_{\text{wire}}), \quad (9.20)$$

assuming the presence of a loop control circuit that keeps the wire temperature (and thus R) constant and allows the voltage U to be measured. Of course, the air temperature T_{air} must also be measured, preferably using a similar method (a cold thin-wire resistance thermometer, see Chap. 7) that delivers highly resolved turbulent temperature data. For further details on hot-wire (and hot-film) anemometers, see [9.42]; for more on air density, please refer to Chap. 5.

9.3.5 Laser Doppler Anemometers

Laser Doppler anemometers tend to be applied more commonly in laboratories and wind tunnels than in the atmosphere, with its fluctuating aerosol concentration. Such anemometers usually employ two monochromatic light beams that cross at a small angle ϕ . The beams generate a standing interference field, and the frequency of the fluctuations is equal to the Doppler shift between the incident and scattered light. The frequency f is proportional to the velocity component u_a parallel to the measurement axis [9.3] (see also Fig. 9.8) such that

$$f = \frac{|u_a|}{d_f}, \quad (9.21)$$

where d_f is the period of the interference field, which depends on the wavelength of the light and the angle ϕ .

The simplest geometry involves the reflection of a single light beam of wavelength λ (and frequency $f_{\text{laser}} = c/\lambda$, where c is the speed of light) by an air particle moving along the direction of light propagation with a velocity component u . Due to the Doppler shift,

Fig. 9.8 Schematic of a dual-beam laser Doppler anemometer

the reflected light (along the direction of light propagation) is shifted in frequency (f_{scatter}) towards the blue when the particle is moving towards the photodetector and towards the red when the particle is moving away from the sensor. The velocity component u_a can be calculated using

$$u_a = \frac{\lambda}{2} (f_{\text{laser}} - f_{\text{scatter}}). \quad (9.22)$$

A two-beam geometry allows the measurement of the velocity component v perpendicular to the direction of propagation of the light. In this case, the laser beam is split into two beams with identical wavelengths that are focused at an angle ϕ . A photodetector on the opposite side of the focus detects the two beams with different frequencies f_1 and f_2 due to the movement perpendicular to the beam axis. The corresponding velocity component of the scattering particle is

$$v = \frac{\lambda (f_2 - f_1)}{2 \sin \frac{\phi}{2}}. \quad (9.23)$$

Further details on laser Doppler anemometers (LDAs) can be found in [9.42, 43].

9.3.6 Pitot-Static or Prandtl Tubes

In order to measure the wind velocity norm $u = |\mathbf{u}|$ using Bernoulli's equation (see Chap. 10) along with a Pitot-static tube (also known as a Prandtl tube) in combination with (for instance) a wind vane, it is necessary to measure the pressure p_{stag} at the stagnation point of the tube (i.e., the sum of the kinetic and potential energies of the flow) as well as the static air pressure p_s ; see Fig. 9.9. The wind velocity can then be calculated

Fig. 9.9a–c Schematics of various Pitot tube configurations: (a) simple Pitot tube (sum of the dynamic and static pressures), (b) static tube (static pressure only), and (c) Pitot-static tube (Prandtl tube)

using (10.9) (see Chap. 10) as the dynamic pressure enhancement, i.e.,

$$u = \sqrt{2 \frac{p_{\text{stag}} - p_s}{\rho}}. \quad (9.24)$$

9.3.7 Wind Vanes

The wind vane is the classical instrument for measuring the wind direction. It is a second-order dynamical system (see Chap. 2). A wind vane consists of a wind direction indicator that can rotate about a vertical axis. The wind produces a torque on the vane that is proportional to the square of the wind speed and turns the vane in the direction of the wind. Turbulence generates oscillations that over- and undershoot the true wind direction ϕ_f . Wind vanes are designed to achieve a sufficiently short response time and high resolution. The damped natural wavelength is given by [9.3]

$$\lambda_d = Pu, \quad (9.25)$$

where P is the period of the damped oscillation. The undamped natural wavelength is

$$\lambda_n = \lambda_d \sqrt{1 - D^2}, \quad (9.26)$$

where D is the damping ratio, which should be between 0.3 and 0.7 [9.4] to limit any overshooting [9.44] and achieve a reasonable response time [9.45], and which is also given by a distance constant d , often for 50% of the change in wind direction (see Fig. 9.10). The damping ratio can be obtained from [9.35, 44, 46, 47]

$$D = \frac{1}{\sqrt{1 + \left[\frac{\pi}{\ln(a_2/a_1)} \right]^2}}, \quad (9.27)$$

where a_1 is the deviation of the wind vane and a_2 is the amplitude of the first overshoot, as illustrated in Fig. 9.10.

9.3.8 Scalar and Vector Averaging

The typical averaging interval for wind data is 10 min, although an interval of 30 or 60 min is used in some applications. Due to the vectorial nature of the wind,

Fig. 9.10 Plot showing the parameters involved in the damping of a wind vane

the averaging of wind data at a much greater temporal resolution than 10 min (e.g., 10 s) necessitates special calculations [9.3].

Averaging with time intervals of more than an hour is not meaningful; when the time intervals are large, probability density functions are calculated instead (see Sect. 9.8.1).

Vector Averaging

Vector averaging is the most physically precise of these calculations, although it assumes that the vertical wind component is zero during the averaging period for a horizontal wind field.

Direct averaging of the wind direction leads to systematic mistakes (e.g. averaging northern wind directions 350° and 1° would lead to 180°). Thus for the direction of the mean horizontal wind vector, both horizontal components *u* (9.2) and *v* (9.3) have to be averaged separately. The mean wind components from *N* individual values are defined as

$$\bar{u} = \frac{1}{N} \sum_{i=1}^N u_i \tag{9.28}$$

and

$$\bar{v} = \frac{1}{N} \sum_{i=1}^N v_i \tag{9.29}$$

The mean horizontal wind speed can be calculated from both components as

$$\bar{u}_h = \sqrt{\bar{u}^2 + \bar{v}^2} \tag{9.30}$$

Table 9.5 Direction angle $\bar{\alpha}$ as a function of the signs of the components *u* and *v* of the wind vector [9.3]

\bar{u}	≥ 0	≥ 0	< 0	< 0
\bar{v}	> 0	< 0	< 0	> 0
$\bar{\alpha}$	$\bar{\alpha}'$	$180^\circ - \bar{\alpha}'$	$180^\circ + \bar{\alpha}'$	$360^\circ - \bar{\alpha}'$

and the initial mean wind direction is

$$\bar{\alpha}' = \arctan \left| \frac{\bar{u}}{\bar{v}} \right|, \text{ where } 0^\circ \leq \bar{\alpha}' \leq 90^\circ \tag{9.31}$$

Note that *v* = 0 is not allowed in this equation. In this case, $\bar{\alpha} = 90^\circ$ for *u* > 0 and $\bar{\alpha} = 270^\circ$ for *u* < 0. The true mean direction angle $\bar{\alpha}$ can be obtained from the signs of the components of the wind vector in accordance with Table 9.5.

Scalar Averaging

When the measurements obtained are scalar means (e.g., data from cup anemometers), the mean horizontal wind speed can be calculated as

$$\bar{u}_h = \frac{1}{N} \sum_{i=1}^N u_{hi} \tag{9.32}$$

Since the wind direction scale is discontinuous at north, if there are direction changes that take place via north, the scale must be extended beyond 360° when calculating the mean wind direction.

9.3.9 Influence of the Surrounding Area on Wind Measurements

Wind measurements are significantly influenced by buildings, trees, and other obstacles in the vicinity of

the measurement site. Several more or less phenomenological rules have been developed to aid the selection of measurement sites and the correction of measurements. Very expensive wind tunnel studies or large eddy simulations are needed to exactly determine the influences of nearby obstacles. The methods outlined below are recommended for standard wind measurements.

The World Meteorological Organization (WMO) has developed a clear schema for classifying and correcting wind measurements [9.4, 48]. The recommended height at which measurements should be performed is 10 m. Because not all sites have the ideal characteristics of being exactly flat and having low roughness and no obstacles, it is recommended that stations should be classified as shown in Table 9.6 (see also Chap. 43), and that terrains should be classified based on the roughness length (Table 9.7; see also Chap. 1).

It is generally difficult to correct wind measurements precisely. However, the following three methods can be used to correct wind measurements sufficiently to allow rough comparisons between data obtained at different locations. Note that the methods do not give precisely comparable results, and corrections should only be made if the site is not too rough ($z_0 \leq 0.5$ m).

WMO has proposed a correction method for the station classification mentioned above [9.4, 48] that depends on the roughness length, a flow distortion cor-

rection [9.28, 52], and a topographic correction [9.53, 54]. For the corrected wind speed, it follows that

$$u_{\text{corr}} = u_{\text{meas}} C_F C_T \frac{\ln(10 \text{ m}/z_{0u})}{\ln(z/z_{0u})} \times \frac{\ln(60 \text{ m}/z_{0u}) \ln(10 \text{ m}/z_0)}{\ln(10 \text{ m}/z_{0u}) \ln(60 \text{ m}/z_0)}, \quad (9.33)$$

where z_0 is the roughness length at the site, z_{0u} is the effective roughness length of the terrain upstream of the site, C_F is the flow distortion factor (which is 1 for a free-standing mast), and C_T is the topographic correction factor, which is the ratio of the regional average wind speed to the wind speed at the site (this ratio is 1 for flat terrain). The effective roughness length is a correction for roughness effects and obstacles up to 2 km upstream of the site. To determine the effective roughness length, the climatology (one year) of the standard deviation of the horizontal wind speed σ_{uh} and the standard deviation of the wind direction σ_d (in radians) for sectors of roughly 30° must be applied, i.e.,

$$\frac{\sigma_{uh}}{u} = c_u \kappa \left[\ln \left(\frac{z_0}{z_{0u}} \right) \right]^{-1} \quad (9.34)$$

or

$$\frac{\sigma_d}{u} = c_v \kappa \left[\ln \left(\frac{z_0}{z_{0u}} \right) \right]^{-1}, \quad (9.35)$$

Table 9.6 Recommended classification of wind measurement sites (modified from [9.4, 48])

Class	Minimum distance to obstacles		Angular width (degrees)	Remark	Roughness class (see Table 9.7)	Uncertainty (correction required) (%)
	Surrounding obstacles	Thin obstacles more than 8 m high (masts, thin trees)				
1	> 30 times the height of obstacles	> 15 times the height of thin obstacles	≤ 1.9	Obstacles < 4 m high should be ignored	2–4	–
2	> 10 times the height of obstacles	> 15 times the height of thin obstacles	≤ 5.7	Obstacles < 4 m high should be ignored	2–5	≤ 30
3	> 5 times the height of obstacles	> 10 times the height of thin obstacles	≤ 11.3	Obstacles < 5 m high should be ignored		≤ 50
4	> 2.5 times the height of obstacles; no obstacles with an angular width > 60° and a height > 10 m within 40 m		≤ 21.8	Obstacles < 5 m high should be ignored		> 50
5	Sites that do not meet the requirements of class 4 are not recommended for wind measurements					

Table 9.7 Recommended terrain classification based on the roughness length z_0 [9.4] (updated according to [9.2, 49, 50]); x is the fetch and H is the obstacle height

Class	Surface	Obstacles	Roughness length z_0 (m)
1	Open sea	$x \geq 5$ km	0.002
2	Flat bare soil, snow	No	0.005
3	Open flat terrain, grass	No	0.03
4	Low crops	Occasional obstacles $x/H > 20$	0.1
5	High crops	Scattered obstacles $15 < x/H < 20$	0.25
6	Parkland, bushes	Numerous obstacles $x/H \approx 10$	0.5
7	Suburb, forest	Regular large obstacles	1.0
8	City center	High- and low-rise buildings	2.0

Fig. 9.11 Determination of the factor R_1 (after [9.51], reproduced with the permission of the Danish Technical University, Roskilde, Denmark)

where $c_u = 2.2$, $c_v = 1.9$ [9.2], and the *von Kármán* constant $\kappa = 0.4$.

A similar method was developed by the German Meteorological Service based on older versions of the WMO guidelines [9.4, 55]. This method is based on obstacle width (B) and height (H). For tall, narrow obstacles ($H \gg B$), the distance A between the measuring instrument and the obstacle is

$$\begin{aligned} A &\geq 0.5H + 10B && \text{for } B \ll H \leq 10B \\ A &\geq 15B && \text{for } H > 10B. \end{aligned} \quad (9.36)$$

For $H \approx B$, it follows that

$$A \geq 5(H + B), \quad (9.37)$$

and for flat, elongated obstacles ($H \ll B$),

$$\begin{aligned} A &\geq 0.5B + 10H && \text{for } H \ll B \leq 10H \\ A &\geq 15H && \text{for } B > 10H. \end{aligned} \quad (9.38)$$

When there are circular obstacles of radius r surrounding the installation site (e.g., the site is surrounded by houses or forest clearings), it follows that

$$\begin{aligned} A &\geq \pi r + 10H && \text{for } H \geq \frac{\pi}{5}r \\ A &\geq 15H && \text{for } H < \frac{\pi}{5}r. \end{aligned} \quad (9.39)$$

If the minimum distance A cannot be complied with (9.36)–(9.39), the wind speed will not be corrected, but the instrument's pole must be raised by h' , where

$$h' = \frac{H}{A} (A - A_D). \quad (9.40)$$

Here, A is the distance assessed using (9.38) to (9.41), and A_D is the distance between the obstacle and the actual measurement site.

The European Wind Atlas [9.51] applies a method based on [9.56] to determine the lee side of an obstacle. Accordingly, a corrected wind velocity can be calculated from the measured velocity and the porosity P of the obstacle (buildings: $P = 0.0$; trees: $P = 0.5$) as

$$u_{\text{corr}} = u_{\text{meas}} [1 - R_1 R_2 (1 - P)]. \quad (9.41)$$

The factor R_1 can be obtained from Fig. 9.11, and

$$R_2 = \begin{cases} \left(1 + 0.2 \frac{A}{B}\right)^{-1} & \text{for } \frac{B}{A} \geq 0.3 \\ 2 \frac{B}{A} & \text{for } \frac{B}{A} < 0.3. \end{cases} \quad (9.42)$$

For measurements of turbulent fluxes (see Chap. 55), the recommended distances should be enlarged by a factor of 5–10. The footprint (see Chap. 1) should also be taken into account. Similar conditions must be fulfilled for measurements of the vertical gradients of the horizontal wind speed, which are sometimes gauged to determine the stratification conditions in the atmosphere or energy and substance exchanges (see Chaps. 54 and 57), and are usually performed at small heights (< 10 m). For a discussion of the influence of the sensor installation (i.e., the tower), see Chap. 6. Special requirements may also call for the sensor to be installed at a greater or lower height than normal (e.g., at source height) or the measurement of locally relevant data (e.g., in street canyons).

9.4 Devices and Systems

Anemometers and wind vanes are available as individual instruments or they can be integrated into one system. Rotation anemometers and wind vanes are installed close together, while sonic and thermal anemometers that measure the wind speed and direction are usually integrated into one sensor. Hot-wire, laser, and Pitot anemometers are seldom applied in the atmosphere, but they are used for calibration in wind tunnels.

9.4.1 Rotation Anemometers

Until about 5–10 years ago, cup and propeller anemometers were the most common sensors used to measure wind speed. The cups used in anemometers have a round or preferably conical form, while the propellers have a helicoidal form that ensures a near-cosine response. Both systems consist of two parts: the rotor and the signal generator.

However, rotation anemometers are gradually being replaced by sonic anemometers, which can measure the wind vector with high accuracy and less maintenance than required for rotation anemometers. Classified cup anemometers are still used in the wind energy industry [9.57]. Cup anemometers positioned on high towers can perform measurements in the presence of inclination, acceleration, and vibration.

Handheld cup anemometers are also available. These have dynamo or mechanical counters; the lat-

Fig. 9.12 Cup anemometer (photo © Th. Friedrichs & Co., Schenefeld, Germany)

ter give the windway, which can be recalculated into a wind speed within a certain time interval. Impeller wheel cup anemometers can also be obtained. While cup anemometers (Fig. 9.12) have distance constants of 2–5 m, those of propeller anemometers are on the order of 1–2 m. The latter are also able to measure turbulent fluctuations of up to 1–5 Hz and are available as three-component systems that can determine the wind vector (Fig. 9.13). An overview of different signal generators is given in Table 9.8.

Cup anemometers intended for application in moist and cold ($< 0^{\circ}\text{C}$) weather conditions can be heated. The main components of the anemometer that are heated are the cups, the axis, and the bearings.

9.4.2 Wind Vanes

Wind vanes (Fig. 9.14) must be well balanced or they will adopt a preferred position at low wind speeds. When using mechanical anemometers, the wind direction can be determined using optical, electrical

(potentiometer), or coding methods, as shown in Table 9.9. Potentiometers either have a dead zone near 360° or are 540° multiturn potentiometers. Similar to cup anemometers, heated wind vanes can be obtained for moist and cold weather conditions.

9.4.3 Combinations of a Rotation Anemometer with a Wind Vane

Various designs of systems combining a rotation anemometer with a wind vane are available. The cup anemometer may be separated from the wind vane vertically or horizontally (Fig. 9.15). In the case of horizontal separation, a large distance of about 1.0 to 1.5 m may be used to minimize interactions. When they are separated vertically, the lower of the two sensors may be affected by the mounting brackets.

A widely used sensor is the combination of a wind vane and a propeller anemometer (skyvane, Fig. 9.16). When there are large fluctuations in the wind direction, the wind speed measurement may be reduced due to the cosine response (see Sect. 9.3.1). Furthermore, the wind speed and the wind direction can be calculated from propeller anemometers with 2-D or 3-D designs (Fig. 9.13). An overview of different signal generators is given in Table 9.10.

9.4.4 Sonic Anemometers

Early sonic anemometers had a three-dimensional design, and their measurement paths were predominantly Cartesian oriented [9.27]. They were mainly applied for flux measurements (see Chap. 55). Modern sonic anemometers have larger measurement path angles to reduce flow distortion. Technical progress in the last 10–20 years has reduced the cost of a sonic anemometer dramatically, and this measuring principle is now also available for two-dimensional sensors that measure wind speed and direction. These sensors—which have a relatively open or compact design (Fig. 9.17)—are replacing rotating anemometers and wind vanes,

Table 9.9 Overview of the signal generators used in mechanical wind vanes [9.3]

Transducer	Outputs ^a	Power supply required?	Special features
Potentiometer	AS (Ω)	Yes	Very suitable for simple recorders/displays
Absolute angle encoder	GC, DP (serial or parallel)	Yes	Usually very expensive, encoding depends on manufacturer
(Optoelectronic) encoder	GC, DP (serial)	Yes	Standard, Gray code depends on manufacturer
Encoder with integrated signal converter	SS (mA, V)	Yes	Linear output signal (standard signal)

^a AS scaled but often not linearized analog signal as resistance, voltage, or current signal; DP data protocols, e.g., via RS-232/485, SDI/MODBUS; GC Gray code: serial or parallel; SS linearized standard signal, e.g., 0–20 mA, 4–20 mA or 0–5 V, 0–10 V

Table 9.10 Overview of the signal generators used in combinations of a rotation anemometer with a mechanical wind vanexo [9.3]

Devices combined	Transducer	Outputs ^a	Power supply required?	Special features
Cup anemometer combined with wind vane: vertical arrangement (coaxial)	Electric; see Tables 9.8 and 9.9		Yes	Compact design
Cup anemometer combined with wind vane: horizontal arrangement	Electric; see Tables 9.8 and 9.9		Yes	Large separation between the sensing devices
Wind vane with integrated propeller anemometer	Electric	FS (Hz), GC	Yes	
2-D (3-D) orthogonal propeller anemometer	Optical pulse generator	FS (Hz)	Yes	Suitable for fluctuation measurements

^a FS frequency signal (in Hz); GC Gray code: serial or parallel

even those used by meteorological services. They are available from many manufacturers and often included in complex weather sensors (see Chap. 43). Even one-dimensional sensors have become available; these

are used for measurements in a one-dimensional flow (Fig. 9.17c, industry) or in a combination of three sensors, such as in the wind turbine spinner [9.58] (see also Chap. 51).

Fig. 9.16 Combination of a propeller anemometer with a mechanical wind vane, also called a skyvane (photo © R.M. Young Company/GWU-Umwelttechnik GmbH, Erftstadt, Germany)

An increasing number of designs and signal processing methods are becoming available for eddy covariance measurements. Figure 9.18 illustrates four different sensor types that are widely used. The DA700 (Fig. 9.18a) is the most recent version of the Kaijo-Denki PAT and DAT series of sensors that were used from the 1970s to 1990s in many scientific papers and are described in [9.22, 27]. The CSAT3 (Fig. 9.18b) is based on a prototype constructed at the University of

Washington [9.29], and has been used since the 1990s for scientific measurements. Both of these types are applied to a selected wind direction sector. If there is no preferred wind direction, omnidirectional anemometers are employed; two such sensors are shown in Fig. 9.18c, d. Further details on these sensors are given in Chap. 55.

Due to various issues with eddy covariance measurements, efforts have been made to reduce flow distortion by, for example, using smaller transducers or including a vertically oriented path that permits better resolution of the vertical wind velocity, even in omnidirectional sensors. Similar results of the reduction of the flow distortion are possible analyzing the signals between all transducers and not only along one path and the non-disturbed signals can be selected for the analysis. These investigations are ongoing, because wind tunnel measurements cannot be easily transferred to the turbulent atmosphere above various rough surfaces. Numerical studies are also used to improve anemometer design [9.59].

It is possible to heat a sonic anemometer in moist and frosty weather conditions, but this may influence the data [9.60, 61]. Because of the energy used in the transducers, a thin rough-frost layer does not significantly affect the measurements.

The wind data obtained using a sonic anemometer do not depend on the air density, but the power of

Fig. 9.17 (a,b) Two-dimensional sonic anemometers with open path lengths; the latter has a compact construction (photos © Adolf Thies GmbH & Co. KG, Göttingen, Germany). (c) One-dimensional sonic anemometer (photo © METEK GmbH, Elmshorn, Germany)

Fig. 9.18a–d Different types of three-dimensional sonic anemometers (the anemometers in (a) and (b) are orientated in one wind direction and those in (c) and (d) are omnidirectional types): (a) DA700 (photo © Sonic Corp., Tokyo, Japan), (b) CSAT3B (photo © Campbell Sci. Inc., Logan, UT, USA), (c) R3-50 (photo © Gill Instruments Ltd., Lymington, UK), and (d) uSonic-3 Scientific (formerly USA-1, photo © METEK GmbH, Elmshorn, Germany)

the sound transferred is density dependent. Most instruments have enough power to enable measurements to be performed at altitudes of up to about 5000 m, but the manufacturer should be consulted before performing such measurements.

9.4.5 Thermal Anemometers

Thermal anemometers are robust sensors that are often combined with other sensors (see Chap. 43). This type of sensor type can be used in rough conditions. An example is shown in Fig. 9.19. The signal is either analog or digital (serial output).

9.4.6 Hot-Wire Anemometers

Hot-wire anemometers use a thin metal wire (tungsten is common) or a quartz fiber (e.g., 70 μm) with a thin metal coating (e.g., 0.5 μm of nickel) a few millimeters in length that is mounted on two needle-shaped prongs. The application of a combination of three wires can allow 3-D wind-vector measurements (Fig. 9.20).

Hot-wire anemometers have extremely high frequency responses and fine spatial resolutions compared to other measurement methods. Since the wire is very thin and hot, it is very delicate, it can be contaminated by gases and particles, and it suffers from aging. These sensors are therefore mainly employed in detailed studies of turbulent flows, preferably in clean air (laboratories), or for short field campaigns. Hot-wire anemometers only work correctly when the wind velocity is significant (typically above 0.2 m s^{-1}), but they can be used at transsonic and sonic speeds.

Fig. 9.19 Thermal anemometer (top part) combined with a temperature screen (photo © Lambrecht Meteo GmbH, Göttingen, Germany)

9.4.7 Laser Anemometers

The laser Doppler anemometer (LDA) has several advantages compared with most other techniques discussed in this chapter. First, due to their measurement principle, LDAs do not have to be calibrated! The observed Doppler shift is a linear function of the velocity component. However, the electronics needed to determine the Doppler shift is quite complex. Furthermore,

Table 9.11 Advantages and disadvantages of different wind-measuring methods

Method or device	Advantages	Disadvantages
Cup anemometer	Simple and inexpensive anemometer, choice of many signal formats	Mechanical system, slow response time (large distance constant)
Propeller anemometer	Fast response time (low distance constant), but not good enough for turbulent flux measurements	Mechanically sensitive
Wind vane	Simple and inexpensive wind vane, choice of many signal formats	Mechanical system, slow response time (large distance constant)
Sonic anemometer	Nonmechanical device for measuring wind velocity and wind direction; fast response time, turbulence measurements are possible	Relatively expensive, special data calculations are necessary
Thermal anemometer	Nonmechanical device for measuring wind speed and wind direction	Low accuracy
Hot-wire anemometer	Very high wind velocities, very high resolution	Only for laboratory measurements, very sensitive mechanically
Laser anemometer	Fast-response anemometer	Only for laboratory measurements; requires the presence of a certain aerosol concentration
Pitot anemometer	Very robust, high wind velocities, high resolution	Requires high wind velocities, no wind direction (see multihole probe); beware of icing

**Fig. 9.20** Three-dimensional hot-wire anemometer (photo © Dantec Dynamics, Skovlunde, Denmark)

the measurement setup must be realized with high precision, and the angle ϕ is almost linearly related to the wind component.

LDAs work very rapidly and offer very high temporal resolutions. Also, the measurement volume is extremely small—less than a millimeter in diameter. Since they have no moving parts, LDAs are low maintenance. They do not require contact with the medium and are unaffected by pressure, density, or temperature fluctuations in the flow.

9.5 Specifications

The general requirement for any wind-speed measuring device [9.4] is the ability to measure the wind speed up to 75 m s^{-1} . However, depending on the climate and measurement height (see Chap. 1), this range can be reduced for many sites. The required resolution and uncertainty depend on whether the application involves standard measurements or the measurement

of vertical gradients (which are commonly measured in research or for wind power studies). The typical requirements in both cases are given in Table 9.12. Requirements for standard wind direction measurements are given in Table 9.13. The specifications of the different types of wind sensors are given in Table 9.14.

9.4.8 Pitot-Static or Prandtl Tubes

This method is mainly used at high velocities (e.g., aboard aircraft). A further development of the Prandtl tube is commonly used aboard research aircraft: the so-called multihole probe, which delivers not only the wind vector norm but all three components of the wind vector (see Chaps. 48 and 49).

9.4.9 Comparison of Different Methods

The appropriate wind sensor to use is determined by the measurement task. The essential aspects are the detection limit, resolution, dynamic behavior, measurement range, and either mechanical components or ultrasound. A comparison of the advantages and disadvantages of the various wind sensors described above is shown in Table 9.11.

Table 9.12 Requirements for wind-speed sensing devices

Property	Standard use [9.3, 4]	Vertical gradients for flux calculations [9.3]
Range of wind speeds (m s^{-1})	0–75	Dependent on measurement height
Distance constant (m)	2–5	≤ 3
Response threshold/detection limit (m s^{-1})	≤ 0.5	≤ 0.3
Speed resolution (m s^{-1})	± 0.5	± 0.1
Uncertainty	$\pm 0.5 \text{ m s}^{-1}$ for wind speeds $\leq 5 \text{ m s}^{-1}$ 10% for wind speeds $> 5 \text{ m s}^{-1}$	$\pm 0.1 \text{ m s}^{-1}$

Table 9.13 Requirements for wind-direction sensing devices [9.3, 4]

Property	Wind vane	Ultrasound and thermal anemometers
Angular resolution (degrees)	5 for wind speeds $\geq 1 \text{ m s}^{-1}$	3 for wind speeds $\geq 1 \text{ m s}^{-1}$
Damping ratio	> 0.3	
Uncertainty (degrees)	± 5 at $u \geq 1 \text{ m s}^{-1}$	3 for wind speeds $\geq 1 \text{ m s}^{-1}$

Table 9.14 Specifications of different methods for measuring the wind velocity and direction (given the large number of sensors available, the manufacturer's information should be used to retrieve more specific information on a particular sensor)

Sensor type	Typical uncertainty	Temperature range ($^{\circ}\text{C}$)	Remark
Cup anemometer	$\pm 0.3 \text{ m s}^{-1}$	-40 to $+70^{\text{a}}$	
Propeller anemometer (sky vane)	$\pm 0.1 \text{ m s}^{-1}$	-40 to $+60^{\text{b}}$	$0-35 \text{ m s}^{-1}$
Sonic anemometer	$\pm 0.1 \text{ m s}^{-1}, \pm 2^{\circ}$	-40 to $+70^{\text{a}}$	Resolution 0.01 m s^{-1}
Thermal anemometer	$\pm 0.5 \text{ m s}^{-1}, \pm 3^{\circ}$	-40 to $+70^{\text{a}}$	
Hot-wire anemometer	$\pm 0.01 \text{ m s}^{-1}$	-20 to $+70$	
Laser anemometer			
Pitot anemometer	0.5–5%	-40 to $+70^{\text{a}}$	
Wind vane	$\pm 5^{\circ}$	-40 to $+70^{\text{a}}$	

^a When used at temperatures $< 0^{\circ}\text{C}$ and in moist conditions, the sensor should be heated

^b When used at temperatures $< 0^{\circ}\text{C}$ and in moist conditions, the combined sensor and wind vane should be heated; otherwise, this combined system should only be used at temperatures above zero and in a dry climate

9.6 Quality Control

In contrast to other meteorological elements, the WMO [9.4] has not categorized standards for wind measurements. The ISO standards for wind tunnel calibration are applied to rotation and sonic anemometers [9.34, 41] (see Chap. 4), whereas cup anemometers for the wind energy industry are categorized by the International Electrotechnical Commission (IEC) [9.57]; see Chap. 51. A very general classification is used for sonic anemometers that are employed for flux measurements [9.62, 63]; see Table 9.15 and Chap. 55.

Anemometers are typically calibrated in wind tunnels. Because the calibrations are relatively stable over long periods, long time intervals can be left between calibrations (see Sect. 9.7) if the sensors are not mechanically deformed or corroded. However, wind tunnels provide near-laminar flow, and the characteristics in the turbulent atmosphere may be different to this.

This particularly applies to the flow distortion effects of sonic anemometers, which are usually reduced. For flux measurements performed using sonic anemometers, it is usual to carry out intercomparisons of different sensors. It is recommended that the instruments should not generate flow distortion effects for other sensors, the wind field should have the same turbulence characteristics for all sensors, and an instrument (etalon) for which the characteristics are already known should be used for comparison. For further aspects of such comparisons, see Chaps. 3 and 55.

9.6.1 Wind Tunnel Calibration

Rotation anemometers [9.34] must be calibrated in a wind tunnel to determine the linear transfer function (9.9), the nonlinear transfer function (9.10) (if they are

Table 9.15 Classification of sonic anemometers based on the scheme given in [9.62, 63]

Anemometer class	Application	Sensor type
A	Flux measurements for basic research	3-D anemometer for flux measurements with an open sector of 120–300° when there are no significant flow distortion influences, e.g. Fig. 9.18a,b
B	General use for flux measurements	3-D anemometer for omnidirectional flux measurements (0–360°) when there are flow distortion influences due to the mounting structures, e.g. Fig. 9.18c,d
C	General use for wind measurements	2-D anemometer used only for the wind speed and direction, e.g. Fig. 9.17a,b

to be used to measure low wind speeds), the distance constant (9.11), and the cosine response (9.12); see Sect. 9.3.1 on rotation anemometers. With the exception of the distance constant and the nonlinear transfer function, the same characteristics of other types of anemometers (e.g., sonic anemometers) can also be measured in a wind tunnel.

Requirements for the Wind Tunnel

The wind tunnel should be large enough that the anemometer and of all the constructions required for the calibration cover less than 5% of the cross-sectional

area of a closed wind tunnel or less than 10% of the cross-sectional area of an open wind tunnel (Fig. 9.21). The cross-sectional profile of the anemometer and the constructions needed for calibration should remain the same during the process of calibration. If the diameter of the wind tunnel is too small for the anemometer, it is possible to calibrate the anemometer through comparison with another well-calibrated reference anemometer of the same type.

The wind speed of the tunnel should range from 0 m s^{-1} up to 50% of the maximum wind speed that the anemometer will encounter [9.34]. The speed should be kept constant to within $\pm 0.2 \text{ m s}^{-1}$. It is necessary to monitor the speed of the wind tunnel with well-calibrated (by a certificated institute), sensitive anemometers such as a hot-wire anemometer (Sect. 9.4.6), laser anemometer (Sect. 9.4.7), or Pitot tube (Sect. 9.4.8). The wind speed in the area of the anemometer should be uniform to within $\pm 1\%$. For wind speeds above 10 m s^{-1} , the turbulence intensity (the standard deviation of the mean wind speed divided by the mean wind speed) should be less than 2%. The turbulence intensity can be measured with a hot-wire or laser anemometer.

When determining the response threshold and the distance constant, the air density in the air stream should not vary by more than 3%, and for application of the Pitot anemometer, temperature and air density are necessary. Therefore, these parameters, together with the humidity, should be documented during the calibration.

Performing the Calibration

The lowest calibration point is approximately double the response threshold speed [9.34]. Other calibration points are 10, 20, 30, 40, and 50% of the maximum wind speed that the anemometer will encounter. Before calibration, the wind speed in the tunnel should be in a steady state. The averaging interval employed during calibration is 30–100 s, or even longer for anemometers with impulse output. The calibration should be repeated three times. The linear transfer function can be analyzed using regression analysis (see Chap. 2). If the

Fig. 9.21 Wind tunnel calibration of a sonic anemometer in the low wind speed tunnel of the Technical University Dresden, Germany (photo © L. Siebicke)

relationship between the tunnel speed and the number of rotations or speed of the anemometer is not linear at lower wind speeds (Fig. 9.1), these wind speeds must be excluded from the linear transfer function and analyzed with (9.9), probably with the aid of more calibration points.

The determination of the distance constant should be repeated ten times for tunnel speeds of 5 m s^{-1} and 10 m s^{-1} . First the anemometer should be locked. After unlocking the anemometer, about ten measurements separated by time intervals that depend on the distance constant should be performed. The response time (see Chap. 2) is the time taken for the anemometer to change from 30 to 74% of the steady-state wind tunnel speed [9.34]. The distance constant is the average of all the measurements calculated with (9.11).

The cosine response calculated via (9.12) should be tested (with ten repetitions) for tunnel speeds of 5 and 10 m s^{-1} . To achieve this, the anemometer should be inclined in 5° steps up to 30° using a special construction. The cosine response of a cup anemometer should be negligible up to $10\text{--}20^\circ$ [9.35]. Propeller and sonic anemometers should adhere closely to the cosine response; only small deviations are permissible for the propeller anemometer (Fig. 9.2). If necessary, the range of inclination can be extended to more than 30° .

9.6.2 Zero-Wind Chamber Calibration of Sonic Anemometers

The calibration of sonic anemometers is very stable for a long time. However, before the first use of the anemometer, a zero-point test should be carried out in a closed zero-wind chamber [9.41]. The size of the chamber required depends on the signal power of the anemometer and should be available from the manufacturer. Measurements of the wind components or wind speed in the chamber should be averaged over the same time interval as during the planned measurements. If the value is below the threshold of approximately $0.01\text{--}0.1 \text{ m s}^{-1}$, the test is complete. If not, there should be a check to see whether the test failed due to air flow in the chamber or signal reflection at the walls. If it did fail for either of these reasons, the position of the anemometer in the chamber should be changed. If the test fails again, the anemometer must be recalibrated by the manufacturer.

9.6.3 Specific Quality Control Methods

The following unrealistic values caused by a sensor malfunction or faulty data transmission during standard wind measurements should be identified through default testing and excluded [9.3, 64]:

- Negative values
- Wind speeds below the response threshold with a wind direction of 1° to 360°
- Wind speeds above the response threshold with a wind direction of 0°
- Wind speeds $> 60 \text{ m s}^{-1}$ at elevations $< 600 \text{ m}$ above mean sea level in Central Europe
- Wind speeds $> 80 \text{ m s}^{-1}$ at elevations $> 600 \text{ m}$ above mean sea level in Central Europe
- Wind direction $> 360^\circ$
- A constant wind speed and/or direction for at least six hours.

Meteorological measurements can be tested by comparisons with climatological values regarding the variability of the wind speed and wind direction between two readings, or comparisons with wind measurements of nearby meteorological stations if they are not affected by their surroundings. This allows jumps in the readings (e.g., due to increased friction in the bearings) to be identified. Furthermore, the persistence of constant readings can be checked in order to identify blockages in the sensing device or a failed connection between the sensing device and data processing. The limit values are usually determined based on the typical measurements at the site.

Wind measurements taken at several sites or several altitudes can be tested by comparison with other data. The usual method is to identify measurement errors from a numerical analysis of weather reports for an extended area. The measurement of vertical gradients in the atmosphere near the ground can be checked by applying the typical logarithmic profile and obtaining approximate exponential profiles from tower measurements (see Chap. 1).

The abovementioned test can be performed not only for rotation anemometers but analogously for sonic and thermal anemometers. However, the measurement of standard deviations of wind variables or turbulent fluxes requires more comprehensive testing (see Chap. 55).

9.7 Maintenance

There are some general maintenance rules that should be followed for all wind-measuring instruments [9.3, 4]. The installed measuring system must be included in all maintenance actions (see Chap. 6). This includes the safety standards for masts, attachments, the fitting of a lightning conductor (on the upwind side of the anemometer), and meteorological requirements for the site, such as an undisturbed inflow direction (see Sect. 9.3.9).

Because wind sensors—especially mechanical sensors—are highly affected by environmental conditions, the following issues should be addressed during the maintenance:

- Lubricant viscosity and bearing properties are affected by aging and changes in temperature. Friction increases at low temperatures, which leads to erroneous measurement data. The manufacturers' instructions regarding temperature-related behavior must be observed.
- All wind-measuring instruments are subject to corrosion, especially when they are used in regions with high levels of air pollution, in coastal regions, or at sea. Corrosion effects should be identified and repaired.
- Appropriate measures should be put in place to ensure that birds cannot settle on the measuring instruments. A slightly higher mast close to and downwind of the tower can be helpful.

- Rain and snow can affect the properties of the equipment. In particular rime, hoar frost, and ice formation can completely interrupt the proper functioning of the measuring instrument unless these effects can be minimized (e.g., by heating).

For some sites, special actions are necessary, or the interval between maintenance should be shortened.

The calibration, inspection, and audit intervals of the sensing device and the data transmission and processing systems should be defined based on the required and specified accuracy and temporal changes, as should the interval between calibrations of electrical modules (which may present drift). Additional audits are necessary when the weather conditions (e.g., storms or snowfall) could affect the measurement process and/or the results obtained. Table 9.16 lists the maximum intervals between audits for standard meteorological measurements.

If regular weekly audits (see Table 9.16) of the equipment and the results of quality control (Sect. 9.6) indicate that the measuring and recording equipment is malfunctioning, immediate and more extensive inspections are necessary, as described in the other rows of Table 9.16. If the cause cannot be identified and remedied, the sensor should be replaced.

Table 9.16 Maintenance of wind-measuring systems (updated from [9.3])

Maximum interval	Wind direction (wind vane)	Wind speed (rotation anemometer) ^a	Wind velocity and direction (sonic anemometer)
One week	Time control for digital recordings (time correction where required) Inspection of the data transmission Approximate review of the readings		
Six months	Inspection of the equipment carrier, including the sensing device and its mounting Inspection of the ambient conditions		
		Comparison of the measuring instrument with the reference instrument	
Two years	Inspection of the positioning Sensor calibration		Inspection of the zero-point drift [9.41]
If a check indicates that there is a possible malfunction, the instrument should be replaced			
^a Similar actions for thermal anemometers			

9.8 Application

Wind data are widely used in science, weather prediction, the economy, and technical applications. From an economic perspective, wind climatology is useful for mitigating the damage caused by storm events, and for providing specific forecasts for wind power stations (see Chap. 51). Several technical processes are controlled by wind measurements, such as indoor climate control. All of these examples require precise standard measurements by meteorological stations and/or specific measurements performed near the objects of interest. For many purposes like wind power, building, and construction industry, special recommendations from international and national organizations are available.

Part E of this handbook discusses several methods that require wind data as input. Table 9.17 provides an overview of these methods and the wind measurements they require.

9.8.1 Climatology of Wind Parameters

As mentioned above, mean values of wind speed and direction over climatological periods of weeks, months, and up to 30-year periods are often meaningless, especially for the wind direction. The mean wind speed and its deviation from the long-term average are used to classify the availability of wind energy for wind power applications (see Chap. 51) during a particular period. Probability graphs that show the frequency distributions of different wind speed and wind direction classes (as

shown in Fig. 9.22) are much more useful. Such a graph allows the frequency of a certain wind speed or wind direction class to be determined for a potential application or site description. A frequency distribution such as that shown in Fig. 9.22b is also often presented in polar coordinates (a plot known as a *wind rose*, see Fig. 9.23a). Indeed, the wind-speed frequency distributions for particular wind-direction classes may be plotted in a similar manner (Fig. 9.23b). Such graphs can aid the interpretation of wind data for all wind-dependent processes. They are drawn for climatological periods (30 years) but should not be used for periods of less than ten years when attempting to characterize a site. Homogeneity of instrumentation and site conditions is required. For other purposes, shorter periods are possible.

9.8.2 Geostrophic Wind: Daily and Annual Cycles

The wind field is generated by differences in the amount of solar heat received by different regions of the Earth with the consequence of high- and low-pressure areas in the atmosphere that are significantly modified near the ground and by the rotation of the Earth. Above the atmospheric boundary layer (see Chap. 1), the wind is unaffected by the Earth's surface. This wind is called the geostrophic wind, and its speed can be calculated from the pressure gradients. For a positive Coriolis pa-

Fig. 9.23a,b Typical frequency distributions for the wind direction and wind speed plotted in polar coordinates (wind roses). Plot (a) shows the overall frequency distribution for the wind direction; the distance from the center of the plot is the relative frequency (in %) of the wind-direction class of interest. Plot (b) shows the frequency distribution (0.0–1.0) of the wind-speed as a function of the wind-direction class. Here, the distance from the center of the plot is the wind speed. In these plots, the wind direction and wind speed are split into classes 10° and 1 m s^{-1} wide, respectively (after [9.3] with permission from VDI e.V., Düsseldorf, Germany)

parameter f , the longitudinal component is

$$\overline{u}_g = -\frac{1}{\rho f} \frac{\partial p}{\partial y} \quad (9.43)$$

and the lateral component is

$$\overline{v}_g = \frac{1}{\rho f} \frac{\partial p}{\partial x}, \quad (9.44)$$

where ρ is the air density, p is the pressure, and

$$f = 2\Omega \sin \varphi, \quad (9.45)$$

in which Ω is the angular velocity of the rotation of the Earth and φ is the geographical latitude. Geostrophic wind data can also be derived from pressure observations by meteorological stations and are available in databases.

Within the atmospheric boundary layer and near the ground, the wind speed typically exhibits a daily cycle with low wind speeds at night (when there is stable stratification of the atmosphere) and high wind speeds during the day (when there are unstable and convective conditions). The opposite cycle can be observed on a mountain above the nighttime inversion (see Chap. 1): at this altitude, the wind speed is not affected by the roughness of the Earth's surface, but the wind is slowed during the daytime by thermal processes that occur near to the surface of the mountain. Both of these daily cycles are illustrated in Fig. 9.24.

The annual cycle of the wind speed depends on the climate zone considered. In the temperate zone, high wind speeds are typically seen during transition times (spring and autumn) when low-pressure areas dominate. In other climate zones, wind systems such as trade winds, the monsoon, or even the hurricane season influence the annual cycle.

9.8.3 Gusts

Gusts are sudden, brief increases in the wind speed [9.65] that are barely affected by the surface

Fig. 9.24 Daily cycle of the wind speed on Brocken, an isolated mountain (1142 m ASL) in Northern Germany, and the corresponding cycle about 75 km east of Brocken in the lowlands (Magdeburg, 76 m ASL) on 5 May 2018 during a high-pressure period (data from the DWD—the German Meteorological Service)

roughness or obstacles. Gusts are reported when the peak wind speed is larger than 8 m s^{-1} , the difference between the peak and the lulls is larger than 4.5 m s^{-1} , and the duration of the peak is less than 20 s. Because gusts can potentially cause damage, it is important to record them with anemometers, which requires a measurement range that reaches up to 150 m s^{-1} and an output averaging time of 3 s [9.4]. The sampling frequency should be about 4 Hz [9.66]. The recommended accuracy is only 10% [9.4]. Gusts are the main type of wind that can affect barometric readings [9.67] (see Chap. 10). The gustiness or turbulence intensity can be calculated; for example, for the longitudinal wind component [9.65],

$$g_u = \frac{\sqrt{u'^2}}{U}, \quad (9.46)$$

where U is the magnitude (modulus) of the wind vector. The other wind components and the horizontal wind speed are defined analogously.

9.9 Future Developments

As also seen for other in-situ methods of obtaining atmospheric measurements, there has been a significant reduction in the variety of wind-measuring methods in recent decades. While hot-wire, laser, and Pitot anemometers are only applied for calibration purposes in laboratories, there has been an unmistakable shift from rotation anemometers to sonic anemome-

ters. The number of sonic anemometers available has increased significantly over the last two decades. Specially designed devices that can perform flux measurements and analyze trace gases are available (see Chap. 55), and most manufacturers of meteorological instruments offer 2-D sonic anemometers as individual devices or within compact combined instruments (see

Chap. 43). Thermal anemometers are not an alternative to sonic anemometers and are only used for a few special purposes. Even meteorological services have replaced their rotation anemometers and wind vanes with sonic anemometers, albeit only with 2-D instruments (3-D instruments would offer more possibilities, including the ability to examine the stratification of the atmosphere). Only the wind power industry still recommends the use of rotation anemometers [9.57], and it has directed effort into increasing the accuracy of these instruments (see Chap. 51). Propeller

anemometers are only used in combination with wind vanes.

We can assume that this trend will continue, meaning that sonic anemometers will be the dominant devices used to measure the wind in-situ. Improving flow distortion correction (mainly the transducer correction; see Chap. 55) and facilitating multiple data analysis of all possible measurement paths will increase data accuracy and availability. Furthermore, sensor heating is easier to achieve for sonic anemometers than for rotation anemometers.

Thomas Foken

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

Jens Bange

Centre for Applied Geo-Science
University of Tübingen
Tübingen, Germany
jens.bange@uni-tuebingen.de

Jens Bange is a Professor for Environmental Physics at the University of Tübingen since 2010. He received a PhD in meteorology in 1998 and a diploma in physics in 1992 at the University of Hannover. His research interests include atmospheric turbulence, boundary-layer meteorology, wind-energy research, airborne meteorology, and environmental measurement technology. He is a founding member of the research networks ISARRA and WindForS.

Pressure Sensors

10. Pressure Sensors

Anni Torri, Thomas Foken , Jens Bange 

For measurements of the pressure of the atmosphere, the different techniques in use include liquid barometers, aneroid barometers, and electronic barometers. The history and theory of all these methods is described. Electronic sensors, such as piezoresistive pressure sensors, capacitive pressure sensors, and resonant pressure sensors have recently become the most used devices. Some types are also applicable for turbulence measurements. Besides technical data, the necessary maintenance associated with different methods, as well as the methods of quality control and calibration, are presented.

Pressure is probably the most important meteorological variable because pressure information is necessary for weather prediction and the determination of mean circulation patterns in climatology. The beginning of meteorological measurements is also connected to the first barometer constructed in 1643 by *Torricelli*. However, pressure measurements are also necessary for a wide range of measurement instruments, because many phys-

ical parameters are pressure dependent. Besides the pressure at a certain time and place, the reduced pressure at sea level [10.1] (extrapolated to sea level) is important for regional comparisons. In recent times, classical instruments like liquid mercury barometers—because of regulations for the use of the toxic substance mercury—and aneroid barometers have been widely replaced by electronic instruments.

10.1 Measurement Principles and Parameters

While the hectopascal is the accepted unit for atmospheric pressure in the SI system, other units are still in use, and the number of measurement principles is quite large for this standard parameter in meteorology.

10.1.1 Pressure Units and Quantities

Pressure measurement instruments, in general, measure absolute, gauge, and differential pressure. In meteorology, atmospheric pressure is the most important pressure quantity. Atmospheric pressure is an absolute pressure: the weight of atmosphere per area at a certain time and place. The other pressure measure used in meteorology is pressure trend (Table 10.1). Pressure trend describes the amount of change in pressure over certain time period.

Atmospheric pressure is closely related to altitude in the atmosphere. There are pressure-related calculated parameters used in aviation to describe the height related to a reference level or sea level in pressure, such as HCP (height corrected pressure) or QNH (atmospheric pressure adjusted to sea level).

Independent from the principle of measurement, the pressure (symbol p) is recalculated in meteorology mainly in hectopascals. The International System of Units (SI) unit for pressure is pascal (Pa) or N m^{-2} (Chap. 5). In meteorology, the prefix *hecto* is accepted, with the pressure being given in hectopascals (1 hPa = 100 Pa). This is largely because one hectopascal equals one millibar (mbar), the formerly used unit [10.1]. In some Anglo-American countries, the kilopascal (1 kPa = 1000 Pa = 10 hPa) is also used. Older scales of barometers are graduated in millimeters or inches of mercury under standard conditions ($(\text{mm Hg})_n$ or $(\text{in Hg})_n$), often reduced to millimeter mercury or inch mercury. Standard conditions are 1013.250 hPa, 0.0 °C, and a gravitational acceleration of 9.80620 m s^{-2} [10.2], for which the column of mercury has a height of 760 $(\text{mm Hg})_n$. The units still in use are given in Table 10.2.

10.1.2 Principles of Measurements

There are many kinds of barometers, all of which measure the same quantity, namely atmospheric pressure, but in different ways. Most pressure sensors trans-

form mechanical input to a measure of pressure. This involves either a movement of a film or change in vibration or level of a liquid. The form of the output signal leads us to divide pressure sensors into several groups, as listed in Table 10.3.

10.1.3 Site Considerations

Pressure measurements are typically made indoors or in dry cabinets or enclosures. Influencing factors on the instruments, like radiation, temperature, wind, vibration, must be excluded according to the particular type of instrument. The exact height above sea level of the sensor must be determined.

Table 10.1 Measured parameters of pressure sensors

Parameter	Description	Unit	Symbol
Pressure	Atmospheric pressure on a given surface	hPa	p
Pressure trend or pressure difference	Pressure tendency of trend is the amount of atmospheric pressure change for a 3 h or other specified period ending at the time of observation	hPa per time unit	$\Delta p, p3h$

Table 10.2 Transformation of pressure units (only pascal is a valid SI unit) [10.1]

Unit	hPa	kPa	$(\text{mm Hg})_n$	$(\text{in Hg})_n$
hPa	1	10	1.333224	33.863867
kPa	0.1	1	0.1333224	3.3863867
$(\text{mm Hg})_n$	0.750062	7.50062	1	25.4
$(\text{in Hg})_n$	0.029530	0.29530	0.03937008	1

Table 10.3 Principles of pressure measurements and applications for pressure and pressure tendency

Measuring device	Method			Application

Mercury barometer	×			×	×
Hypsometer		×		×	(×)
Resonator	×			×	×
Aneroid	×			×	×
Electronic	×		×	×	×

10.2 History

The first instruments to measure the atmospheric pressure, dating back to the sixteenth century, were mainly liquid barometers. In the seventeenth century, aneroid barometers and pressure hypsometers followed, while electronic barometers are developments of the twentieth century.

10.2.1 Liquid Barometers

The principle of the liquid barometer has been known since ancient times even though the reason for different levels of a liquid in a cistern with two limbs, where one limb was closed, could not be explained. These instruments are known as weatherglasses or Goethe barometers (Fig. 10.1), and are still available as objects of art for decoration.

Systematic investigations with water and mercury began in the sixteenth century [10.3–5], but at that time problems arose because the existence of the vacuum and the weight of air were unknown. Under the influence of *Galileo Galilei* (1564–1642) at the beginning of the seventeenth century, *Gasparo Berti* (about 1600–1643) and *Raffaello Magiotti* (1597–1656), working in Rome, built a water barometer with a water cistern on the ground and a 10 m long vertical tube with taps at both ends. The tube was filled with water and the upper tap was closed. After opening of the tap near the cistern, the development of a vacuum in the upper part of the tube was observed. Successful experiments with mercury were carried out by *Evangelista Torricelli* (1608–1647), and in about 1643/1644, he developed the

Fig. 10.1 The weatherglass or Goethe barometer. Above the liquid in the cistern of the instrument shown is a gas with a pressure lower than the ambient pressure

mercury barometer. *René Descartes* (1596–1650) and *Blaise Pascal* (1623–1662) assumed that the pressure decreases with increasing altitude. On September 19, 1648, *Florin Périer* (1605–1672) showed this on an ascent of the Puy de Dôme (1465 m). Later, *Robert Boyle* (1627–1691) and *Robert Hooke* (1635–1703) found that the air pressure change is associated with a change of weather phenomena.

Torricelli's experiments with different evacuated tubes at different inclinations showed that the height of the mercury column above the level in the cistern is independent of the form of the tube, which is called the hydrostatic paradox. Immediately after his experiments, different designs of barometers were built [10.5] aiming at a better resolution of the indication scale; *Samuel Morland* (1625–1695) built a barometer with an 88.5° inclined tube to attain a 2.75 m scale length. Hooke combined the open limb of the U-tube with a float and a pointer hand (Fig. 10.2a) in 1665. *Jean Hyacinthe de Magellan* (1723–1790), and possibly Morland some time earlier, made significant changes to a scale barograph (Fig. 10.2b), whereby the weight of the mercury in the tube above the level in the cistern was determined. In addition, two-liquid (e.g., Descartes) and three-liquid (e.g., Hooke) barometers were proposed. Both scientists used, instead of mercury, another less heavy liquid above the mercury level in the part of the tube at the scale. A special type with two liquids is the short tube barometer according to *Guillaume Amontons* (1663–1705) built in 1688 (Fig. 10.2c). An improvement of all barometer types was the so-called *Bunten's* tip (Fig. 10.3) developed in Paris in 1828, which is still in use. An air trap above the tip collects any air that has entered the barometer and prevents it from reducing the vacuum.

Two types of the mercury barometers with cisterns were in use until recent times. The so-called Kew-pattern barometer, designed about 1850 by *John Welsh* (1824–1859), has a fixed cistern, and the barometer scale is constructed so that it allows changes of the level of mercury in the cistern [10.6]. More popular is the Fortin barometer (*Jean Nicholas Fortin*, 1750–1831), where the level of the mercury in the cistern can be adjusted with an ivory pointer [10.4] (Sects. 10.3.3 and 10.4.1).

10.2.2 Aneroid Barometer

In a letter to *Johann Bernoulli* (1667–1748), in 1698, *Gottfried Wilhelm Leibniz* (1646–1716) discussed his idea of using an evacuated box to measure the pressure as a replacement for the not easy to use Torricelli barometer [10.4, 7]. After several unsuccessful developments, such as the marine barometer in 1763 by *Johann Ernst Zeiher* (1725–1784), it was not until

Fig. 10.2a–c Different functional principles of the mercury barometer (after [10.5] with permission from R. Holland): (a) barometer using a hand indicator (R. Hooke); (b) scale barometer (J.H. de Magellan); (c) two-liquid barometer with reduced tube length (G. Amontons); mercury is in tubes 1 and 3 and the lower parts of types 2 and 4; the other liquid has a much lower weight

Fig. 10.3 Bunten's tip (after [10.5] with permission of R. Holland (L: air trap, S: tip))

1844 that *Lucien Vidie* (1805–1866) constructed the first aneroid barometer, which was patented in the same year in London and Paris. He used a strong evacuated brass chamber with a corrugated diaphragm. The force against the air pressure was achieved with 33 helical springs. In a later French patent (1845), he used an external spring; one of the first instruments is shown in Fig. 10.4. In a patent of 1858, he used a split C-form leaf spring. Both systems are still in use (Sect. 10.3.4).

At nearly the same time, *Eugène Bourdon* (1806–1884) used an evacuated curved type tube with an elliptical cross section, which was patented in France in 1849 and is called the Bourdon tube. The instrument is rarely used in meteorology except for balloon soundings and calibration, but it is still the basis for manometers. After a 10-year legal struggle, Vidie was finally accepted as the inventor of the aneroid barometer and could use the name for his instrument (1858). Both instruments were shown at the world exhibition of 1851 in London.

Two changes were made in the second half of the nineteenth century. First, the use of a spiral spring inside an evacuated brass box to provide a force against the atmospheric pressure was developed by *Antoine Redler* (1817–1892), who built the first instruments for

Fig. 10.4 View of the first Vidie barometer with external spring (1845) (photo © R. Holland)

Vidie, and second, a bimetal spring for temperature correction was introduced by *Otto Bohne* in 1863 in Berlin.

10.2.3 Hypsometer

The hypsometer was one of *Alexander Humboldt's* (1769–1859) instruments during his expedition to Latin America (1799–1804) [10.8] and uses the dependence of the boiling point of water on the pressure. Less is reported about this instrument in textbooks of the history of meteorology. A short history and full description was found in [10.9]. The first description of thermometers used for measurement of the boiling point of water and, therefore, the air pressure came from *Daniel Gabriel Fahrenheit* (1686–1736) in 1724 [10.11] and *Tiberius Cavallo* (1749–1809) in 1781 [10.12]. After the first theory of evaporation by *John Dalton* (1766–1844) in 1810, *Francis John Hyde Wollaston* (1762–1823) improved the instrument in 1817 [10.13]. The temperature measurement was no longer made in boiling water but in the water steam above it, and a reservoir was included in the thermometer capillary to enlarge the scale within

Fig. 10.5 A cross-sectional view of a silicon pressure sensor from the early 1970s (after [10.10] with permission from Emerald Publishing Limited). Note the planar (non-microengineered) diaphragm mounted on the support ring and the diffused rather than implanted *gauges* (piezoresistors)

the relevant temperature range. However, the theory behind the hypsometer was founded in 1834 by *Émile Clapeyron* (1799–1864). Hypsometers were used for pressure measurements during balloon expeditions and as pressure sensors in radiosondes [10.14] up to the end of the last century but are now no longer used [10.1].

10.2.4 Electronic Barometers

The transition from mercury barometers and aneroids to electronic barometers started with the combination of metal aneroids with an electronic measurement circuit. The reading of an indicator by the human eye or the print on a barograph were replaced by an electronic output connected to a computer or a digital display in the next step.

In the 1960s, silicon technology enabled the development of silicon pressure sensors. Earlier, the effect of piezoresistance in silicon was discovered in 1954 by

Table 10.4 Selected historical length scales for pressure measurements [10.5]

Country	Period of time in use	Name	Length (cm)	Scale divider	Name	Length (mm)	Scale divider
France	up to 1840	Pied de Roi	32.433940	12	Pouce	27.070	12

C.S. Smith [10.15]. This was the starting point of the development work to replace bulky electromechanical sensors with MEMS (microelectromechanical system) sensors [10.16, 17]. Figure 10.5 shows one of the first piezoresistive silicon MEMS sensors.

In the early days, thin silicon diaphragms were first manufactured by drilling and later—in the 1970s—by anisotropic etching of silicon [10.18]. Anisotropic etching enabled the development of silicon capacitive sensors in the late 1970s [10.19, 20].

10.3 Theory

After some basics about static and dynamic pressure and the pressure correction at sea level follows the theory of all relevant measurements methods.

10.3.1 Static and Dynamic Pressure

The basis for the understanding of the static and the dynamic pressure of a flow (e.g., the atmosphere) is the Euler momentum conservation equation [10.21–23] for an adiabatic and inviscid flow with velocity \mathbf{u} and the time t

$$\begin{aligned} \frac{d\mathbf{u}}{dt} &= \frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u}\nabla)\mathbf{u} \\ &= -\text{grad } \Phi - \frac{1}{\rho} \text{grad } p = 0. \end{aligned} \quad (10.1)$$

In a length scale regime of in-situ measurements, the influence of the Earth's rotation can usually be neglected. This is why (10.1) does not contain the Coriolis force but only the air density ρ and gradients of pressure p and geopotential Φ . Since turbulence and any fast changes at any fixed location are excluded in the experimental setup, stationarity ($\partial \mathbf{u} / \partial t = 0$) can be assumed, leaving only the advection term on the left-hand side of (10.1)

$$(\mathbf{u}\nabla)\mathbf{u} = -\text{grad } \Phi - \frac{1}{\rho} \text{grad } p. \quad (10.2)$$

Applying the Weber transformation [10.24]

$$\text{grad } |\mathbf{u}|^2 = 2(\mathbf{u}\nabla)\mathbf{u} + 2\mathbf{u} \times (\text{rot } \mathbf{u}) \quad (10.3)$$

and assuming that the flow is not rotating ($\text{rot } \mathbf{u} = 0$) the Eulerian equation (10.1) transforms to

$$\begin{aligned} (\mathbf{u}\nabla)\mathbf{u} &= \frac{1}{2} \text{grad } |\mathbf{u}|^2 \\ &= -\text{grad } \Phi - \frac{1}{\rho} \text{grad } p. \end{aligned} \quad (10.4)$$

10.2.5 Historically Relevant Pressure Units

Because of different length scales in different countries, pressure measurements were not comparable before the metric system was applied in most countries in the nineteenth century. The inch is still in use in only some Anglo-American countries (Table 10.2). A selection of historically relevant length scales—which were used for barometer scales—is given in Table 10.4.

Finally, assuming a divergence-free, i.e., incompressible flow (sound waves are neglected), the nabla operator can be pulled out

$$\text{grad} \left(\frac{|\mathbf{u}|^2}{2} + \frac{p}{\rho} + \Phi \right) = 0. \quad (10.5)$$

Integration in space provides the commonly known Bernoulli equation [10.23]

$$\rho \frac{|\mathbf{u}|^2}{2} + p + \rho \Phi = \text{const}. \quad (10.6)$$

Bernoulli's equation (10.6) shows that kinetic (first term) and potential (second and third term) energy are in balance. That is, in an incompressible and non-rotating stationary flow, at each location (here locations 1 and 2) the sum of potential and kinetic energy must be the same

$$\rho \frac{|\mathbf{u}_1|^2}{2} + p_1 = \rho \frac{|\mathbf{u}_2|^2}{2} + p_2, \quad (10.7)$$

and if the measurement situation position 1 is not too far away from position 2, so that the geopotential Φ is the same at both locations and disappears in (10.7). A pitot tube (also known as a Prandtl tube [10.24], see Chap. 9), measures the total p_{stag} in a bore hole at the tip (stagnation point) of a tube pointing directly into the fluid flow with velocity \mathbf{u} . At the tip the velocity is, of course, zero. Thus, (10.7) becomes

$$p_{\text{stag}} = \rho \frac{|\mathbf{u}|^2}{2} + p_s. \quad (10.8)$$

i.e., the pressure p_{stag} at the stagnation point is the sum of both kinetic and potential energy, with the latter expressed by the static air pressure p_s .

Now, a pitot-static tube has an additional bore hole along the tube, where the flow is assumed to be undisturbed, and the static air pressure p_s can be expected.

The pressure difference between the tip and this static port is identical to the dynamic pressure enhancement

$$p_q = p_{\text{stag}} - p_s = \rho \frac{|\mathbf{u}|^2}{2} \quad (10.9)$$

and can be used to calculate the fluid velocity $|\mathbf{u}|$ for given air density ρ (Chaps. 9, 48, and 49).

However, any instrument assigned to measure the static air pressure only has to make sure that no dynamic pressure enhancement p_q disturbs the measurements. That is, at the position of any static-pressure sensor the component of the flow velocity \mathbf{u} perpendicular to the sensor has to be insignificant (see also the principle of a static head in Sect. 10.3.2).

10.3.2 Corrections

A comparison of pressure measurements from different locations with different altitudes requires that they are reduced to sea level. Furthermore, the possible influence of the wind velocity must be corrected or excluded.

Reduction of the Pressure to Sea Level

The air pressure is a function of the height and the temperature given by the hydrostatic equation [10.21, 22]

$$dp = -g\rho dz, \quad (10.10)$$

with the pressure p in Pa, the height z in m, the gravity acceleration g in m s^{-2} , and the air density ρ in kg m^{-3} . The latter is given by the gas equation

$$\rho = \frac{p}{R_d T_v}, \quad (10.11)$$

where R_d is the gas constant of dry air ($287.059 \text{ J kg}^{-1} \text{ K}^{-1}$) and T_v the virtual temperature in K (Chap. 7). Because of the dependence of the temperature and gravity acceleration on height, a standard gravity acceleration (Chap. 5; for pressure correction $g_0 = 9.80620 \text{ m s}^{-2}$ is recommended [10.1, 2]) and a mean virtual temperature are applied. Instead of the height in m, the geopotential height Z is used ((1.11); see Chaps. 1 and 5; below 1500 m the difference between the geometric height, and the geopotential height is $< 1 \text{ m}$ [10.25]). From the integration of (10.10), it follows that ((1.12))

$$p_0 = p_s \exp \frac{g_0 Z_s}{R_d T_{\text{mv}}}, \quad (10.12)$$

with the pressure at sea level p_0 in hPa, the pressure at the station level p_s in hPa, the height of the station above

sea level Z_s in gpm ($1 \text{ gpm} = 9.8 \text{ m}^2 \text{ s}^{-2}$), and the constant (in practice, the mean is used) virtual temperature of a column from the sea to the station level T_{mv} in K, which can be calculated as [10.1]

$$T_{\text{mv}} = T_s + \frac{aZ_s}{2} + cE_s, \quad (10.13)$$

with the temperature at the station T_s in K, the water vapor pressure of saturation at the station E_s in hPa, and the mean gradients $a = 0.0065 \text{ K gpm}^{-1}$ and $c = 0.12 \text{ K hPa}^{-1}$. A factor for the reduction of the pressure to sea level is given in Table 10.5.

For heights below 50 m, the pressure correction can be done with a constant value [10.1]

$$p_0 = p_s \left(1 + \frac{Z_s}{29.17 T_{\text{mv}}^*} \right), \quad (10.14)$$

where T_{mv}^* is the mean annual normal value of the virtual temperature at the station in K.

The pressure reduction according to the standard atmosphere [10.25] uses a temperature at sea level of 15°C .

Wind Correction

The air flow around buildings or the housing of the barometer can, according to the Bernoulli equation, generate pressure fluctuation [10.26, 27], e.g., 0.4 hPa for a wind velocity of 8 m s^{-1} [10.27] or 5 hPa for a wind velocity of 45 m s^{-1} [10.26] are reported in the literature. This can be corrected by sampling with a static head [10.28], shown in Fig. 10.6. Aneroid and electronic barometers can simply be connected to a static head, which should be located in an open environment not affected by buildings, etc. For measurement of the turbulent pressure fluctuations, static heads are required [10.29]. Static heads are commercially available, but comparisons are still an outstanding issue [10.1].

10.3.3 Liquid Barometers

The physical basis of liquid barometers is the hydrostatic equation (see, also (10.10))

$$\Delta p = \rho g \Delta h, \quad (10.15)$$

where h is the height of the liquid column. According to (10.11), the density is a function of the temperature, see Chap. 5. Therefore, temperature and gravity corrections are necessary. In order to obtain acceptable column heights (less than 1 m) for the pressure difference between vacuum and normal pressure at sea level, mercury was selected as a liquid due to its high density ($1.35951 \times 10^4 \text{ kg m}^{-3}$ at 0°C [10.1]). Instead

Table 10.5 Factor for the pressure reduction to sea level according to (10.12); the geopotential height is identical with the geometric height in m with an error lower 1 m

Fig. 10.6 Schema of a static pressure probe (static head) (after [10.28] with permission of the American Meteorological Organization)

of U-tubes, systems with a large cistern for the liquid under ambient pressure and a thin tube with vacuum are applied (Fig. 10.7a). The air pressure balances the

weight of mercury in the tube, which is equal to the weight of the air column. The expansion or contraction of tubes and mercury due to temperature changes and gravity must be corrected (Sect. 10.4.1).

Because the pressure is proportional to the height of the mercury in the tube between the upper level in the tube and in the cistern, a fixed scale is not practicable. Therefore, barometers with a movable scale of the Kew-pattern barometer type and with a fixed scale and an index of the Fortin barometer type are in use (Fig. 10.7b). The latter has an adjusting screw that moves a membrane so that the upper level of the mercury in the cistern is always at the same height.

10.3.4 Aneroid Barometers

The aneroid barometer has remained nearly unchanged since the middle of the nineteenth century, except for the use of new material and small modifications.

Fig. 10.7a,b Principle of a liquid barometer (a) and barometer scales (b) (after [10.30] with permission from VDI e. V. Düsseldorf, Germany)

A theoretical equation for the calibration of an aneroid barometer is [10.31, 32]

$$p = \frac{16Et^4}{3R^4(1-\nu^2)} \left[\frac{y}{t} + 0.488 \left(\frac{y}{t} \right)^3 \right], \quad (10.16)$$

with the pressure p in Pa, the modulus of elasticity E in N m^{-2} , the deflection of the diaphragm center y in m, the diaphragm thickness t in m, the diaphragm radius R in m, and Poisson's ratio ν , which for metals is $1/3$. The deflection ratio y/t of the diaphragm is a linear function of the pressure in the case of a coated diaphragm, or a curved line for a flat-plane diaphragm.

Mainly two mechanical systems are employed [10.33], which are shown in Fig. 10.8: first the system with the external spring (Vidie, 1845) and secondly an instrument with a split C-form leaf spring (Vidie, 1858). The screw is necessary to reduce the pressure to sea level and for calibration.

10.3.5 Hypsometer

The theory of the hypsometer is based on the Clausius–Claperyon equation [10.21, 22], see Chap. 8, even though the instrument was developed earlier

$$e(T) = e_0 \exp \left(\frac{\lambda_w}{R_w T_0} \frac{T - T_0}{T} \right), \quad (10.17)$$

with the water vapor pressure e at the temperature T , the water vapor pressure e_0 at the temperature $T_0 = 273.15 \text{ K}$ (6.112 hPa), the heat of evaporation λ_w , and the gas constant of water vapor R_w , see Chap. 5. It is evident that the hypsometric method is one of the most direct methods of pressure measurements, not requiring any further corrections. For the calculation of the altitude from the pressure measurements, the barometric equation should be used (Sect. 10.3.2).

10.3.6 Electronic Barometers

Electronic barometers convert ambient pressure to an electrical signal. Electronic pressure sensors are available over a wide pressure range from vacuum pressure sensors to heavy industry pressure measurement needs. The variety of the different kinds of electronic pressure sensors is also large. In this section, only barometric sensors and three different pressure measurement methods are discussed more in detail: piezoresistive, capacitive, and resonant sensors.

Piezoresistance

The effect of piezoresistance is similar to the strain gauge effect in a metal material, but there is a fundamental difference: the metal strain gauge effect is caused by geometric deformation of the resistor, whereas the piezoresistance is caused by the change of resistivity of the material. In addition, piezoresistivity is, in general, anisotropic and is typically two orders of magnitude larger [10.34].

In the fabrication of piezoresistive sensor chips of silicon, micromachining technologies are used. Micromachining—referring to the dimensions of the mechanical structures processed—can be controlled to an accuracy of microns. The piezoresistive sensor contains a silicon chip with a thin square, rectangular, or circular diaphragm and four piezoresistors [10.35]. Pressure causes the diaphragm to flex, inducing a stress on the diaphragm and also on buried piezoresistors. The resistors are located near the edge center of the bending film, where the maximum stress occurs.

The change in pressure (mechanical input) is converted to a change in resistance (electrical output). The thickness of the film is chosen to match the required pressure sensor range.

The sensor's resistors can be connected in a Wheatstone bridge configuration or a four-terminal structure. These circuits are chosen because of the small size of

Fig. 10.8a,b The mechanic of the aneroid barometer (after [10.33] with permission of R. Holland): (a) an external spring and (b) a split C-form leaf spring, both according to Vidie

the piezoresistive effect compared with the temperature dependency of a silicon resistor.

The output of this kind of sensor in a Wheatstone bridge is [10.34]

$$V_{out} = 0.51(1 - \nu)p \frac{a^2}{h^2} \pi_{44} V_S, \quad (10.18)$$

where V_S is the supply voltage of the bridge, π_{44} the piezoresistive coefficient of silicon—a function of the doping level of silicon and crystal orientation, a the half width of the diaphragm, h the thickness of the diaphragm, p the applied pressure, and ν the Poisson ratio of silicon.

In general, the output is

$$V_{out} = \frac{\Delta R}{R} V_S, \quad (10.19)$$

where the relative change of piezoresistance depends on the stress on the resistor, material properties, and geometry.

Capacitive Pressure Sensors

The first capacitive pressure sensors had metal diaphragms, but micromechanical sensors with silicon diaphragms are now becoming more popular due to their reliability and good long-term stability. Ceramic

materials like alumina are also used as a material for capacitive pressure sensors, especially in industrial applications.

A commonly used structure for a capacitive pressure sensor has two parallel plates of conductive material, one fixed and the other a flexible diaphragm (Fig. 10.9). Applied pressure causes the diaphragm to deflect and changes the capacitance. The thickness of the bending diaphragm and dielectric material between the plates defines the pressure measurement range. A strength of this technique is the low temperature dependence of the measurement signal compared with piezoresistive sensors.

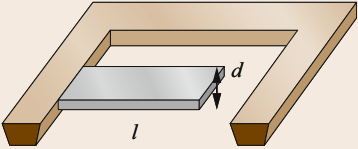

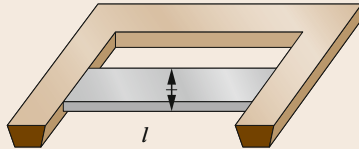

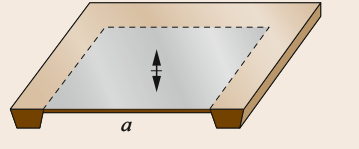

Fig. 10.9 A schematic figure of a capacitive sensor structure; for symbols see text (after [10.36] with permission from Pearson Prentice Hall)

Table 10.6 Three basic resonant structures and their fundamental flexural resonance frequencies f_0 , where E is Young's modulus, ρ the air density, and ν Poisson's ratio (after [10.37] with permission from IOP Publishing)

Beam	Bridge	Diaphragm
		
$f_0 = 0.162 \frac{d}{l^2} \sqrt{\frac{E}{\rho}}$	$f_0 = 0.615 \frac{d}{l^2} \sqrt{\frac{E}{\rho(1-\nu^2)}}$	$f_0 = 1.654 \frac{d}{a^2} \sqrt{\frac{E}{\rho(1-\nu^2)}}$

The relationship between the applied pressure P and the relative capacitance change $\Delta C/C$ due to deflection y of the diaphragm is

$$\frac{\Delta C}{C} = \frac{(1-\nu^2)a^4}{16Edt^3}P, \quad (10.20)$$

where a is the diaphragm radius, t is the diaphragm thickness, $E = \text{Young's}$ modulus, p is the applied pressure, and d is the initial separation of the plates.

The above equation is a first-order estimate of the capacitance change, especially if the size of the capacitor is small as in surface micromachined sensors. For small parallel plate capacitor structures, the so-called edge effect of the electric field becomes remarkable.

Resonant Pressure Sensors

Resonant pressure sensors use a resonating mechanical structure to sense the deflection of the pressure-sensitive structure (e.g., diaphragm, bellow, tube). Applied pressure causes a change in the resonant frequency of the oscillation. There are several different ways to excite and detect the oscillation of the resonator [10.37], Table 10.6.

Single crystal quartz is a common choice of material for resonant pressure sensors due to its good stability and low hysteresis. In academic studies, other piezoelectric materials like PZT (lead zirconate titanate) or ZnO-coated silicon have also been used as res-

Fig. 10.10 Electrostatic excitation principle for a cantilever beam (electronic excitation and capacitive detection) (after [10.37] with permission from IOP Publishing)

onator materials. For piezoelectric materials like quartz, resonant sensors rely on the piezoelectric effect. In a piezoelectric material, an applied electric field causes a mechanical strain in the material. This effect can be used to excite a resonator (i.e., piezoelectric excitation).

Electrostatic Excitation Principle

Polysilicon and single-crystal silicon are also widely used as resonator materials. For silicon resonators, an electrostatic excitation is used. The principle of excitation and detection of vibration can be seen in Fig. 10.10 for a cantilever.

10.4 Devices and Systems

There is a trend towards the application of electrical sensors, but liquid barometers and aneroid barometers are still in use and are described in the following section as well.

10.4.1 Liquid Barometers

Because of international regulations, instruments with toxic mercury are no longer allowed to be produced,

sold, or applied [10.38, 39]. Only historical instruments may be used as reference instruments or shown for demonstration. Therefore, the following section about mercury barometers is only of interest for historical data. Furthermore, some alternative instruments are shown.

Mercury Barometer

The principle construction of a barometer of the Fortin type is shown in Fig. 10.11 together with a produced

Fig. 10.11a,b Mercury barometer of the Fortin type: (a) schematic view (after [10.30] with permission from VDI e. V., Düsseldorf, Germany); (b) sensor (photo © Theodor Friedrichs & Co., Schenefeld, Germany)

model. Because of the restrictions on application, only the sensor-specific corrections and the pressure reduction to normal conditions (sea level and 0 °C) may be of further relevance.

The pressure readings on the mercury barometer p_m must first be temperature corrected for the cubic thermal expansion of mercury $\alpha = 1.818 \times 10^{-4} \text{ K}^{-1}$ and the linear thermal expansion of the scale (e.g., for alloy of brass and nickel silver, $\beta = 0.184 \times 10^{-4} \text{ K}^{-1}$). Secondly, the volume correction of the mercury must be done with the coefficient of linear thermal expansion of the cistern η and the total volume of mercury in the fixed-cistern barometer V , and the effective cross-sectional area of the cistern A [10.1, 40]; for A and V , see the manufacturer's instructions,

$$p_t = -p_m(\alpha - \beta)t - (\alpha - 3\eta)t \frac{4V}{3A}. \quad (10.21)$$

The reduced pressure for the conditions of the barometer at sea level and 0 °C is

$$p_{\varphi H} = p_t \frac{g_{\varphi H}}{g_n}, \quad (10.22)$$

with the standard acceleration of gravity, $g_n = 9.80665 \text{ m s}^{-2}$ and the acceleration of gravity for a given geographical latitude φ [10.41]

$$g_{\varphi 0} = 9.80620(1 - 2.6442 \times 10^{-3} \cos 2\varphi + 5.8 \times 10^{-6} \cos^2 2\varphi). \quad (10.23)$$

Finally, a correction for the height of the station H is necessary

$$g_{\varphi H} = g_{\varphi 0} - 3.086 \times 10^{-6} H + 1.118 \times 10^{-6} (H - H'), \quad (10.24)$$

where H' is the mean altitude within a radius of 150 km around the station.

For synoptical applications, the pressure must be reduced to sea level according to (10.12) or Table 10.5.

When making an observation with a mercury barometer [10.1], the attached thermometer should be read first. This reading should be taken as quickly as possible. If the barometer is not of a fixed-cistern type, the necessary adjustment should be made to bring the

Fig. 10.12 Eco-celli barometer with the barometer on the *left-hand side* with red silicone fluid and a thermometer on the *right-hand side* (photo © Dingens Barometers and Clocks, Hechtel, Belgium)

mercury in the cistern into contact with the fiducial point. The vernier is correctly adjusted when its horizontal lower edge appears to be touching the highest part of the meniscus. The reading should be taken to the nearest 0.1 hPa. Usually, it is not possible to read the vernier to any greater accuracy.

Changes in index errors of mercury barometers may be caused by a drift due to variations in the capillary depression of the mercury surfaces as a result of contamination, due to a rise of air bubbles through the mercury column into the air trap (see Bunten's tip, Fig. 10.3), observer error resulting from failure to tap the barometer before taking the reading, or improper setting of the vernier or fiducial point. A change in correction within 0.1 hPa may be neglected unless persistent; a correction between 0.1 and 0.3 hPa may be provisionally accepted.

Mercury-Free Liquid Barometers

The principle of mercury-free liquid barometers is similar to that of the Goethe barometer (Sect. 10.2.1). The volume above the liquid reservoir is not evacuated and the height of the liquid column can be reduced even for liquids with high density, typically a silicon fluid. As an example, the Eco-celli barometer is shown in Fig. 10.12, with the U-tube of the barometer on the left and a ther-

Fig. 10.13 Ship's aneroid barometer with scales in hPa and in mmHg (photo © Feingerätebau K. Fischer GmbH, Drebach, Germany)

момeter that is necessary for temperature correction on the right. The left limb of the barometer is filled with gas and the liquid, while the right limb has the scale and is connected to atmospheric pressure. The resolution of the scale is larger than for mercury barometers. Such types of barometers are used for education and demonstration but not for science or meteorological observations.

10.4.2 Aneroid Barometers

The chambers of aneroid barometers are made from materials (steel or beryllium copper) that have elastic properties and can themselves act as springs. Typical are mechanical systems with hands (Fig. 10.8) that allow readings better than 0.2 hPa. Alternatively, a ray of light may be deflected over the scale. Instead of these mechanical analog techniques, certain barometers are equipped with a manually operated micrometer whose counter indicates the pressure directly in tenths of a hectopascal [10.1]. Aneroid instruments are portable and robust.

Mechanical aneroid barometers are still in use, but for meteorological stations and research, these instruments are replaced by electrical sensors. An example of a ship barometer is shown in Fig. 10.13. For private use, the instruments are available in many designs. Still in use at climatological stations are barographs using the aneroid principle (Fig. 10.14). The hand is replaced by a recording lever with a pen. For recording, the instru-

Fig. 10.14a,b Aneroid barograph: (a) schematic view (after [10.30] with permission of VDI e. V., Düsseldorf, Germany); (b) sensor (photo © Feingerätebau K. Fischer GmbH, Drebach, Germany)

ment has a clockwork (e.g., one turn per week) drum with recording paper. To increase the scale, a block of some aneroid chambers can be applied. All aneroid instruments are for indoor use but can also be used in dry conditions outdoors. To reduce errors caused by mechanical levers, optical and digital devices can improve the reading accuracy. The Bourdon tube is no longer applied for meteorological measurements, except for calibrations.

For practical application [10.1] the instrument should always be used in the orientation of the calibration (vertical or horizontal). The sensor should measure the pressure at the level of the instrument. Only over the ocean and for low land stations can a constant difference of the pressure at sea level and at the level of the instrument be assumed and corrected with the screw on the instrument. Temperature compensation can be assumed and a gravity correction is not necessary.

Possible errors [10.1] are a weakened spring or a change of the elasticity of the chamber. The first can be corrected with the bimetallic link in the lever system or by leaving a certain amount of gas inside the aneroid chamber. The second is the reason for hysteresis. Annual comparisons with standard barometers are required. Good instruments do not experience a change of the value within 1 year of more than 0.1 hPa.

The requirements for the barograph (Fig. 10.14) are similar [10.1]. The paper for registration should have a scale of 10 hPa per 1.5 cm so that the scale errors should not exceed 1.5 hPa. The instrument should be fully temperature compensated. The friction between the pen and the paper is important. To reduce errors

related to the pen, barographs have a large aneroid chamber. Good instruments do not experience a change in value within 1 or 2 months of more than 0.2 hPa.

10.4.3 Hypsometer

Since the description of the hypsometer by Wollaston in 1817 [10.13], no significant changes have been made. Figure 10.15 shows a hypsometer employed for balloon flights, with a water reservoir and a heater. The thermometer was placed in the tube, which was filled with water steam after boiling of the water. Above the bulb of the thermometer a small reservoir was included in the capillary to enlarge the scale.

For radiosondes, the hypsometer was miniaturized [10.14]. Instead of mercury-in-glass thermometers, electrical sensors such as thermistors [10.42] or thermocouples [10.43] were used, see also Chap. 46.

10.4.4 Electronic Barometers

The construction of electronic barometers can vary widely. Electronic pressure transmitters offer a wide variety of output options, both digital and analog. Most common analog output range is voltage output $V_{OUT} = 0-5$ V. The variety of digital output protocols used depends on the application field and continent. Displays and data logging features are available, and measurement parameters like sampling rate or averaging can be adjusted. One should check the unit's datasheet and manual for proper output scaling and protocol details.

Piezoresistive Pressure Transmitters

Silicon piezoresistive pressure sensors have been the most popular MEMS sensor over the past decades. These sensors are small in size, have a good linearity, and do not need any special signal processing (Fig. 10.16). Therefore, pressure transducers based on piezoresistive sensors are cheaper compared to capacitive and resonant sensors. They are widely used in commercial products like small weather stations and watches. A challenge with these sensors is the long-term drift in the resistors due to, for example, surface effects.

Piezoresistive sensors have a temperature dependency that has to be compensated. It is recommended to use transmitters with built-in temperature compensation over the operating temperature range. When the temperature sensor is placed next to the pressure sensor on

the circuit board, no bias error due to temperature difference between the pressure sensor chip and the temperature sensor used for compensation will occur. Note that the compensated temperature range is, in some cases, narrower than the operating temperature range for a transmitter. In choosing an electric pressure transmitter a careful comparison of datasheets is needed.

Overpressure is the maximum pressure applied to the pressure sensor without changing its output characteristics (pressure measurement performance). Piezoresistive sensors withstand an overpressure typically equal to a few times its full-scale pressure.

Capacitive Pressure Sensors

Silicon capacitive pressure sensors have high sensitivity, good long-term stability, and less temperature

dependence than piezoresistive sensors (Fig. 10.17). Capacitive barometric sensors exist with stabilities of 0.01%/year. For reference level measurements, the effect of temperature, although small, has to be compensated with a built-in temperature sensor. The response time of Si capacitive pressure sensors is short. A lower power consumption is a benefit, for example with solar power use in weather stations. Silicon capacitive sensors withstand overpressure well due to the elastic properties of silicon. They also tolerate mechanical shocks or vibration and, therefore, can also be used in buoys, radiosondes, and moving vehicles. Note that for

some transmitters, there is a difference in calibration if the device is mounted vertically or horizontally.

Parallel plate capacitive sensors are also manufactured from ceramic material and metal. Metallic sensors are widely used in heavy industrial applications.

Resonant Pressure Sensors

Several different sensor element technologies can be used in resonant pressure sensors. Piezoelectric-based transducers rely on the piezoelectric effect, which occurs when a crystal reorients under stress forming an internal polarization. These resonant pressure transducers (RPTs) use the piezoelectric effect to drive the quartz sensor into resonance, much like a quartz crystal oscillator (Fig. 10.18). Therefore, a pressure change will change the resonance frequency of the resonating structure. These sensors have high sensitivity and resolution. On the other hand, they can be quite fragile and large in size if there is, for example, a Bourdon tube as a force generating structure.

Silicon (or polysilicon) resonators manufactured using MEMS techniques are smaller in size and not as fragile as those using quartz resonators. One example of a silicon resonator structure in a pressure sensor ele-

Fig. 10.19 Schematic view of the RPT sensor, a silicon resonator (©DRUCK, a Baker Hughes Business, reprinted with permission)

ment can be seen in Fig. 10.19. In this multilayer sensor structure, there is a pressure sensitive diaphragm and a resonator of single-crystal silicon connected to the diaphragm. A pressure change causes a deflection of the diaphragm, which induces a change in the resonant frequency of the resonator.

These sensors are now the most accurate electronic pressure transducers, with an accuracy of 0.08 hPa at room temperature (15–45 °C). Due to their high sensitivity, these kinds of sensors can be used to detect very small dynamic changes in pressure, for example with infrasound. For instance, tsunamis, vol-

canic eruptions, large explosions, wind mills, and avalanches generate infrasound. Measurement of pressure differences at these frequencies can be used to detect these phenomena or events. A low noise level is also beneficial in these microbarometer applications [10.44].

10.4.5 Piston Gauge

Piston gauges are very accurate instruments with an uncertainty of about 0.05 hPa and can be used as primary standard for calibration. They have a very low drift and the calibration interval is about five years [10.1, 45]. They are available in accredited calibration laboratories or national metrology institutes.

The piston rotates without any lubrication in a cylinder driven by a motor. For absolute pressure measurements a vacuum gauge is necessary. Two systems are available.

Piston Gauges with a Dynamometer Gauge

The sensor undergoing calibration and the piston gauge are connected with a pressure hose. The preselected pressure is generated by the pressure controller and acts on the piston. This is connected to a dynamometer in an evacuated area that measures the force. The very low force due to the residual gas is negligible. The residual pressure of the vacuum is measured with a vacuum gauge and must be taken into account by the piston gauge controller. The pressure can be calculated with a temperature-corrected effective area and the measured force (Fig. 10.20a) [10.1].

Fig. 10.20 (a) Piston gauge with a dynamometer; (b) loaded piston gauge (after [10.1] with permission from WMO)

Table 10.7 Advantages and disadvantages of the different methods

Devices	Advantages	Disadvantages
Mercury barometer	Accurate reference instrument	Toxic mercury application no longer possible
Aneroid barometer	Easy to handle instrument, moderate accuracy	Normally no electrical output signal
Hypsometer	Accurate system without any corrections	Difficult to use, not for precise measurements near sea level
Piezoresistive pressure sensors	Small electronic sensor	Moderate accuracy, higher power consumption
Capacitive pressure sensors	Accurate electrical sensor with a good stability	
Resonant pressure sensors (quartz or silicon)	Accurate reference instrument	Laboratory size instruments (only quartz resonators)
Piston gauge	Highly accurate	Only for specialized calibration laboratories

Piston Gauges with a Loaded Piston

This piston gauge measures weight and not pressure and is, therefore, directly traceable to SI units. The piston is loaded with weights and, due to the absence of the dynamo, it has the lowest possible uncertainty.

The masses are lifted up by a pressure controller. At a certain height, a motor accelerates the piston with a temporarily connected belt. The motor stops at a certain speed after disconnection of the belt. Due to the low friction, the rotation speed remains nearly constant for up to about half an hour, de-

pending on the weight. The system is covered with an evacuated bell, and the residual pressure must be taken into account by the piston gauge controller (Fig. 10.20b) [10.1].

10.4.6 Comparison of the Methods

Because mercury barometers can no longer be used, and aneroid barometers are not accurate enough, the comparison of the different methods is more or less restricted to the electronic sensors given in Table 10.7.

10.5 Specifications

The range of pressure measurements in the atmosphere is given by the extreme values measured and are within the range from 850 to 1100 hPa at sea level. The local values must be reduced according to the height above

sea level ((10.12) and Table 10.5). Further specification of the measurement methods are given in Table 10.8. For individual devices, see the instructions of the producer.

Table 10.8 Specification of different measurement methods for barometric pressure (typical values)

Method	Uncertainty	Temperature range (°C)	Remark
Mercury barometer	±0.1 hPa	−38 to 50	[10.1]
Aneroid barometer – temperature drift – hysteresis	±0.3 hPa, ±1 hPa ^a 0.3 hPa per 50 K 0.3 hPa, 1 hPa ^a per 50 hPa	−10 to 50	[10.1, 30]
Hypsometer			Dependent on resolution of the thermometer and range of heights
Si piezoresistive sensor	±0.4 hPa	−40 to 85	Long-term stability 0.25 hPa/year not included in accuracy
Si capacitive sensor	±0.1 hPa at 20 °C, ±0.15 hPa	−40 to 60	
Resonant pressure sensor	±0.08 hPa at 15–45 °C, ±0.1 hPa	−40 to 85	Typical temperature range, depends on model and manufacturer
Piston gauge	< ±0.05 hPa		Laboratory calibration instrument

^a barograph

10.6 Quality Control

A good practice is to regularly check the pressure reading of the barometer against a reference barometer. Even the best class of barometers has some long-term drift, and the behavior of the drift can change as the device gets older. The calibration curve provided with a new barometer is not valid many years later. A comparison also indicates if there is a need for maintenance of the barometer.

10.6.1 Reference Barometer

The WMO recommends as the primary standard barometers a precision dead weight tester (piston gauge with loaded piston), producing a calibrated pressure related to the precision weight and the gravity field [10.1, 45].

Electronic barometers, such as silicon diaphragm barometers with long-term stability, are secondary standards [10.45]. Similar devices can be used as working or traveling standards. The WMO organizes international barometer comparisons to compare national working standards with primary or secondary standards [10.1].

10.6.2 Calibration

Electronic pressure transmitters are typically maintenance free but a regular calibration is recommended. A calibration interval of 1 year is a good starting point, depending on air pollution. If the pressure difference in calibration is small compared to specifications, the interval can be lengthened.

Before a comparison with standard barometers or calibration and adjustment, it is important to make sure that no temperature gradients disturb the comparison and that the device under test and the reference device are on the same level (no height correction needed). If the unit cannot be moved to a calibration laboratory, the calibration can be done on site, but the uncertainty of calibration is typically larger due to environmental conditions. The ambient temperature should be stable

within ± 1 K, and the calibration setup should not be in direct sunlight. If the unit is not calibrated at the site, it has to be properly packed for transportation to avoid the effects of mechanical shock on calibration.

A typical calibration setup consists of a pressure controller, a vacuum pump, a pressure supply (e.g., a gas cylinder), and a pressure reference. In some pressure controllers, there is an internal pressure reference. Piston gauges can also act as a reference [10.1, 45, 46]. A requirement for pressure standard uncertainty is 0.1 hPa.

Pressure points in the calibration are chosen from 0 to 100% full scale of the unit under test (e.g., 850–1050 hPa) and should be uniformly distributed over the whole range. Both increasing and decreasing pressure series should be measured in the calibration procedure. For most electric barometers it is possible to make offset and span adjustments based on the calibration results. After the adjustment, the calibration procedure should be repeated (Fig. 10.21). A multipoint calibration and adjustment can be done by the device manufacturer.

In aneroid barometers, there is typically an adjustment screw behind the device. Therefore, it is only possible to do a one-point adjustment. For aneroids, it is important to check whether calibration should be done in a vertical or horizontal position.

10.6.3 Comparison with a Reference Barometer

If a pressure controller is not available, a one-point comparison with a reference barometer can be done at the ambient pressure. This is not a calibration. The comparison should be performed in stable or only slightly changing ambient pressure and at low wind speeds. This is to minimize the uncertainty caused by changing environment conditions. As with laboratory calibrations the unit and reference instrument should acclimate to am-

Fig. 10.21 Calibration procedure (after [10.1] with permission from WMO)

bient conditions before the comparison is done. Some aneroids are quite nonlinear and, therefore, it is recommended to do the comparison as close to 1013 hPa as possible [10.47].

10.6.4 Specific Quality Control Methods

With electric barometers a real time quality control can be performed. There are devices that have two or three pressure sensors inside one device. This enables quality control of the measurement data in real time by

comparison of the pressure readings of these pressure sensors.

To identify unrealistic values due to malfunctions of the sensor or data transmission, with the default test the following values should be excluded:

- Negative values
- Reduced values at sea level lower than 940 hPa or larger than 1050 hPa (these values can only be accepted under specific synoptic situations)
- Constancy of the pressure over 6 h.

10.7 Maintenance

The pressure transmitter should be checked regularly, and immediately if, based on quality control of the data, the need for maintenance is suspected. Things to be checked (in addition to calibration or comparison) are:

- Mounting of the barometer to ensure the correct height of the barometer.
- The pressure inlet should be kept clean and free. Especially in outdoor assemblies there is a risk that the barbed fitting is stuck due to bugs or droplets,

for example. This can be also judged based on data, if the pressure output seems not to follow the pressure trend (comparison with another barometer close by).

Typical maintenance intervals are given in Table 10.9. At sites where the environmental conditions are harsher (air pollution, smog, large temperature variations, vibration (on a vehicle)), the maintenance intervals have to be considered on a case-by-case basis.

Table 10.9 Maintenance of pressure measurement systems. If the check reveals a possible malfunction, the instrument is to be replaced

Maximum interval	Aneroid barometer	Piezoresistive	Capacitive	Quartz crystal resonator	Piston gauge
2 months	Barograph: Comparison with standard barometer	Pressure inlet should be kept clean and free (no droplets, bugs)	Pressure inlet should be kept clean and free (no droplets, bugs)	Pressure inlet should be kept clean and free (no droplets, bugs)	
1 year	Comparison with standard barometer	Comparison with standard barometer	Comparison with standard barometer	Comparison with standard barometer	
5 years					Recalibration

10.8 Application

Pressure measurements are not only related to meteorology. Many technical disciplines and medicine need accurate pressure measurements. Electronical sensors are included in many instruments. Two applications will be highlighted, the use in meteorology and climatology and for air navigation.

10.8.1 Meteorology and Climatology

Typical averaging intervals for pressure are 10 min, with 30 or 60 min also being possible. Recently, the sampling rate is much higher, at 1–10 s. For standard meteoro-

logical measurements in Central Europe (for other time zones, the data must be changed accordingly), the true daily mean is calculated from the 24 single pressure values p_i , recorded at 1-hour intervals between 23:50 Coordinated Universal Time (UTC) of the previous day and 22:50 UTC of the current day [10.48]

$$\overline{p_{\text{day}}} = \frac{1}{24} \sum_{i=0}^{23} p_i \quad (10.25)$$

The climatological daily mean is calculated according to (10.25), analogously to the true daily mean.

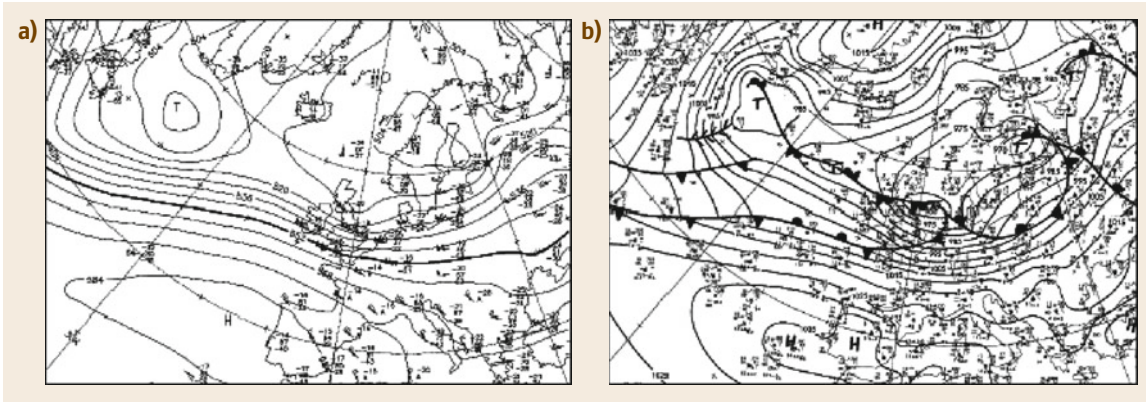

Fig. 10.22a,b Weather charts. (a) geopotential heights in gpdm for the 500 hPa isobaric layer; (b) pressure at sea level; Central Europe, January 18, 2007, 12 UTC, heavy storm *Kyrill* (after [10.49])

The typical meteorological application is for weather charts, with the first being constructed by *Heinrich Wilhelm Brandes* (1777–1834) in 1826 [10.50]. These are geographical maps with isobars for a particular time of measurements (Fig. 10.22b) and indicate low and high-pressure areas. Frontal systems are also analyzed. This type of chart is only used for sea level. For levels in the troposphere, charts with the geopotential height in geopotential dekameters (gpdm) of a layer with constant pressure are constructed. The typical pressure layers are 925, 850, 700, 500, and 300 hPa. According to (10.12), large heights are related to warm air below the isobaric layer and low heights to cold air (Fig. 10.22a).

10.8.2 Pressure Measurements for Aircrafts

Exact pressure measurements are essential for aircraft navigation. The relevant pressure values are given with the typical Q-codes used by the ICAO (International Civil Navigation Aviation) based on Morse telegraphy and introduced by the International Radiotelegraph Convention in 1912. The QFE code is referred to as *atmospheric pressure at aerodrome elevation (or at runway threshold)*. This pressure can differ from that of

the barometer, which differs in altitude by several meters. The QFE pressure is calculated by linear correction of the barometric pressure.

To make pressure measurements at different airports comparable, the QFE pressure is reduced to sea level using the ICAO standard atmosphere [10.25, 51] (ISA) with a constant air temperature of 15 °C (Chaps. 1, 5). This value is referred to as QNH pressure (*the altimeter subscale setting to obtain elevation when on the ground*), and is used for setting the altimeter to indicate the flying height above sea level. With *standard pressure* (1013.2 hPa) set, the altimeters indicate *pressure altitude (flight level)*. This value is applied above the transition altitude that is 18 000 ft in Northern America and different for each airport in Europe and most of the other countries.

According to the ISA the mean pressure gradient is 27 ft hPa^{-1} . Under real conditions, because cold air is denser than warm air, the actual altitude may be different from the readings of the altimeter, with the altimeter overestimating the altitude in cold air and underestimating the altitude in warm air with respect to ISA levels. Because all aircrafts fly with altimeters based on the ISA, this is only a problem over high mountains in cold air, where the true altitude should be used.

10.9 Future Developments

Pressure measurement instruments have changed a lot over the last 100 years as electronic barometers have replaced mercury barometers. The level of automation has increased, enabling installation of barometers in remote sites or, for example, on unmanned ships.

The internet of things (IoT) is now a hot topic and offers more ways to transfer data. This technology megatrend also sets some new requirements for measuring instruments. IoT could offer a larger number of measurement instruments and a denser network of measurement data that would improve local weather forecasting (Chap. 44).

Anni Torri

Vaisala Oyj
Vantaa, Finland

Anni Torri is senior scientist working at Vaisala Oyj, a global company manufacturing and marketing products and services for environmental and industrial measurement. She received a PhD in Physics at the University of Helsinki.

Thomas Foken

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

Jens Bange

Centre for Applied Geo-Science
University of Tübingen
Tübingen, Germany
jens.bange@uni-tuebingen.de

Jens Bange is a Professor for Environmental Physics at the University of Tübingen since 2010. He received a PhD in meteorology in 1998 and a diploma in physics in 1992 at the University of Hannover. His research interests include atmospheric turbulence, boundary-layer meteorology, wind-energy research, airborne meteorology, and environmental measurement technology. He is a founding member of the research networks ISARRA and WindForS.

Radiation Se

11. Radiation Sensors

Klaus Behrens

Instruments for measuring various characteristics of broadband solar and terrestrial radiation have been developed and used for just over 100 years. While in the early years nearly all possible measurement methods were tested and applied, nowadays mainly thermoelectric and (only for solar radiation) photoelectric detectors are adopted. Currently, only these methods can offer output signals with low uncertainties as well as a high degree of automatic data recording in loggers or even preprocessing in the instruments themselves followed by data transmission using different protocols. The investigation of special spectral regions, e.g., ultraviolet (UV) and photosynthetically active radiation (PAR), requires instruments with photoelectric detectors and filters. The separation of solar radiation into its direct and diffuse components requires additional devices. In addition to these subjects, different calibration methods, maintenance measures, and quality control are also described in this chapter.

Radiation processes dominate the Earth's weather and climate as well as life on our planet. The Sun delivers the necessary energy in the form of electromagnetic radiation in the so-called thermal-optical region at wavelengths between 200 and 25 000 nm at the top of the atmosphere, being primarily responsible for driving the physical, chemical, and biological processes that occur within the atmosphere as well as at its bound-

aries with the hydro-, litho-, cryo-, and biosphere. As it passes through the atmosphere, solar radiation suffers extinction processes, such that the solar spectrum at the surface only extends over the region between about 300 and 3000 nm. Furthermore, because of the temperature of the Earth, heat exchange with space occurs in the thermal or terrestrial spectral region (about 3000 to 50 000 nm), resulting in radiative equilibrium.

These boundary wavelengths vary depending on the atmospheric composition and constituents as well as its temperature.

Firstly, important astronomical effects such as the inclination of the Earth's axis, the changing distance from the Earth to the Sun as it moves around its orbit, and the rotation of our planet around its own axis generate steady changes in the solar radiation fluxes received by the Earth. Secondly, different atmospheric constituents, which are unequally distributed in space and time, change the incoming solar radiation on its way from the top of the atmosphere to the ground and the part that is reflected back into space, as well as the thermal radiation emitted by the surface and the atmospheric gases, constituents, and clouds. Radiation fluxes that change in both space and time are thus found at every point on the Earth's surface as well as within the atmosphere, contributing to the exchange of energy.

Furthermore, the interaction of solar radiation with atmospheric constituents and clouds on its path

through the atmosphere, which are highly wavelength-dependent effects, allows the remote derivation of changing atmospheric features (e.g., the optical thickness of aerosols and/or atmospheric gases such as water vapor, ozone, etc.).

Therefore, it is absolutely essential to monitor the integral/broadband as well as spectral radiation fluxes in space and time at different scales for atmospheric physics, climate, and applied sciences (agriculture, energy, environment, etc.). Investigations of broadband radiation are mainly used when considering the radiation and energy balance, while it is necessary to apply spectral data for the investigation of atmospheric features and biological processes.

As a result of these diverse effects, radiation-measuring devices are considered in different chapters of this handbook (e.g., Chaps. 29, 34, 37, 38).

This chapter deals with classical in-situ instruments used from the ground. Furthermore, instruments used to acquire sunshine duration are also described.

11.1 Measurement Principles and Parameters

Before introducing the measured parameters, it is necessary to make some basic remarks regarding radiometric terminology. Table 11.1 presents the radiometric quantities according to [11.1].

The irradiance and the radiant flux density are the quantities most widely used in the field of radiation measurements from the ground, describing the radiation power of processes related to an area, while the radiant exposure or irradiation represents the integral or sum over time of the irradiance, thus indicating the global radiation (energy) received during a day. These quantities must be considered as functions of wavelength if they are applied for special spectral regions.

11.1.1 Measured Parameters

Radiation measurements are highly complex, because they have to cover a wide spectral range with different features and components. Furthermore, it is necessary to consider, depending on the goals of the investigation, wide parts of the spectrum using broadband measurements, or in other cases highly resolved spectral measurements. Hence, many different parameters are measured, as summarized in Table 11.2 and deduced as given in Table 11.3.

Investigations in many disciplines of atmospheric physics, including meteorology as well as climatology and applied sciences, require the acquisition of dif-

ferent solar and terrestrial broadband radiation fluxes near the surface from the upper half-space (sky) and lower half-space (ground) as components of the radiation balance. Because biological, human, technical, and chemical processes and their surfaces, respectively, act partially selective, it is necessary to consider the corresponding quantities in narrow spectral regions or even at single wavelengths.

The terms *short-wave* and *long-wave* radiation are also used for solar and terrestrial radiation, respectively. The use of the terms *solar* and *terrestrial* has the advantage that there is a clear link with the origin of these radiative quantities. The terrestrial spectral range is part of the whole infrared spectral region (Sect. 11.3.1). Furthermore, the potential confusion with *short* and *long* radio waves is thus excluded.

(Extraterrestrial) direct solar radiation is scattered and absorbed on its way to the Earth's surface by air molecules, atmospheric constituents, and clouds in the Earth's atmosphere. Therefore, it is necessary to measure the remaining direct solar radiation (E) and the diffuse solar radiation ($E_d\downarrow$) originating from the sky at the Earth's surface. In most cases, the total solar radiation or global radiation ($E_g\downarrow$) is measured as the sum of the vertical component of the direct solar radiation ($E \cos(z)$) and the diffuse component ($E_d\downarrow$), because this is easier technically

$$E_g\downarrow = E \cos(z) + E_d\downarrow, \quad (11.1)$$

Table 11.1 Radiometric quantities

Name	Symbol	Unit	Relation	Remarks
Radiant energy	Q	J = W s	–	–
Radiant flux	Φ	W (J s ⁻¹)	$\Phi = \frac{dQ}{dt}$	Power
Radiant flux density	$(M), (E)$	W m ⁻²	$\frac{d\Phi}{dA} = \frac{d^2Q}{dAdt}$	Radiant flux of any origin crossing an area element
Radiant exitance	M	W m ⁻²	$M = \frac{d\Phi}{dA}$	Radiant flux from any origin emerging from an area element
Irradiance	E	W m ⁻²	$E = \frac{d\Phi}{dA}$	Radiant flux from any origin incident onto an area element
Radiance	L	W m ⁻² sr ⁻¹	$L = \frac{d^2\Phi}{d\Omega dA \cos \vartheta}$	The radiance is a conserved quantity in an optical system
Radiant exposure (irradiation)	H	J m ⁻²	$H = \frac{dQ}{dA} = \int_{t1}^{t2} E dt$	May be used for, e.g., hourly or daily sums of global radiation, etc.
Radiant intensity	I	W sr ⁻¹	$I = \frac{d\Phi}{d\Omega}$	May be used only for radiation outgoing from <i>point sources</i>

Table 11.2 Parameters measured by radiation instruments at the ground

Parameter	Description	Unit ^a	Symbol ^a
Direct solar radiation ^b	Radiation incident with irradiance E on a plane perpendicular to the radiation's direction from the solid angle of the solar disc solar energy application: direct normal irradiance (DNI)	W m ⁻²	E, E_λ
Diffuse solar radiation	Radiation incident on a horizontal plane with irradiance $E_d \downarrow$ from the upper half-space, excluding the solar disc (2π sr) solar energy application: diffuse horizontal irradiance (DHI)	W m ⁻²	$E_d \downarrow, E_{d,\lambda} \downarrow$
Global solar radiation	Sum $E_g \downarrow$ of the vertical component of the direct $E \cos(z)$ and diffuse solar radiation $E_d \downarrow$ incident on a horizontal plane from the upper half-space (2π sr) solar energy application: global horizontal irradiance (GHI)	W m ⁻²	$E_g \downarrow, E_{g,\lambda} \downarrow$
Upward solar radiation	Reflected solar radiation $E_r \uparrow$ impinging from the lower half-space on a horizontal plane (2π sr)	W m ⁻²	$E_r \uparrow, E_{r,\lambda} \uparrow$
Downward terrestrial radiation	Thermal radiation of the atmosphere $E_1 \downarrow$ from the upper half-space (2π sr)	W m ⁻²	$E_1 \downarrow, E_{1,\lambda} \downarrow$
Upward terrestrial radiation	Thermal radiation of the surface $E_1 \uparrow$ from the lower half-space (2π sr)	W m ⁻²	$E_1 \uparrow, E_{1,\lambda} \uparrow$
Net solar radiation	Difference between the global and reflected solar radiation on a horizontal plane $E_s^* = E_g \downarrow - E_r \uparrow$	W m ⁻²	$E_s^*, E_{s,\lambda}^*$
Net terrestrial radiation	Difference between the downward and upward terrestrial radiation on a horizontal plane $E_1^* = E_1 \downarrow - E_1 \uparrow$	W m ⁻²	$E_1^*, E_{1,\lambda}^*$
Downward (total) radiation	Total of the global solar and atmospheric/downward terrestrial radiation $E \downarrow = E_g \downarrow + E_1 \downarrow$	W m ⁻²	$E \downarrow, E_\lambda \downarrow$
Upward (total) radiation	Total of the reflected solar and upward terrestrial radiation $E \uparrow = E_r \uparrow + E_1 \uparrow$	W m ⁻²	$E \uparrow, E_{1,\lambda} \uparrow$
Radiation balance	Sum of the solar and terrestrial net radiation $E^* = E_s^* + E_1^* = E \downarrow - E \uparrow = (E_g \downarrow + E_1 \downarrow) - (E_r \uparrow + E_1 \uparrow)$	W m ⁻²	E^*, E_λ^*

^a The symbol E with the corresponding unit W m⁻² is chosen here because radiation E measurements at the ground are typically carried out as measurements of irradiance

^b For space-based measurements, this parameter is called the total solar irradiance (TSI)

Table 11.3 Other relevant parameters for radiation measurements

Parameter	Description	Unit	Symbol
Albedo	Ratio of the reflected solar radiation $E_r\uparrow$ impinging from the lower half-space on a horizontal plane (2π sr) to the total or global solar radiation incident on a horizontal plane from the upper half-space (2π sr)	dimensionless	ρ, ρ_λ

where z is the solar zenith angle. The solar upward radiation ($E_r\uparrow$) is the result of reflection of the incoming global radiation at the surface.

The downward terrestrial radiation or downwelling infrared radiation ($E_1\downarrow$) is emitted by atmospheric gases, constituents, and clouds in the atmosphere according to their temperature, while the upward terrestrial radiation or upwelling infrared radiation ($E_1\uparrow$) is mainly emitted by the Earth's surface according to its temperature (thermal radiation). Only a small part of the downward terrestrial radiation is reflected by the surface, and it is included in the upward terrestrial radiation. The downward and upward terrestrial radiation components lie within the same spectral region, so it is impossible to separate the measured upward terrestrial radiation into the parts that are emitted versus reflected by the surface.

Considering that nearly all radiation processes are wavelength sensitive, it is also necessary to consider and measure the corresponding spectral quantities or parameters in special cases, e.g., $E_{g,\lambda}\downarrow$. Some examples include photosynthetically active radiation (PAR) and ultraviolet (UV) radiation.

11.1.2 Measurement Principles

Instruments suitable for measuring radiation have been developed since about 1850. Because radiant energy and radiant power cannot be measured directly, one uses detectors that transform radiation into the energy of another type of response, e.g., thermal, electrical, chemical, or pyroelectric. The wide spectral region from about 300 to 50 000 nm (Sect. 11.3.1) to be explored, together with the wide range of radiation flux densities and (as noted in Sect. 11.1.1) the necessity to investigate broadband and spectrally resolved radiation separately, lead to great challenges regarding the development of radiation instruments. Because of the possibility of rapid changes in the radiation flux density, especially in the solar part of the spectrum, such sensors must also exhibit quick response times. A further challenge is to meet the requirement to measure the radiation quantity of interest as accurately as possible whilst the sensor has to be applied in a certain way or placed within the body of the instrument. Mainly, nonselective thermal detectors are applied to investigate

broadband radiation in the solar and terrestrial parts of the spectrum, while photoelectric sensors are only used to measure spectral regions of the solar radiation. Especially at the beginning, nearly all methods to make radiation measurements were tried out. However, nowadays, mainly methods where the sensor signal enables automatic acquisition of the quantity and the results are reproducible and traceable to the International System of Units (SI) are applied.

In general, radiation instruments are also called radiometers. Meteorological radiation instruments can be separated into several types according to the parameter they measure (Table 11.4).

Generalizing, it can be stated that the classical radiation instrument, being used for continuous field measurements covering the solar or/and terrestrial spectral region, has a thermopile as the receiver, protected by glass or a silicon dome that is coated with a special cutoff filter. Meanwhile, instruments that are applied to investigate only a smaller, special part of the solar spectrum use photodiodes as sensors. Details concerning the main types of instruments and their typical and different features are discussed in Sect. 11.4.

11.1.3 Measurement Sites

Considering that the environmental conditions at a site may influence the measurement results, the World Meteorological Organization (WMO) has performed [11.1, Annex 1.D.] *siting classifications for surface observing stations on land*, which are valid in general, and also published the text of the common ISO/WMO standard [11.2]. A site as a whole does not have a single classification number; rather, each parameter measured at a site has its own class, which may sometimes be different from the others.

Table 11.5 summarizes the classification regarding the measurement of solar radiation parameters from the upper half-space, which may help to classify a site.

In general, the selection of a measurement site depends on the goal of the investigations. It should be representative for the problem to be solved. For example, a site that is representative for the description of a larger region should not be influenced by small-scale topographic or local features (hills or industry), while a site typical for a special microclimate may have

Table 11.4 Classification of radiation instruments

Type of instrument	Parameter measured	Viewing angle (sr)	Remarks
Pyrheliometer	Direct solar radiation	5×10^{-3}	Used as: – Primary standard (absolute pyrheliometer) Receiver: cavity – Secondary standard (for calibration) – Field instrument Receiver: thermopile protected by glass (Sect. 11.4.1) Spectral pyrheliometer: with broad- or narrow-band filters Special case: sun photometer (Chap. 29), spectral radiometer Receiver: photodiode
Pyranometer	Upward looking: global or diffuse solar radiation Downward looking: reflected solar radiation	2π	Used as: – Working standard – Field instrument Receiver: thermopile protected by (a) glass dome(s) (Sect. 11.4.2) (spectral) pyranometer: Receiver: photodiode (Sect. 11.4.2; Chaps. 29, 37)
Pyrgeometer	Upward looking: downward terrestrial radiation Downward looking: upward terrestrial radiation	2π	Used as: – Working standard – Field instrument Receiver: thermopile protected by a silicon dome coated by a special cut on filter blocking the solar radiation (Sect. 11.4.3)
Pyrradiometer	Upward looking: total (global solar + downward terrestrial) radiation Downward looking: total (reflected solar + upward terrestrial) radiation	2π	Used as: – Working standard – Field instrument Receiver: thermopile protected by a polyethylene dome (Sect. 11.4.4)

Table 11.5 Classification of sites where solar radiation parameters from the upper-half space are measured [11.1] (φ : geographical latitude, h_S : altitude of Sun)

Class	Global and diffuse radiation	Direct radiation and sunshine duration
General	Close obstacles must be avoided. Shading due to natural relief is not taken into account for the classification. Nonreflecting obstacles below the visible horizon can be neglected. An obstacle is considered as reflecting if its albedo is greater than 0.5. The reference position for elevation angles is the sensing element of the instrument	Close obstacles must be avoided. Shading due to natural relief is not taken into account for the classification. Obstacles below the visible horizon can be neglected. The reference position for angles is the sensing element of the instrument
1a	$\varphi < 60$: $h_S > 5^\circ$: no shade onto the sensor $\varphi \geq 60$: $h_S > 3^\circ$: no shade onto the sensor	$h_S > 3^\circ$: no shade onto the sensor
1b	No nonshading reflecting obstacles with angular height above 5° and total angular width above 10° .	
2a	$\varphi < 60$: $h_S > 7^\circ$: no shade onto the sensor $\varphi \geq 60$: $h_S > 5^\circ$: no shade onto the sensor	$h_S > 5^\circ$: no shade onto sensor
2b	No nonshading reflecting obstacles with angular height above 7° and total angular width above 20°	
3a	$\varphi < 60$: $h_S > 10^\circ$: no shade onto the sensor $\varphi \geq 60$: $h_S > 7^\circ$: no shade onto the sensor	$h_S > 7^\circ$: no shade onto the sensor
3b	No nonshading reflecting obstacles with angular height above 15° and total angular width above 45°	
4	No shade for more than 30% of daytime, or any day of the year	No shade for more than 30% of daytime, or any day of the year
5	Shade projected during more than 30% of the daytime, for at least one day of the year	Shade projected during more than 30% of the daytime, for at least one day of the year

such characteristics. If measurement of upward radiation fluxes is required, it is also essential to select a site with a typical and representative surface to fulfill this objective.

In the case of planned long-term measurements, it is important that the surroundings of the chosen site should not be changed, to ensure the homogeneity of the time series to be acquired. Therefore, regular supervision of the station and its surroundings and documentation thereof are of major importance. Panoramic cameras or all-sky images are very helpful to accomplish horizon mapping.

According to [11.1], the following general requirements can be formulated:

The site should be readily accessible for construction and dismantling, but mainly for maintenance of all the equipment. The instruments should be securely attached and horizontally leveled if it is not intended to take special measurements, e.g., on tilted surfaces.

Upper Half-Space (Direct and Diffuse Solar Radiation, Global Radiation, and Downward Terrestrial Radiation)

In the ideal case, the site will be free from any obstructions above the sensor. If finding such a site is impracticable, the site must be as free as possible of obstructions that could shadow the receiver at any time of the year.

The horizon should not be limited by buildings, vegetation (trees or bushes), etc. above an elevation angle of 5° , especially within the azimuthal range between sunrise and sunset during the year, to record mainly direct solar radiation. Antennas and similar slender objects can be tolerated if their azimuthal angle is small ($< 1^\circ$) and they do not block the direct beam of radiation. Because light-colored walls or other objects (e.g., large window areas or photovoltaic panels) cause reflections that will enhance the solar diffuse radiation, pyranometers should not be installed close to them. Furthermore, it must be ensured that no strong local emitters of exhaust gases or dust lie in the direct vicinity of the site. Also, note that solar and terrestrial instruments should not be exposed to artificial radiation sources of light and heat, respectively.

Lower Half-Space (Reflected Solar Radiation and Upward Terrestrial Radiation)

In principle, the same conditions and precautions considered appropriate for the upper-half space also apply for down-facing pyranometers and pyrgeometers. How-

Fig. 11.1 Diameter of the area influencing the measurements of a down-facing pyranometer or pyrgeometer as a function of the installation height of the sensor (after [11.4] reprinted with permission from VDI – The Association of German Engineers)

ever, one must especially bear in mind that the ground should be appropriate to solve the task, considering the field of view of the instrument. According to [11.3], a sensor installed at a height 2 m above the surface will receive 90% of the radiation from a circle of 12 m diameter, and 95% from an 18-m circle. Figure 11.1 shows the diameter of the area influencing such measurements as a function of the installation height of the sensor. To ensure that the mounting rod disturbs the measurements as little as possible, it should be as thin as possible and with a polar position when the instrument points to the equator.

In regions with a lot of snow, there should be a mechanism to adjust the height of the pyranometer or pyrgeometer to keep the distance between the instrument and the snowpack as constant as possible. Furthermore, it should be ensured that maintenance of down-facing equipment is realized such that the reflecting features of the surface will not have an influence, too.

Radiation measurements on towers, special platforms, and ships require specific precautions (see also Chap. 7). In particular, for measurements from research vessels and ships, which are subject to continuous tilting motions, simple gimbal mountings may diminish such disturbances. Nowadays, computer-controlled roll–pitch–yaw angle-compensating systems or platforms are available.

11.2 History

Although, nowadays, solar and terrestrial radiation are of fundamental importance for meteorological processes and life in relation to other quantities, when their measurement started, the thermometer and barometer had been in use for about 200 years in physics and were already applied in regional meteorological networks.

The first, poor measurements were made around the middle of the 19th century. By the end of that century, about a dozen, highly specialized institutes and observatories around the globe were studying radiation and its measurements from the meteorological and climatological points of view.

Only the International Geophysical Year (IGY) 1957/58, one aim of which (among a lot of geophysical objectives) was to promote radiation measurements, encouraged homogenization of such measurements and the enlargement of the number of stations, although the Commission for Instruments and Methods of Observation (CIMO) of the WMO had already demanded a general improvement and extension of radiation measurements in its first session in 1953 [11.5]. The publishing of the *IGY Instruction Manual* [11.6] accomplished this highly valuable contribution. Thereafter, the World Radiation Data Center (WRDC) (<http://wrdc.mgo.rssi.ru/>, Accessed 05 July 2021) was established in St. Petersburg in 1964.

Around the start of the 1990s, the ongoing development of radiation measurements received an impetus from the climate community, resulting in the establishment of the Baseline Surface Radiation Network (BSRN) as a project of the Global Energy and Water Cycle Experiment (GEWEX) under the auspices of the World Climate Research Program (WCRP) ([11.7], see Chap. 63). Distinct targets mainly in terms of accuracy and rules for data acquisition and handling as well as maintenance were presented and summarized in the *BSRN Operations Manual* [11.8, 9], leading to investigations and improvements of such instruments. It highlighted the generation of high-quality and comprehensive datasets from sites representing a typical climate and/or atmospheric conditions such as aerosols or clouds. In 2004, the BSRN was designated as the global baseline network for surface radiation measurements for the Global Climate Observing System (GCOS). These data are gathered and provided by the World Radiation Monitoring Center (WRMC) operated by the Alfred Wegener Institute (AWI) (<https://bsrn.awi.de/>, Accessed 05 July 2021).

The first comprehensive reviews on radiation instruments were published by *Fritz Albrecht* (1896–1965) in 1935 [11.10] and *Walter Mörkofer* (1892–1976) in 1939 [11.11]. About 30 years later, in 1969, the book entitled *Solar Radiation* by *Nathan Robinson* [11.12]

came out. In 1986, *Claus Fröhlich* (1936–2019) and *Julius London* (1917–2009) edited on the request of WMO a *Revised Instruction Manual on Radiation Instruments and Measurements* [11.13], an updated guide of the IGY manual. Furthermore, Chap. 7 of the so-called WMO–CIMO Guide [11.1], which has since become a *living document*, provides a good overview on how to conduct radiation measurements in the framework of the WMO.

11.2.1 Pyrheliometers

A pyrheliometer measures direct solar radiation in a full opening angle of 5° , although in the past this angle was not standardized and older instruments may deviate from this. In some cases, rectangular apertures were applied, too (e.g., the Ångström and Michelson–Marten pyrheliometers) (see also Tables 11.2–11.4).

Nowadays, all instruments for measuring direct solar radiation at the ground are called pyrheliometers, independently of whether they require calibration, while previously pyrheliometers that required calibration were called actinometers.

Pouillet's Pyrheliometer (1838)

According to different sources [11.10, 11, 14], the first measurements of direct solar radiation with absolute albedo crude results were carried out by *Claude Servais Mathias Pouillet* (1790–1868) in 1838 using his pyrheliometer (Fig. 11.2). This pyrheliometer consisted of a flat, water-filled cylindrical capsule made from sheet silver with capacity of about 100 cm^3 . The front side, which was directed towards the Sun, was blackened with soot. The bulb of a thermometer extended into the capsule from the back side. The measurement was made by the so-called dynamical method. A 5 min period of irradiating the front side of the capsule was sandwiched between shading periods of 5 min at the beginning and end of the measurements. The temperatures were determined at the beginning and end of the measurements (t_0 , t_3) as well as at the switching points (t_1 , t_2) from shade to irradiation and vice versa. Knowing the heat capacity of the water-filled capsule c (which is difficult to determine and therefore highly error prone), the irradiance E_1 can then be calculated as

$$E_1 = \frac{c}{\tau} \left[t_2 - t_1 + \frac{(t_1 - t_0) + (t_3 - t_2)}{2} \right]. \quad (11.2)$$

Later, this instrument was improved by *Violle* (1874) and *Crova* (1877) as well as other scientists. However, irradiances measured using all these pyrheliometers were incorrect because of the negative influ-

Fig. 11.2 Pouillet's pyrheliometer. A: blackened receiver (metallic container filled with water); D, C: alignment checks; T: thermometer bulb (after [11.15] © Bureau international des Poids et Mesures. Reproduced by permission of IOP Publishing. All rights reserved)

ences of, e.g., wind, convection, and large inertia, which could not be eliminated.

Around the end of the 19th century, a breakthrough was achieved with the development of the Ångström compensation pyrheliometer in 1893 by *Knut Ångström* (1857–1910) [11.16] and the water-flow pyrheliometer by *Charles Greeley Abbot* (1872–1973) in 1905 [11.17].

Ångström Compensation Pyrheliometer (1893)

Ångström used two identical thin, blackened Manganin strips, arranged in parallel at the end of a tube, each bearing on its back an electrically insulated but thermally contacted thermocouple. Both strips were placed in an electrical circuit, which was linked to a flexible shutter situated at the front of the tube. While the tube with the strips, behind two rectangular apertures, was directed perpendicular to the sunbeams, this shutter alternately shaded one strip. During the measurement, the shaded strip was heated by an electrical current while the other strip was irradiated by the Sun. When the thermocouples are connected differentially in a galvanometer circuit, this instrument shows zero if the power of the controlled heater current equals the power of the Sun. However, this equality is only valid if the left- and right-hand strips and their thermocouples are

identical. Because this is difficult to achieve, in practice the left- and right-hand sides are alternately heated and irradiated to overcome any possible asymmetry and the mean current i_m is computed as

$$i_m = \frac{i_{L1} + i_{L2} + 2i_R}{4}, \quad (11.3)$$

where i_{L1} , i_{L2} , and i_R the current readings of the left- and right-hand strips, respectively.

Finally, the direct solar irradiance (E) can be calculated as

$$E = ki_m^2, \quad (11.4)$$

where k is a constant related to the particular instrument. In the case of an absolute instrument, k can be determined from various parameters of the instrument such as the absorptivity and length of the strips as well as the electrical resistance per unit length of the strips. In practice, this difficult task was only carried out for the first accurately built pyrheliometer, while the value of k for other sensors was determined by side-by-side comparison with the Sun as the radiation source. Figure 11.3 shows the schematic circuit and a photograph of the Ångström pyrheliometer.

The method of compensation of the power of the Sun by electrical power, which can be determined very exactly, was first applied by Ångström in meteorology, while independently *Ferdinand Kurlbaum* (1857–1927) used this principle in experimental physics.

In 1905, at the Conference of the Directors of Meteorological Services in Innsbruck, the Ångström pyrheliometer was recommended for observation of solar radiation. One of the original Ångström pyrheliometers (A-70) situated in Sweden was adopted as a reference and established a link to the Ångström scale, the first scale for solar radiation measurements in the world [11.15].

Even nowadays, the compensation of heat fluxes generated by the absorption of radiant flux by a precisely determined electrical flux forms the basis for the construction of absolute pyrheliometers. This crucial development became successful with the transition from the use of direct to comparative calorimetry [11.18].

Water-Flow Pyrheliometer (1905), Water-Stir Pyrheliometer (1913), Silver-Disk Pyrheliometer (1909)

Based on its working principle, Abbot's water-flow pyrheliometer (Fig. 11.4) is actually a calorimeter, because the irradiance is computed based on exact knowledge of the amount of water, the difference in temperature between the water at the inlet and outlet, and the time of exposure. The water flows between the walls of an irradiated conical receiver. However, after

(b) Two Ångström pyr heliometers of different generations (*right*: A-584; *left*: A-140) manufactured in Sweden without any auxiliary equipment (photo: K. Behrens)

Fig. 11.4 Cross-section of Abbot's water-flow pyr heliometer (after [11.10])

the radiation measurement, a coil of known resistance in the instrument is used to generate the same amount of heat as produced by the solar radiation and thereby verify the result. In this regard, the process of compensation is again applied. In contrast to the Ångström pyr heliometer, the receiver of the water-flow pyr heliometer is constructed using an advantageous type of cavity. Later [11.19], the water-stir pyr heliometer was developed at the Smithsonian Institute to confirm the measurement results of the water-flow pyr heliometer. This new instrument had a similar design and operating principle to the water-flow pyr heliometer, but instead of a continuous water flow, a closed system was used and the water was stirred during the solar heating. Furthermore, it was again possible to verify the results using a coil based on the compensation principle.

As early as 1902, based on the above-described Pouillet pyr heliometer and its modification by Tyn-

dall, Abbot constructed the silver-disk pyr heliometer (Fig. 11.5), which was improved and led in 1909 to the type described in [11.20]. This instrument was very stable and used as a secondary standard which had to be calibrated by comparison with a standard (a water-flow or water-stir pyr heliometer). Because it was impossible to use these water-flow and water-stir pyr heliometers at other locations, Abbot [11.20] in 1911 wrote:

The purpose of the silver disk pyr heliometer is merely to furnish readings proportional to the intensity of radiation of the sun, and comparable one with another at all times and places, but not to furnish independent means of reducing these readings to true heat unit. [...] They must therefore be regarded as secondary instruments, useful only for relative readings, unless standardized by comparison with true standard pyr heliometers.

Fig. 11.5 (a) Cross-section of the silver-disk pyrheliometer (after [11.10]). (b) View of the silver-disk pyrheliometer SI 19 with its open circular entrance and shutter (photo: K. Behrens)

Comparisons between water-flow and water-stir pyrheliometers as well as different silver-disk pyrheliometers led to the definition of the revised Smithsonian scale of 1913 [11.21], which was disseminated all over the world with the help of silver-disk pyrheliometers.

Marvin Pyrheliometer (1910)

The Marvin pyrheliometer resembles the silver-disk pyrheliometer in its construction, but instead of a mercury-in-glass thermometer, it uses a resistance wire for temperature determination. Furthermore, in contrast to the silver-disk pyrheliometer, it is fixed on a clock-driven equatorial mount that allows automatic tracking of the Sun. A shutter is mounted on the end of the tube and opened or closed alternately using magnets activated by a clock at the end of each minute. Instruments with this configuration were used by the US Weather Bureau for several years [11.22].

Pyrheliometers with a Thermopile Sensor

This subsection describes various pyrheliometers with one common feature, viz. they all use a thermopile (Sect. 11.3) as a sensor to convert the received radiant energy into electrical energy. According to [11.10, 11], Crova applied a thermopile for radiation measurements for the first time as early as 1885. However, because of the use of copper–iron thermoelements, which generated only a small thermovoltage, this principle did not gain wide acceptance.

Later, *Sawinoff* (1912), *Dorno-Thilenius* (1920), and *Linke* (1921) also developed pyrheliometers that used different thermopiles with better features as detectors, but these instruments also did not receive

wide acceptance for other reasons [11.10]. The instrument constructed by *Sawinoff* was refined by *Yanishkevsky* [11.23] and furthermore applied in the USSR.

A breakthrough was achieved by *Wladyslaw Gorczynski* (1879–1953) in 1924 [11.24] by implementing the thermopile engineered by *Willem Jan Henri Moll* (1876–1947) [11.25] to construct a new pyrheliometer. It was set in a

solid cylinder which was closed at one end by an ebonite plate with two terminals, and at the other end by a heavy brass lid, into which a protecting window is fixed. [11.24]

In contrast to the thermopile used by Crova, the new type developed by Moll using Constantan–Manganin strips offers several advantages: it was free from zero errors, had a rugged form, fast operation, and high sensitivity. In combination with an appropriate recording millivoltmeter and a clock-driven equatorial mount, it was possible to gather daily profiles of direct solar radiation (Fig. 11.6). Furthermore, Gorczynski note that he could apply various filters to investigate different parts of the solar spectrum and that it was easy to use after calibration, especially because of the ability to record measurements at ordinary stations.

In 1932, *Franz Linke* (1878–1944) together with *Karl Feussner* (1902–1982) used also the Moll thermopile but embedded in a copper block with five internal diaphragms. This massive block served as a heat sink and stabilized the temperature conditions for the whole instrument. This instrument (Fig. 11.7), known as the the Linke–Feussner pyrheliometer (or also the *Panzeraktinometer* in German because of the massive

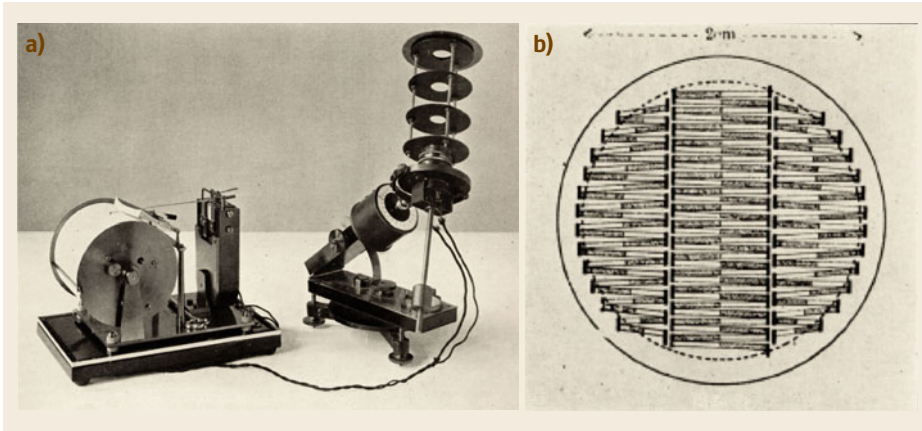

Fig. 11.6 (a) The Moll–Gorczyński pyrheliometer equatorially mounted on a clock drive and connected to a recording drum. (b) The implemented large thermopile (after [11.24])

Fig. 11.7 (a) Two Linke–Feussner pyrheliometers of different generations. The one on the left was manufactured by Kipp and Zonen in the 1950s and later, while that on the right is from the first generation from the 1930s. (b) A thermopile from a first-generation instrument (photos: K. Behrens)

block [11.14]) was manufactured more than 30 years by Kipp and Zonen in the Netherlands.

At the beginning of the 1950s, a further pyrheliometer named the Eppley normal incidence pyrheliometer (NIP) was developed. It has a copper–Constantan thermopile with a circular receiver mounted in a brass tube with two view-limiting baffles. The tube is closed by a quartz window in front, filled with dry air, and sealed [11.12].

Measurements by all of these thermoelectric pyrheliometers show a dependence on the ambient temperature. The Linke–Feussner pyrheliometer is equipped with a mercury-in-glass thermometer to enabling correction for this effect. Later, the NIP was changed several times to reduce its dependence on the ambient temperature by employing a new thermopile, a temperature-compensating circuit, and a double-walled tube. These changes led to measurements with

improved uncertainty related to the ambient temperature dependence. Furthermore, an embedded thermistor could be used to determine the temperature of the instrument for such corrections.

The NIP and Moll–Gorczyński pyrheliometer are typically closed by a front window, mounted on an equatorial tracker, connected to corresponding recorders, and used as *all-weather* instruments, while all the other instruments had to be operated manually and only under fair weather.

Because of the interest in obtaining information about the spectral distribution of the solar radiation, a wheel fit with colored glass filters could be mounted in front of the entrance of the Moll–Gorczyński pyrheliometer or NIP, or included as a standard feature in the Linke–Feussner pyrheliometer. Frequently, the internationally recommended bandpass filters OG1, RG2, and RG8 manufactured by Schott and Gen. (Germany)

with respectively cut-on values of 525, 630, and 710 nm and cut-off values of 2800, 2800 and 2700 nm were used [11.6].

It is important to mention that, to obtain accurate results, the reading voltmeter, usually a moving-coil instrument, had to be selected very carefully because of the different sensitivity and resistance values of thermopiles. Similarly, this also applied in the past to the instrument selected for the rarely performed recordings of direct solar radiation.

Michelson Bimetallic Actinometer (Pyrheliometer)

In 1905, *Vladimir Alexandrovitsch Michelson* (1860–1927) in Moscow developed a pyrheliometer with a rectangular aperture which used a very thin blackened strip made of iron and nickel steel as the sensor [11.26]. In contrast to the several Smithsonian instruments, it was very sensitive, because of its low heat capacity. The strip located in a metal block with a small hole was alternately shaded and irradiated, causing it to bend. The resulting change in position, observed using a microscope, corresponds to the change of temperature and therefore amount of irradiance.

This instrument was changed and improved by various scientists. Probably the most well-known changes were made by *Wilhelm Marten* (1874–1949) and later *Konrad Büttner* (1903–1970), because the resulting instruments are mentioned, for instance, in the *IGY Instruction Manual* [11.6]. Marten improved this instrument (Fig. 11.8) several times between 1912 and 1928 [11.27], and it was equipped with different recommended [11.6] colored glass filters for the measurement of separate spectral regions. The device constructed by Michelson and Marten depends on the ambient tem-

perature, leading to changes in the zero point (shaded phase), while *Büttner* [11.28] added a second strip to compensate for this effect.

11.2.2 Pyranometers

A pyranometer, mounted upward facing, can measure the global or—when additionally equipped with a shadow band/ring or a disc—the diffuse solar radiation with a viewing angle of 2π sr. When looking downward it measures the reflected solar radiation (see also Tables 11.2–11.4). If upward- and downward-facing pyranometers are combined into a single unit, the result is sometimes called an *albedometer*. However, this name is incorrect, because the albedo is defined as the ratio of the total reflected solar irradiance to the global irradiance. Indeed, this quantity cannot be measured directly. In contrast, it is possible to measure the solar net radiation immediately by applying a differencing circuit between an upward- and downward-looking pyranometer using thermopiles as detectors, for instance. This type of instrument is called a *net radiometer*. A second way to calculate the solar net radiation is as the difference between the downward- and upward-directed fluxes. Using these fluxes, it is of course also possible to calculate the albedo, too (Tables 11.2–11.4).

The first adequate and properly functioning pyranometer was that of *Hugh Longbourne Callendar* (1863–1930), a British physicist. Its first version was described in a paper by *Callendar* and *Fowler* in 1906 [11.30], in which they reported on the total solar eclipse in August 1905.

The horizontal bolometer was of the usual type designed for recording the vertical component of sun and sky radiation. It consisted simply of a pair of platinum thermometers wound on a horizontal mica plate fixed in a sealed glass bulb. One of the thermometers being coated with black enamel is raised to a higher temperature than the other by exposure to radiation. The difference is very nearly proportional to the intensity of the radiation, and is automatically recorded on an electrical recorder of the usual type. It is, of course, necessary for an instrument intended to be exposed in all weathers that the surface receiving radiation should be protected by a glass bulb [11.30].

Later on, this was called the *Callendar pyrheliometer* [11.31] or *Callendar bolometric sunshine receiver* [11.32], and an improved version with two black and two shiny platinum grids was mainly applied in the USA and Great Britain over a number of years. Simple

Fig. 11.9a–c The Moll–Gorczyński *solarimeter* as described in the text. (a) Pyranometer with screen measuring diffuse solar radiation. (b) Pyrheliometer on a holder together with a pyranometer in a wooden box. (c) (Weatherproof) pyranometer with recording drum prepared for continuous measurements (after [11.29])

recording with the help of a self-adjusting Wheatstone bridge enabled its easy and successful use, although some important shortcomings were presented as early as 1915 [11.32].

Further pyranometers were developed by *Abbot and Aldrich* (1884–1965) in 1916 [11.33, 34] and *Anders Ångström* (1888–1981) in 1919 [11.35], who tried to apply the idea of *Knut Ångström*, viz. the method of electrical compensation as applied in his well-known and successful pyrheliometer, to pyranometers. It is of some interest to indicate here that US instruments were also able to measure the thermal radiation during nighttime if operated without the glass hemisphere, blocking wavelengths greater than about 3000 nm. However, because of various shortcomings and other factors, these instruments did not gain permanent acceptance.

It is important to note that *Abbot and Aldrich* devised the term *pyranometer* for an instrument measuring the solar radiation from the Sun and sky and applied it for the first time in [11.33].

Pyranometers with Thermopile Sensors

As already mentioned in the section on pyrheliometers, thermopiles have proved to be nearly ideal sensors for the measurement of irradiance.

In contrast to pyrheliometers, which only use *black* thermopiles, in the case of pyranometers it is possible to use *black* as well as *black-and-white* thermopiles. The most well-known and only historically relevant pyranometer with a black thermopile is the instrument developed by *Gorczyński* [11.29], frequently called a *solarimeter* (Fig. 11.9). The original thermopile as used in the pyrheliometer was specially adapted for use in the pyranometer to avoid the influence of the changing angle of incidence of the solar beam. This new thermopile was embedded in a brass cylinder covered by a glass hemisphere. The version designed primarily for direct readings consisted of a solarimeter combined with a millivoltmeter in a wooden box. The same type of thermopile arranged in a pyrheliometric tube closed by a spher-

cylindrical lens or flat glass disc and mounted on a special holder could also be connected to the millivoltmeter. This set was completed by a circular sunscreen. This system allowed alternate measurements of the global, diffuse, and direct solar radiation. A second version applied for continuous recording consisted of the same weatherproof solarimeter mounted on a special holder for permanent outdoor installation and connected to a recorder. Extensive investigations, especially of the recording system, soon revealed various deficiencies, which led to improvements. One of the most important points was the introduction of the pyranometer with a second glass hemisphere to stabilize the nighttime zero points, as mentioned in [11.11]. The *solarimeter* was manufactured by Kipp and Zonen (the Netherlands) and consequently advanced to one of today's state-of-the-art pyranometers.

As early as 1923, the US Weather Bureau in cooperation with the US Bureau of Standards [11.36] developed “a very convenient form of a thermoelectric recording pyrheliometer” consisting of an annular black inner and a white outer ring with thermocouples arranged behind them, covered by a glass dome (Fig. 11.10a). Later, this instrument was manufactured and improved by Eppley Laboratory Inc. It was known as the 180° *pyrheliometer* (Fig. 11.10b) and, despite known shortcomings, was applied in US networks for decades thereafter.

Also, *black-and-white* thermopiles were used in a checkerboard configuration. According to [11.10], Sawinoff in 1922 and later *Volochine* in 1932 developed this kind of sensor [11.37]. While in the construction of Volochine the checkerboard was surrounded by a black area, the thermopile of Sawinoff was embedded in a white surface. The instrument made by Sawinoff, after a refinement by *Yanishevsky* [11.23], was later applied in the USSR.

A further possibility is the radial arrangement of the *black-and-white* thermopiles like a star. According to [11.11], an early representative of this type is the pyranometer introduced by Linke in 1934 (Fig. 11.11).

Fig. 11.10a,b 180° pyrheliometer – US Weather Bureau version (a) (after [11.36]) and Eppley Laboratory Inc. version (b), widely known as the *light bulb* (photo: K. Behrens)

Fig. 11.11 Two star pyranometers from different generations: *Left* a modern one manufactured by Fa. Ph. Schenk, Wien and *right* a historical version from the 1930s (photo: K. Behrens)

Robitzsch Bimetallic Pyranometer

As early as 1915, *Max Robitzsch* (1887–1952) [11.38] first reported an instrument based on two nearly equal bimetallic thermometers, one blackened and the other polished, arranged coaxially such that end A of the first was fixed to a ground plate while end B was free. End B' of the second thermometer was rigidly connected to end B, while excluding thermal conduction. The free end A' of the second thermometer held a transfer lever to record on a rotating drum. Because of its construction, this *thermograph* does not show any deflection if both thermometers have the same temperature. However, insolation results in a temperature difference between the blackened and polished thermometers, being proportional to the irradiance. Because the system is sensitive to air movement, it was protected using a glass cuvette. This paper was entitled *Vorläufige Mitteilung über einen neuen Sonnenscheinautographen* (Preliminary information about a new sunshine recorder), because it was his intention to develop an improved sunshine recorder that could also record

the changing irradiance, a feature that existing sunshine recorders did not offer. In the following years, *Robitzsch* improved this instrument step by step based on its known imperfections [11.39]. In 1930, in cooperation with the Fuess company of Berlin, which manufactured the instrument (Fig. 11.12), great progress was achieved. Meanwhile, the application of available thermometers made from industrial welded bimetallic sheet metal which did not exhibit any individual differences, improved spectrally stable paints, and the use of three instead of two stripes (bimetallic thermometers) led to an instrument which fulfilled the demands for a simple and easy-to-use pyranometer with the ability to record the changing irradiance using an ink pen on a chart mounted on a clock-driven drum. The system consisting of the bimetallic sensor, transfer lever, and recording drum was placed in a weatherproof metal case. An aperture over the sensor was protected by a glass dome, enabling the transmission of solar but excluding thermal radiation. He described this instrument in depth in the paper [11.40]. Later, in a paper from 1938 [11.41],

Fig. 11.12a,b
Robitzsch pyranograph manufactured by Fuess. (a) Instrument in working mode, (b) cover removed, showing details of the bimetallic receiver and recording drum (photos: K. Behrens)

Robitzsch reported on the calibration of this instrument as well as its imperfections (e.g., dependence on temperature, and azimuth and altitude of the Sun) and the impossibility of eliminating these effects as well as the resulting uncertainty in such measurements.

Despite its weak spots, this type of instrument was widely used and manufactured, not only in Germany but also in Great Britain and Italy, mainly because of its simplicity and possible use at remote stations.

11.2.3 Pyrgeometers

A pyrgeometer measures the terrestrial downward or upward radiation with a viewing angle of 2π sr (Tables 11.2–11.4). Transferring his successful idea of electrical compensation from the solar to terrestrial spectral region, in 1905 *Knut Ångström* [11.42] constructed a compensation pyrgeometer (Fig. 11.13), which is only usable at night. In contrast to the pyr heliometer, where one strip is irradiated and heated by the Sun while the other is shaded and heated by an electrical current, two blackened and two blank metallic strips with different emissivity, mainly in the thermal spectral region, were applied in the case of the pyrgeometer.

In this design, the distinct sky-facing strips emit different amounts of energy, leading to a temperature difference between the blackened and blank strips. This difference in temperature is determined by thermoelements at the back of the strips and equalized using an electrical current as in the pyr heliometer. Furthermore, it was possible to use a mercury-in-glass thermometer to determine the instrument (body) temperature, which is required to calculate the atmospheric downward radiation.

However, it proved very difficult to determine the value of the constant of the pyrgeometer that is required to calculate the terrestrial downward radiation. Therefore, *Ångström* decided to calibrate the pyrgeometer with the help of a black body, finally resulting in good results.

Fig. 11.13 Ångström pyrgeometer (photo: K. Behrens)

Because the sensor strips are freely exposed to the sky, measurements with this pyrgeometer are only possible in fair weather. Furthermore, it is very sensitive to changes in wind speed. Therefore, proper measurements can only be obtained on clear and calm nights.

As mentioned above in the section on pyranometers, in 1916 *Abbot* and *Aldrich* [11.33, 34] developed pyranometers which could measure downward terrestrial radiation without their glass domes only during the nighttime. In 1922, *Aldrich* [11.43] described a special instrument named after the Greek word *Melikeron*, meaning *honeycomb*. Because of doubt regarding whether the absorbers (sensors, black paints) used in previously applied methods were also good enough in the terrestrial spectral region, an approximately *black body* absorber was tried as the sensor. Honeycomb-like tubes were formed into a relatively large sensor area of about 3×3 cm². A temperature difference arose between the *honeycomb* sensor

and the instrument body when the sensor was exposed to the night sky and was measured by thermoelements. The loss of heat by radiation from the sensor was compensated by an electrical current. Comparisons between the Ångström pyrgeometer and the Melikeron showed differing results, so it was stated [11.43] that further investigations were necessary.

The above-mentioned limitations concerning the dependence of the Ångström pyrgeometer on weather conditions also apply to the described Smithsonian instruments. Therefore, recording terrestrial radiation using these instruments is impossible.

11.2.4 Pyrradiometers

A pyrradiometer measures the downward total (global solar + downward terrestrial) or upward total (reflected solar + upward terrestrial) radiation in a viewing angle of 2π sr (see also Tables 11.2–11.4). If a downward- and an upward-facing pyrradiometer are combined into one unit, it is called a *total net radiometer*. It is possible to determine the total net radiation in three ways:

- Directly measuring the total net radiation using only one thermopile with hot upward-facing and cold downward-facing junctions, because the difference in temperature is proportional to the net irradiance
- Measure the total net radiation immediately by applying a differentiating circuit between a downward- and upward-looking pyrradiometer using two thermopiles as detectors
- Calculate it as the difference between the measured downward- and upward-directed fluxes (Tables 11.2–11.4).

Like pyranometers, pyrradiometers also use thermopiles as sensors. The first suitable instruments were constructed in the late 1940s and the beginning of the 1950s. Because of the urgent need for information regarding the downward and upward terrestrial radiation fluxes for use in the atmospheric sciences prior to the

planned IGY, an *intercomparison of longwave radiation instruments* was organized in Hamburg, Germany. Sixteen different models participated in these comparisons, which were carried out for two weeks in each of September 1955 and May 1956. Most of them were still under development or suffered from other restrictions that did not allow continuous measurements under all weather conditions [11.6]. As a result, it was stated that it was not possible “to publish formal recommendations on the reliability and the value of the different designs” [11.44]. Some instruments, for instance the Gier and Dunkle ventilated radiometer [11.45], worked with unprotected receivers, where the constant airflow over the sensors should avoid the effect of changing wind speed on the detector plates. However, such basic approaches did not finally gain acceptance.

Another instrument that participated was the Schulze radiation balance meter ([11.47], Fig. 11.14). Two thermopiles, one upward and one downward facing, enabled separate measurements of the radiation fluxes from the upper and lower half-spaces. Because of this, the upper and lower part of the balance meter can be considered to represent single pyrradiometers. When the receivers are connected in opposition, the total net radiation (radiation balance) is measured. At that time, the most important innovation made by *Rudolf Schulze* (1906–1974) was the introduction of Lupolen-H (polyethylene). Lupolen has the outstanding feature of transmitting radiation between 300 and 50 000 nm, i.e., the solar and terrestrial regions of the spectrum, which is important for atmospheric physics. As seen in Fig. 11.15, the transmission curve of Lupolen-H is quite stable over the whole region at about 80%, with the exception of three bands in the thermal region. This results in distinct sensitivities for the solar and thermal areas. Therefore, it is necessary to conduct separate calibrations for these two regions. The thermopiles, each protected by a weatherproof hemispherical Lupolen shield, are located at the center of a white-coated cylinder. Air is blown into the cylinder from one side and continuously flows around both hemispheres.

Fig. 11.14 Schulze radiation balance meter with blower (photo: K. Behrens)

Fig. 11.15 Transmission of Lupolen-H (after [11.46])

A thermocouple measuring the body temperature allowed the calculation of the atmospheric downward and upward radiation, assuming that the global and reflected radiation were additionally measured using separate pyranometers. At that time, such shielded instruments were highly advantageous for continuous measurements of solar and terrestrial irradiance. Their disadvantage was the requirement to use pyranometers during daytime in parallel with separate solar and terrestrial fluxes, which inevitably leads to greater uncertainties in the determination of the thermal radiation. The Schulze radiation balance meter, which later achieved acceptance and widespread use, was frequently investigated and its imperfections improved as far as possible. Furthermore, similar instruments were developed by other scientists [11.48] and manufactured, too.

11.2.5 Pyrheliometric Scales

Comparisons between Ångström and silver-disk pyrheliometers (Sect. 11.2.1), representing the Ångström scale and the Smithsonian scale (revised 1913), respectively, made at different sites and institutions showed various nonnegligible differences, which should not exist. As a consequence, the Commission for Solar Radiation (CSR), which was established by the Conference of Directors of Meteorological Services in 1905 in Innsbruck, solved the problem of these differences between the two scales by the adaption of a 3.5% difference at their meeting in 1923. From this moment, radiation values were to be reported on the Smithsonian scale by using a silver-disk pyrheliometer or by augmenting results from an Ångström pyrheliometer by 3.5% [11.15]. The discussions and comparisons went on thereafter, and two further pyrheliometers were developed. In cooperation between the Potsdam Meteorological Observatory and the Physikalisch-Technische Reichsanstalt in Berlin, a double water-stir pyrheliometer was developed [11.49], while in 1932 *Abbot* and *Aldrich* [11.50] at the Smithsonian Institution constructed after a proposal by *Shulgin* in 1927 [11.51]

an improved double water-flow pyrheliometer based on the 1905 instrument. Both new instruments used cavities as receivers and applied the compensation method of electrically generated heat. However, the problems and reasons for the differences between these two scales could not be solved [11.15].

In preparation for the International Geophysical Year (IGY) 1957/58, one aspect of which was the organization of worldwide radiation measurements, it was necessary, because of the parallel use of the two pyrheliometric scales, to homogenize the measurements. Experts participating at the International Radiation Conference at Davos in 1956 found a *solution* by defining the International Pyrheliometric Scale 1956 (IPS 1956) based on the following relations:

$$\begin{aligned} \text{IPS 1956} &= \text{Ångström scale} && + 1.5\% \\ \text{IPS 1956} &= \text{Smithsonian scale rev. 1913} && - 2.0\% \end{aligned}$$

This definition was adopted by the Commission for Instruments and Methods of Observation (CIMO) of the WMO and introduced as mandatory by the WMO effective 1 January 1957 [11.6].

Furthermore, the CIMO organized the First International Pyrheliometer Comparison (IPC I) with the goal of implementing IPS 1956 worldwide. IPC I in 1959 and later IPC II in 1964 took place at the Physikalisch-Meteorologisches Observatorium Davos (PMOD). During these comparisons, the Swedish Ångström pyrheliometer A-158 was chosen as the reference instrument because it was directly traceable to A-70, which represented the Ångström scale. Hence, applying the given correction value, it was simple to relate measurements to the IPS 1956 level as desired. As a result of these comparisons, the calibration factors for all the participating pyrheliometers were adjusted to give the same readings as the A-158. In 1969 at Carpentras, France, the Regional Pyrheliometer Comparison of the Regional Association VI (RA VI) of the WMO took place. As a result of this comparison and of IPC III, which took place one year later again at Davos, a malfunction

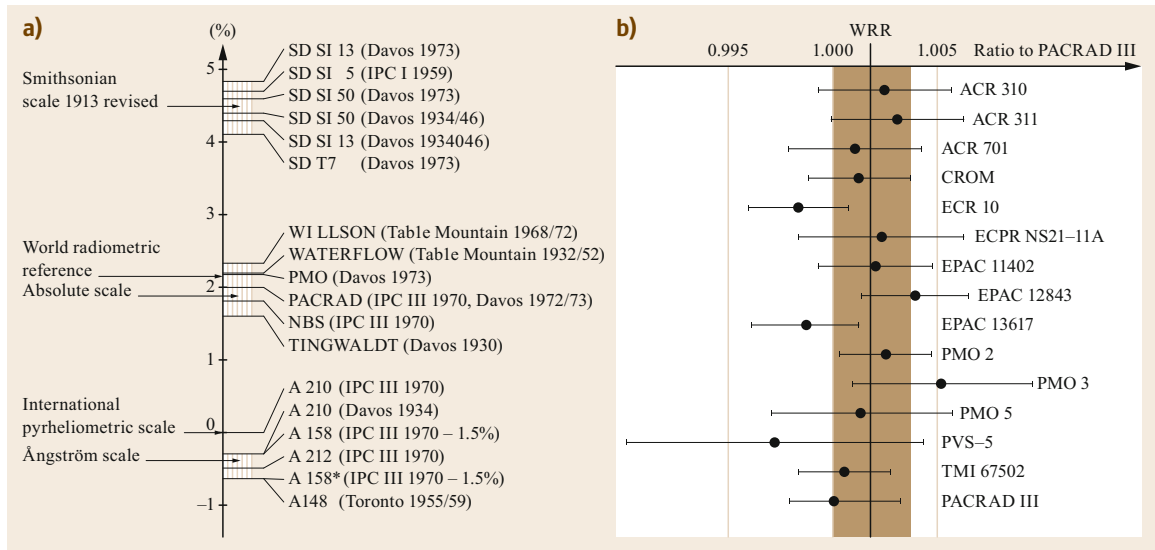

Fig. 11.16 (a) Summary of relations between different scales used for meteorological radiation measurements. (b) Summary of results of 15 absolute radiometers with different designs and origins and the definition of the WRR (after [11.13])

of the A-158 was ascertained, meaning that the defined IPS 1956 was not in conformity with its definition, leading to some confusion.

In several institutions in the USA, Belgium, the USSR, and Switzerland, a new generation of so-called absolute radiometers (pyrheliometers) was developed during the late 1960s and early 1970s by applying the compensation principle with electrically calibrated cavity receivers. This type of instrument is still in use and makes up the backbone of the traceability and comparability of worldwide solar radiation measurements. (For further information see Sect. 11.4.1.)

The results of IPC III in 1970, in which two of these new cavity radiometers already participated, and the increasing number of different absolute radiometers introduced in the following years enabled new investigations to answer open questions concerning the true radiation scale. At PMOD, where the World Radiation Center (WRC) was established in 1971, many comparisons between Ångström and silver-disk pyrheliometers as well as radiometers of the new type were carried out between 1971 and 1974 and during IPC IV, which took place in 1975. Additionally, old pyrheliometer measurements back to the 1930s were critically reviewed. These actions led to better understanding of the discovered problems [11.13]. Finally, the findings shown in Fig. 11.16a led to the definition of the World Radiometric Reference (WRR). Conversion from IPS 1956 to WRR can be realized by applying the relation

$$\frac{\text{WRR}}{\text{IPS}_{1956}} = 1.022. \quad (11.5)$$

WRR was enforced as mandatory by the WMO effective 1 January 1981.

The WRR was defined based on measurements by 15 cavity radiometers of 10 different types (Fig. 11.16b), which were absolutely characterized, while a subgroup of at least four of these of different types form the World Standard Group (WSG). The WRR represents the SI units of solar irradiance, with an estimated accuracy of better than $\pm 0.3\%$ [11.52]. The instruments of the WSG have to fulfill several criteria, first defined in [11.52] and later improved on in [11.1]. The WSG is kept at the WRC at PMOD, to enable intercomparison with the other members of the WSG at least once a year [11.1]. At the request of the CIMO, in 1970 the Executive Committee (EC) of the WMO decided to conduct IPCs every 5 years. Indeed, it is now difficult to imagine correct worldwide solar radiation measurements without the IPCs, because they represent the only opportunities to ensure worldwide traceability and comparability of solar radiation measurements versus the WRR, which is highly important when analyzing climate records gathered at different locations. Furthermore, IPCs are important for checking the long-term stability of the WSG. This is firstly realized by comparison within the WSG, and secondly with the help of the regular participation of regional and national standard pyrheliometers in the IPCs, mostly being cavity radiometers in recent times. Furthermore, the IPCs provide very good opportunities for capacity building regarding all questions related to radiation measurements. A report from the latest IPC-XII in 2015 as well as its results are given in [11.53].

The National Metrology Institutes (NMI) maintain the SI scale of radiant power, which is implemented using cryogenic absolute radiometers and also applies the compensation principle. Currently, these instruments are restricted to narrow beams of laser light and work at much lower power levels than solar radiometers and thus cannot measure solar irradiance. In 1991, an indirect comparison of the WRR as the solar irradiance scale versus the SI scale of radiant power took place in London, where using a special transfer standard, the cryogenic radiometer of the National Physical Laboratory (NPL) of the UK and a WSG radiometer were compared for the first time [11.54]. This intercomparison was repeated in 1995 and 2008 with improved general setups. In all three cases, agreement of both scales within the uncertainty of the comparisons was confirmed [11.55, 56].

The problems occasionally arising with single instruments of the WSG since 2005, which had been used at that time for more than about 30 years, indicated that they were approaching the end of their lifetime. The need to overcome these problems as well as other imperfections that were already known led in 2007 to a joint project of the PMOD/WRC, NPL, and Federal Office of Meteorology of Switzerland (METAS) to develop a cryogenic solar absolute radiometer (CSAR) [11.57], allowing the measurement of solar irradiance as well as radiant power. According to [11.57, p. 7], the main goal of this project was “to design and build a cryogenic radiometer suitable to replace the WRR as standard for solar irradiance

measurements” and secondly “to design and build the CSAR for space flight.” Replacing the WRR by CSAR will enable direct traceability of solar irradiance measurements to the SI radiant power scale, because this instrument may be incorporated into the corresponding and very important key comparisons of the Bureau international des Poids et Mesures (BIMP), which is mandatory for primary SI standards. Because the CSAR operates on the ground in a vacuum, for measuring solar irradiance it is absolutely essential to close the entrance with a material which transmits the solar spectrum reaching the Earth’s surface, preferably without hindrance. A detailed description of the CSAR is provided in [11.58], while a monitor to measure the integral transmittance (MITRA) and its characterization are depicted explicitly in [11.57]. CSAR participated in the IPC for the first time in 2010, resulting in minor improvements.

In 2010, the WMO formally signed the International Committee for Weights and Measures (CIPM) Mutual Recognition Arrangement (MRA) and designated PMOD/WRC to represent the measurement quantity of solar irradiance, meaning that the WRR has been accepted within the SI system.

The fourth comparison between the WRR irradiance scale and SI power scale took place as previously at the NPL and also for the first time at the Laboratory for Atmospheric and Space Physics (LASP) in Boulder, USA, which is equipped with a TSI radiometer facility (TRF) [11.59]. The comparison with the TRF showed that the WRR is 0.34% higher than the SI scale [11.60].

11.3 Theory

Radiation processes are responsible for the radiative equilibrium of the Earth, balancing the incoming solar with the outgoing terrestrial energy at the top of the atmosphere (TOA). A recent study on the global energy balance implies a subtle effect of radiative energy entering the subsurface of the Earth, albeit with some uncertainty (Fig. 11.17). It is very important to measure the radiation at the surface of the Earth as addressed within this chapter to reduce such uncertainty. To understand the physical processes and reasons behind the change of the radiation fluxes between the TOA and ground, it is necessary to measure these fluxes at the TOA and all levels in the atmosphere. These quantities are determined by special radiometers onboard satellites and airplanes at the TOA and intermediate levels, respectively (Chaps. 37, 38) as well as by radiosondes for vertical sounding and near the surface, and by spectral radiometers (Chaps. 28, 29, 34).

11.3.1 Optical Spectrum of Solar and Terrestrial Radiation

Measurements of the spectral distribution of solar radiation show a maximal irradiance at about 500 nm. Applying Wien’s displacement law with this wavelength, the temperature of the Sun’s surface can be estimated as about 5800 K. On the other hand, using the Stefan–Boltzmann law and knowledge about the solar irradiance at the mean Sun–Earth distance outside the atmosphere (solar constant), it is also possible to derive a temperature for the surface of the Sun of about 5800 K. Figure 11.18 shows the blackbody irradiance at 5800 K considering the Sun–Earth distance, and at 300 and 250 K corresponding to temperatures on the Earth’s surface. Furthermore, the solar irradiance at the TOA and at the surface at the solar zenith angle (SZA) of 30° are shown, revealing the well-known textbook

Fig. 11.17 Mean global energy balance of Earth and solar and terrestrial radiation fluxes (in W m^{-2}) on their paths through the atmosphere, as well as the influencing processes of absorption and scattering and latent and sensible heat fluxes also transferring energy from the surface to the atmosphere (after [11.61])

Fig. 11.18 Irradiances of solar and terrestrial spectrum at sea level calculated with libRadtran (after [11.62, 63]) using data of US standard atmosphere at sea level (Chap. 1)

structure due to absorption by atmospheric gases. Additionally, the atmospheric downward radiation at the surface (labeled *thermal SUR_in*), the terrestrial upward radiation at the surface (denoted *thermal SUR_out*), and at the TOA (indicated *thermal TOA_out*) in the thermal (terrestrial) region are plotted on the same figure. The *thermal SUR_out* plot is similar in shape to the blackbody irradiance at 300 and 250 K, and lies between them, meaning that the surface in this special case is irradiating like a blackbody at about 288 K (about 15 °C), while the features of the plots of *thermal TOA_out* and *thermal SUR_in* are not so smooth because of the effects of emission and absorption by the atmosphere. All these calculations were carried out with libRad-

tran2.0.1 [11.62, 63], using the data for the US standard atmosphere (Chap. 1) profile between sea level and the upper bound of the atmosphere as input data. These results show that, as mentioned above (Sect. 11.1.1), it is necessary to investigate the spectral region from about 300 to about 50 000 nm. It is seen that the blackbody curves at the temperatures of the Sun and the Earth overlap at a low level of irradiance at the long- and short-wave end, respectively. Also, the irradiances of solar and thermal radiation calculated by libRadtran overlap more or less at the surface level, depending on the atmospheric conditions, in the spectral area between about 3 and 4 μm . The following conclusions can thus be drawn regarding the conduction of radiation measurements:

- A spectrally nonselective detector covering the whole wide region is preferred.
- It is possible to distinguish between the solar and terrestrial part.
- It is impossible to distinguish between the origin of radiation in the spectral area between about 3 and 4 μm , resulting in imperfect measurements.

Based on past experience as described in Sect. 11.2, and considering the urgent need for automatic data acquisition, only sensors delivering an electrical output are currently considered. These are based on the thermoelectric method (Sect. 11.3.2), mainly applying the approved thermopile and covering the whole solar and terrestrial spectral range, and for special cases in the solar area the more recent photodiode-based method (Sect. 11.3.3), as described below.

11.3.2 Thermoelectric Method

The thermoelectric method was first applied available after the discovery of the thermoelectric effect by Thomas Johann Seebeck (1770–1831) in 1821 (Chap. 8). According to the thermoelectric or Seebeck effect, a voltage originates in an electric circuit consisting of two different conductors (A, B) whose junctions are at different temperatures T_1 and T_2 (Fig. 11.19).

The resulting thermovoltage or electromotive force (EMF) depends on the Seebeck coefficients S of the dissimilar conductors and the temperature difference between the junctions. The greater the difference between the materials and thus their Seebeck coefficient in the electrothermal series, the greater the resulting EMF for a given temperature difference. For frequently used, e.g., copper-Constantan, junctions (Constantan is a copper-nickel alloy), the Seebeck coefficient is $41.5 \mu\text{V K}^{-1}$ at 273 K (see also Chap. 8) for a single thermocouple. Because a single junction generates a very low EMF, they are usually interconnected as a series of several thermocouples. Thermopiles can be designed with different shapes, depending on the location and realization of the active (hot) or passive (cold) junctions (Fig. 11.20).

Fig. 11.19 Schematic of thermocouple consisting of two dissimilar wires (A, B) whose junctions are at different temperatures T_1 and T_2 , generating an electromotive force (EMF)

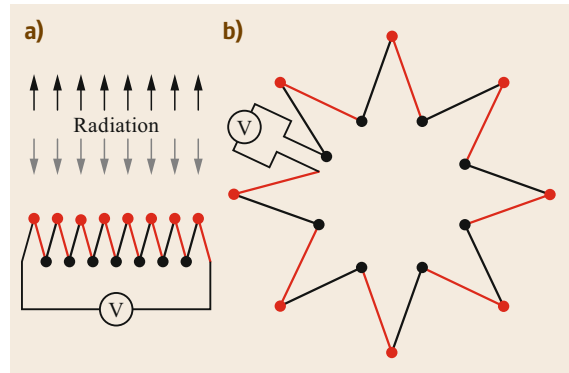

Fig. 11.20 (a) Thermopile, where the active (hot) junctions (red dots) are irradiated, while the passive ones (black dots) are shielded and at a more or less stable reference temperature level. Applied in black thermopiles (see, e.g., Sect. 11.2.2). (b) Active (red dots) and passive (black dots) junctions are located at the same level. The temperature difference between the hot and cold junctions is realized by achieving different levels of absorption, mainly using different paints, applied in black-and-white thermopiles (see, e.g., Sect. 11.2.2). In both pictures the thick red and black lines represent dissimilar wires

Thermopiles are, as suggested by their name, thermal sensors that transform radiant into thermal energy. The resulting temperature increase or difference between the active and passive junctions is finally converted into a measurable voltage.

There are two types of black thermopiles and one type of black-and-white thermopile. While black-and-white thermopiles are only used in pyranometers, black thermopiles are applicable in all broadband radiation instruments. In any case, the active junctions are blackened and irradiated, while the passive ones remain at a *reference* level, which can be realized in three different ways:

- Different absorption
- Different heat conduction (heat sink)
- No interaction with the radiation source.

For each type, the temperature difference originating between the hot and cold thermocouples generates an EMF that is proportional to the irradiance.

For a black-and-white thermopile, the thermocouples are typically located at the same level (Fig. 11.20b; Sect. 11.2.2). The hot junctions are in close thermal contact to blackened circular plates or segments, or arranged in a checkerboard configuration, while the cold junctions are thermally spliced with the corresponding white ones. The differential absorption of the black

and white surfaces ensures a temperature difference between the junctions and generates a voltage that is proportional to the irradiance.

The two types of *black* thermopiles (Fig. 11.20a) differ in how the temperature difference between the active and passive thermocouples is generated. In the case of the classical Moll thermopile (Sects. 11.2.1 and 11.2.2), the different heat capacity of the hot and cold junctions (heat sink) is used, while in the second case, the active junctions are irradiated by the incident solar or terrestrial radiation while the passive ones are facing toward the bottom of the instrument and are in close thermal contact with it, forming the heat sink. In this case, the passive junctions do not interact with the radiation source.

The Moll design uses very thin (0.005 mm) strips of soldered Manganin and Constantan, which are blackened. The ends of these strips are soldered to copper bars, which are fastened with electrical isolation but good thermal contact to a thick brass plate (see, e.g., Figs. 11.6, 11.7). In this way, a minimal heat capacity of the hot junctions in relation to the maximal heat capacity of the passive one can be realized. An advantage of these thin, nearly massless elements is that they instantaneously reach an equilibrium temperature [11.24].

Beside the frequently used copper-Constantan and Manganin-Constantan, combinations of other alloys are also applied. Constantan and Manganin are trade names. Constantan consists of 55% Cu, 44% Ni, and 1% Mn, while Manganin is composed of about 84% Cu, 12% Mn, and 4% Ni.

Also, over the course of time, different paints and lacquers have been tested and improved. For several years now, paints that exhibit flat and nonselective absorption over the whole spectral region of interest from about 300 to 50 000 nm have been applied.

In recent years, rapid development has occurred in microsystems engineering, enabling the fabrication of novel thermopiles with tiny dimensions in comparison with classical devices. Like the classic ones, these thermopiles are still based also on the effect discovered by Seebeck. Furthermore, they work like the described black thermopiles. In these new thermopiles, the hot junctions are located in the center and are irradiated while the cold ones are located at the perimeter and connected to the heat sink. The thermopile itself is a thin film encapsulated in a can (Fig. 11.21b). Also, these detectors exhibit a flat spectral response across the relevant region from the ultraviolet up to the far infrared. Because of their small dimensions and tiny thermal mass as well as thermal conductivity, they offer essentially improved performance parameters, for instance, response time [11.64, 65].

Fig. 11.21a,b Novel sensor with thermopile located inside a can (b), and the back of the sensor (a) of the new pyranometer ER08-S from Middleton Solar, Australia (see also Fig. 11.29) (photo courtesy of D. Mathias, Middleton Solar)

11.3.3 Photodiode-Based Method

Compared with thermopiles, photodiode-based sensors are a recent introduction to the field of radiation measurements. Based on semiconducting material such as silicon, the internal photoelectric effect becomes important. A photodiode is based on a semiconducting n-p junction formed between a material with electron vacancies (p-type semiconductor) and a material with excess electrons (n-type semiconductor). If such a system is illuminated, an electrical current arises, being roughly proportional to the incoming irradiance. Photodiode-based sensors respond to the number of incident photons of a specific wavelength and not to the energy, resulting in a difference between the external quantum efficiency and the irradiance, which causes wavelength dependence and a spectral mismatch.

The advantages of photodiodes include their very low production cost and very fast response times of about 10^{-5} s, depending on the thickness of the n-p junction. One disadvantage is their spectral response, as seen in Fig. 11.22, which is not flat and only covers the range from 400 to 1100 nm, typical for silicon photodiodes, resulting in a spectral mismatch, especially on clear days, when Rayleigh scattering is significant. However, also under a cloudy sky, the agreement with measurements taken using thermopiles is still not good. Nevertheless, photodiodes are applied for special tasks in the solar range, especially if the demands regarding uncertainty are not high, for instance when measuring sunshine duration. Furthermore, when used with special filters, they become highly suitable, for instance for PAR measurements. In contrast to thermopiles, photodiodes transform the incoming radiant energy directly into electrical energy, thus enabling the use of automatic data acquisition systems.

Fig. 11.22 Spectral response of photodiode-based silicon pyranometer and thermopile pyranometer as well as the solar radiation spectrum at sea level. *Blue*: Solar radiation spectrum at sea level, *green*: spectral response of silicon pyranometer, *red*: spectral response of thermopile pyranometer (after [11.66])

11.3.4 Separation of Solar and Terrestrial Radiation

As is generally known and as described in Sect. 11.3.2 from the theoretical point of view, model calculations show that the solar and terrestrial spectra overlap in the range between 3 and 4 μm . However, it is necessary for many reasons to investigate the solar and terrestrial separately.

It was already known in the past that glass is a suitable material to achieve this requirement to distinguish the solar from thermal spectral region. However, this cannot achieve exclusive measurement of the terrestrial part of the spectrum.

In the late 1960s, Eppley Laboratory Inc., USA, a manufacturer of radiation instruments, first commercially offered a dome made from KRS-5 (thallium bromide-iodide) combined with a vacuum-deposited interference filter to block solar radiation, resulting in gray transmission from 4 to 50 μm [11.13].

As an example, the transmission of a glass dome typically used for pyranometers to measure solar radiation and the transmission of a silicon dome together with its special coatings applied to the CG4 pyrgeometer of Kipp and Zonen B.V., the Netherlands [11.67] are shown in Fig. 11.23 and 11.24, respectively.

The results shown in Fig. 11.23 reveal that the transmission of the glass dome for pyranometers is flat at a level above 90% between about 350 and 2000 nm with a steep edge at the cut-on, while at the cut-off it first shows a steep slope up to the 30% level, then a rather gentle slope up to about 4000 nm. The 50% points are given as 305 and 2800 nm by the EKO Instruments Co., Ltd. Japan [11.68], when applied to, e.g., the MS-802

Fig. 11.23 Typical spectral transmission of glass as used with several EKO pyranometers (e.g., MS802) (after [11.68])

pyranometer. Depending on the kind of glass that is chosen, which is frequently not specified, other manufacturers state values between 285 and 2800 nm or 300 and 2800 nm. Kipp and Zonen B.V. [11.69] and Hukseflux Thermal Sensors B.V. [11.70] have specified their use of quartz domes with 50% points of 200 to 3600 nm and 20% points of 190 to 4000 nm. These pyranometers equipped with quartz domes can measure the total solar spectral range reaching the surface of the Earth.

Fig. 11.24 Spectral transmittance of dome applied on CG4 pyrgeometer of Kipp and Zonen (after [11.67])

In contrast to the transmission curve of glass (Fig. 11.23), the example curve of the pyrgeometer dome shown in Fig. 11.24 is not flat unfortunately, which depends on the features of the silicon dome and the special coating applied. Kipp and Zonen B.V. [11.67] specifies its pyrgeometer domes with 50% points from 4.5 to 42 μm , while Hukseflux Thermal Sensors B.V. [11.71] state nominal transmission from

4.5 to 40 μm , with specific values given in the product certificate. Nevertheless, pyrgeometers with such domes can measure terrestrial radiation in the thermal spectral range without sunlight even in daytime. Note that all pyrgeometers currently available on the market use similar materials, all of which do not offer flat spectral transmission, resulting in uncertainties in the measurement of terrestrial irradiance (Sect. 11.4.3).

11.4 Devices and Systems

In principle, radiation measurement instruments are single devices which can be categorized according to the origin of the radiation and the spectrum they cover. Such devices can also be categorized according to their opening or viewing angle, or according to the target of such measurements in the case of solar radiation. Furthermore, one can also consider whether the instrument is single or combined, and pointing to the upper or lower hemisphere. For the measurement of specific quantities such as direct or diffuse solar radiation, supplementary equipment such as a solar tracker is necessary. Other devices, such as ventilation and heating units, have also been developed to improve the quality of such measurements in combination with the radiation instrument. All of the radiation devices described below offer an electrical interface for direct measurements or recording, although these instruments are not considered here.

11.4.1 Pyrheliometer

A pyrheliometer measures the direct solar irradiance on a surface perpendicular to the rays from the Sun (see also Tables 11.2–11.4). This means that their receivers have to follow the path of the Sun continuously. Nowadays, this is achieved by modern computer-controlled trackers, while in the past such alignment was done manually or was clock driven. A pyrheliometer consists of a sensor (a thermal detector such as a thermopile

or a cavity absorbing the incident radiation) mounted in a view-limiting device. In most cases, this is a tube or diaphragm tube, defining the field-of-view geometry. As noted in Sect. 11.2.1, pyrheliometers with different opening angles were constructed and applied in the past, because there were no rules defining this important feature. Typical opening half-angles covered the range between 2.5° and 7.5°. Referring to [11.13], the opening half-angle of 2.5° and slope angle of 1° recommended for all new pyrheliometer designs in [11.72] represent a compromise to minimize the measurement of circumsolar radiation while remaining consistent with sufficient tracking tolerances (Fig. 11.25).

Because the apparent solid angle of the Sun is only about 0.5°, there is an additionally contribution due to the acquisition of the Sun's aureole. This circumsolar radiation depends on the atmospheric turbidity and changes continuously depending on changing atmospheric constituents and conditions.

As stated in [11.73], three different types of device can be distinguished:

- Absolute pyrheliometers
- Compensation pyrheliometers
- Pyrheliometers without self-calibration capability.

Absolute Pyrheliometers

According to [11.72], an absolute pyrheliometer is principally a realization of the scale of irradiance. In this

Fig. 11.25 View-limiting geometry: The opening half-angle is $\arctan R/d$; the slope angle is $\arctan(R-r)/d$. (Adapted from [11.1])

case, the instrument's constant is determined by a so-called characterization. The physical properties of all the parts of the instrument influencing the measurement

result must be determined using laboratory experiments, model calculations, or typical values, to finally describe the deviations from ideal behavior. The resulting reduction factor enables the calculation of the irradiance from the output signal of the instrument. Blackbody receivers and electrically calibrated differential heat flux meters are typical features in the design of absolute pyrheliometers used today.

As already mentioned in Sect. 11.2.5, in the late 1960s and at the beginning of the 1970s, a number of absolute pyrheliometers, also called *self-calibrating pyrheliometers*, were developed at several institutions in the USA, Belgium, the USSR, and Switzerland. They can mainly be distinguished based on the sensors, cavity type, and operation mode applied, as presented in Table 11.6.

A comprehensive description of the construction, functionality, and features of these absolute pyrheliometers, also called cavity radiometers, is provided in [11.18]. Detailed information about each type of instrument is available in special papers published by those who constructed these pyrheliometers [11.74–79].

Table 11.6 Summary of self-calibrating cavity pyrheliometers (after [11.13])

Identification	Sensor and mode	Cavity type	Cavity–heat flow meter arrangement ^a	Aperture area (cm ²)	Characterization ^b
ACR: active cavity radiometer developed by R.C. Willson, Jet Propulsion Laboratory, Pasadena, CA, USA	Resistance thermometer sensor operated in active mode	Classical cone modified to remove meniscus at bottom point, specular paint		0.5	E and M
CROM: developed by D. Crommelynck, Institut Royal Meteorologique de Belgique, Bruxelles	Flux meter with integrated thermopile operated in active mode	Cylindrical in each of two cavities with flat bottom and diffuse paint		0.5	E
H–F: developed by J. Hickey and R. Frieden, The Eppley Laboratory, Inc., Newport, RI, USA	Circular plated and wire-wound thermopile operated in passive mode	Inverted cone within a cylinder, specular paint		0.5	E and T
PACRAD: primary absolute cavity radiometer, developed by J.M. Kendall, Jet Propulsion Laboratory, Pasadena, CA, USA	Discrete junction thermopile, operated in passive mode	Classical cone with truncated inverted cone above, diffuse paint		1.0	M
PMO: developed by R.W. Bruss and C. Fröhlich, Physikalisch-Meteorologisches Observatorium, Davos, Switzerland	Mark 2 has a discrete thermopile, mark 6 a resistance thermometer, both operated in active mode	Inverted cone within a cylinder, specular		0.2	E
TMI: developed by J.M. Kendall, Technical Measurements Inc.	Discrete junction thermopile, usually operated in passive mode	Inverted cone in cylinder, semispecular paint		1.0	E and T

^a The drawings illustrate the cavity–heat flow meter arrangements:

— cavity, = heat flow meter, // heat sink

^b E: characterization by experimental methods

M: characterization based on model calculations

T: characterization based on typical values

According to Table 11.6, absolute pyrheliometers are operated in either *active* or *passive* mode. Operation in active mode means that, during the whole measuring period consisting of alternately closed (shaded) and open (irradiated) phases, a constant heat flux is maintained, while in the passive mode electrical heating is only provided in the shaded phase at the beginning of each measurement series. In the active mode, the difference in electrical power during the two phases is proportional to the radiative power.

As mentioned in Sect. 11.2.5, the cryogenic solar absolute radiometer (CSAR) [11.57, 58] embodies the state of the art in absolute pyrheliometry, because it establishes a link between the self-calibrating cavity pyrheliometers of the 1970s, satellite radiometers, and the (laboratory) radiometers of the National Metrology Institutes (NMI) representing the SI.

Typically, absolute pyrheliometers are only used in fair weather for calibration purposes as reference instruments because they have open apertures (Sect. 11.6.1). Additionally, Eppley Laboratory, Inc. offers H-F-type absolute pyrheliometers with a window that closes the aperture for use in all weather conditions and realize continuous, highly precise measurements of direct solar radiation.

Compensation Pyrheliometers

A typical and the most well-known compensation pyrheliometer is that of Knut Ångström [11.16] described in Sect. 11.2.1, so it is not necessary to repeat its description here. This device applies the compensation technique, meaning that the incident radiation flux is equalized by a corresponding electrically generated heat flux. It has an ambiguous position historically, because the constant of the first instrument was derived from the properties of the pyrheliometer (as for an absolute pyrheliometer) and later the constants of other instruments of the same type were determined by side-by-side comparison. By today's standards, the derivation of the constant for this first compensation pyrheliometer is not comparable to the characterization achieved with current absolute pyrheliometers. The Ångström compensation pyrheliometer is inferior in quality compared with recently introduced self-calibrating pyrheliometers, but it remains a stable instrument that has served as a standard for many years.

Pyrheliometers Without Self-Calibration Capability

Pyrheliometers without a self-calibration capability include typical station or field pyrheliometers. Very stable instruments such as the silver disk pyrheliometer, Michelson bimetallic actinometer, Linke–Feussner pyrheliometer, and Eppley NIP (see also Sect. 11.2.1)

have been used to calibrate other *lower*-class pyrheliometers or pyranometers (Sect. 11.6). Furthermore, pyrheliometers in this group have been applied to determine the Linke turbidity factor T [11.6, 12, 80] or if equipped with colored glass filters (Sect. 11.2.1) to calculate the Ångström turbidity coefficient β [11.6, 12, 81, 82], assuming that the Sun and its vicinity of not less than 15° are not covered by any clouds. These kinds of measurement are spot measurements which are mainly carried out by manual alignment of the pyrheliometer to the Sun. With the availability of sun photometers (Chap. 29), the derivation of the optical depth, which provides more information, gradually replaced these kinds of turbidity determinations. Continuous measurement of direct solar radiation requires a weatherproof pyrheliometer with a sensor delivering an output signal suitable for recording and which is mounted on an equatorial tracker that steadily follows the Sun's path. Currently, these demands are only fulfilled by pyrheliometer instruments equipped with thermopiles. In the past, such trackers were clock or electromechanically driven. However, because of the lack of suitable pyrheliometers (between the 1950s and 1990s, only the NIP was available commercially) and trackers, only a few stations worldwide measured direct solar radiation continuously.

This situation changed at the beginning of the 1990s, when microelectronics had become established and computer-controlled solar trackers and data recording systems became available. Additionally, the demand for improved, accurate all-weather pyrheliometers for science (e.g., BSRN) and industry (e.g., solar industry) emerged. As a result, manufacturers developed new instruments, whereas the imperfections of known devices were mainly eliminated or ameliorated by the addition of various new features.

Pyrheliometers without self-calibration capability that are currently available on the market share the following characteristics: They all use thermal detectors (thermopiles) as receivers, located at the end of a tube, and these are all black thermopiles (Sect. 11.3.2). The (front) aperture of the tube is covered by glass. Concerning the opening angle, they all fulfill the important criteria recommended by the WMO (Sect. 11.4.1), so that direct solar radiation is measured uniformly worldwide.

Available pyrheliometers (see Fig. 11.26 for examples) differ in terms of the detector selected and/or their internal setup, which in most cases is proprietary. Furthermore, the covering front glasses are different but span the spectral region from at least 300 to 3000 nm. In many cases, types of glass with somewhat wider spectral coverage are applied. Pyrheliometers with novel thermopile sensors and very short time constants of about ≤ 0.5 s are now available (Sect. 11.3.2), fulfill-

Fig. 11.26 Tracker with different modern pyrheliometers without self-calibration capability. *Top row:* EKO MS-56 and Eppley sNIP, *bottom row:* Kipp and Zonen CHP1 and Hukseflux DR01 (from left to right) (photo: K. Behrens)

ing the new criteria for so-called *fast response pyrheliometers* [11.73]. The temperature dependence of the receivers is, for instance, compensated using electronic compensation circuits. Furthermore, some instruments are equipped with thermistors or Pt-100 thermometers to measure the temperature of the instrument and thus enable subsequent temperature correction (for specifications, see Table 11.9).

Not only have the performance properties regarding direct measurements been improved, but other devices for pyrheliometers, such as ventilation and heating systems for the window to avoid the effects of dew, rime, and raindrops on the front glass, have also been manufactured. Some of these instruments also offer ingress protection against dust and water (IP67). While in the past, pyrheliometers only offered a classical analog voltage output, in some cases the user can now additionally select between different output methods or communication protocols such as Modbus or RS-485. Also, so-called smart instruments are available, allowing a direct link to a personal computer (PC) with the possibility of collecting different types of data and controlling many parameters.

Because this development, especially concerning so-called smart features, has been very fast, it is recommended to check the specification to select a pyrheliometer with the desired features. Furthermore, the statements regarding the deployment and measurement site given in Sect. 11.1.3 are valid and should be considered, too.

Nearly all instruments currently on the market still offer the classical analog voltage output (U) generated by the detector. In this case, the direct solar irradiance (E_1) can be calculated using the known sensitivity (S) as

$$E_1 = \frac{U}{S}. \quad (11.6)$$

Because the sensitivity of most sensors lies in the range between about 7 and $15 \mu\text{V} (\text{W m}^{-2})^{-1}$, they generate voltages of about 10 mV at an irradiance of 1000 W m^{-2} , assuming a sensitivity of the pyrheliometer of $10 \mu\text{V} (\text{W m}^{-2})^{-1}$. In the case when corrections are necessary to calculate the direct solar irradiance, e.g., due to temperature dependence, the manuals of each instrument should contain corresponding instructions.

In the framework of the BSRN, the Variable Conditions Pyrheliometer Comparison (VCPC) was organized at the Solar Radiation Research Laboratory (SRRL) of the National Renewable Energy Laboratory (NREL) in Golden, Colorado. It took place from November 2008 to September 2009, during which 29 pyrheliometers (all the types of thermopile instrument available on the market at that time, plus some experimental types) and three all-weather absolute pyrheliometers of H-F type participated. The goal was to determine how commercial pyrheliometers performed under different real weather conditions. The results were, as expected, that the windowed cavity radiometers showed the smallest uncertainty of about 0.5%, followed by a group with better than 0.9%, while the remaining pyrheliometers still performed better than 1.4% at a 95% confidence level. Two of the 29 pyrheliometers could not be included in this analysis because of their too large deviations. Details including the experimental setup and results were published in [11.83].

The specifications regarding the different types of pyrheliometer are given in Sect. 11.5, while their calibration is described in Sect. 11.6.

11.4.2 Pyranometers

A pyranometer measures the solar radiation incident from a viewing angle of 2π sr on a flat surface (Tables 11.2–11.4). A pyranometer consists of a sensor, usually implemented in a metallic body. The detector faces the radiation source, which is normally the sky with the Sun, or other surfaces reflecting the sunlight such as the ground if it looks downward, or a mixture of both in the case of an inclined installation. Nowadays, only sensors with an electrical output are applied in pyranometers (Sects. 11.3.2 and 11.3.3). These detectors transform the incident radiant energy into either thermal energy, generating a temperature difference between the active and passive junctions of a thermopile which is converted into

an electromotive force (EMF), or directly into electric energy in the case of photodiodes.

Like other types of instrument, pyranometers are nonideal and their output signal is influenced by several parameters, allowing to classify the quality of the different pyranometers. These specification lists are given by WMO in the CIMO-Guide [11.1] as recently updated by the ISO [11.73] (Sect. 11.5, Table 11.8). Some of these points are considered below.

Depending on their construction, thermopiles are protected against wind, precipitation, and dust by one or two glass domes, as well as to prevent heat losses and exchange of thermal radiation with their surroundings. The use of cut-glass hemispheres is important for the observance of the cosine law, while the use of simple and not appropriately treated flat glass would yield a dependence on the angle of incidence of the radiation, influencing the directional response. Recently, thermopiles with receivers that are additionally covered by a diffusor have also become available, while most photodiodes are also situated behind a diffusor, too. Pyranometers are generally all-weather instruments and therefore robust in design. Furthermore, thermopile instruments are equipped with a sun shield to prevent heating of the pyranometer body. In many cases, pyranometers have a drying cartridge filled with silica gel to absorb humidity inside the body and thus prevent condensation. The newer types also offer ingress protection against dust and water (IP67) and are almost sealed, thus not requiring such a drying cartridge.

While in the past pyranometers offered only the classical analog voltage output, in some cases the user can now additionally select between different output methods or communication protocols such as Modbus or RS-485. Also, so-called smart instruments are available, allowing a direct link to a PC with the possibility of collecting different data and controlling many parameters.

Because this development, especially concerning so-called smart features, has been very fast, it is recommended to study the specification to select a pyranometer with the desired features.

Currently, nearly all instruments on the market, independent of their type as discussed below, still offer the classical analog voltage output (U) generated by the detector. In this case, the global solar irradiance ($E_{g\downarrow}$) can be calculated from the known sensitivity (S) as

$$E_{g\downarrow} = \frac{U}{S}. \quad (11.7)$$

Because the sensitivity of most sensors lies in the range between about 7 and 15 $\mu\text{V} (\text{W m}^{-2})^{-1}$, they generate voltages of about 10 mV for an irradiance of 1000 W m^{-2} , assuming a sensitivity of the pyranometer of 10 $\mu\text{V} (\text{W m}^{-2})^{-1}$. If it is necessary to apply corrections, e.g., due to temperature dependence, the manuals of each instrument contain corresponding instructions.

The specifications for different pyranometers are given in Sect. 11.5, while their calibration is described in Sect. 11.6.

As seen above, only thermopiles or photodiodes are applied as sensors in pyranometers, where the former can be divided into black and black-and-white types (Sect. 11.3.2). Furthermore, the statements given in Sect. 11.1.3 regarding the deployment and measurement site are valid and should be considered, too.

Pyranometers with Black Thermopiles

Typically, pyranometers based on black thermopiles include two glass domes, because these thermopiles are particularly sensitive to the impact of changes in their heat balance (for an example, see Fig. 11.27). In the case of a black thermopile, the passive junctions pointing inside the body of the instrument are in close thermal contact with it, functioning as the heat sink. In contrast to the *undisturbed action* of the passive junctions, the active ones are influenced by the target incident solar radiation and the resulting heating. However, the ideal heat conduction from the active to passive junctions (heat sink) is disturbed by the loss of heat via advection and convection as well as radiative exchange in the thermal spectral region. The two glass domes are thus necessary to reduce these processes, especially the

Fig. 11.27 Two different pyranometers of black thermopile type: SR12 (left) and SR22 (right), here without ventilation unit (manufacturer: Hukseflux Thermal Sensors B.V., the Netherlands, photo: K. Behrens)

Fig. 11.28 Irradiance of pyranometers from Kipp and Zonen B.V. depending on the net thermal radiation at nighttime ($\text{sza} > 95^\circ$) from 1 to 30 April 2016 at the Meteorological Observatory Lindenberg – Richard-Aßmann Observatory, Germany. (The red marks cover big central parts of the green ones, and the marks of the CM22 partly cover the marks of the CM21)

radiative exchange, which results in the so-called thermal offset. This arises because, in most cases, the sky is colder than the pyranometer body and especially the glass domes [11.84]. Therefore, this thermal radiative flux diminishes the temperature of the active junctions. This process is always active but can be masked by greater incoming solar radiation [11.85]. In particular, at nighttime, they can cool down below the passive ones or the corresponding body temperature, resulting in negative readings. The magnitude of this thermal offset (or so-called zero offset) is proportional to the net thermal radiative flux. This zero offset is one parameter of the specifications on the pyranometer classification list (Sect. 11.5, Table 11.8), and all manufacturers try to minimize it for their instruments.

This feature is exemplarily demonstrated for Kipp and Zonen pyranometers (Fig. 11.28) of different types and quality, although it applies to all pyranometers with black thermopiles of all makes. The CM22 has the highest quality, because of the inclusion of two quartz domes and their special manufacturing with the pyranometer body, while the other instruments have only glass domes. The CM21 is also equipped with two domes, while the other two instruments of CM3 type are only furnished with one dome. The CM3 forms part of the net radiometers CNR1 and CNR4. Both single pyranometers CM21 and CM22 as well as the CNR4 are ventilated and heated. The CNR4 is the successor to the CNR1, which has not been produced for several years now. This figure shows the typical features of these different quality classes. The CM22 and CM21 show almost no scatter or dependence on the thermal radiative flux, while the CNR4 and especially the unventilated CNR1 exhibit a lot of scatter as well as some outliers, indicating the strong influence of the exchange processes as well as the dependence on the thermal radiative flux.

The above-described features are typical of pyranometers with black thermopiles from all manufacturers. However, in recent years, pyranometers and/or thermopiles have been improved using various methods that are partly invisible to the user because of proprietary technologies, mainly in relation to the sensors. For instance, careful ventilation of the pyranometer body and domes in combination with appropriate heating can diminish thermal offsets. Moreover, good ventilation protects against or reduces the effects of dew, rime, dust, and precipitation that in general disturb radiation measurements and represent error sources.

Pyranometers with Novel Black Thermopiles

As mentioned in Sect. 11.3.2, novel thermopiles based on the principles of black ones are now available. The EKO MS-80 and Middleton Solar ER08-S (Fig. 11.29) are pyranometers that use this new type of thermopile. In contrast to the classic black thermopile type, they have only one glass dome. This is sufficient, because these novel thermopiles have some interesting new features. One is the absence of thermal offsets. This is achieved because the thermopile is encapsulated in a can while the sensor (Sect. 11.3.2, Fig. 11.21) is implemented in the pyranometer body. Because of their small dimension, they react very fast and can be optimized regarding other features. Ventilation and heating are only needed to prevent dew, rime, dust etc. from attaching to the glass dome. The sensors are located behind a quartz diffusor in the case of the MS-80, and underneath a diffusor made from PTFE (polytetrafluoroethylene, better known by the trade name *Teflon*) in the case of the ER08-S. By this means, the directional response lies within the range of class A of the ISO specifications (Sect. 11.5, Table 11.8). A further important and impressive feature is the quick response time of less than 0.5 s for both instruments.

Pyranometers with Black-and-White Thermopiles

As the name implies, in this type of pyranometer, visible black-and-white circular plates or segments are typically arranged in a star or checkerboard configuration. Currently, only three types of black-and-white thermopile pyranometer are manufactured: the star pyranometer by Schenk in Austria, the black-and-white model 8-48 pyranometer by Eppley Laboratory Inc., USA (Fig. 11.30), and the checkerboard-type SF-06 pyranometer (a refinement of the Yanishevsky M-80 pyranometer) by Peleng company in Belarus.

In contrast to black thermopile pyranometers, these sensors are only protected by one dome. A second dome is not necessary because the active and passive junctions underneath the distinctly colored surfaces (Sect. 11.3.2) are at the same level and it is assumed that the thermal radiation is equally absorbed by the black and white paints. Furthermore, both types of junction are subjected to the same ambient influences. Hence, zero off-set is not a problem for this type of pyranometer. Pyranometers with black-and-white thermopiles show a slow response to changes in irradiance, while their directional response only fulfills the specifications of ISO class C [11.73] (Sect. 11.5, Table 11.8).

Fig. 11.30 Star pyranometer (left) and black-and-white pyranometer (right) (photo: K. Behrens)

Photodiode-Based Pyranometers

Photodiode-based pyranometers use a photoelectric receiver, being a silicon photodiode in most cases (Sect. 11.3.3), thus they are frequently called Si pyranometers. The sensors are mainly placed in small metallic cylinders whose aperture is closed by a cone-shaped diffusor made of a synthetic material. This diffusor ensures that the directional response demands are met, and its shape ensures that rain will run off. In the case of heating, the deposition of dew or rime can be prevented. In general, photodiodes have a restricted spectral response from about 400 to 1100 nm (Sect. 11.2.2, Fig. 11.22), a range in which about 70% of solar energy is incident. Nevertheless, important ranges below and above these limits are not covered. Consequently, photodiodes may only be applied for measurements of solar radiation, while the terrestrial spectral range is excluded. Moreover, the sensitivity of these detectors depends on the wavelength and is not spectrally flat, like that of a thermopile. The subsampling of the solar spectrum together with this nonflat spectral response result in a spectral mismatch on both cloudless and cloud-covered days, resulting in greater uncertainty. Furthermore, they also exhibit temperature dependence.

Nevertheless, photodiode-based pyranometers have gained wide acceptance, especially in the photovoltaic sector, because the spectral features of Si pyranometers and photovoltaic cells are very similar. The production costs of these instruments are low, hence they can be applied in applications where great accuracy is not strictly required. In comparison with the classic thermopile, a photodiode has a very short response time of only a few milliseconds. Therefore, photodiodes are preferred sensors for use in rotating shadowband radiometers, too (Sect. 11.4.6). Furthermore, it should be mentioned that photodiode pyranometers are explicitly considered in the latest ISO update [11.73] (Sect. 11.5), in contrast to its predecessor.

11.4.3 Pyrgeometers

A pyrgeometer (for an example, see Fig. 11.31) measures the terrestrial downward or upward radiation in a viewing angle of 2π sr on a planar surface (Tables 11.2–11.4). Typically, it has the same construction as a pyranometer, with the important difference that the glass dome is replaced by a special filter that blocks solar radiation (Sect. 11.3.4). Black thermopiles are applied as the sensor in all recent pyrgeometers.

Except for the first steps described in Sect. 11.2.3, the successful development of pyrgeometers started with the advent of the Eppley precision infrared pyrgeometer (PIR) first described in [11.86]. This pyrgeometer consisted of a wire-wound plated copper–Constantan thermopile embedded in an aluminum casting acting as the heat sink within copper. The thermopile was protected by a 50-mm-diameter hemisphere of KRS-5 (thallium bromide-iodide) on whose internal surface an interference filter was deposited to block solar radiation. The cut-on was between 3 and 4 μm , with a cut-off at 50 μm [11.86]. Over time, this instrument underwent various improvements, including the replacement of the KRS-5, which deteriorated under the influence of environmental exposure, by a silicon dome. Furthermore, beside the body temperature (the temperature of the cold junctions of the thermopile), the dome temperature was also measured using a thermistor, located at the rim of the dome and used to include the influence of the incident irradiance [11.87].

Fig. 11.31 Two Eppley PIRs (*center*) flanked by two Kipp and Zonen CG4 pyrgeometers within a ventilation unit on an Eppley SMT tracker modified at Meteorological Observatory Lindenberg – Richard-Aßmann Observatory for the use of four instruments to shade and protect the pyrgeometer domes for additional solar beam heating (photo: K. Behrens)

Again, within the goals of the BSRN, it was necessary to improve the measurements of the atmospheric and terrestrial radiation fluxes. Further important steps forward in this regard were made at the Physikalisch-Meteorologisches Observatorium Davos/World Radiation Center (PMOD/WRC). First, the measurement of the dome temperature of the PIR was changed by replacing the thermistor on the rim by three glued at 45°, pointing to the north, southeast, and southwest. In a second step, an improved pyrgeometer equation based on the formula of [11.88] was derived, and thirdly the PIR was characterized as a blackbody [11.89]. The new formula for the calculation of the atmospheric downward irradiance ($E_1\downarrow$) is

$$E_1\downarrow = \left(\frac{U_1\downarrow}{S_1\downarrow} \right) (1 + k_1\sigma T_b^3) + k_2\sigma T_b^4 - k_3\sigma (T_d^4 - T_b^4), \quad (11.8)$$

based on the voltage generated by the thermopile ($U_1\downarrow$) and its sensitivity ($S_1\downarrow$). k_i ($i = 1, 2, 3$) are specific correction factors, σ is the Stefan–Boltzmann constant, and T_d and T_b are the temperatures of the dome and body of the pyrgeometer, respectively. In contrast to the formula given in [11.88], this one is more complete and takes into account higher-order terms. Like the sensitivity for each pyrgeometer, the correction factors k_i must be derived using an elaborate procedure by changing the dome and body temperatures of the pyrgeometer as well as the radiation temperature of the blackbody. This extended pyrgeometer equation (11.8) can only be applied if at least one dome thermistor is present and if the correction factors k_i have been determined as just mentioned. In all other cases, the atmospheric downward irradiance ($E_1\downarrow$) of the Eppley PIR is calculated using the known sensitivity ($S_1\downarrow$) with the simpler equation

$$E_1\downarrow = \frac{U_1\downarrow}{S_1\downarrow} + \sigma T_b^4 - K\sigma (T_d^4 - T_b^4). \quad (11.9)$$

This formula (11.9), often called the Albrecht equation, may also be obtained from (11.8) by considering special assumptions and equals the formula given in [11.88].

At the beginning of the 2000s, Kipp and Zonen B. V. presented a new pyrgeometer called the CG4. It has a similar construction to other Kipp and Zonen pyranometers, but the thermopile is covered by a meniscus-shaped silicon dome that blocks the solar spectral range (Sect. 11.3.4, Fig. 11.24). This dome is in good thermal connection with the pyrgeometer body and thus at the same temperature, so it is not necessary to measure the dome temperature explicitly. Its field of view is 180° like the PIR.

Later, pyrgeometers also became available from other manufacturers, sometimes with a flat filter above the thermopile to block solar radiation, but a restricted viewing angle between 150° and 170° , resulting in greater uncertainty. Some of these pyrgeometers are equipped with a dome or window thermistor, while others are not. It is thus important for the user to study the specifications of each instrument. Typically, this information is also given in the calibration certificate. In the case in which a dome thermistor is available, (11.9) has to be used to determine the atmospheric downward irradiance ($E_{1\downarrow}$). In the absence of a dome thermistor, this quantity is calculated more simply as

$$E_{1\downarrow} = \frac{U_{1\downarrow}}{S_{1\downarrow}} + \sigma T_b^4. \quad (11.10)$$

Since, as mentioned above, a pyrgeometer is very similar in construction to a pyranometer, it is obvious that ventilation and heating units will also improve the data quality, because they prevent dew, rime, and other disturbing deposits from forming on the dome.

Pyrgeometers are general all-weather instruments and therefore robust in design. Furthermore, they are equipped with a sun shield to prevent heating of the pyrgeometer body. In many cases, pyrgeometers have a drying cartridge filled with silica gel to absorb humidity inside the body to prevent condensation. Newer types offer ingress protection against dust and water (IP67) and are virtually sealed, thus not needing such a drying cartridge.

While in the past pyrgeometers only offered the classical analog voltage output, in some cases the user can now additionally select between different output methods or communication protocols such as Modbus or RS-485. Also, so-called smart instruments are available, allowing a direct link to a PC with the possibility of collecting different data and controlling many parameters.

Because this development, especially concerning so-called smart features, has been very fast, it is recommended to study the specification to select a pyranometer with the desired features. Furthermore, the statements given in Sect. 11.1.3 regarding the deployment and measurement site are valid and should be considered, too.

The calibration of pyrgeometers and their traceability to SI is described in Sect. 11.6.

11.4.4 Pyrradiometers

A pyrradiometer measures the total (global solar + terrestrial downward) radiation or total (reflected solar + terrestrial upward) radiation incident from a viewing angle of 2π sr on a flat surface depending on where

the receiver is facing (Tables 11.2–11.4). Combining a downward- and upward-looking pyrradiometer allows the measurement in a viewing angle of 4π sr, and such an instrument is called a *total net radiometer*. The sensors in pyrradiometers are black thermopiles, in most cases embedded in metallic cylinders that nowadays are generally covered by Lupolen-H (polyethylene) hemispheres. The thickness varies between about 0 and 0.05 mm. The thicker ones are self-supporting, while the others are continuously filled with dry compressed air or nitrogen. Frequently, these instruments are offered as total net radiometers. Their status is almost the same as already described in Sect. 11.2.4 and has not really changed or improved. Such instruments are still manufactured by a handful manufacturers around the globe and are used where the demands regarding uncertainty are not very high.

For these instruments, the classical analog output voltage (U) generated by the detector is still typical. The total irradiance (E_{\downarrow}) from the upper hemisphere can then be simply calculated using the known sensitivity (S_{\downarrow}) as

$$E_{\downarrow} = \frac{U_{\downarrow}}{S_{\downarrow}} \quad (11.11)$$

and for the lower hemisphere as

$$E_{\uparrow} = \frac{U_{\uparrow}}{S_{\uparrow}}, \quad (11.12)$$

assuming that the sensitivity in the solar and terrestrial spectral ranges are equal. However, this is typically not the case because of the different transmission of the Lupolen-H hemispheres in the solar and terrestrial regions (Sect. 11.2.4, Fig. 11.15). These differences result from the distinct kinds of polyethylene used and also depend on the thickness and aging of the hemispheres. The transmission in the terrestrial region may be lower by up to 20% compared with that in the solar range. Several methods have been applied to solve this problem. Assuming that there is only a small difference, only one factor is used and (11.11) and (11.12) can be applied as normal. A second option is to determine the sensitivities for the solar and terrestrial regions and assume that these values are valid in general for a particular type of radiometer and polyethylene. In one approach, the blackened surface of the thermopile is partly covered with white paint to equalize the different sensitivities for the solar and terrestrial range [11.48, 90]. However, the best solution to this problem is the individual determination of each sensitivity through a corresponding calibration. The total irradiance (E_{\downarrow}) can then be calculated as

$$E_{\downarrow} = \left(\frac{U_{\downarrow}}{S_{1\downarrow}} \right) + E_{g\downarrow} \left(1 - \frac{S_s\downarrow}{S_{1\downarrow}} \right) \quad (11.13)$$

for the upper hemisphere, and correspondingly for the lower hemisphere as

$$E_{\uparrow} = \left(\frac{U_{\uparrow}}{S_{\uparrow}} \right) + E_r \uparrow \left(1 - \frac{S_s \uparrow}{S_{\uparrow}} \right), \quad (11.14)$$

where S_{\downarrow} , $S_s \downarrow$, $S_s \uparrow$, and S_{\uparrow} are the corresponding sensitivities. However, this clean solution requires measurements of the global and reflected solar irradiance in parallel using pyranometers.

If the pyradiator is additionally equipped with a temperature sensor like a Pt-100 or thermistor to measure the body temperature (T_b in K) of the pyradiator, it also becomes possible to determine the atmospheric downward radiation (E_{\downarrow}) albeit only during nighttime by applying the relation

$$E_{\downarrow} = \frac{U_{\downarrow}}{S_{\downarrow}} + \sigma T_b^4. \quad (11.15)$$

Assuming equal transmission in the solar and terrestrial regions of the polyethylene and measuring also the global radiation separately, the atmospheric downward radiation (E_{\downarrow}) can be calculated as

$$E_{\downarrow} = \left(\frac{U_{\downarrow}}{S_{\downarrow}} \right) - E_{g \downarrow} + \sigma T_b^4 \quad (11.16)$$

during the whole day. The terrestrial upward radiation can then be calculated by applying (11.16) in an equivalent manner for an upward-facing pyradiator. The addition of the term σT_b^4 in (11.15) and (11.16) includes the emission from the instrument itself, because the thermopile gives only the *net radiation* corresponding to the temperature difference between the sky and the surface of the instrument.

The preceding remarks already reveal the problems and uncertainties related to the use of pyradiometers. Another critical point is the aging of the polyethylene hemisphere, which influences its transmissivity, mainly depending on its exposure to ultraviolet (UV) radiation. Currently, polyethylene seems to be the only material available to protect the sensor over the whole spectral region covering the solar and terrestrial regions. Further influences have not yet been considered. The calibration of a pyradiator is not simple and has to be done separately for the solar and terrestrial ranges (Sect. 11.6.1).

11.4.5 Net Radiometers

According to Table 11.2 (Sect. 11.1.1), net radiometers are instruments that allow the measurement of the solar net ($E_s^* = E_g \downarrow - E_r \uparrow$), terrestrial net ($E_l^* = E_{\downarrow} - E_{\uparrow}$), and total net radiation ($E^* = E_s^* + E_l^*$). Therefore, the four main components are measured by pyranometers

(Sect. 11.4.2) in the solar range and by pyrgeometers (see Sect. 11.4.3) in the terrestrial range, as well as by pyrrometers across the whole spectral region, with the corresponding down- and upward radiation fluxes. Because a single radiometer captures a hemisphere of 2π sr, net radiometers cover the whole sphere of 4π sr. From a technical point of view, the net radiation can be realized in the following three ways:

- Directly measuring the net radiation using only one thermopile with hot upward-facing and cold downward-looking junctions, because the difference in temperature is proportional to the net irradiance (single sensor)
- Directly measuring the net radiation by applying a differencing circuit between a downward- and upward-looking radiometer with two thermopiles as detectors (two sensors)
- Calculating it as the difference between the measured downward- and upward-directed fluxes, or in the case of the total net radiation as the total of all four components (four-sensors).

In practice, all of these versions are realized, whereby the uncertainty of the results improves but the cost increases from the first to third solution, a statement that is valid in general.

Normally, all such instruments are equipped with a bubble level so that they can be leveled horizontally. They are mainly mounted at about 2 m above the ground. During the setup, the remarks in Sect. 11.1.3 must be taken into account, and one must additionally ensure that the area below a down-facing instrument is free of the instrument itself and other obstacles.

Solar Net Radiation and Albedo

In most cases, manufacturers combine two thermopiles or two pyranometers (upward and downward facing) into one instrument. Depending on the application requirements, instruments are available in which the thermopiles are covered by only one glass dome or by two domes for higher quality, reaching the criteria for class A pyranometers (Sect. 11.5, Table 11.8). Frequently, these instruments are not ventilated or heated, thus the problems of zero offsets as well as of dew, rime, and dust debris mentioned in Sect. 11.4.3 increase the uncertainty and may diminish the quality of the measurements. Often the thermopiles are selected or adjusted such that their sensitivities match, which offers the advantage that the user can decide whether to apply a differencing circuit or not. Usually, a calibration of the single detector is possible.

Most manufacturers use black thermopiles, but instruments with (star-type) black-and-white thermopiles are also available. The combination of a photodiode

pyranometer would lead to unusable results because of the wavelength-dependent spectral response of the receiver and the different wavelength dependences of the reflected solar radiation and that coming from the upper hemisphere. Although by definition both upward- and downward-pointing instruments should receive radiation from a viewing angle of 2π sr, some manufacturers restrict the viewing angle of the downward-looking pyranometer slightly using a special screen. This prevents incidence of the radiation beam during sunrise and sunset, which is not part of the reflected radiation, onto the sensor. Normally, this effect is not very important, but when measurements are to be carried out at a location with lower surroundings (e.g., on the top of a hill) or the instruments are mounted at higher levels on masts, it may influence or even falsify the data. Furthermore, manufacturers offer special kits and rods to support the mounting.

Frequently, this type of instrument is called an *albedometer*, but this name is incorrect because the albedo is the ratio of the upward- and downward-directed solar radiation and cannot be measured. Theoretically, the albedo can be calculated immediately after the measurement, for instance with the help of a microprocessor, but such an instrument providing a direct output of the albedo is still not known.

To meet high demands in terms of uncertainty and quality, it is possible to combine two, upward- and downward-looking high-quality pyranometers equipped with ventilation and heating to determine the solar net radiation or albedo (Fig. 11.33).

Because the measurements of the described quantities are typically carried out using pyranometers, they are calculated from the ratios of the voltage (U) and the sensitivities (S) of the sensors as shown in (11.7), (11.18), and (11.19). Furthermore, the statements made in Sect. 11.1.3 regarding the deployment and measurement site as well as in Sect. 11.4.2 concerning the handling and features of pyranometers are valid and should also be considered.

Terrestrial Net Radiation

As stated above regarding the solar net radiation, in the case of the terrestrial net radiation it is also possible to combine pyrgeometers into a corresponding net radiation instrument. Because this is only a minor requirement, mainly for pure scientific applications, manufacturers do not offer this type of instrument as standard. However, they will be produced on request, as shown in Fig. 11.32 for the case of an Eppley double direction precision infrared radiometer (DDPIR). The reason for this design is to reduce uncertainty. Note that the DDPIR was not operated as a standalone instrument but was rather part of a total net radiation measurement system, being supplemented with

Fig. 11.32 An Eppley DDPIR net radiometer consisting of two PIR fit together in a case, which also contains the ventilation unit with heater (photo: K. Behrens)

two pyranometers to measure the solar net radiation (Fig. 11.33). Two fully equipped (with body and dome thermistors) PIRs were implemented in a special case with heaters and ventilation units to ensure a constant airflow around the pyrgeometer body and dome and provide protection against multiple environmental influences such as dew, rime, dust, etc. Furthermore, in this special case, the downward and upward terrestrial irradiance can be calculated by applying (11.8) (Sect. 11.4.3).

Total Net Radiometers

In contrast to the on-request production of terrestrial net radiometers, manufacturers do provide a wide offering of total net radiometers. This begins with the simple CNR2 Lite from Kipp and Zonen B.V., continues with the net radiometers based on pyrrometers and simple four-component radiometers described and discussed in Sect. 11.4.4, and finishes with systems composed of two high-end pyranometers and pyrgeometers. The latter systems are manufactured only on request or must be assembled by the user.

The CNR2 Lite matches the features described above and is the simplest way of realizing a net radiometer, i.e., a so-called single-sensor net radiometer. The thermopile (active junctions upward pointing, passive ones downward looking) is fit with black PTFE conical absorbers on both sides. Because all environmental influences such as wind, rain, dew, rime, dust, etc. hit the unprotected sensor, deviations from the correct results are unavoidable. Comparisons made between the predecessor of the CNR2 Lite, the similarly constructed NR-Lite, and a four-component system constructed from an Eppley precision spectral pyranometer (PSP) and PIR pyrgeometer revealed systematic deviations concerning the Sun elevation and wind speed with a large scatter of up to 20 W m^{-2} [11.91]. Further single- and two-sensor net radiometers include the pyrrometers mentioned in Sect. 11.4.4.

Fig. 11.33 Different net radiometers during a comparison in summer 2013 at the Boundary Layer Measuring Field Falkenberg of the Meteorological Observatory Lindenberg – Richard-Aßmann Observatory, mounted on a special rack about 2 m above the ground. The DDPIR (Eppley Laboratory, Inc. USA), two single CG4 pyrgometers (Kipp and Zonen B. V., the Netherlands) fit in a ventilation unit (with heater) (Eigenbrodt GmbH and Co. KG, Germany) measuring the components of the terrestrial down- and upward irradiance and a CM24 consisting of two CM21 pyranometers (Kipp and Zonen B. V., the Netherlands) also fit in a ventilation unit (with heater) (Eigenbrodt GmbH and Co. KG, Germany) measuring the components of the solar down- and upward irradiance. All instruments including the ventilation units were replaced by successors and will not be produced anymore (photo: K. Behrens)

For a single-sensor detector offering the classical analog voltage output (U) with a known sensitivity (S), the total net irradiance (E^*) can be simply calculated as

$$E^* = \frac{U}{S}. \quad (11.17)$$

Four-sensor net radiometers use a single detector for the acquisition of each of the four different quantities contributing to the total net irradiance (E^*) as follows:

- Global irradiance ($E_g \downarrow$), measured with an upward-facing pyranometer as

$$E_g \downarrow = \frac{U_{g \downarrow}}{S_{g \downarrow}} \quad (11.18)$$

- Reflected solar irradiance ($E_r \uparrow$), measured with a downward facing pyranometer as

$$E_r \uparrow = \frac{U_{r \uparrow}}{S_{r \uparrow}} \quad (11.19)$$

- Atmospheric (terrestrial) downward irradiance ($E_1 \downarrow$), measured with an upward-facing pyrgometer as

$$E_1 \downarrow = \frac{U_{1 \downarrow}}{S_{1 \downarrow}} + \sigma T_b^4 \quad (11.20)$$

- Terrestrial upward irradiance ($E_1 \uparrow$), measured with a downward facing pyrgometer as

$$E_1 \uparrow = \frac{U_{1 \uparrow}}{S_{1 \uparrow}} + \sigma T_b^4. \quad (11.21)$$

All the first terms on the right-hand side of (11.18)–(11.21) consist of the ratio of the voltage (U_x) to the sensitivity (S_x) of the corresponding sensor. In the case of the terrestrial downward and upward irradiance, the term σT_b^4 , where σ is the Stefan–Boltzmann constant and T_b is the temperature of the pyrgometer body in kelvin, has to be added, representing the irradiance of the surface of the thermopile due to its own emissivity. This must be added because the first term contains only the net irradiance, which is proportional to the temperature difference between the irradiating surface (sky or ground) and thermopile.

The following complex quantities can be derived from these individual components

- The solar net irradiance

$$E_s^* = E_g \downarrow - E_r \uparrow. \quad (11.22)$$

- The terrestrial net irradiance

$$E_1^* = E_1 \downarrow - E_1 \uparrow. \quad (11.23)$$

- The total net irradiance

$$\begin{aligned} E^* &= E_s^* + E_1^* \\ &= (E_g \downarrow - E_r \uparrow) + (E_1 \downarrow - E_1 \uparrow). \end{aligned} \quad (11.24)$$

- The albedo

$$\alpha = \frac{E_r \uparrow}{E_g \downarrow}. \quad (11.25)$$

Such measurements of the individual components are the best method to determine these complex quantities of the net irradiance, and manufacturers offer instruments therefor. They consist of two pyranometers, two pygeometers, and a thermometer (Pt-100, thermistor) to measure the instrument's body temperature to form one single net radiometer fit in a common housing, where the four individual voltages and the temperature can be recorded separately. In most cases in these net radiometers, sensors such as black thermopiles covered by only one dome are used, so they cannot measure with the highest quality. Examples include the CNR4 (Kipp and Zonen, B.V.), the NR01 (Hukseflux, B.V.), and the MR-60 (EKO). If a better class is demanded or desired, it becomes necessary to combine single high-end instruments offered by different manufacturers, as shown in Fig. 11.33, for instance. If single radiometers must be applied, that must be mounted close together without hampering the field of view, so that the downward-pointing instruments in particular look at the same area with the same features.

Furthermore, the statements given in Sect. 11.1.3 concerning the measurement site and mounting as well as in Sects. 11.4.2 and 11.4.3 regarding the handling and features of pyranometers and pygeometers are valid for these combined instruments, too.

11.4.6 Multi Radiometers

For years, multi radiometers have been used in applied sciences as well as meteorology. These systems with at least one sensor allow the determination of the three radiation quantities in the solar spectral range from the upper hemisphere, viz. global, diffuse, and direct solar irradiance. The main reason for such a construction is to save money. Ordinarily, this is associated with an increased uncertainty of the measurements. Because multi radiometers are mostly complex instruments, it is recommended to study their datasheets and manuals to obtain information about their usage, signal output, interfaces, etc.

Rotating Shadowband Radiometers (RSRs)

Rotating shadowband radiometers are also called rotating shadowband irradiometers (RSIs) or rotating shadowband pyranometers (RSPs). They consist of a photodiode-based pyranometer and a motorized shadowband that rotates around the pyranometer, e.g., once per minute. During the rotation, the sensor is shaded only for a short time in each circulation, enabling the measurement of the diffuse solar irradiance ($E_d\downarrow$), while in the remaining time the global solar irradiance ($E_g\downarrow$) is recorded. RSRs are subject to the common restrictions already mentioned in Sect. 11.4.2 regarding

the use of photodiode as sensors, especially in terms of a limited, nonflat spectral response and the resulting greater uncertainty. Postprocessing is applied in most models to improve the generated data by correction of known errors caused by shadowband effects and photodiode characteristics.

Two types of RSR are available: A system with *continuous* rotation of the shadowband, and a second one with *discontinuous* rotation. In both types, the rotation occurs once per minute, and both types start their data acquisition with the measurement of the global irradiance with the shadowband in its rest position (nadir) below the sensor. The RSR with continuous rotation, which is also called a burst or sweep type, then starts its full turn of the shadowband, which requires about 1 to 2 s at a constant angular velocity. During this time, data are recorded at a high sampling rate of about 1 kHz. A sensor with a very short response time, such as a photodiode, is thus required. The minimum of this scan is assigned to the moment of shading the detector and corresponds to the diffuse irradiance. The measurement using an RSR with discontinuous rotation proceeds in a similar way, but the shadowband first rotates more slowly, and secondly stops turning immediately before and after the position where the sensor is totally shaded and the diffuse irradiance is measured. These stops last about 1 s each. In this case, only four data points are available. The points before and after covering the sensor are used for specific correction of the diffuse irradiance. Also in the case of a continuous rotation RSR, the data from the so-called shoulders before and after the selected minimum are used to correct the diffuse irradiance. Control of the discontinuously rotating RSR requires greater effort, because exact alignment to shade the sensor completely is required to measure the diffuse irradiance.

The first RSR model was described in 1982 [11.92], being called at that time the dial radiometer and working in the continuous mode, while later in 1986 [11.93], a microprocessor-controlled RSR applying discontinuous rotation was reported. The objective of such constructions is the measurement of the global ($E_g\downarrow$) and diffuse ($E_d\downarrow$) solar irradiance nearly simultaneously using one instrument and the calculation of the third missing but desired quantity, viz. the direct solar irradiance (E), as

$$E = \frac{E_g\downarrow - E_d\downarrow}{\cos(z)}, \quad (11.26)$$

where z is the solar zenith angle. The use of only a single instrument to measure these three quantities allows great cost savings with respect to the classical system consisting of at least two pyranometers equipped

Fig. 11.34 MRF-7 in use (sensor just shaded) at Meteorological Observatory Lindenberg – Richard-Aßmann Observatory (photo: K. Behrens)

with a thermopile as well as a shadowband or solar tracker and a ventilation unit. In particular, RSRs became popular for photovoltaic and concentrating solar power (CSP) applications.

Later, the technique of a discontinuous rotating RSR was applied in the multifilter rotating shadowband radiometer (MFRSR) [11.94] (Fig. 11.34), providing the broadband irradiance of the direct, diffuse, and global solar components as well as the same quantities in six narrow spectral channels at 415, 500, 615, 673, 870, and 940 nm, which allows the derivation of the aerosol optical depth (AOD, see Chap. 29). In the recent version (MRF-7), the broadband irradiance is measured by a micro-thermopile, whereas photodiodes are used for the spectral channels as before.

Improvements regarding the correction of systematic errors, uncertainty analysis based on the *Guide to the Expression of Uncertainty in Measurement* (GUM), and a special calibration method for RSRs are described in [11.95–97].

SPN1 Sunshine Pyranometer

Another multi radiometer is the SPN1 sunshine pyranometer [11.98] (Fig. 11.35). Like the rotating shadowband radiometers, this instrument also enables the measurement of global, diffuse, and direct solar irradiances. However, in contrast to RSRs, it has no moving parts and the sensors are miniature thermopiles. The seven sensors are arranged on a hexagonal grid which is covered by a computer-generated shadow mask so that at least one sensor is always totally irradiated while at least one other is completely shaded. Under the assumption of isotropic diffuse radiation, the completely shaded sensor (that with the minimum reading) receives 50% of the diffuse radiation while the sensor with the maximum reading (that which is fully irradiated) re-

Fig. 11.35 SPN1 at Meteorological Observatory Lindenberg – Richard-Aßmann Observatory (photo: K. Behrens)

ceives the complete direct irradiance at the horizontal surface plus 50% of the diffuse one. Herewith, the readings can be calculated as

$$\begin{aligned} \text{DIFFUSE} &= 2 \cdot \text{MIN} \\ \text{DIRECT} &= \text{MAX} - \text{MIN} \\ \text{GLOBAL} &= \text{DIRECT} + \text{DIFFUSE} = \text{MAX} + \text{MIN} \end{aligned}$$

The single readings of the different thermopiles are internally processed, and the corresponding voltages of the global and diffuse irradiances are available continuously at the analog output interface. Furthermore, there is the possibility of a direct link to a computer via an RS232 serial link, and corresponding software enables access to much information, including the three radiation quantities as well as the derived sunshine duration. Despite the usage of thermopiles, the spectral response (50% points assumed) is restricted to 400 to 2700 nm, covering mainly the UV spectral range, but the response time is short at < 200 ms.

RaZON+

The RaZON+ (Fig. 11.36) also provides the three solar radiation quantities from the upper hemisphere, but in a different way. RaZON+ is an all-in-one smart system consisting of a Global Positioning System (GPS)-controlled solar tracker equipped with a pyrhelimeter PH1 and a pyranometer PR1, which is shaded by a disc, as well as internal data logging with Ethernet and WiFi web access. This means that the system does not have any analog interface and is only connected via the RaZON+ web interface and a standard browser on the owner's system (PC, tablet, or smartphone). The pyrhelimeter PH1 and pyranometer PR1 are specially designed only for use in the RaZON+. The sensors of both radiometers are thermopiles with very short response times of < 0.2 s, and both sensors are located behind a quartz diffusor. In the case

Fig. 11.36 RaZON+ (manufacturer: Kipp and Zonen B.V., the Netherlands): a solar tracker with pyr heliometer and shaded pyranometer measuring direct (E) and diffuse ($E_d\downarrow$) solar irradiance on the roof platform of the Meteorological Observatory Lindenberg – Richard-Abmann Observatory in Lindenberg, Germany (photo: K. Behrens)

of the PH1, a specially designed collimation tube with an open aperture provides the required view-limiting geometry (Sect. 11.4.1, Fig. 11.25), diminishes soiling, and enables drainage of rainwater, being situated in front of the sensor system, while that of the PR1 is covered by a machined and polished glass dome. The PR1 does not show the typical thermal offsets observed for thermopile instruments (Sect. 11.4.2) despite being covered by only one dome. This feature and also the short response time indicate that the sensors are similar to the novel black thermopiles mentioned in Sect. 11.3.2. Despite the usage of a quartz diffusor and thermopile, in both cases the spectral range is limited to 310 to 2700 nm. The data are sampled at 1 Hz, and the built-in processor calculates the 1-min mean irradiances of the direct (E), diffuse ($E_d\downarrow$), and global ($E_g\downarrow$) irradiances as the sum of the two values using (11.1) (Sect. 11.1.1), which is in principle the best solution for determining these three quantities [11.99]. Furthermore, the sunshine duration is additionally derived from the direct (E) solar irradiance (Sect. 11.4.7). All these data are stored locally within the RaZON+ system for 365 days. The RaZON+ offers all-weather ingress protection (IP65), while the PH1 and PR1 offer IP67 protection.

Photosynthetically Active Radiation (PAR) Sensor

PAR is the part of the solar radiation that plants use for photosynthesis, being specific to different plants and crops. Investigations [11.100] have shown that it is best to standardize and define the spectral region from

400 to 700 nm as PAR. Photosynthesis is a quantum process by which photons excite reactions in chlorophyll molecules of plants in a wavelength-dependent fashion. Therefore, the PAR is typically expressed as the photosynthetic photon flux density (PPFD) in units of $\mu\text{mol m}^{-2} \text{s}^{-1}$. Furthermore, photons with shorter wavelengths have higher energy than those with longer wavelengths, resulting in a mismatch between the energy and photon flux densities. However, with the help of weighting functions, the PAR can also be expressed as the irradiance integrated over the wavelength interval between 400 and 700 nm.

Because PAR is defined between 400 and 700 nm, photodiode-based sensors are typically applied in PAR measuring instruments. Therefore, the Si sensor is covered by a combination of a diffusor and special interference filter that approximately emulates the weighting function of PAR. These parts are fixed in a small metallic body, resulting in a weatherproof instrument. Being based on the same detectors, PAR instruments have features similar to those of Si pyranometers (Sect. 11.4.2), or in other words, PAR or quantum sensors are like photodiode-based pyranometers adapted for a special purpose. The quality of such detectors mainly depends on the successful emulation of the weighting function of PAR. The best results in measuring the PPFD are achieved using spectroradiometers (Chap. 28), because they enable detailed acquisition of spectral radiation in the target spectral range of PAR. Concerning the deployment of PAR sensors, the rules and recommendations already mentioned regarding the site for general measurements (see, e.g., Sect. 11.1.3) still apply. In the case of other objectives, for instance, the frequently applied measurement of PAR within plant stands, deviation from these standards is clearly unavoidable.

Further information concerning PAR is summarized in [11.101].

UV Radiation Sensors (see also Chap. 28)

Ultraviolet (UV) radiation lies in the spectral area below 400 nm to about 100 nm. The UV region is subdivided into three parts, amongst which UV-C in the range below 280 nm is not important at the Earth's surface, because radiation with wavelengths < 290 nm is absorbed by ozone in the stratosphere. Consequently, the remaining part reaching the surface strongly depends on the thickness of the ozone layer in the stratosphere. The range between 400 and 315 nm is the so-called UV-A region, while the remaining area (315–280 nm) called UV-B is especially important for humans. On the one hand, it is responsible for sunburn and diseases, while on the other hand it also enables the production of vitamin D. Furthermore, UV-B also influences the change of material properties. Hence, there is great interest in collecting data in this particular spectral range.

As seen in Fig. 11.18, the irradiance between about 290 and 400 nm covers a large dynamic range of about $10^3 \text{ W m}^{-2} \mu\text{m}^{-1}$ but represents a fraction of less than 10% of the total or global solar irradiance, resulting in very high demands for such sensors. A thermopile cannot fulfill these requirements because of its low sensitivity. A detector based on the already considered Si photodiode is also ruled out, because it is not sensitive to wavelengths below 400 nm. However, photodiodes made from other materials such as gallium arsenide phosphide (GaAsP) can be implemented beneath a combination of a diffusor and special filters, mounted in bodies already successfully applied in traditional or Si pyranometers, frequently covered by a dome made from quartz or glass. The diffusor ensures the fulfillment of the cosine law, considering that the sensor receives diffuse radiation, and thereby prevents a dependence of the direct solar radiation on the angle of incidence.

The importance of the distinct spectral UV regions is accommodated by manufacturers by the production of corresponding adapted instruments, including for the special erythral action spectrum. Like the above-mentioned instruments, UV instruments are general all-weather devices and therefore robust in design. Depending on their construction, some instruments are equipped with a drying cartridge filled with silica gel to absorb humidity inside the body to prevent condensation. The newer types offer ingress protection against dust and water (IP67) and are virtually sealed. Furthermore, they are offered with the classical analog output or the possibility to select between different output methods or communication protocols such as Modbus or RS-485, respectively. Also, so-called smart instruments are available, allowing a direct link to a PC with the possibility of collecting different data and controlling many parameters.

Because this development, especially concerning the so-called smart features, has been very fast, it is recommended to study the specifications to select an instrument with the desired features. Furthermore, the statements given in Sect. 11.1.3 regarding the deployment and measurement site are valid and should also be considered.

The best results in measuring UV radiation are achieved by applying spectroradiometers (see also Chap. 28), because they enable high spectral resolution, which is of exceptionally importance in the UV-B range with its large dynamic range.

In contrast to broadband radiometers, in which thermopiles are mainly applied as sensors, the calibration of UV instruments is primarily achieved using standard lamps and is traceable to SI via the National Metrology Institutes (NMIs) (see also Sect. 11.6.).

11.4.7 Sunshine Duration Instruments

Sunshine duration measurements represent one of the oldest methods to indicate solar radiation. According to [11.1],

the term “sunshine” is associated with the brightness of the solar disc exceeding the background of diffuse sky light, or, as is better observed by the human eye, with the appearance of shadows behind illuminated objects. As such, the term is related more to visual radiation than to energy radiated at other wavelengths, although both aspects are inseparable.

From a historical point of view, the Campbell–Stokes sunshine recorder is the most well-known and widespread instrument worldwide for the determination of sunshine duration. As early as 1853, J. F. Campbell (1821–1885) reported for the first time on a sunshine recorder consisting of a glass sphere, which worked like a burning glass, fit in a wooden bowl. It was improved based on a proposal from Sir G. G. Stokes (1819–1903) in 1879, replacing the wooden bowl by a metallic one and applying a card holder, achieving its well-known appearance as shown in Fig. 11.37.

Well-known investigations and comparisons of sunshine duration instruments and measurements have revealed differences of up to 20%, resulting in the recommendation for an *interim reference sunshine recorder* (IRSRR) by the WMO [11.102] in 1962, being of Campbell–Stokes type with defined specifications and the objective of reducing these measurements to a common reference level. Despite the intended improvements, further investigations [11.103] revealed serious deficiencies, including a wide variation of the irradiance threshold to produce a burn on the recorder card of between about 100 and 300 W m^{-2} when using this instrument. Consequently, in 1981, the WMO [11.104] considered among other factors:

- The fact that traditional Campbell–Stokes sunshine recorders do not in fact record the duration of bright sunshine with sufficient consistency
- The difficulty in defining the concept of *sunshine* because of its relationship to physiological effects
- The urgent need to adopt a common threshold value for *sunshine* so that irradiance-based instruments provide compatible data.

and thus recommended:

Fig. 11.37a,b The classical Campbell–Stokes sunshine recorder (a) (photo: Dr. Alfred Müller – Meteorologische Instrumente KG – R. Fuess) and (b) two instruments (EKO MS-093 and Meteoservic SD6 digital sunshine detector) applying electrical methods (photo: K. Behrens)

- The adoption of a threshold value for bright sunshine of 120 W m^{-2} of direct solar irradiance
- That (WMO) members incorporate this threshold value in the specification of instruments, with an accuracy of $\pm 20\%$
- That the interim reference sunshine recorder be recognized as merely providing an index of sunshine duration, and that its status as a reference be removed.

Hence, the sunshine duration during a given period is defined as the sum of time for which the direct solar irradiance exceeds 120 W m^{-2} . This new threshold is physically based and metrologically traceable but implies a new precariousness with its wide inaccuracy of $\pm 20\%$.

Like at the beginning of the 1980s with the Eppley NIP (Sects. 11.2.1 and 11.4.1), only one commercial weatherproof pyrheliometer as well as a few expensive solar trackers were available to determine the sunshine duration defined in this way. Even today, this situation has not changed much, because in national meteorological networks sunshine duration is not determined using a pyrheliometer but rather by other methods. Indeed, this development started in the 1970s with the beginning of the automatization of meteorological networks, where the Campbell–Stokes device had to be replaced by sensors providing an electrical output (Fig. 11.37b). For this purpose, manufacturers mainly applied photodiode sensors (Sect. 11.3.3), which can be used in many different ways to measure sunshine duration.

According to [11.1], the WMO distinguishes the following five methods for the determination of sunshine duration:

- Pyrheliometric method
- Pyranometric method
- Burn method
- Contrast method
- Scanning method.

Except for the classical burn (Campbell–Stokes) method, the others are electrical. The pyrheliometric method corresponds to the definition, while the use of two pyranometers to measure the global and diffuse solar radiation allows the direct solar radiation to be calculated with a result that also corresponds with the definition of this quantity. If only one pyranometer measures the global solar radiation, it becomes necessary to apply an algorithm to estimate the sunshine duration [11.105, 106]. The contrast and scanning methods are also electrical and use photodiodes as detectors, albeit in different ways. Corresponding instruments are offered by several manufacturers. Despite the traceable definition of sunshine duration, the use of very different (old and new) methods for its derivation is also possible, with a large but permissible uncertainty. Again as a consequence, problems in data comparability may result [11.107].

In contrast to the methods discussed in previous sections for determining the various radiation quantities that are traceable to SI, it is difficult to accomplish this for sunshine duration. Moreover, it is generally

accepted that sunshine duration contains very little information, viz. only the time during which the direct solar radiation at normal incidence exceeds a (poorly defined) threshold. From this point of view, sunshine duration is only of historical importance as a proxy to prolong time series of global radiation dating back to the 19th century (Sect. 11.8.1). Nevertheless, sunshine duration is still used, for instance, in relation to health resorts or weather forecasts, because humans may simply associate sunshine duration with an impression of climate or weather.

11.4.8 Supplementary Equipment

Supplementary equipment can be categorized into two groups, which may overlap in some cases:

- Necessary equipment for the direct execution of specific measurements (e.g., shadow bands, shadow discs/balls, solar trackers)
- Equipment for improvement and quality assurance of measurements (e.g., ventilation and heating, cleaning, shadow discs).

Measurements of direct solar irradiance are only possible if the corresponding instrument, viz. the pyrheliometer, continuously follows the Sun's path during the day (Sects. 11.2.1 and 11.4.1). While this alignment or tracking was long done manually or using simple clock-driven devices, electromechanical systems based on the frequency of the alternating current (AC) were later applied. The disadvantage of such systems was that they only turned in one direction, so the pyrheliometer cable had to be put back each morning. Moreover, daily adjustment for the changing declination of the Sun was at least necessary for equatorially mounted pyrheliometers, in addition to occasional alignment checks to correct any instability in the AC frequency. The application of step motors and remote control via PCs provided only a short but supporting interim solution, whereas the breakthrough in this regard was achieved in the 1990s when microcontrollers were applied to control the trackers, addressing all the mentioned issues. State-of-the-art solar trackers now also include GPS and Sun sensors (for active tracking) and adopt the plug-and-play principle. Nowadays, many manufacturers offer solar trackers in several configurations and for different applications, including with large payloads. A typical example is shown in Fig. 11.38, demonstrating the complete acquisition of the solar and terrestrial radiation fluxes from the upper hemisphere with a high quality level. The solar tracker is equipped with a pyrhe-

Fig. 11.38 Fully equipped solar tracker (solar tracker and radiation instruments: Kipp and Zonen B.V., the Netherlands; ventilation and heating units: Fa. Eigenbrodt GmbH and Co KG, Germany) at the Boundary Layer Measuring Field Falkenberg of the Meteorological Observatory Lindenberg – Richard-Aßmann Observatory (photo: K. Behrens)

liometer for direct solar radiation, two pyranometers to measure global (unshaded in the center) and diffuse radiation (the shaded one), and a pyrgeometer (also shaded) to measure the downward terrestrial radiation.

Such coincident and independent acquisition of the three solar radiation quantities enables their mutual checking because, according to (11.1) (Sect. 11.1.1), the total of the diffuse irradiance ($E_d \downarrow$) and the vertical component of the direct irradiance ($E \cos(z)$) should equal the global irradiance ($E_g \downarrow$). Therefore, it is important that the geometry of the pyranometer/shade disc (shaded opening angle and slope angle) agree with the field-of-view angle of the pyrheliometer (Sect. 11.4.1). Furthermore, the shading of the pyrgeometer prevents heating of the dome and improves the quality of the atmospheric downward irradiance ($E_1 \downarrow$) measurements. Shade discs may also be replaced by shade balls of an equal diameter.

Regarding measurements of the diffuse irradiance ($E_d \downarrow$), it is appropriate to use a pyranometer with small zero offset because, on very clear days, the diffuse irradiance may represent only about 10% of the global radiation. The thermal offset is of great importance in this regard.

In the past and even now, mainly for economic reasons, trackers are not deployed to cover the area of national networks. Rather, since the early days, shadow bands or shadow rings have been developed and accepted as an alternative to reduce costs, despite their well-known deficiencies as replacements. Shadow rings

block not only the radiation from the desired field-of-view angle corresponding to the pyrheliometer but moreover the irradiance from other parts of the sky, resulting in an underestimation of the diffuse irradiance ($E_d \downarrow$). As early as 1956 [11.108], the following formula was derived to describe the fraction of blocked diffuse solar irradiance in the case of isotropic conditions and for a ring with $b/r < 0.2$

$$\frac{E_{d \downarrow v}}{E_d \downarrow} = \left(\frac{2b}{\pi r} \right) \cos^3 \delta \times \left[\left(t_0 \frac{\pi}{180} \right) \sin \varphi \sin \delta + \cos \varphi \cos \delta \sin t_0 \right], \quad (11.27)$$

where $E_{d \downarrow v}$ is the obscured diffuse irradiance, $E_d \downarrow$ is the unobscured diffuse irradiance, b is the width of the shadow ring, r is the radius of the shadow ring, δ is the declination of the Sun (in degrees), φ is the geographic latitude of the location (in degrees), and t_0 is the hour angle of the Sun (in degrees) between sunrise and noon or sunset and noon, respectively.

Based on this ratio, a correction factor f can be defined as

$$f = \frac{1}{1 - E_{d \downarrow v}/E_d \downarrow}, \quad (11.28)$$

which has to be applied to the measured diffuse irradiance.

In the case of $\varphi = 52.5^\circ$ and $b/r = 0.169$, the correction factor f lies between 1.013 at winter solstice and 1.106 at summer solstice, while at the equinox $f = 1.070$. Unfortunately, the irradiance from the sky is

rarely isotropic. Therefore, to improve on this by considering actual climatological conditions (cloudiness and atmospheric turbidity), it is necessary to determine the correction factor f experimentally by measuring the diffuse irradiance ($E_d \downarrow$) simultaneously using a shadow disc and shadow ring. Unfortunately, no standardization has taken place in this regard to date. However, in [11.109], a method and extended formula based on (11.27) are described to reduce the variation between measurements using different shadow rings and locations.

The shadow ring is mounted on two rails oriented parallel to the Earth's axis, positioned over a pyranometer such that the center of the ring coincides with the sensor at equinox. The ring has to be moved along the rails according to the declination of the Sun. The adjustment of the ring should be checked at least every 2 days, if possible during sunshine. Exact descriptions regarding the mounting and operation are given in the manuals of the various manufacturers.

Because of the increasing demands regarding automatization of stations, a shadow ring controlled by a microcontroller is now also available (Fig. 11.39).

The importance of using ventilation and heating systems, especially for pyranometers and net radiometers using black thermopiles to reduce and stabilize nighttime offsets, was emphasized in Sects. 11.4.2 and 11.4.4. Moreover, such systems also support all kinds of radiation sensors by ensuring and improving the quality of the resulting data by keeping them free of dew, rime, dust, etc., or removing them faster. Typical solutions for external ventilating and heating systems, which are mainly applied for thermopile instruments, are shown in Fig. 11.39.

Fig. 11.39a,b Pyranometer assembled in a ventilation and heating unit with shadow ring. (a) Old units with ring manually adjusted along rails. (b) New units with ring remotely controlled by a microcontroller and moved once a day by a stepper motor on each rail. (Ventilation and heating unit as well as shadow ring (old and new systems) Fa. Eigenbrodt GmbH and Co KG, Germany; pyranometer: Kipp and Zonen B.V., the Netherlands (photos: K. Behrens))

Table 11.7 Advantages and disadvantages of different devices

Device	Advantages	Disadvantages
Absolute pyrheliometer	Realization of the irradiance scale, smallest uncertainty	Expensive; very special pyrheliometer
Pyrheliometer without self-calibration capability	Considerably cheaper than absolute pyrheliometer	Calibration is necessary; higher uncertainty than absolute pyrheliometer
Pyranometer with black thermopile	Flat spectral response, available for all classes of uncertainty	Two domes necessary to reduce thermal offset
Pyranometer with novel black thermopile	Limited thermal offset; flat spectral response; very short time response	
Pyranometer with black-and-white thermopile	Limited thermal offset	Not available with smallest uncertainty; responsivity depends on azimuth and temperature
Photodiode-based pyranometer (Si pyranometer)	Very short time response; lightweight, small; considerably cheaper than thermopile pyranometer	Restrictions in spectral response, spectral mismatch; not available with smallest uncertainty
Multi radiometer	At least two quantities with one instrument; very short time response; lightweight, small; cheaper than corresponding pyranometer and/or pyrheliometers systems	Restrictions in spectral response, spectral mismatch; not available with smallest uncertainty
Diffuse solar irradiance ($E_d\downarrow$) measured with a pyranometer on a solar tracker with shadow disc	Best measurement; field-of-view angle of the pyrheliometer and shadow disc agree	Expensive
Diffuse solar irradiance ($E_d\downarrow$) measured with a pyranometer and shadow ring	Considerably cheaper than with tracker	Correction methods can never provide true values
Terrestrial radiation measured with a pyrradiometer		Separation of the terrestrial spectral range is only possible by subtraction of the solar global or reflected radiation measured in parallel; polyethylene domes degrade quickly
Terrestrial radiation measured with a pyrgeometer	Best measurement	

Especially in some Si pyranometers and thus RSR, a heater is included in the body of the instrument. In the case of thermopile pyranometers, an entirely new approach was introduced with the SR30-D1 (Hukseflux B.V., the Netherlands), in which recirculating ventilation and heating (RVH™) technology was applied based on the circulation of slightly warmer air between the inner and outer domes.

Furthermore, for use on ocean platforms, cleaning systems have been developed based on splashing dis-

tilled water over pyranometer and pyrgeometer domes as well as the front glasses of pyrheliometers to wash away salt deposits.

11.4.9 Comparison of Devices to Measure Radiation Parameters

The advantages and disadvantages of the different devices for measuring radiation parameters are presented in Table 11.7.

11.5 Specifications

Specifications of instruments are necessary to compare their features. Concerning broadband radiation instruments, specifications are provided by both the World Meteorological Organization (WMO) and International Organization for Standardization (ISO), being very similar up to the end of 2018, at which time a new ISO stan-

dard [11.73] was published to consider new demands and the state of the art. As always, the ISO standard considers only instruments for measuring hemispherical solar and direct solar radiation but explicitly includes new *photoelectric* sensors. Furthermore, the additional properties of *spectrally flat* and *fast response* were in-

Table 11.8 Pyranometer classification list (excerpt of [11.73])

Parameter Name of the class	Name of the classes, acceptance intervals, and width of the guard bands (in brackets)		
	A	B	C
Response time: time for 95% response	< 10 s (1 s)	< 20 s (1 s)	< 30 s (1 s)
Zero offset: (a) Response to -200 W m^{-2} net thermal radiation	$\pm 7 \text{ W m}^{-2}$ (2 W m^{-2})	$\pm 15 \text{ W m}^{-2}$ (2 W m^{-2})	$\pm 30 \text{ W m}^{-2}$ (3 W m^{-2})
(b) Response to 5 K h^{-1} change in ambient temperature	$\pm 2 \text{ W m}^{-2}$ (0.5 W m^{-2})	$\pm 2 \text{ W m}^{-2}$ (0.5 W m^{-2})	$\pm 8 \text{ W m}^{-2}$ (1 W m^{-2})
(c) Total zero offset including effects (a) and (b) and other sources	$\pm 10 \text{ W m}^{-2}$ (2 W m^{-2})	$\pm 21 \text{ W m}^{-2}$ (2 W m^{-2})	$\pm 41 \text{ W m}^{-2}$ (3 W m^{-2})
Nonstability: percentage change in responsivity per year	$\pm 0.8\%$ (0.25%)	$\pm 1.5\%$ (0.25%)	$\pm 3\%$ (0.5%)
Nonlinearity: percentage deviation from the responsivity at 500 W m^{-2} due to changes in irradiance within 100 to 1000 W m^{-2}	$\pm 0.5\%$ (0.2%)	$\pm 1\%$ (0.2%)	$\pm 3\%$ (0.5%)
Directional response (for beam radiation): range of errors caused by assuming that the normal incidence responsivity is valid for all directions when measuring from any direction (with an incidence angle up to 90° or even from below the sensor) for a beam radiation whose normal-incidence irradiance is 1000 W m^{-2}	$\pm 10 \text{ W m}^{-2}$ (4 W m^{-2})	$\pm 20 \text{ W m}^{-2}$ (5 W m^{-2})	$\pm 30 \text{ W m}^{-2}$ (7 W m^{-2})
Clear sky global horizontal irradiance spectral error	$\pm 0.5\%$ (0.1%)	$\pm 1\%$ (0.5%)	$\pm 5\%$ (1%)
Temperature response: percentage deviation due to changes in ambient temperature within the interval from -10 to 40°C relative to the signal at 20°C	$\pm 1\%$ (0.2%)	$\pm 2\%$ (0.2%)	$\pm 4\%$ (0.5%)
Tilt response: percentage deviation from the responsivity at 0° tilt (horizontal) due to changes in tilt from 0° to 180° at 1000 W m^{-2} irradiance	$\pm 0.5\%$ (0.2%)	$\pm 2\%$ (0.5%)	$\pm 5\%$ (0.5%)
Additional signal processing errors	$\pm 2 \text{ W m}^{-2}$ (2 W m^{-2})	$\pm 5 \text{ W m}^{-2}$ (2 W m^{-2})	$\pm 10 \text{ W m}^{-2}$ (2 W m^{-2})

cluded, and more intuitive names were introduced for the classes (A, B, and C). However, the old names of secondary standard, first class, and second class already differed from those of the WMO, viz. high quality, good quality, and moderate quality. Generally, the ISO specification as well as the WMO characteristics are independent of the technology applied by the manufacturer and are only valid for well-maintained instruments working under the same conditions. Furthermore, the classes express a ranking, but this does not mean that a lower-class instrument will give worse results in corresponding measurement conditions, if the parameter responsible for the lower ranking does not determine the task at

hand. In any case, the selection of an appropriate sensor is important regarding the accordance of its response time with the sampling rate of the data logger, for instance, and similarly for its spectral response.

The corresponding characteristics in the WMO document [11.1] cover pyrheliometers, pyranometers, and pyrrometers. Unfortunately, no equivalent information is available concerning pyrgeometers.

Excerpts from the pyranometer and pyrheliometer classification lists of the ISO standard [11.73] are reproduced in Tables 11.8 and 11.9. For details, including comments regarding the parameters, direct reference to this document is very important and useful.

Table 11.9 Pyrheliometer classification list (excerpt of [11.73])

Parameter	Name of the classes, acceptance intervals, and width of the guard bands (in brackets)			
	AA*	A	B	C
Response time: time for 95% response	See Note 1	< 10 s (1 s)	< 15 s (1 s)	< 20 s (1 s)
Zero offset:				
(a) Response to 5 K h ⁻¹ change in ambient temperature	±0.1 W m ⁻² (0.05 W m ⁻²)	±1 W m ⁻² (0.5 W m ⁻²)	±3 W m ⁻² (0.5 W m ⁻²)	±6 W m ⁻² (1 W m ⁻²)
(b) Complete zero offset including effect (a) and other sources	±0.2 W m ⁻² (0.05 W m ⁻²)	±2 W m ⁻² (0.5 W m ⁻²)	±4 W m ⁻² (0.5 W m ⁻²)	±7 W m ⁻² (1 W m ⁻²)
Nonstability: percentage change in responsivity per year	±0.01% (0.01%)	±0.5% (0.25%)	±1% (0.25%)	±2% (0.25%)
Nonlinearity: percentage deviation from the responsivity at 500 W m ⁻² due to changes in irradiance within 100 to 1000 W m ⁻²	±0.01% (0.01%)	±0.2% (0.1%)	±0.5% (0.2%)	±2% (0.2%)
Clear sky direct normal irradiance spectral error	±0.01% (0.005%)	±0.2% (0.05%)	±1% (0.5%)	±2% (1%)
Temperature response: percentage deviation due to change in ambient temperature within the interval from -10 to 40 °C relative to the signal at 20 °C	±0.01% (0.01%)	±0.5% (0.25%)	±1% (0.5%)	±5% (0.5%)
Tilt response: percentage deviation from the responsivity at 0° tilt (horizontal) due to changes in tilt from 0° to 90° at 1000 W m ⁻² irradiance	±0.01% (0.1%)	±0.2% (0.2%)	±0.5% (0.2%)	±2% (0.5%)
Additional signal processing errors	±0.1 W m ⁻² (0.1 W m ⁻²)	±1 W m ⁻² (0.5 W m ⁻²)	±5 W m ⁻² (2 W m ⁻²)	±10 W m ⁻² (2 W m ⁻²)

Note 1: Pyrheliometers of this class are mainly used as reference instruments for the calibration of other pyrheliometers. They are often absolute pyrheliometers, for which an unambiguous definition of response time is not possible. For instance, it depends on the mode of operation (e.g., active or passive). To avoid confusion and because the response time is of marginal significance for calibration under stable sky conditions, the response is omitted for this class.

* This class was first time introduced in this ISO standard [11.73]

11.6 Quality Control

Quality control is critically important to achieve useful and comparable datasets for scientific analysis. This starts with a reproducible and traceable calibration to SI for the instrument and ends with verification of the generated data, including documentation of any changes throughout the process. In the case of broadband radiation measurements, this traceability to SI does not occur via the National Metrology Institutes but uses the World Radiation Center (WRC) located at the Physikalisch-Meteorologisches Observatorium Davos (PMOD) in Switzerland.

11.6.1 Calibration of Radiation Instruments

Regarding the separation between the solar and terrestrial spectral ranges, see Sects. 11.3.1 and 11.3.4.

Instruments Operating in the Solar Spectral Range

All calibrations in the solar spectral range are based on the World Standard Group (WSG) representing the World Radiation Reference (WRR) (Sect. 11.2.5). Currently, absolute pyrheliometers (Sect. 11.4.1) of the PMO, CROM, TMI, PACRAD and H-F type are members of the WSG (Fig. 11.40). These instruments are operated by the staff of the WRC.

The task of the PMOD/WRC is to disseminate the WRR all over the world, which mainly happens during the international pyrheliometer comparisons (IPCs) that take place every 5 years. During the IPCs, the WRR is transferred to the reference instruments of the regional radiation centers (RRC) and/or national radiation centers (NRC) (Sect. 11.2.5). Corresponding rules and

Fig. 11.40 Several absolute pyrheliometers at the PMO Sun tracker during IPC-XII in September/October 2015. *Red arrows* indicate the six absolute pyrheliometers composing the World Standard Group (WSG) and representing the World Radiometric Reference (WRR), while the *yellow arrow* points to the cryogenic solar absolute radiometer (CSAR, Sect. 11.2.5) (photo: K. Behrens)

procedures are governed by the CIMO-Guide [11.1] and ISO standards [11.110–112]. In general, calibrations should only be carried out by special laboratories such as the WRC, RRCs, and NRCs that possess the necessary equipment and well-trained staff. The RRCs are given in [11.1].

Calibration of Pyrheliometers

The calibration of pyrheliometers must be conducted by side-by-side comparison with a reference pyrheliometer and using the Sun as the radiation source. It is important that the reference pyrheliometer be traceability to the WSG and is equal to or better in quality than the pyrheliometers being calibrated in terms of uncertainty. Furthermore, such calibration should take place in clear and stable atmospheric conditions. Detailed procedures are given in [11.1, 110]. The following method may be applied:

- Outdoor – Sun as source
 - *Side-by-side comparison of the reference pyrheliometer and the pyrheliometer being calibrated*
Reference instrument: a pyrheliometer of higher class.
The method can be applied to any type of pyranometer; for details see [11.1, 110].
Execution: Both pyrheliometers are installed side by side on a solar tracker, and the direct irradiance (E) of the reference pyrheliometer and the voltage (U) of the pyrheliometer being calibrated are recorded; the sensitivity (S) of

the pyrheliometer being calibrated is then calculated as

$$S = \frac{U}{E}. \quad (11.29)$$

Calibration of Pyranometers

Several procedures can be used to calibrate a pyranometer. There are some outdoor methods that use the Sun as the source, while others use artificial light sources to provide the radiation for both the reference and test pyranometers. The light source never serves as a reference when calibrating pyranometers. As in the case of pyrheliometers, it is obvious that the reference instrument must be traceable to the WSG. Beside the main goal of calibration, the sensitivity or responsivity, temperature dependence, directional response, and other characteristics of a pyranometer can also be studied. The following methods can be applied:

- Outdoor – Sun as source
 - *Alternating Sun-and-shade method*
Reference instrument: a pyrheliometer.
The method can be applied to any type of pyranometer; calibration should take place during clear and stable atmospheric conditions; for details see [11.1, 111].
Execution: The horizontally adjusted pyranometer being calibrated is alternately shaded and unshaded by a shadow disc, whose field-of-view angle corresponds to that of the pyrheliometer; it is necessary to record the voltage in the unshaded ($U_{\text{un}\downarrow}$) and shaded phase ($U_{\text{s}\downarrow}$) of the horizontally adjusted pyranometer under test as well as the direct solar irradiance (E) determined by the reference pyrheliometer; z is the solar zenith angle of the corresponding time; the sensitivity (S) of the pyranometer under test can then be calculated as

$$S = \frac{U_{\text{un}\downarrow} - U_{\text{s}\downarrow}}{E \cos z}. \quad (11.30)$$

- *Continuous Sun-and-shade method*
Reference instrument: a pyrheliometer and a pyranometer.
The method can be applied to any type of pyranometer; for details see [11.1, 111].
Execution: The horizontally adjusted pyranometer under test and measuring the voltage (U_{\downarrow}) is installed side by side with the reference pyrheliometer and reference pyranometer measuring the solar irradiances E and $E_{\text{d}\downarrow}$, respectively; the field-of-view angle of the shadow disc of the shaded reference pyranometer should

correspond to those of the pyrheliometer; z is the solar zenith angle at the corresponding time; the sensitivity (S) of the pyranometer under test can then be calculated as

$$S = \frac{U\downarrow}{E \cos z + E_d\downarrow} \quad (11.31)$$

- *Side-by-side comparison of the reference pyranometer and pyranometer under test*

Reference instrument: a pyranometer of higher class.

The method can be applied to any type of pyranometer; for details see [11.1, 112].

Execution: The horizontally adjusted reference pyranometer and the pyranometer under test are installed side by side, and the global irradiance ($E_g\downarrow$) of the reference and the voltage ($U\downarrow$) of the pyranometer under test are recorded; the sensitivity (S) of the pyranometer under test can then be calculated as

$$S = \frac{U\downarrow}{E_g\downarrow} \quad (11.32)$$

- Indoor – artificial light source

For any indoor calibration, both the reference pyranometer and the pyranometer under test should be of the same type to prevent a spectral mismatch, because the spectral response of artificial light sources is not the same as that of sunlight:

- *Integrated sphere*

Reference instrument: a pyranometer.

The method can be applied to any type of pyranometer if they are of the same type; for details see [11.1, 112].

Execution: The horizontally adjusted reference pyranometer and the pyranometer under test are installed side by side near the bottom at the same level in the sphere, and the global irradiance ($E_g\downarrow$) and voltage ($U\downarrow$) are recorded; the sensitivity (S) of the pyranometer under test is calculated using (11.32).

- *Direct beam*

Reference instrument: a pyranometer.

The method can be applied to any type of pyranometer if they are of the same type; for details see [11.1, 112].

Execution: In a climatic chamber, the horizontally adjusted reference pyranometer and the pyranometer under test are installed side by side at a certain distance on a rolling table, such that only one of the two is irradiated by a beam; alternately, the reference pyranometer and the pyranometer under test are exposed to the beam, and the global irradiance ($E_g\downarrow$) and the voltage ($U\downarrow$) are recorded, respectively; the zero point between the beam measurements by both instruments is recorded and used in the analysis; the sensitivity (S) of the pyranometer under test can then be calculated using (11.32).

Instruments Operating in the Terrestrial Spectral Range

Currently, all calibrations in the terrestrial spectral range are based on the World Infrared Standard Group of Pyrometers (WISG), representing the interim reference for infrared radiation measurements [11.113, 114]. The WISG consists of two modified Eppley PIR and two Kipp and Zonen CG4 pyrometers (Sect. 11.4.3). Since its establishment, the WISG has been very stable ($\pm 1 \text{ W m}^{-2}$) [11.115]. These instruments are operated by the staff of the WRC.

One of the tasks of the PMOD/WRC is to provide the infrared radiation reference and disseminate the defined infrared scale all over the world. The PMOD/WRC offers a calibration service for pyrometers upon request and provides the opportunity of calibration with the WISG at the prospective international pyrometer comparisons (IPgC). In general, calibrations should be done only by special laboratories such as the PMOD/WRC and/or RRCs that possess the necessary equipment and well-trained staff.

Fig. 11.41 Shaded pyrometers of PIR and CG4 type of the WISG, assembled in a ventilation and heating unit at a Sun tracker during IPgC-II on the roof of PMOD/WRC Davos in September/October 2015 (photo: K. Behrens)

Remarks Regarding the History and Base of Traceability of WISG to SI

Despite the progress concerning improvements of the determination of terrestrial radiation fluxes with pyrgeometers as described in Sect. 11.4.3, deficiencies remained in outdoor measurements due to the calibration by a blackbody emitting a Planck spectrum versus the real atmospheric spectrum (Sect. 11.3.1, Fig. 11.18) as well as the nonflat dome spectrum (Sect. 11.3.4, Fig. 11.24), which is similar for all currently available pyrgeometers. The construction of the windowless absolute sky-scanning radiometer (ASR) at PMOD/WRC, which is described in detail in [11.116], overcame these problems, enabling measurements of atmospheric downward irradiance during nighttime and their traceability via a blackbody to the absolute temperature standard. In this case, the well-calibrated thermistors applied in the blackbody link the irradiance measurements in the terrestrial region to SI [11.116], while, in the solar spectral range, traceability to SI is ensured with the help of substitution of the irradiance by an electrical current (Sects. 11.2.5 and 11.4.1). The ASR, more than 10 pyrgeometers from international institutions (included two pyrgeometers from the later established WISG), an atmospheric emitted radiance interferometer (AERI), and radiative transfer models (MODTRAN, moderate resolution atmospheric transmission, and LBLRTM, line-by-line radiative transfer model) participated in two international radiometer comparisons (IPASRC-I and II) under midlatitude summer and dry Arctic winter conditions. The results of both comparisons showed very good agreement (within $\pm 2 \text{ W m}^{-2}$) between the participating instruments as well as model calculations [11.117, 118].

In 2012, at PMOD/WRC and at the National Renewable Energy Laboratory (NREL) in the USA, two independently designed and calibrated absolute radiometers measuring atmospheric downward irradiance were developed, called the Infrared Integrating Sphere Radiometer (IRIS) [11.119] and Absolute Cavity Pyrgeometer (ACP) [11.120] (Fig. 11.42), respectively. Both instruments are windowless systems and can thus only be operated during nighttime when measuring the atmospheric downward irradiance. They avoid the above-mentioned problems of the classical pyrgeometers whose receivers are covered by a filter. The IRIS radiometer is calibrated to a well-characterized blackbody whose temperature measurements are traceable to SI [11.121], while the ACP uses an in-situ self-calibration technique. Both instruments agree within $\pm 1 \text{ W m}^{-2}$ [11.115] and confirm the present state regarding the WISG and SI, because recalibrations of WISG with ASR no longer take place.

Fig. 11.42a,b ACP (a) and IRIS (b) during IPgC-II on the roof of PMOD/WRC Davos in September/October 2015 (photos: K. Behrens)

In 2018, the CIMO decided to establish a governance framework for WISG and its traceability to the International Standard of Units (SI) [11.122].

Calibration of Pyrgeometers (Check of Sensitivity S_1 of Field Pyrgeometers)

At the moment, there are still no ISO standards or other WMO documents governing or providing sufficient guidance on the calibration of pyrgeometers. However, based on experience obtained in the framework of the BSRN and at the IPgCs that took place at PMOD/WRC in 2010 and 2015 [11.123] as well as the procedure applied at PMOD [11.124], it is possible to provide the following recommendation for the determination of only the sensitivity S_1 of a pyrgeometer:

- The basis of any analysis is (11.8)–(11.10) (Sect. 11.4.3), depending on the type of pyrgeometer used and whether dome temperatures are measured.
- In general, in the presence of dome thermistors, the correction factors k_f or K in (11.8) and (11.9) can only be determined using blackbodies and further supplementary instruments as used in [11.89] or described in [11.121], allowing the characterization of pyrgeometers.

- Comparisons with reference pyrgeometers should be carried out only outdoors during nighttime under a clear sky in stable atmospheric conditions.
- It is mandatory that the reference pyrgeometer be certified as traceable to the WISG.
- The horizontally adjusted reference pyrgeometer and the pyrgeometer under test should be installed side by side, and the atmospheric downward irradiance ($E_1\downarrow$) of the reference and the voltage ($U\downarrow$) of the pyrgeometer under test as well as their body (t_b) and dome (t_d) temperatures are recorded; in the case *without dome thermistors*, the sensitivity (S_1) of the pyrgeometer under test can then be calculated as

$$S_1 = \frac{U_1\downarrow}{E_1\downarrow - \sigma T_b^4}, \quad (11.33)$$

- whereas in the case *with dome thermistors*, the Albrecht equation is used

$$S_1 = \frac{U_1\downarrow}{E_1\downarrow - \sigma T_b^4 + K\sigma(T_d^4 - T_b^4)}. \quad (11.34)$$

- In the case *with dome thermistors* (mainly in the case of PIRs), one uses

$$S_1 = \frac{U_1\downarrow(1 + k_1\sigma T_b^3)}{E_1\downarrow - k_2\sigma T_b^4 + k_3\sigma(T_d^4 - T_b^4)}, \quad (11.35)$$

- where k_i ($i = 1..3$) and K are specific correction factors of the pyrgeometer under test, determined beforehand using a blackbody cavity and available on a certificate, σ is the Stefan–Boltzmann constant, and T_d and T_b are the temperatures of the dome and body of the pyrgeometer in kelvin.

Instruments Operating in Both the Solar and Terrestrial Spectral Ranges

Instruments operating in both the solar and terrestrial spectral ranges are called pyrradiometers (Sect. 11.4.4). They measure the total (global solar + terrestrial downward) radiation or total (reflected solar + terrestrial upward) radiation incident from a viewing angle of 2π sr on a flat surface depending on how the receiver is facing (Tables 11.2–11.4). Combining a downward- and upward-looking pyrradiometer allows measurements in a viewing angle of 4π sr. Such an instrument is called a *total net radiometer*. The calibration of pyrradiometers is extensive and complex, because two totally different spectral ranges are measured simultaneously using one sensor. Therefore, only a brief description is possible here.

Case 1: upward-looking pyrradiometer measuring total (global solar + terrestrial downward) radiation:

- The calibration in the solar spectral range for the determination of the sensitivity $S_s\downarrow$ takes place by applying the *outdoor* methods described for pyranometers (the application of indoor calibrations is not recommended because the very large error sources increase the underlying uncertainties)
- The calibration in the terrestrial spectral range for the determination of the sensitivity $S_1\downarrow$ takes place by applying the *outdoor* methods described for pyrgeometers

Case 2: total net radiometer measuring total (global solar + terrestrial downward) and (reflected solar + terrestrial upward) radiation with one sensor or two sensors applying a differentiating circuit between a downward- and upward-looking radiometer (Sect. 11.4.5):

- The calibration enables only the determination of the sensitivity S ; the best and simplest method is an outdoor comparison of the instrument under test with a four-sensor net radiometer.

11.6.2 Specific Quality Control of Measured Data

Specific quality control of the gathered data is possible at different levels, starting in some cases with verification of the raw data and finishing with its upload to a database or appropriate file system. In most cases, the data acquisition chain including the quality control is automatized. However, the level of automation depends on many factors, such as the computer and programming resources, the number of quantities to be checked, possible redundant and/or complementary measurements, the kind of results to be output (static or interactive), etc. But, independently of the technical capabilities, quality control should start (at least daily) with a visual check of the recorded time series. Furthermore, quality control has to be adapted to local requirements and capabilities.

At all levels, the simplest method to check data is a comparison with physical limits. Because radiation quantities oscillate, it is necessary to check that they remain within appropriate lower and upper bounds. Generally, the measured values of solar radiation quantities (Table 11.2) depend on parameters that vary on an annual and daily basis, viz. the declination of the Sun, the geographical latitude, and the local time. Derived from these parameters, the altitude of the Sun or solar zenith angle (z) determines the upper limit, while the lower limit is zero. The bounds of terrestrial irradiance quantities also depend on the temperature and composition of the atmosphere (gases and clouds, and their base

height) for the upper half-space and mainly the temperature of the underlying surface in the case of the lower half-space. Moreover, such verification of single quantities can be extended to combinations of independently measured quantities.

Additionally, comparisons with modeled and/or satellite data are also helpful methods. Here, of course, it must be ensured that the atmospheric conditions during the measurements indeed correspond to the model input data. In the case of satellite data, the time of the measurements on the satellite and ground should be similar and the atmospheric conditions within the covered satellite pixel should agree as far as possible with those at the station. Good results are particularly available in cloudless conditions at local noon [11.125]. A further, comprehensive method for quality control of global solar radiation measurements at ground level using satellite-based products is given in [11.126]. As the basis of this method are validated satellite products, it is not very suitable for immediate verification processes during data acquisition.

Based on the fundamentals described above, various principles [11.127] were established and successfully applied in the framework of the BSRN [11.128] and also implemented when programming the code of the BSRN Toolbox 2.0 [11.129]. The following equations concerning the solar irradiance given in [11.127] enable the calculation of the upper bounds of *extremely rare limits* (meaning in this context that these bounds may be exceeded in only very rare cases) for the solar quantities

$$\begin{aligned} &\text{Global solar irradiance } (E_g \downarrow) \\ E_g \downarrow &= 1.2E_{0,a} \cos(z)^{1.2} + 50 \end{aligned} \quad (11.36)$$

$$\begin{aligned} &\text{Diffuse solar irradiance } (E_d \downarrow) \\ E_d \downarrow &= 0.75E_{0,a} \cos(z)^{1.2} + 30 \end{aligned} \quad (11.37)$$

$$\begin{aligned} &\text{Direct solar irradiance } (E) \\ E &= 0.95E_{0,a} \cos(z)^{0.2} + 10 \end{aligned} \quad (11.38)$$

$$\begin{aligned} &\text{Reflected solar irradiance } (E_r \uparrow) \\ E_r \uparrow &= E_{0,a} \cos(z)^{1.2} + 50, \end{aligned} \quad (11.39)$$

where $E_{0,a}$ is the direct solar irradiance without the atmosphere (solar constant) adjusted for the Earth–Sun distance and the solar zenith angle z .

The lower bounds for all these mentioned quantities are set to -2 W m^{-2} . This value considers the uncertainty originating if black thermopiles are used for such measurements (Sect. 11.4.2), although solar irradiance during nighttime is exact zero. In the case of downward terrestrial irradiance ($E_1 \downarrow$), the lower and upper bounds are set to 60 and 500 W m^{-2} , respectively.

The corresponding values for the upward terrestrial irradiance ($E_1 \uparrow$) are 60 and 700 W m^{-2} . Examples for the upper limits of global and direct normal irradiance during the diurnal cycle in the course of the year between the equator and 75° N are given in Fig. 11.43, indicating their possible spread. These upper limits are slightly higher in the Southern Hemisphere, because of the shorter distance between the Sun and Earth at the aphelion which takes place in January (summer in the Southern Hemisphere). The pattern of diffuse solar irradiance and reflected solar irradiance are similar to those of the global solar radiation, as can be deduced from (11.36), (11.37), and (11.39). Furthermore, another important aspect of data verification is to check that the diffuse solar irradiance and reflected solar irradiance never exceed the simultaneously measured global solar irradiance, and that in the best case, the maximum reflected solar irradiance (gathered over a fresh snow cover) is about 90% of the global irradiance.

An example of the combination of independently measured quantities is the comparison, based on (11.1), of the global irradiance ($E_g \downarrow$) measured with a pyranometer with the total of the diffuse ($E_d \downarrow$) and the vertical component of the direct solar irradiance ($E \downarrow \cos z$) measured by a shaded pyranometer and a pyrliometer, respectively (Sects. 11.4.6 and 11.4.8 [11.99]). The, in general, good agreement between the independently measured quantities, which are situated at a 1 : 1 line, is displayed in Fig. 11.44. However, some outliers are also visible, which should be checked in detail with the objective of identifying the possible cause.

According to [11.127], the downward ($E_1 \downarrow$) and upward ($E_1 \uparrow$) terrestrial irradiance may be checked simply using the independently measured air temperature by applying (11.40) and (11.42), while in [11.130], slightly different constants are used (11.41), (11.43)

$$\begin{aligned} &\text{Downward terrestrial irradiance :} \\ 0.4\sigma(T_a)^4 &< E_1 \downarrow < \sigma(T_a)^4 + 25 \end{aligned} \quad (11.40)$$

$$\begin{aligned} &\text{Downward terrestrial irradiance :} \\ 0.7\sigma(T_a)^4 &< E_1 \downarrow < \sigma(T_a)^4 \end{aligned} \quad (11.41)$$

$$\begin{aligned} &\text{Upward terrestrial irradiance :} \\ \sigma(T_a - 15)^4 &< E_1 \uparrow < \sigma(T_a + 25)^4 \end{aligned} \quad (11.42)$$

$$\begin{aligned} &\text{Upward terrestrial irradiance :} \\ \sigma(T_a - 10)^4 &< E_1 \uparrow < \sigma(T_a + 10)^4, \end{aligned} \quad (11.43)$$

where σ is the Stefan–Boltzmann constant and T_a is the air temperature in kelvin. It is assumed that the air temperature T_a is measured nearby and at the same height as the pyrgeometer.

The proposed bounds obtained using both relations are shown in Fig. 11.45 to reveal the difference. The

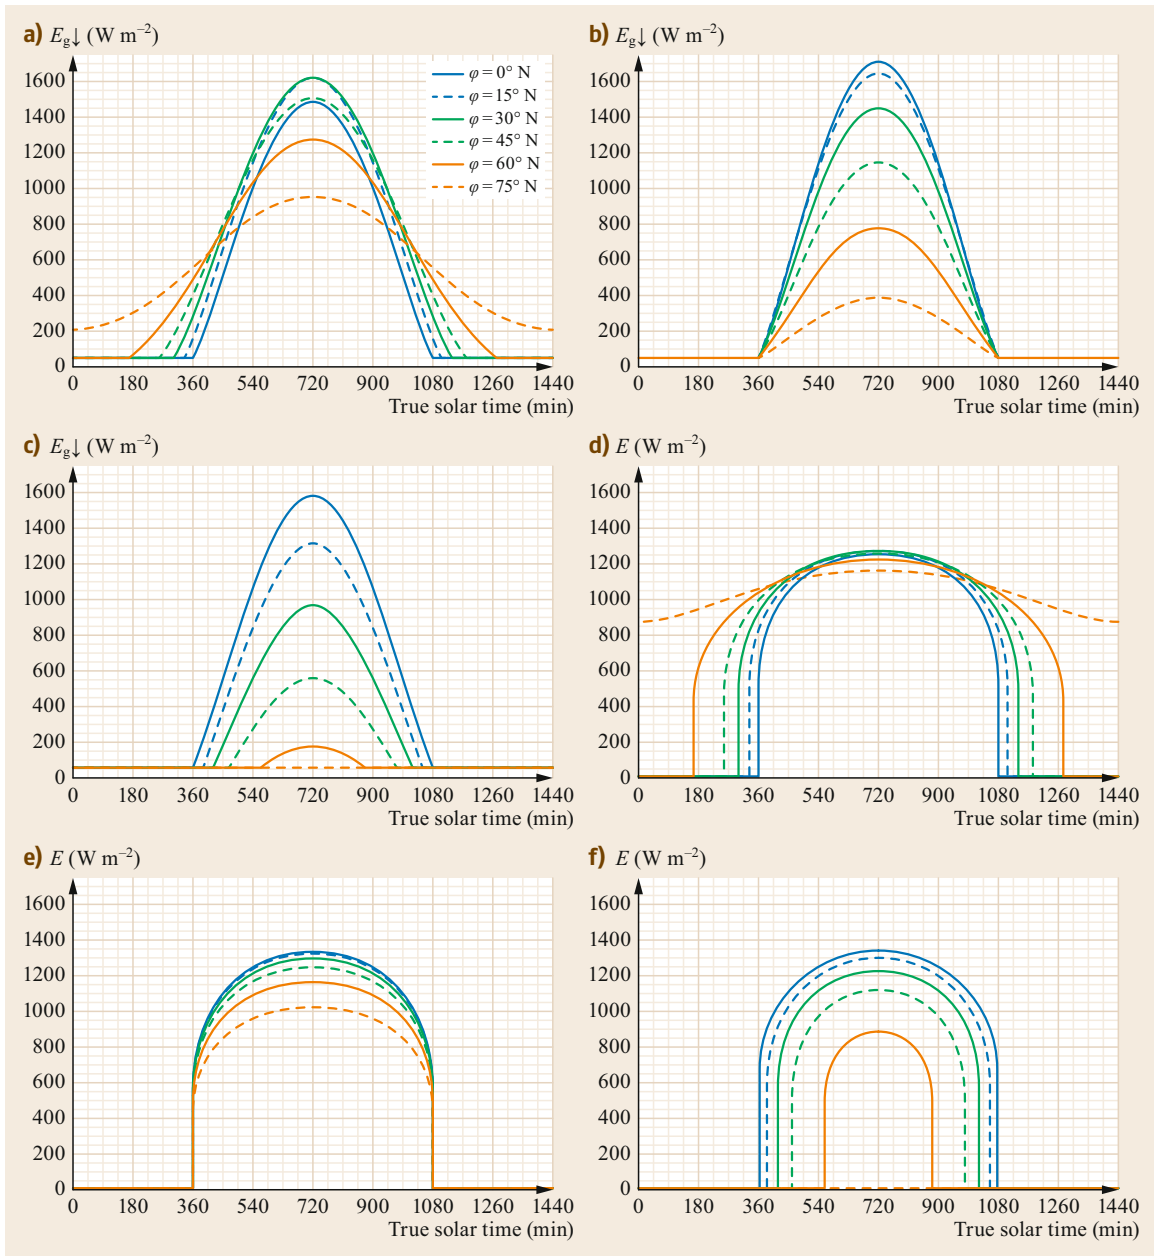

Fig. 11.43a–f Daily courses of global irradiance $E_{g\downarrow}$ (a–c) and direct solar irradiance E at normal incidence (d–f) at extreme rare limits calculated based on (11.36) and (11.38) for six geographic latitudes φ at summer solstice ((a) global solar irradiance; (d) direct normal irradiance), equinox ((b) global solar irradiance; (e) direct normal irradiance), and winter solstice ((c) global solar irradiance; (f) direct normal irradiance) for the Northern Hemisphere

bounds derived from relation (11.40) are labeled *upper and lower bound 1*, while the limits calculated from (11.41) are labeled *upper and lower bound 2*.

In this example, after a nearly overcast night, the clouds dissolved at around 9 UTC and the sky became very clear (Fig. 11.45a). At this time, the downward ter-

restrial irradiance ($E_i\downarrow$) was so low that lower bound 2 was touched. In the summer case (Fig. 11.45b), during approximately the first 4 h, the sky was also overcast but with very low and warm clouds, so that the originating downward terrestrial irradiance ($E_i\downarrow$) was so large that it touched upper bound 2. These examples

Fig. 11.44 Scatter plot of monthly 1-min global irradiance ($E_{g\downarrow}$) measured with a pyranometer (CM 22) on the y-axis and the total of the diffuse ($E_{d\downarrow}$) and the vertical component of the direct solar irradiance ($E_{\downarrow}\cos(z)$) measured by a shaded pyranometer (CM 22) and a pyrhemometer (CH 1), respectively, on the x-axis, from May 2016 at the Meteorological Observatory Lindenberg – Richard-Abmann Observatory, Germany. The assembly of the instruments is similar to that shown in Fig. 11.38 ►

Fig. 11.45a,b Downward terrestrial irradiance ($E_{i\downarrow}$) for (a) a winter (09.02.2017) and (b) a summer case (17.07.2017) measured with a CG4 pyrgeometer at the Meteorological Observatory Lindenberg – Richard-Abmann Observatory (Germany) and the corresponding lower and upper bounds according to (after [11.127, 130]) when applying (11.40) and (11.41)

show that the adopted limits of bound 2 are very close, while lower bound 1 is particularly small in comparison.

Beside the radiation quantities, it is also necessary to check the temperature of the instrument, especially of a pyrgeometer, because this is an important input

quantity determining both the downward ($E_{i\downarrow}$) and upward ($E_{i\uparrow}$) terrestrial irradiances (Sects. 11.4.3–11.4.5). One simple possibility here is a comparison with the air temperature, which is available in most cases. Limits may be derived from climatological data for the corresponding region.

11.7 Maintenance

Generally, maintenance is very important if high-quality data are to be gathered. It starts with on-site maintenance of sensors and the supplementary equipment and continues with data acquisition up to the storage systems. Only well-attended instruments and accessories will enable given standard uncertainties to be attained. It is important to point out that it is necessary to document *all* activities with the instrument and its behavior as well as their time and date. Such compre-

hensive and clear maintenance documentation will facilitate the search for the causes of any deviations from the norm or errors. For detailed and comprehensive maintenance descriptions, the BSRN Operation Manual [11.9] and CIMO-Guide [11.1] are recommended reading. Furthermore, information given in specific instrument and sensor manuals should also be considered.

Nowadays, technical systems such as video cameras may support inspections, especially at remote stations,

Table 11.10 Maintenance requirements for radiation instruments and supplementary equipment

Maximum interval	System	Task
1 week	Radiation sensor	Cleaning dome, front window and check for scratches state/color of thermopile Check for internal condensation Check for horizontal adjustment Check for damage of radiation screen
	Ventilation system	Check for sufficient air stream (rotational speed of motor)
	Cable	Check for damage and loose connections
	Solar tracker	Check for alignment and horizontal adjustment
1 month	Radiation sensor	Check desiccant
	Ventilation system	Check and clean or replace filter
6 months	All instruments	Check to determine aging
	Radiation sensor	Check horizon for possible changes influencing the measurement (e.g., instrument shading (Sect. 11.1.3))
12/24 months	Radiation sensor, voltmeter	Calibration according to the rules given by the manufacturer and/or responsible authorities (e.g., National Metrology Institutes)

and high-performance fans can blow raindrops away from domes and front glasses of pyranometers, pyrgeometers, and pyrhemometers faster, ensuring better results (Sect. 11.4.8). Furthermore, automatic systems enable monitoring of the rotational speed of motors, data loggers, and computers. However, it must be remembered that these systems themselves also need maintenance. In general, maintenance must be adapted by considering the requirements and state of the whole data acquisition process.

If possible, at least daily on-site inspection and maintenance should be performed. If, for instance, a traditional, mechanical shadow band is used for measurements of the diffuse solar irradiance, then it is *mandatory* to check and adjust it daily. This is also the case if a pyrhemometer is fed by a one-axis tracker following the Sun. Likewise, a daily time check of the data acquisition systems and PC is also critical. Table 11.10 presents the minimum verification requirements in certain intervals.

11.8 Applications

As mentioned above, radiation in the so-called thermal-optical region is relevant from every point of view for physical as well as chemical processes within the atmosphere and its interaction at the boundaries with the hydro-, litho-, cryo-, and biosphere. As a consequence, radiation data are used in meteorology and climatology as well as in applied sciences (agriculture, energy, environment, etc.).

11.8.1 Climatology of Radiation

One aspect of climatology is the analysis of time series. As an example, the time series of the annual total global solar radiant exposure ($H_g \downarrow$) at Potsdam (Germany) covering the time span from 1893 to 2018 is shown in Fig. 11.46. It consists of two sections. The first part from 1893 to 1936 is based on measurements of sunshine duration (Sect. 11.4.7), converted to global solar radiant exposure using the well-known regression between global radiation and sunshine duration [11.131]. The second part, starting in 1937, is based

on measurements made with pyranometers. Moreover, since 1937, diffuse solar radiation and direct solar radiation at normal incidence have also been measured in parallel, using a shaded pyranometer and pyrhemometer, which provides a useful verification of the data (Sect. 11.6.2) [11.132].

This figure shows large and fast oscillations in the annual totals, superimposed on an oscillation at lower frequency. The time spans with comparatively low irradiation at the beginning of the 20th century and around the 1980s, well known in literature [11.133, 134] as *global dimming*, are clearly visible. In general, an increasing trend is noticeable, being particularly steep in the last 40 years as a consequence of a cleaner atmosphere and lesser cloudiness.

11.8.2 Daily and Annual Cycles

In most cases, presenting the course of the radiation components over time, e.g., on a daily plot, is based on data compression by means of averaging either in the

Fig. 11.46 Annual (1893–2018) total global solar radiant exposure ($H_g\downarrow$) in MJ m^{-2} (blue tracks) at Potsdam ($\varphi = 52.4^\circ \text{ N}$, $\lambda = 13.1^\circ \text{ E}$), the 100-year average 1901–2000 (green), 11-year moving averages (red tracks) as well as a curve displaying 70-year oscillation (orange)

data logger or later on in the PC, for instance. Currently, typical sampling rates in the radiation measurement field are 1 Hz, commonly compressed to means over 1 or 10 min or longer, depending on demands (see, e.g., Sect. 11.8.3). An example of two daily courses is shown in Fig. 11.47, displaying a day (02.07.2018) with intermittent cumulus clouds and a cloudless day (03.07.2018) in 2018. After a cloudless night and morning up to 8 UTC (minute 480) at the same irradiance level of about $E_g\downarrow \approx 700 \text{ W m}^{-2}$ on both days, cumulus clouds developed on 02.07.2018. In the left picture, the impact of these clouds is clearly visible in the large oscillation of all four radiation balance components, while the right figure displays the typical diurnal cycle of a cloudless Central European summer day.

In climatological evaluations, in addition to irradiance, another quantity that is often displayed is the irradiation as a sum of the separate measurements or as a product of the mean irradiance and the number of seconds in the interval of interest. The Hovmöller plot (Chap. 1) is one example of how annual variations can be presented (Fig. 11.48).

11.8.3 Radiation on Tilted Surfaces

The use of alternative energy sources and technologies is gaining in importance, leading to increasing interest (e.g., from the energy industry) in knowledge about the solar irradiance received by tilted and vertical surfaces. Usually, only the global solar irradiance on a horizon-

Fig. 11.47a,b Daily courses of 10-min means of radiation balance (Table 11.2) consisting of its components the global solar $E_g\downarrow$ (blue), upward solar $E_r\uparrow$ (green), downward terrestrial $E_l\downarrow$ (orange), and upward terrestrial $E_l\uparrow$ (red) irradiances, measured at the Boundary Layer Measuring Field Falkenberg of the Meteorological Observatory Lindenberg – Richard-Aßmann Observatory on (a) 02.07.2018 and (b) 03.07.2018. Because of the geographical location of this site ($\varphi = 52.16^\circ \text{ N}$; $\lambda = 14.17^\circ \text{ E}$), the true solar noon on these days was at 11:08 UTC

Fig. 11.48a,b
Hovmöller plot of the global solar radiation (a) and the downward terrestrial radiation (b), measured in 2011 (Bayreuth, Ecological–Botanical Garden) (after [11.135])

tal plane is measured in networks. Radiation data for arbitrary inclined surfaces can be derived from the direct and diffuse solar irradiances and relevant azimuthal and inclination angles using an algorithm [11.136]. At Potsdam Meteorological Observatory (Germany), two experimental datasets were obtained from south-facing pyranometers tilted at inclination angles of 30°, 45°, 60°, and 90° and pyranometers mounted vertically (at an inclination angle of 90°) and directed towards the

four main cardinal directions. Figure 11.49 shows example daily courses of the hourly mean global solar irradiance on the tilted and vertical surfaces.

Both plots in Fig. 11.49 show the typical features of inclined and vertically oriented pyranometers measuring global solar irradiance. In the left-hand plot, the global radiation on the surface inclined at 30° significantly exceeds that measured on the horizontal surface, whilst the results for the 45° surface almost reach the

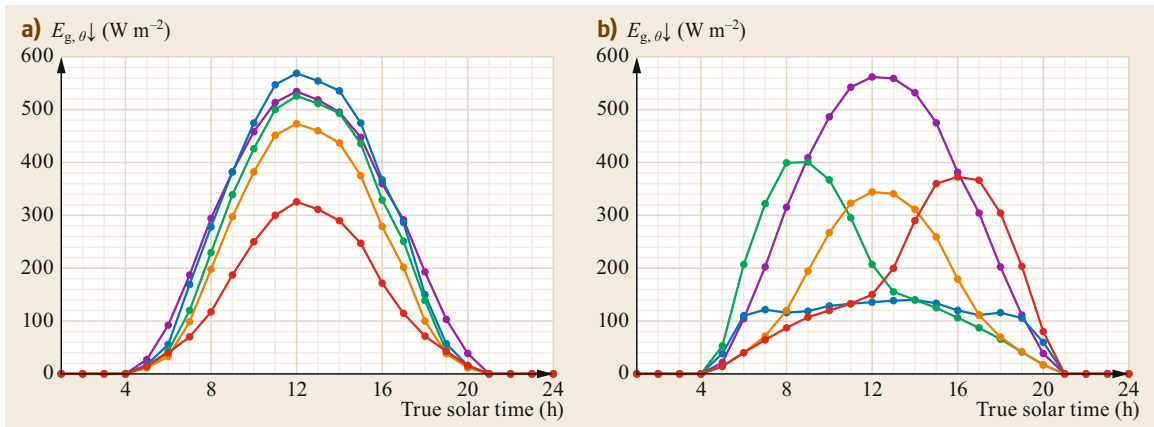

Fig. 11.49 (a) average hourly mean global solar irradiance ($E_{g,\theta\downarrow}$) in W m^{-2} of south-facing pyranometers at different tilt angles θ [$\theta = 0^\circ$ (purple), 30° (blue), 45° (green), 60° (orange), and 90° (red)] (Potsdam, $\varphi = 52.4^\circ \text{ N}$, $\lambda = 13.1^\circ \text{ E}$, June, 1977–1981); (b) average hourly mean global solar irradiance ($E_{g,\theta\downarrow}$) of pyranometers mounted vertically (inclination angle of 90°) and directed to the four main cardinal directions (N (blue), E (green), S (orange), and W (red)) and a horizontally mounted (purple) pyranometer (Potsdam, $\varphi = 52.4^\circ \text{ N}$, $\lambda = 13.1^\circ \text{ E}$, June, 1973–1980)

Fig. 11.50 Hovmöller plot of annual variation of surface temperature, measured in 2011 (Falkenberg boundary layer measuring field, Meteorological Observatory Lindenberg – Richard-Abmann Observatory) (after [11.4])

same level. This is a consequence of the angle of incidence of the direct solar radiation. At this geographical latitude of 52.2°N , the sun shines almost perpendicularly onto the 30° surface at noon. In contrast to the averaging period of 8 years for the vertically mounted pyranometers in the left figure, the results for the inclined surfaces obtained over 5 years do not yet display an ideal shape. In the right-hand plot, the curves of the east- and west-facing vertical devices show their maxima at midmorning and midafternoon, respectively, as expected. Because more convective clouds occur in the afternoon during summertime, the maximum irradiance measured by the westward-looking vertical pyranometer is lower than that measured by the eastward-directed device. Again, because of the angle of incidence of the direct solar radiation, the highest value measured by the vertically mounted south-facing sensor is lower than for the eastward- and westward-looking instruments. In the measurements by the vertical pyranometer looking north, the subsidiary maxima in the early morning and late afternoon are due to the direct solar radiation received by this instrument.

11.8.4 Radiation Temperature

Based on the Stefan–Boltzmann law (11.44),

$$E = \varepsilon \sigma T^4, \quad (11.44)$$

describing the relation between the irradiance (E) of an (ideal) blackbody and its temperature (T), with the

emissivity ε and the Stefan–Boltzmann constant σ , it is possible to determine the radiation temperature or rather the so-called effective (equivalent) blackbody radiation temperature, if the irradiance is known. The emissivity ε captures the deviation from an ideal blackbody, for which ε takes a value of 1.

The effective temperature of the sky (T_{sky}) can be calculated from the downward terrestrial irradiance ($E_{1\downarrow}$) as

$$T_{\text{sky}} = \left(\frac{E_{1\downarrow}}{\sigma} \right)^{1/4}, \quad (11.45)$$

while the effective temperature of the surface (T_{surf}) can be derived from the upward terrestrial irradiance ($E_{1\uparrow}$), as measured with upward- and downward-facing pyrgeometers, respectively (Sects. 11.4.3 and 11.4.5). In both cases, it is assumed that the sky or surface emits like an ideal blackbody, which is never actually true, thus the result is called the *effective* temperature.

Furthermore, the radiation temperature can also be determined using radiation thermometers or pyrometers, mainly developed for industrial applications and not discussed in this chapter. These instruments operate preferably in the range between 8 to $12\ \mu\text{m}$, the so-called atmospheric window (Sect. 11.3.1, Fig. 11.19; the plots of *thermal TOA_out* and *thermal SUR_in* at around $10\ \mu\text{m}$). Also in this case, the determined radiation temperature is only approximate because an ideal blackbody radiator or exact knowledge of the emissivity is assumed.

11.9 Future Developments

Classical in-situ radiation instruments for measurements from the ground have been developed for more than 100 years. Nevertheless, as shown by the implementation of novel black thermopiles, new ideas are still being applied. New instruments will be more compact and require less maintenance, as well as offering improved

measurement uncertainty as demanded by modern users, especially in the scientific community. Moreover, instruments will become increasingly smart, which will include different types of communication (from traditional wired to various types of wireless connection) and data handling methods. The individual corrections to a single

sensor based on its characterization can be stored in the instrument and immediately applied to provide a correct result to the user. At the same time, it is necessary to ensure that the processing is and remains traceable.

Traditional radiation measurements will also remain very important for science and many practical applications in the future. The required data quality covers the spread from good and stable data for practical use up to high-quality data with information on the uncertainty for scientific applications. Moreover, the *complete* integration of solar and terrestrial radiation

measurements and corresponding reference instruments into SI will be solved, addressing the remaining questions and problems. This will also be important for atmospheric physics and climatology in terms of obtaining the global radiation budget by combining data from very different origins.

Furthermore, radiation data from ground measurements will be applied in combination with data derived from satellites, using the advantages of both the area coverage of satellites and individually configurable and precise measurements from the ground.

Klaus Behrens

Nuthetal, Germany
klaus.behrens@mailbox.org

Klaus Behrens studied meteorology at Humboldt University then worked at Potsdam Meteorological Observatory on radiation climatology and broadband radiation measurements. He worked at the BSRN station in Lindenberg up to his retirement in 2017, being also the scientist responsible for the radiation network of the German Meteorological Service and the Regional Radiation Centre (RA VI of WMO) of Lindenberg Meteorological Observatory. He was also with CIMO of WMO.

In-situ Preci

12. In-situ Precipitation Measurements

Arianna Cauteruccio , Matteo Colli , Mattia Stagnaro , Luca G. Lanza , Emanuele Vuerich

This chapter describes the measuring principles and technological solutions available for in-situ measurements of liquid (rain) and solid (snow) atmospheric precipitation. They can be classified into catching and non-catching precipitation gauges. Instruments belonging to the first family are generally based on gravity-related measuring principles (weighing, tipping buckets, floating devices), while the second group includes instruments based on optical, acoustic, and microwave principles (e.g., disdrometers). All instruments are subject to both systematic (often unknown) biases and measurement uncertainties, depending on the design, the measuring principle, the algorithms used for data interpretation and correction, etc. Moreover, environmental factors affect the measurement accuracy as well, depending on the atmospheric conditions at the collector, the siting characteristics, etc. Typical environmental factors include the gradients of atmospheric temperature, wind speed, and solar radiation and may result in a significant underestimation of accumulated precipitation. The present chapter addresses the achievable accuracy of instruments for in-situ measurement of liquid and solid precipitation, based on both the outcomes of the recent WMO intercomparison initiatives and the accurate laboratory and field tests presently ongoing within the activities of the WMO/CIMO Lead Centre on Precipitation Intensity (Italy).

According to the *Guide to Instruments and Methods of Observation* [12.1] published by the World Meteorological Organization (WMO), precipitation is defined as

the liquid or solid products of the condensation of water vapour falling from clouds. The total amount of precipitation which reaches the ground in a stated period is expressed in terms of the vertical depth of water (or water equivalent in the case of solid forms) to which it would cover a horizontal projection of the Earth's surface.

Precipitation intensity is defined as

the amount of precipitation collected per unit time interval.

Atmospheric precipitation is commonly experienced in our everyday lives and activities, in both business and leisure time, and its impact is manifest in major socioeconomic sectors including transportation, agriculture, safety, tourism, and recreation.

The extraordinary role of atmospheric precipitation in human society (and natural ecosystems as well) justifies the need to obtain accurate quantitative measurements of the amount of water reaching the ground surface and the duration and intensity of precipitation events.

12.1 Measurement Principles and Parameters

Precipitation varies considerably in both space and time. It is erratic and intermittent in nature, and is composed of a large number of hydrometeors, each of them with its own size, shape, density, and fall velocity in reaching the ground, according to specific frequency distributions. Due to the complex processes of nucleation, accretion, melting, and interactions between the hydrometeors (see e.g., [12.2]), the resulting characteristics of precipitation depend on the generating weather phenomenon and climate at any specific location (temperature, humidity, etc.). In addition, the fall trajectories of single particles are affected by local conditions at a site, including wind and shading by obstacles, and by the aerodynamic behavior of the outer body of the measurement instrument itself.

12.1.1 Measurement Principles

Precipitation is among the most challenging environmental measurements, and accurate measurement of the amount of water that would ultimately land on a well-defined portion of the ground surface in undisturbed conditions is a difficult task. This is the aim of the so-called in-situ measurements at the ground, with the instrument located precisely where the information is sought, at a single location immersed in the precipitation process.

Precipitation measured at a single location is representative of a limited area in space,

the size of which is a function of the length of the accumulation period, the physiographic homogeneity of the region, local topography and the precipitation-producing process [12.1].

Weather radar and, more recently, satellites are used to define and quantify the spatial distribution of precipitation from a remote sensing perspective, with the sensor generally located far from the precipitation process. The information is inferred from the observed modifications of other physical quantities due to the interference with the precipitation process (e.g., active/passive microwave, infrared temperature).

In-situ precipitation gauges, however, provide the only direct measurement of precipitation at the ground and are usually referred to as the *ground truth*. Remote sensing techniques for extensive observations (essentially weather radar, aircraft, and satellite-borne radiometers) still require the use of in-situ measurements for calibration and validation purposes. Following [12.3],

measurements at the ground have been proved indispensable, despite advances in several areas of remotely sensing of precipitation. Ground truth seems to be inseparable from any study on precipitation. A better understanding of the behavior of precipitation on the ground with direct measurements can lead to more effective estimations by using other methodologies.

12.1.2 Measured Parameters

The parameters measured by precipitation instruments range quite widely: basic instruments simply inform the status of the rain in that moment, i.e., whether it rains or not, while others detect the particle size distribution of hydrometeors. Traditionally, however, the equivalent volume of water received by a collector through

Table 12.1 Measured parameters of precipitation sensors

Parameter	Description	Unit	Symbol
Rain depth	The total volume of liquid precipitation deposited in a given time interval per unit area of the horizontal projection of the ground surface	mm	RA
Snow depth	The liquid water equivalent of the total volume of solid precipitation deposited in a given time interval per unit area of the horizontal projection of the ground surface	mm	SA
Rainfall intensity	The rain depth per unit time interval	mm h^{-1}	RI
Snowfall intensity	The snow depth per unit time interval	mm h^{-1}	SI
Particle size	The characteristic dimension (usually the diameter assuming spherical shape) of hydrometeors	mm	D
Number of particles	Number of hydrometeors per class of particle size	–	$N(D)$
Particle fall velocity	Velocity of hydrometeors at the ground surface	mm s^{-1}	v

Table 12.2 Other relevant parameters for precipitation measurements

Parameter	Description	Unit	Symbol
Temperature	Ambient temperature	$^{\circ}\text{C}$	T
Wind velocity	Average wind velocity at the sensor's height	mm s^{-1}	U_w
Wind direction	Prevailing wind direction expressed in degrees clockwise from due north	$^{\circ}$	U_d

an orifice of known surface area in a given period is assumed as the reference variable, namely the precipitation depth. The measurement unit of precipitation amount is therefore linear depth, usually expressed in millimeters, obtained as the ratio of the precipitated cumulative water volume over the surface area of the collector.

Under the restrictive hypothesis that precipitation is constant over the accumulation period, a derived variable—the precipitation rate or intensity—can be easily calculated. Using short time intervals ensures that the estimated intensity is close to the real flow of water ultimately reaching the ground. The measurement unit of precipitation intensity is linear depth per unit time, usually expressed in millimeters per hour.

This approximate measure of the precipitation rate has long been accepted as sufficiently accurate to meet the requirements of both scientific and technical applications. Reasons for this are on the one hand that most traditional applications in hydrology operate at the basin scale, thus dealing with aggregated rainfall over large space and timescales, while on the other hand the available technology of measurement instruments—especially in terms of data storage and transmission capabilities—was lower than today.

Although quantitative data regarding the amount (depth) of liquid and solid precipitation are the basis for many practices, the intensity of precipitation has become a variable of almost equal significance. Rainfall and snowfall intensity data are extremely relevant in the case of severe weather. For example, it is clear that events with extremely high precipitation rates affect all types of transportation; they may also destroy crops and vegetation. Precipitation intensity has now been introduced by WMO as a measured parameter, in line with

the present recommendations on weather reporting (Table 12.1).

In addition, most automatic precipitation gauges provide the amount of precipitation at a relatively short time resolution, usually less than 1 min. Users of precipitation measurements typically require information on accumulated rainfall/snowfall for longer time intervals, for example, the hourly, daily, monthly, and even annual total rain depth. Modern non-catching instruments include optical and acoustic principles to derive information including drop size distribution (DSD), fall velocity of single drops, crystal types (Table 12.1) and other relevant parameters (Table 12.2).

12.1.3 Requirements

Research and technological development in the field of precipitation measurements obviously proceed at a different pace, so that the instruments commonly deployed on the territory do not have the same level of accuracy of research-devoted instruments installed at a few experimental sites. Even the research instruments in some cases are used under the blind assumption of a high level of accuracy (because of the physical principle used to measure rainfall), but often no evidence is made available to support this assumption. This is the case, for example, with various types of disdrometers, as it was recently shown that their calibration is still a problem [12.4].

Requirements from the many users of precipitation data are becoming tighter and tighter, and sound research and applications in the geosciences require enhanced quality in precipitation measurement. The interpretation of rainfall patterns, speculation about the nature of the rain field, scaling versus nonscaling issues,

rainfall event modeling and forecasting efforts, everyday engineering applications, etc., are all based on the analysis of precipitation data that are measured at very fine resolution. Therefore, the relevance of precipitation intensity measurements has increased dramatically, and very high values are increasingly recorded, due to the shortening of the reference period. High accuracy is also sought in the upper range of precipitation intensity.

The timescales required for calculation of precipitation intensity at the ground are already much shorter than in traditional applications. The design and management of urban drainage systems, flash flood forecasting and mitigation, transport safety measures, and in general most of the applications where precipitation data are sought in real time, call for enhanced resolution of such information in time (and space), even down to the scale of 1 min in many cases.

The thirteenth session of the WMO Commission for Instruments and Methods of Observation (CIMO-XIII, 2002), as a result of an Expert Meeting held in Bratislava, Slovakia in 2001, noted that significant efforts were necessary to obtain the required information about uncertainties in precipitation intensity measurement. For liquid precipitation, CIMO-XIII adopted the measurement range and related uncertainties recommended by the expert team, published in the *WMO Guide to Instruments and Methods of Observation* (WMO-No. 8) [12.1] and reported in Table 12.4.

Instruments based on modern technology are increasingly deployed as part of or simply to replace traditional monitoring networks, especially in developed countries, where the high cost of such instruments

can more easily be borne. However, little information is available to the user on biases and uncertainties associated with such instruments, and corrections are very seldom applied. Therefore, the quality of the new data sets is not necessarily higher (and is sometime even lower) than what is obtained from traditional networks, while additional inhomogeneities of the time series are added to the picture, with serious consequences, for example, in climate-related studies.

12.1.4 Siting Considerations

Precipitation measurements aim to obtain a sample that is representative of the true amount of water falling over the area that the measurement is intended to represent [12.1]. The quality of the measurement is very sensitive to the exposure of the instrument to the surrounding environment. Appropriate siting is therefore crucial in obtaining accurate precipitation measurements.

The WMO Guide no. 8 [12.1] specifies that

the best sites are often found in clearings within forests or orchards, among trees, in scrub or shrub forests, or where other objects act as an effective windbreak for winds from all directions.

However, the presence of obstacles and other instruments close to the precipitation gauge should be avoided. The [12.1] imposes certain distances for any obstacle, and defines siting classes depending on the slope of the surrounding area and the type and height of obstacles.

12.2 History

In human history, abundant atmospheric precipitation often had a positive acceptance, while the lack of it was sometimes viewed as a visitation from god and a punishment for human sins. The need for the occurrence and recurrence of precipitation is historically evidenced by the presence of dedicated gods in most ancient religions (Chac—Mayan god of rain, Ishkur—god of rain and storm in the Mesopotamian mythology, Baal—god of storm in the Phoenician mythology, Seth—the *Lord of storm* for Egyptians, and many others). As a first reward in response to good conduct by the acolytes, the Torah promises rainfall, “something that is a natural prerequisite for all specific material blessings” (Akeidat Yitzchak 70:1). However, the Book of Amos (4:6–8) reports: “I also withheld rain from you when the harvest was still three months away (. . .), yet you have not returned to me”. Still today, many religions convene the

acolytes to pray for the occurrence of rainfall in periods of intense drought. An exceptional amount of precipitation is equally negative, since it generates floods and inundations, with associated damage and victims, being nowadays among the most common natural disasters on planet Earth.

12.2.1 History of Precipitation Measurements

The early need for measuring atmospheric precipitation in precise quantitative terms in human history seems to be of religious, agricultural, or even taxation-related origins.

Ancient religious texts dated about 400 BCE are often cited in literature as the oldest written documentation of the practice of measuring precipitation in

Palestine [12.2, 5, 6]. The rainfall amount was used to define droughts and the limits of the fast period, thus the question:

How much rain must fall to constitute the first rainfall? 'Enough to fill a utensil three handbreadths in height', the words of R. Meir. I. R. Judah says, 'The first is to be a handbreadth [of rain], the second, two handbreadths, and the final one, three handbreadths' (Jerusalem Talmud, Ta'anit 1, 3).

The utensil mentioned in the text was assumed to be an initial version of a rain gauge, and an estimate of the yearly precipitation in Palestine (divided into three rain periods) was derived from the use of the *handbreadth* (the width of a hand used as an indication of length) by *Julius von Hann* (1839–1921) [12.7]. From the same measurement unit, even the size of the rain gauge was estimated. However, a second version of the same religious text contends:

How long should it continue to rain to warrant the community breaking their fast? [Until the rain has penetrated] as far as the knee of the plough enters the soil; this is the opinion of *R. Meir*. The Sages, however, say: in the case of arid soil one handbreadth, in the case of moderately soft soil two handbreadths, and in the case of cultivated soil three handbreadths. (Babylonian Talmud, Ta'anit 25b).

This second version, as indicated by *Jehuda Feiliks* [12.8] and reported by [12.9], makes it clear that the quantity used to define the limits of the fast period was actually a qualitative measurement of water content in the soil (or infiltration) rather than the rainfall amount, and linked to the penetration of a plough (the actual utensil) into the soil. Therefore, no mention of rainfall measurements is actually contained in such religious texts, although it is clear that the occurrence and amount of rainfall has ruled religious practices since very old times.

An ancient Indian treatise on statecraft, economic policy, and military strategy, called *Arthashastra* and written in Sanskrit, contains clear reference to rainfall measurements in the past [12.10]. Possibly the work of several authors over centuries, its authorship is often attributed to *Kautilya*, a scholar at *Takshashila*, the teacher and guardian of Emperor *Chandragupta Maurya*. Composed, expanded, and redacted between the second century BCE and third century CE, the *Arthashastra* was influential until the twelfth century, when it disappeared. *Shamasastri* rediscovered the text

in 1905 and published it in 1909; the first English translation was published in 1915.

In Book II—The Duties of Government Superintendents, Chapter V—The Duties of the Chamberlain, the *Arthashastra* instructs:

In (front of) the store-house a bowl with its mouth as wide as an *aratni* (the distance from the elbow to the tip of the hand) shall be set up as rain gauge (*varshamána*).

Again, in Chapter XXIV—The Superintendent of Agriculture, it is said that:

the quantity of rain that falls in the country of *Jángala* is 16 dronas [1 drona = $13.2 \times 10^{-3} \text{ m}^3$ of water]; half as much more in moist countries. (...) When one-third of the requisite quantity of rain falls both during the commencement and closing months of the rainy season and two-thirds in the middle, then the rainfall is (considered) very even.

The chapter concludes by indicating the intended use of such measurements, stating:

according as the rainfall is more or less, the superintendent shall sow the seeds which require either more or less water.

In China, the earliest documented memory of rainfall measurement seems to appear in an ancient treatise entitled *Shushu jiu Zhang* (1247), or *Mathematical Writings in Nine Sections*, by *Qin Jiushao* (1202–1261), a Chinese mathematician who first developed a method for solving simultaneous linear congruences. The book is divided into nine *categories*, each containing nine problems related to calendrical computations, meteorology, surveying of fields, surveying of remote objects, taxation, fortification works, construction works, military affairs, and commercial affairs [12.11]. The treatise contains a problem on the shape of rain gauges, discussing the determination of the rain falling on a given area of ground from the depth of rainwater collected in vessels of conical or barrel shape [12.12]. It seems that at that time there was one in each provincial and district capital. The same book shows that snow gauges were also in use. These were large cages made of bamboo, and the author gives sample problems concerning them.

In Korea, the first documented rain gauge measuring rainfall by collecting rainwater in a barrel dates back to 1441 (23rd year of King *Sejong's* reign). However, the only specimen surviving until today was made in 1837 (third year of King *Heonjong's* reign) in the form of a barrel-shaped rain gauge, 31.5 cm high and having

a diameter of 15.3 cm (Treasure 561° of the National Treasures of South Korea, designated within the heritage preservation system of the country). A ruler was used to measure the rainwater depth collected in the barrel. The rain gauge has an associated square stone stand, added when it was on display at the National Gongju Museum. The Korean Meteorological Administration and the National Palace Museum of Korea have also preserved some further rain gauge pedestals made of stone or marble, but the associated rain gauges did not survive.

Father *Benedetto Castelli*, born in Brescia (Italy) in 1578, was an Italian mathematician who entered the Benedictine Order in 1595. He is recognized as the inventor of the rain gauge in 1639 because he was the first to measure rainfall associated with a given interval of time, and therefore the first to measure rainfall intensity (or the average rainfall intensity) at a given site. He designed the first rainfall intensity gauge at the S. Peter Monastery in Perugia (Italy) in order to study the relationship between the observed precipitation and the stages of the Trasimeno Lake in central Italy, following a drought period affecting agriculture in the region.

In a letter to *Galileo Galilei* (1564–1642) in 1639, he writes:

Given a bucket made of glass, with a cylindrical shape one palm high and half a palm wide, after pouring some water in order to cover the bottom of the bucket, I noted accurately the level of water and left it exposed to the rainfall for a period of one hour.

Assuming that the depth of water would have been the same in any similar nearby bucket (and therefore over the lake area), and noting that for a rainfall duration of 8 h at a similar rate the total water would have been eight times the measured one, Castelli managed to predict the water level rise in the Trasimeno Lake.

This is actually the first documented use of the concept of rainfall intensity as measured by a rain gauge, although the simple bucket used is a storage instrument in modern terminology (Sect. 12.3). For this reason, the first WMO/CIMO Lead Centre on Precipitation Intensity established in Italy in 2010 (www.precipitation-intensity.it, Accessed 05 July 2021) is now dedicated to the memory of, and named after, Benedetto Castelli and his historical work on precipitation measurements. Based on refinements of the instrument used by Castelli in the first half of the 17th century in Italy, both *Giovanni Poleni* (1683–1761) in Padova and *Paride M. Salvago* in Genova started regular observations of precipitation, and analogously in many other countries (e.g., B. Franklin since 1725).

According to *Asit K. Biswas* [12.13], *Sir Christopher Wren* (1632–1723), one-time president of the

Royal Society, conceived the earliest English rain gauge in 1662. Unlike the previous instruments, which were all of the nonrecording type, the inventor developed an automatic tipping-bucket rain gauge, which was realized later in 1679. The author notes that reference to the Wren tipping-bucket rain gauge can be seen in the review of the book *De l'origine des Fontaines* by *Pierre Perrault* (1611–1680) in the *Philosophical Transactions* for 1675. The review states that:

the like to which (estimation of the quantity of rain) hath been attempted here, and proposed to the R. Society, some years since, by Sir. Christopher Wren, who by the contrivance of a rain-bucket had taken an account of all the water that fell for a considerable time. By his weather-clock had, among other particulars, not only taken in the measuring of the quantity of rain that falls, but also the time when it falls, and how much at each time.

The invention of the tipping-bucket rain gauge marks the start of modern rainfall intensity measurements, which today are largely obtained using the same measuring principle, although many other instruments based on different principles are also available today, as detailed in Sect. 12.3 below.

12.2.2 Evolution of Acquisition Systems

Similarly to the measuring principles and instrument design, the whole measurement chain has evolved through the years at the pace of technological development. The technological evolution experienced by acquisition systems affects the measurement accuracy and the capability to meet stringent user requirements in terms of resolution, accuracy, sensitivity, etc.

The electronic recording and digital storage of the measured data in the data logger have largely overcome the traditional mechanical transmission of the modifications induced by the accumulated precipitation on the moving parts of the system. Generally, recording was obtained by a moving pen in contact with a paper chart mounted on a rotating cylinder controlled by a clockwise spring mechanism. The resulting charts report the accumulated rainfall, or the number of impulses of the counting mechanism as a function of time, depending on the measuring principle (Sect. 12.3).

The use of electronic circuits allowed the changes induced by precipitation as sensed by the instrument to be transformed into voltage changes and recorded in some digital form. This increased the resolution of the measured data and reduced the uncertainty due to the mechanical recording systems, resulting in a dramatic reduction of the time interval over which changes in the rain signal could be sensed and recorded. The precision

of the temporal labeling of each recorded impulse or voltage change also improved.

One of the major implications is the improved capability of measuring precipitation intensity, since the measured precipitation amount is associated with a much shorter interval than was possible in the past. Since many natural and man-made systems respond to the precipitation intensity forcing rather than to the accumulated water depth (e.g., flash floods, urban drainage systems), the improvement is tangible and valuable for modern applications.

In parallel with the evolution of data acquisition systems, the telemetering capabilities have evolved as well in recent times and are still evolving today. Any need to visit remote gauge stations in order to transfer the recorded measurements to the central archiving site has now vanished thanks to the automated transmission of the data via radio, telephone, or satellite links. In rare cases gauge stations are connected by cable and can transfer data directly over the network. Local storage in the data logger is still preserved for redundancy and safety reasons and can be downloaded, for example, during inspection or maintenance visits.

As an immediate advantage of the data transmission capabilities of modern instruments, the flow of data can now be managed automatically at the archiving station, including the application of quality control procedures, preparation of synthetic reports (e.g., daily average, maximum hourly precipitation intensity, daily accumulation), and data processing in general. This enables failures to be detected in the measurement chain, including instrument problems such as clogging or power supply failures, and timely maintenance to be activated as needed.

The major advantage, however, is the fact that data transmission is made practically instantaneous, so that the information about the ongoing precipitation is obtained at a centralized control station within minutes, and the assessment of impending flooding in urban areas, for example, or level rise in channels can be made in real time. This dramatically improves the efficacy of flood warning systems and the operation of water control systems in a variety of applications.

12.2.3 Homogeneity of Historical Precipitation Records

The technological evolution of the precipitation measurement chain also affects the statistical characteristics of historical records, first of all in terms of the homogeneity of recorded time series. Changes in the instrumentation, acquisition systems, data transmission, and post-processing algorithms indeed introduce both abrupt shifts and smoothed trends in the historical

records. These changes should be extensively documented and the related information made available as metadata, although often—especially for past years—this is not the case. While the most relevant shifts in the time series can be easily identified using suitable statistical tools, detecting smoothed trends may require a long period of measurements, since they are hidden in the natural variability of the precipitation process.

Introducing modern technology is always beneficial, and monitoring networks are continuously updated with more reliable and accurate gauges. However, in the case of precipitation, caution should be exercised and such developments accompanied by the appropriate procedures to ensure homogeneity, or at least to clearly document them in the metadata. Even the progressive introduction of the practice of instrument calibration to ensure the traceability of precipitation measurements is prone to generating inhomogeneity, since the oldest data most probably derive from poorly calibrated instruments.

Calibration issues are evident, for example, with the most common technology used to measure precipitation intensity around the world, i.e., the tipping-bucket rain gauge. As described in Sect. 12.4, this instrument is affected by intrinsic systematic mechanical biases that can be easily adjusted by means of dynamic calibration. Good knowledge of systematic sampling and mechanical errors is available in the literature, with efficient correction methodologies widely tested and discussed (see e.g., [12.14–19]).

This notwithstanding, the errors associated with the tipping-bucket device are often understated by the user, even by national meteorological services (NMS), and data are seldom corrected to account for such errors, with non-negligible consequences in terms of the quality and reliability of the derived data sets (see e.g., [12.20]). Moreover, the time series recorded at each location would experience an artificial climatic trend toward increasing climatological precipitation if mechanical errors affecting historical data were systematically neglected. Since rain gauge manufacturers are progressively distributing dynamically calibrated instruments and smart interpretation algorithms embedded in the data logger, the risk of introducing artificial trends in rainfall time series is far from just academic.

Finally, the reduction of the time resolution of precipitation intensity measurements increasingly allows higher intensity values to be measured that were also present in the past but had been smoothed by the measurement process itself. This might support the false notion that precipitation intensity is increasing at a given location, when in fact the improved measuring capabilities are simply enabling a better representation of the precipitation process at a finer timescale.

12.2.4 Instrument Testing and Intercomparisons

The history of instrument intercomparisons in the case of precipitation measurements dates back significantly to past centuries, experiments in the field being reported by Stow [12.21] and recently by Goodison [12.22]. This is in line with the well-established awareness of the relevance of intercomparison in atmospheric sciences. Father Francesco Denza, member of the Italian Meteorological Society, stated already in 1872 that:

...in order that meteorological studies produce advantages for human beings ...it is not only necessary to have lots of observatories and observations/measurements be done with intelligence and accuracy, but it is moreover requested a meteorological investigation with same methodology and with well compared instruments.

An overview of the list of WMO intercomparisons of precipitation gauges, including the reference standard measurement used and the results obtained, and a short description of each intercomparison was provided by [12.23]. Early international rain gauge intercomparison efforts were focused on accumulated amounts of precipitation, low-intensity events (including solid precipitation), and sometimes only on qualitative rainfall intensity (*RI*) information (light, moderate, and heavy). The *International Comparison of National Precipitation Gauges with a Reference Pit Gauge* [12.24] and the *WMO Solid Precipitation Measurement Intercomparison* [12.22] were conducted comparing only the accumulated amounts of precipitation. Precipitation intensity was first investigated in the *WMO Intercomparison of Present Weather Sensors/Systems* [12.25], but this intercomparison did not focus in particular on quantitative values, and precipitation intensity was reported as a qualitative parameter (light, moderate, heavy).

The latest international intercomparison efforts were designed to assess and compare quantification and catching errors for both catching and non-catching types of rainfall intensity gauges, with an emphasis on high rainfall intensity.

Following the recommendations of the WMO/CIMO Expert Meeting on Rainfall Intensity held in Bratislava, Slovakia, in 2001, the WMO first organized a laboratory intercomparison, followed by a field intercomparison. Only catching-type instruments were considered for the laboratory intercomparisons, while both catching and non-catching types were included in the field intercomparison.

In September 2004, The WMO Laboratory Intercomparison of Rainfall Intensity (*RI*) Gauges was launched simultaneously in the laboratories of the Royal Nether-

lands Meteorological Institute, Météo-France, and the Department of Environmental Engineering (University of Genova, Italy). As recommended by the thirteenth session of the Commission for Instruments and Methods of Observation (CIMO-XIII), Bratislava, Slovakia, 23.09.–03.10.2002, a standardized procedure for generating consistent and laboratory-reproducible flow rates for use as the laboratory reference rainfall intensity was developed for calibration of catching-type gauges. All participating instruments, manufactured in various countries, were catching-type gauges, and a pair of instruments was available for each type. The main objective of the intercomparison was to test the performance of different types of precipitation gauges based on different measuring principles under documented conditions. Results can be found in the final report [12.26].

To ensure the continuity of the performance assessment, a Field intercomparison (2007/2009) was organized, where the instruments already tested in the laboratory were given priority. The results reported an estimation of the overall operational accuracy to be expected in the measurement of *RI* in the field and can be found in the final report of the intercomparison [12.4] and in various published papers [12.27–30].

The WMO/CIMO agreed in 2010 to organize an intercomparison for assessing the impact of automation on the measurement of snowfall, snow depth, and solid precipitation in cold climates, dubbed the WMO Solid Precipitation Intercomparison Experiment (WMO–SPICE). The SPICE objectives focus on the use of automatic instruments for measuring and reporting:

- Precipitation amount, over various time periods (minute, hour, day, season), as a function of the precipitation phase, with a focus on solid precipitation
- Snow on the ground (snow depth); as snow depth measurements are closely tied to snowfall measurements, the intercomparison planned to investigate the linkages between them.

SPICE provides guidance on the use of modern automated systems for measuring solid precipitation amount and snow depth, and recommends appropriate automated field reference system(s) for the unattended measurement of solid precipitation in cold climates. Recommendations are presented for adjustments to account for the undercatch of solid precipitation due to gauge exposure as a function of variables available for an operational site such as wind, temperature, and precipitation type. Additionally, the sources and magnitudes of errors due to instrument characteristics, field exposure, shielding, environmental conditions, and data processing methods are investigated. The final report of SPICE was published by WMO in December 2018 [12.31].

12.3 Theory

Precipitation is measured using various methods, and the theory behind precipitation measurements encompasses basic mechanical, electromechanical, optical, and acoustic principles.

12.3.1 Measurement Principles and Accuracy

Many types of instruments and measurement techniques are in operational use. Because of the extended experience, most of these techniques are well described and understood, but new instruments are appearing and still need deeper testing and investigation [12.26]. Recommendations on standardization of equipment and exposure are well documented [12.1], while procedures for instrument calibration have been proposed in the literature. The basic classification of precipitation gauges is between catching and non-catching instruments. In the first case, precipitation is collected into a container for a given period before water is conveyed to the sensor and measured. They may or may not include a funnel to convey the collected precipitation toward a nozzle for dispensing water to the sensor unit. In non-catching instruments, the precipitation flux is *sensed* when crossing or impacting on a given section, or volume, of the atmosphere in the vicinity of the ground surface. Instruments of the first family are generally based on gravity-related measuring principles (weighing, tipping, floating devices), while the second group includes optical, acoustic, and microwave principles.

All instruments are subject to both systematic (bias) and random measurement errors (Sect. 12.6), depending on the construction of the device, the measuring principle, the algorithms used for data interpretation and correction, etc. The errors themselves can be classified into catching- and counting-type errors.

The errors due to the weather conditions at the collector and those related to wetting, splashing, and evaporation processes are referred to as catching errors. They all indicate the ability of the instrument to collect the total amount of water falling over the projection of the collector's area at ground level. Non-catching instruments (which are based upon a contactless measurement) have no collector and may also show *catching* errors, which in this case implies that the instrument is not able to let the full amount of precipitated water pass through the area or volume where the measurement is taken.

Counting errors are related to the ability of the instrument to correctly quantify the amount of water that is collected or detected by the instrument. They can be experienced in both catching and non-catching types of instruments, although in the latter case, the assessment

of such errors is very difficult and hard to be performed in controlled laboratory conditions. These errors may originate from the very different aspects of the sensing phase, since the available instruments differ, for example, in the measuring principle applied, construction details, or operational solutions.

The impact of such errors on the overall accuracy of precipitation measurements at a site also varies in relation to the type of precipitation (solid, liquid, or mixed) and the range of precipitation intensity. The counting inaccuracies generally have a much stronger impact on the measurement of liquid precipitation, with sampling errors generally affecting low rates and mechanical or dynamic errors mainly affecting higher rain rates. The catching capabilities of the gauge assembly are a major issue in the case of solid precipitation measurements or whenever the rate of liquid precipitation is very low [12.32].

The impact of inaccurate measurements on the results of scientific investigation in precipitation-related fields is not yet fully clear nor quantified [12.33]. With the exception of a few dedicated papers (e.g., [12.20, 34–36]), or papers dealing with the analysis of measurement errors themselves [12.14–17, 37], the issue of how deeply the accuracy of the data sources actually affects the obtained results is rarely addressed. The scarce attention paid to the quality of data often gives rise to serious doubts about the significance of the experimental results made available in the literature. Obviously the effects will not be dramatic in all cases, since the error propagation could be negligible as well, depending on the application.

Nonetheless, scientific soundness requires that all possible uncertainties be properly taken into account, and it is therefore clear that the quality of basic data sources—such as precipitation measurements—should not be an exception. In addition, certified accuracy is needed for meteo-hydrological networks operating within the framework of a quality assurance system.

12.3.2 Volumetric Methods

Precipitation accumulates on the surface of the ground whenever it is not allowed to infiltrate (impervious surfaces) or run away along the terrain slope because of gravity forces (flat or concave surfaces). Accumulation enables the preservation of the water in natural or man-made reservoirs in order to exploit it for various purposes. One such purpose is precipitation measurement, and volumetric methods simply detect how much water is cumulatively collected within a given period in a small reservoir of known geometry.

Water Level

Measurements based on the water level employ a calibrated container, usually a cylinder, used to collect precipitation. The level reached by the water surface is periodically measured to obtain the volume of water accumulated in a given period, based on the known cross section area of the container. Since the method is quite trivial, the earliest measurements of precipitation (Sect. 12.2.1) were based on a direct reading of the water level accumulated in a container.

The measurement can be performed by an operator reading the level directly on a graduated cylinder or by pouring the water collected by the gauge into a reference container of known volume. Usually measurements are performed once or twice a day, then the container is emptied. Depending on the length of time between measurements and the environmental conditions (temperature, humidity), evaporation from the container can significantly affect the measurement accuracy.

An improvement of this method employs a float inside the container to measure the water level and record the data on a strip chart. In automatic precipitation gauges, the measurement of the water level collected in the container is performed by automatic sensors based on conductivity, acoustic distance, or hydrostatic pressure measurements.

Tilting Siphon

A tilting siphon is a particular method that differs from the more traditional water level measurements by employing the automatic emptying principle.

The tilting siphon mechanism consists of a bucket that collects the precipitation and a float connected to a pen that records the signal on graph paper attached to a drum. The float rises with the water level in the container and its movement is recorded by the pen. When the water reaches the top, the bucket tips over one side, and the siphon comes into operation and releases the water outward. The natural siphon recorder consists of two coaxial tubes; when the water reaches the top of the outer tube, the siphon mechanism is activated. The siphoning stops abruptly once the air reaches the top of the tube.

12.3.3 Gravimetric Methods

Gravimetric methods use the action of gravity on the collected water to detect the precipitation amount or intensity. The weight of a given water volume is exploited either directly, by measuring the induced deformation or vibration of sensitive elements, or indirectly by activating the movement of mechanical parts, releasing droplets, etc.

Fig. 12.1 Scheme of the tipping-bucket measuring principle

Tipping bucket

The mechanical principle of tipping-bucket gauges (TBG) was the first used to measure precipitation intensity. It consists of a tilting balance holding a bucket divided into two compartments having the same volume (Fig. 12.1). The compartments are balanced on a horizontal axis in unstable equilibrium, and two stop screws allow the initiation of the movement to be adjusted, i.e., setting the volume of water required to trigger the rotation, and avoid complete tilting on one side. The water mass content of the bucket is constant (M (g)). Therefore, by assuming the density of water $\rho = 1 \text{ g cm}^{-3}$, the corresponding volume (V (cm^3)) is derived, and consequently the corresponding accumulation height (h (cm), usually expressed in mm) is retrieved after dividing by the surface area of the collector (S (cm^2)).

When precipitation occurs, the gauge conveys the water to the twin compartments placed under the funnel through a nozzle. The balance starts moving when one compartment reaches the critical volume. During the rotation the first compartment moves to the emptying position and the second compartment moves below the water flux. The bucket takes a small but finite amount of time to tip, and during the first half of its motion, additional rain may enter the compartment that already contains the calculated amount of rainfall; therefore, this water is lost and not measured (Sect. 12.6.1). The water losses during the tipping movement result into a systematic mechanical error inducing an underestimation bias that increases with the rainfall intensity. This must be corrected by means of suitable calibration procedures (Sect. 12.6.1).

The rotation of the bucket is used to trigger a reed relay (a pen writing on a rotating chart in ancient ver-

sions) and to produce an electrical impulse per each tip as the signal output, which is then recorded by a data logger or an analogue-to-digital converter. This mechanism provides a continuous measurement process without the need of manual interaction. Given the nominal bucket volume, the total volume is calculated from the number of tips in a chosen time interval (1 min is recommended). However, the rainfall intensity is best calculated from the information about inter-tip times, obtained by recording the time stamp of each tip.

Weighing

Precipitation is collected in a bucket and the weight of the container, together with the collected water, is recorded by means of a spring mechanism or using a system of balance weights (Fig. 12.2). The weighing of the container allows the volume of water present in the gauge collector to be measured, and the precipitation rate can be calculated as the difference between the amount of water from two consecutive measurements over a given time interval.

Generally, these gauges do not use any mechanical moving part in the weighing mechanism, and only elastic deformation occurs. The weighing mechanism depends on the sensor employed in the instrument to obtain the water weight of the bucket and usually uses a balance, a load cell, or vibrating wire load sensors.

Recently, fiber Bragg grating (FBG) technology has been developed to measure the rainfall water weight. The FBG has been employed to measure the deformation of a cantilever beam induced by a collecting tilting bucket [12.38] or applied on a rubber thin film with a defined cross section area [12.39]. In the latter case, the rain weight loads the rubber film and causes the deformation of the fiber, changing the grating wavelength.

Fig. 12.2 Scheme of the weighing measuring principle

Drop Counting

In the drop-counting catching-type gauge, the precipitation collected by the funnel is conveyed to a calibrated thin nozzle, which starts dispensing droplets with a known volume. A suitable sensor, usually optical, detects the transit of each falling droplet as dispensed by the nozzle and counts the total number of droplets falling within a specific interval.

The size of each droplet depends mainly on the dimensions and characteristics of the dispensing nozzle, but also on the precipitation rate, which affects the frequency of droplets released and the drop formation and detachment process.

The volume of the droplets dispensed by the nozzle requires calibration. By measuring the dropping frequency, and possibly adjusting for the droplet volume changes with frequency, the precipitation depth (or intensity) is obtained.

12.3.4 Optical Methods

Instruments that use optical methods to measure precipitation are typically called disdrometers, and their technology is based mainly on infrared or laser sensors (Fig. 12.3). These methods are able to sense the precipitation particles falling through a measuring area, detect the type of precipitation (rain, snow, hail), measure the number, transit time, and dimensions, and provide the precipitation rate or amount by integrating over the to-

Fig. 12.3 Scheme of the optical measuring principle

tal number of particles in a given time window. The type and size of particles are usually obtained by measuring their fall velocity and assuming a fixed relationship between the fall velocity, size, and density.

Infrared Methods

The infrared gauges measure precipitation by detecting the irregularities in the infrared light beam of the sensor. These irregularities, known as scintillations, are induced by the precipitating particles falling within the infrared sampling volume; by measuring scintillation intensity, the sensors provide precipitation information.

Laser Methods

Optical disdrometers based on laser technology are composed of one or two thin laser light sheets to detect particles crossing the beam. Each particle falling within the laser beam occludes part of the transmitted laser light and decreases the light intensity in proportion to the particle diameter.

12.3.5 Other Methods

Impact Methods

These methods exploit the kinetic energy of the falling droplets impacting on the exposed surface of the instrument. A plastic or metal membrane is used at the measurement surface to sense the impact of single precipitation particles. In some systems, the mechanical movement of the membrane is transduced into an electrical signal by an attached moving coil system. In other solutions, the amplitude and the frequency spectrum of vibrations generated by precipitation particles hitting the membrane are detected and analyzed to determine the number and size of the particles, and therefore the

precipitation amount (or intensity), over a given time window.

Thermodynamic Methods

These methods employ the thermodynamic effect of the latent heat of water to obtain the measurement of both solid and liquid precipitation intensity.

The concept involves monitoring of the electrical power needed to maintain the sensor's temperature constant and high enough to melt and evaporate the snow or rain. The power provided to the sensor depends on the amount of water on the collector, while it is affected by ambient temperature, wind, and humidity conditions. Two sensor surfaces are used, one designated to collect the particles and facing upward, and one serving as the reference, facing downward to avoid collecting any precipitation. The two sensors are influenced by the same temperature, wind, and ambient humidity conditions, but only the upper one is exposed to precipitation. The difference in the power supplied to the twin sensors is attributed to the latent heat absorbed by precipitation, and is employed to determine the precipitation rate.

Microwave Methods

The microwave disdrometers use small radars to acquire the spectrum of the signal backscattered by falling particles. The intensity of the backscattered signal is related to the number of particles, and using a Doppler shift, the fall velocity of particles can be obtained.

Fourier processing of the signal is typically executed by a processor that calculates average spectrum, retrieves drop size distribution from this spectrum, and finally calculates the accumulated precipitation over a given time resolution.

12.4 Devices and Systems

The various measuring principles are exploited by different types of instruments, each of them characterized by specific measurement biases and uncertainties.

12.4.1 Catching-Type Gauges

Catching-type instruments are the traditional and by far the most common type of instrument employed worldwide for the measurement of atmospheric precipitation. They are subject to catching errors, since their capability to collect the amount of precipitation that would reach the equivalent surface area at the ground in the absence of the instrument is seldom guaranteed, and their collection efficiency may be low in the presence of wind. They are also subject to counting errors depending on the measuring principle adopted.

Storage Gauges

The storage gauge consists of a container with a known geometry, and the measuring principle is based on the water level. The most common gauges have a cylindrical shape, but different shapes, especially with reduced section area at the bottom, are used to enhance the measurement of light precipitation events (e.g., see Fig. 12.4).

The gauges are made of metal, glass, or plastic. To permit the reading of the water level by the operator, a transparent gauge is preferable; otherwise a transparent window of glass is provided in many metal buckets. Graduation marks are drawn on the container to allow the reading of the water level.

Since these gauges are able to measure the volume of water inside the collector, they are not suitable in the

Fig. 12.4 Plastic storage gauges developed for agricultural purposes (WMO-METAGRI project; photo © Mattia Stagnaro)

case of solid precipitation. Although deicing liquid may be employed to melt snow precipitation, these instruments are not recommended for use in cold regions.

If the measurement is performed by an operator, the reading of the water level is taken once or twice a day. When automation is employed by introducing different methods to measure the water level inside the gauge, the time resolution increases and can reach the 1 min recording time interval recommended by WMO. The measurements taken by this type of rain gauge are affected by evaporation losses, especially in the case of low recording time resolution.

One particular type of capacitive rain gauge measures the water collected by storing it in a deep cylinder that contains two electrodes acting as the plates of a capacitor, the water between the plates performing the role of dielectric. By including the capacitor in a tuned circuit, the water depth can be measured. It must be emptied periodically.

Tipping-Bucket Gauges

Tipping-bucket rain gauges (TBRs) are widely employed in national meteorological services worldwide to measure rain and snow depth and the associated precipitation intensity. The reasons for extensive use of this type of instrument include their relative ease of maintenance and limited production costs.

The instrument uses a metallic or plastic twin bucket balance to measure the incoming water. It is equipped with a funnel that collects and conveys the water through a nozzle in an alternating manner into the two compartments of the tipping bucket. The gauge typically has a cylindrical shape (Fig. 12.5), although aerodynamic shapes were recently developed to reduce the impact of wind on the collection efficiency of the

Fig. 12.5 Tipping-bucket gauge (photo © Emanuele Vuerich)

gauge (Sects. 12.6.1 and 12.6.3). The tipping of the bucket moves a magnet that triggers a reed relay contact and is recorded by a data logger.

Although there is no standard for the construction of precipitation gauges, recommendations from the WMO and the many years of experience with tipping-bucket instruments have led to typical solutions (now widely accepted), especially for the size of the collector area and the volume of the bucket compartments. Actually, these two construction characteristics are related to each other through the instrument sensitivity, which is generally required to be between 0.1 and 0.5 mm, with 0.2 mm being the most common. The collector area is usually between 200 and 1000 cm². For a tipping-bucket instrument with a 400 cm² collector and sensitivity of 0.2 mm, the bucket size would be 8 cm³.

The shape of the bucket and the collector vary with the manufacturer but the bucket size is quite standardized. It is indeed a sort of compromise between a very small size to limit sampling error during low-intensity precipitation, and a large size to better handle high-intensity events.

The main advantage of tipping-bucket gauges is the automatic emptying principle: when the bucket tips, the water is released outside the instrument body through dedicated apertures. However, the presence of moving parts in the sensor requires periodic maintenance of the instrument (Sect. 12.8).

Weighing Gauges

A weighing gauge (WG) consists of a bucket, usually made of metal or plastic, used to collect and measure liquid and solid precipitation by means of a weighing principle. This type of gauge is widely used to measure solid precipitation because it does not require the snow

Fig. 12.6 Weighing gauge (photo © Emanuele Vuerich)

to be melted before taking the measurement. In the absence of an automatic emptying system, the dimensions of the container are usually larger than for other instruments, and this leads to the common *chimney* shape, with a larger section area at the bottom (Fig. 12.6). The capacity of the bucket can vary with the manufacturer and ranges from 250 to 1500 mm. Low-capacity models should be avoided in areas where large accumulation may occur over a short period of time. The addition of oil or other evaporation suppressants inside the container allows a film to be formed over the water surface to minimize evaporation losses (Sect. 12.6.1).

The large capacity of the bucket has the objective of minimizing the emptying operation, which is manually performed in many cases. Some instruments use an automatic emptying principle based on a siphon. A small automatically emptying weighing gauge has recently been developed, consisting of a balance that measures the weight of the water collected in alternating fashion in the two compartments of a tipping bucket (conveyed through a funnel and a nozzle). When the bucket tips, the water is released outward, and the empty compartment is then placed under the nozzle to be filled and weighed. This automatic emptying principle leads to a reduction in the size of the instrument and ensures that the amount of weighted water is small and constant, therefore increasing the resolution of the gauge. However, these emptying principles result in underestimating precipitation during the emptying process, which can be long when using the siphon or short but frequent in the tilting-bucket gauges. Moreover, the presence of moving parts, typical of tipping-bucket rain gauges, requires additional maintenance operation. Note that the sensitivity of the weighing system can be very high (e.g., 0.01 mm), although the actual gauge sensitivity is generally lower due to the need to eliminate noise from the high-resolution raw signal. The resolution of the transducer affects the noise filtering ef-

iciency, resulting in lower sensitivity that in many cases is comparable to that of tipping-bucket gauges.

Drop Counter

The catching-type drop-counting gauge consists of a funnel that collects the precipitation and conveys water toward a calibrated nozzle, which starts dispensing droplets within an internal chamber before releasing them outside the instrument. An optical sensor is located below the nozzle and detects each falling drop. The rainfall intensity can be calculated from the drop releasing frequency by assuming a constant volume for the calibrated droplets. A recent study [12.40] using dynamic calibration tests (Sect. 12.6.2) revealed that the volume of the released droplets varies with the drop frequency. Traditional calibration of this instrument, assuming a constant volume of the droplets as declared by the manufacturer, is not compliant with WMO requirements. Instead, by using the dynamic calibration curve to adjust the drop size according to the detected frequency, the performance can be improved to meet the WMO recommendations.

The resolution of drop-counting gauges depends on the size of the droplets generated by the nozzle, in the order of 0.005 mm of precipitation, and is suitable for the measurement of light precipitation rates. Indeed, an operational limit of this type of instrument is given by the rainfall intensity at which the water flux from the nozzle starts to be continuous or irregular. The measured frequency then abruptly decreases, and very high inaccuracies result. A stand-alone installation is therefore discouraged, and a collocated rain gauge is required to avoid significant underestimation of severe rainfall intensity.

12.4.2 Non-Catching-Type Gauges

These instruments differ from traditional ones in that the precipitation flux is not collected in any container, but just *sensed* when crossing or impacting a given section, or volume, of the atmosphere in the vicinity of the ground surface. Non-catching instruments are drawing increasing interest from national weather services (NWS) due to the lower maintenance required and unattended operation. They have a number of advantages over the more common catching-type gauges, including the possibility to provide information beyond precipitation intensity alone (e.g., drop size distribution, visibility, etc.), and are especially suitable for automatic weather stations. Having neither a funnel nor a collector, their calibration and uncertainty evaluation are more difficult than for catching-type gauges, since direct comparison with an equivalent reference flow rate is not possible.

Optical Disdrometers

Optical disdrometers consist of a laser or infrared emitter, a receiver, and a digital signal processing unit (Fig. 12.7). The distance between the emitter and the receiver is usually of the order of some tens of centimeters, and the measuring beam is a few centimeters wide. This sensor measures the diameter and velocity of hydrometeors and, from these measurements, identifies the type of precipitation and calculates rainfall rate and amount, reflectivity, visibility, and drop size distribution. The diameter of the particles typically ranges between 0.2 and 8 mm and allows the volume of each droplet to be derived. Consequently, the rainfall intensity can be directly calculated by integrating over the number of particles detected in a given time period, usually ranging from 15 s to 1 min. Depending on the diameter and fall velocity, measurements are grouped into different precipitation classes.

When hydrometeors cross the sensing volume of the disdrometer, the measuring beam is partially obscured. The shadow on the receiver leads to a decrease in the voltage generated by the receiver's photodiode. The digital signal processing unit monitors the photodiode voltage and calculates the diameter of the drop from the minimum observed voltage during the passage of the drop. The velocity is calculated from the duration of the voltage reduction by dividing the sum of the diameter and beam breadth by the drop residence time.

The R resolution is typically between 0.001 and 0.005 mm h⁻¹, so it is possible to measure even very light rain (drizzle events). The maximum detectable precipitation rate varies with the instrument, and ranges from 200 to more than 1000 mm h⁻¹.

The collision of droplets is a possible error source; in that case, droplets are detected as a single *macro-drop*, leading to a systematic overestimation of the water volume. In order to reduce this error, a statistical correction is applied. Measurement errors can also occur when droplets cross the rim of the light sheet; in this case, the droplets are interpreted as smaller particles than they are in reality, causing an underestimation of the volume.

Impact Disdrometers

Impact disdrometers can be divided into two categories: acoustic disdrometers and displacement disdrometers.

Acoustic disdrometers record an electrical signal using a piezoelectric sensor whenever a drop falls on a diaphragm. Based on the relationship between kinetic energy and drop size, this electrical signal is converted into kinetic energy via the measured acoustic energy. The accuracy of drop size estimation is limited due to differences in the acoustic response from the various parts of the diaphragm. The instrument is also limited with regard to measuring small drops, because

Fig. 12.7 Optical non-catching-type gauge (photo © Emanuele Vuerich)

the diaphragm is not sensitive enough and because of the splashing. In addition, higher intensities are hardly measured due to the background noise, which reduces the measurement accuracy.

Displacement disdrometers translate via magnetic induction the energy generated by drops falling on the top surface and estimate the sizes of rain drops by analyzing the associated electrical pulses. The instrument consists of a surface exposed to precipitation and connected to a magnet that, after displacement induced by the raindrop impact, slides within a coil, activating magnetic induction.

Both acoustic and displacement disdrometers are designed to measure liquid precipitation, since the energy of the droplets is directly proportional to the mass and density of the water droplets. Snowflakes and hailstones, on the other hand, have a completely different impact on the sensors, and lead to underestimation or overestimation of the precipitation measurements. A proper calibration of impact disdrometers was recently proposed with the aim of adapting this type of instrument for measuring hail precipitation events [12.41].

Thermodynamic Sensor

The thermodynamic sensor is a new type of instrument recently developed to measure light or solid precipitation [12.42]. The system consists of two identical heated aluminum plates, one facing upward to collect the precipitation, and the other facing downward to serve as a reference. The lower plate is insulated from

Fig. 12.8 Microwave precipitation gauge (photo © Emanuele Vuerich)

the top plate and serves as a reference because it is only affected by wind and ambient temperature and not by precipitation. The two plates are heated to nearly identical constant temperatures (above 75 °C), hot enough to melt large snowflakes in a few seconds. The plates are

maintained at a constant temperature during wind and precipitation conditions by either increasing or decreasing the supplied power. During precipitation, the top plate cools because of the melting and evaporation of the hydrometeors, and the difference between the power required to heat the top plate and the bottom one is proportional to the precipitation rate. The two plates are usually located at a height of 2 m above the ground. The diameter of the plate is large enough to permit collection of falling rain or snow particles and small enough that power demand during heavy precipitation events and high wind speed is not too high.

To convert the power difference to a liquid-equivalent rate, a theoretical conversion factor is calculated, assuming that 100% of the heat of vaporization/sublimation from the precipitation is transferred to the instrument. The conversion factor is based on the area of the plate, the heat capacity of water, the density of water, and the latent heat of sublimation and evaporation. The shape of the instrument body is designed in order to minimize the wind-induced undercatch [12.42], which is however quite low, and was quantified in a recent study [12.43]. This instrument provides precip-

Table 12.3 Advantages and disadvantages of the different methods

Device	Advantages	Disadvantages
Storage gauge (manual)	No power supply, no moving parts, low cost, and easy operation	Not suitable for solid precipitation, reading of the water level only once or twice a day, evaporation losses, operator-related reading uncertainty, limited capacity (requires manual emptying)
Water level gauge	Wide range of intensity, high temporal resolution	Not suitable for solid precipitation, lower sensitivity, limited capacity (requires manual or automatic emptying)
Weighing gauge	No funnel required, no mechanical moving parts. Liquid and solid precipitation. Wide range of intensity, high temporal resolution. High accuracy after dynamic calibration	Influence of dynamic response. Manual emptying: large size, the shape enhances the wind effect on the collection. Periodic emptying maintenance. Automatic emptying: no measure while emptying
Tipping-bucket gauge	High accuracy after dynamic calibration, high temporal resolution. Low cost and simple mechanics. Long-term experience available. No emptying required, small size	Upper intensity limits depending on sensitivity, sampling errors. Heating required to measure solid precipitation. Maintenance of mechanical parts and to prevent clogging
Drop counter	High sensitivity, high accuracy after calibration for low precipitation intensity	Upper intensity limits, not suitable for stand-alone installation. Requires maintenance to prevent clogging
Optical disdrometer	Derives precipitation intensity from particle diameter and velocity measurements and provides additional information such as visibility and particle size distribution (PSD)	High cost. Error due to drop collisions and when particles cross the rim of the light sheet. No standardized calibration available
Impact disdrometer	Small size, low cleaning maintenance	Influence of the drop impact position on the surface. Noise for high precipitation intensity. Not suitable for small drops, snowflakes, and hailstone measurements. No standardized calibration available
Thermodynamic sensor	Small size, suitable only for low precipitation intensity	Additional power consumption. No standardized calibration available
Microwave sensor	Low cleaning maintenance. Provides additional information on columnar profile of vapor content, non-raining cloud liquid water, and temperature	High cost, additional power consumption. No standardized calibration available

itation measurements every minute and can accurately measure rainfall rates up to 35 mm h^{-1} .

Microwave Sensor

Since the 1960s, microwave-based technologies have been developed and improved in both the communication and meteorological fields. Ground-based microwave radiometry (Fig. 12.8) has its traditional applications in meteorology in the estimation of columnar profiles of vapor content, non-raining cloud liquid water, and temperature [12.44].

Precipitation measurements employing microwave sensors have appeared in recent decades, and are based on the signal power reduction through the atmosphere during a precipitation event.

The attenuation and scattering of the sensor emissions are related to the precipitation rate, but also depend on the physics of the precipitation particles, such as the liquid or solid phase and the different particle sizes, but the frequency of the emitting signal also has a fundamental role [12.44, 45]. Radar disdrometers have *RI* resolution up to 0.1 mm h^{-1} .

12.5 Specifications

Following the outcomes of the *WMO Field Intercomparison of Rainfall Intensity Gauges* [12.4, 27] and the decisions of the WMO CIMO (Annex I and II of the CIMO XV Session Report, Helsinki, Finland, 02.–08.09.2010), the CEN (Comité Européen de Normalisation) Technical Report no. 16469 [12.46] recommended the specifications presented below. Terminology and related concepts are also consistent with WMO [12.1], *ISO Guide to the Expression of Uncertainty in Measurement* [12.47] and the *International Vocabulary of Metrology* [12.48].

Specifications for precipitation measurement instruments depend on the intended use of the derived information (Sect. 12.8); therefore, recommendations are reported here with reference to the highest level of performance and do not necessarily apply to all applications. Network managers aiming at a broad spectrum of users may need to conform to such specifications in order to meet the requirements of the most demanding application. Those managing a single station (or a small network) for a specific use may reduce the required performance to fit their need.

12.5.1 Specifications for Catching-Type Gauges

Catching-type gauges should follow the recommendations detailed in the WMO Guide no. 8 [12.1].

12.4.3 Comparison of the Methods

Automatic stations have replaced manual measurements in many developed countries, while manual methods remain common practice in less developed regions of the world. Storage gauges are indeed the most widely used instrument for rain depth measurements, while tipping-bucket gauges are the most common for rainfall intensity measurements. The low cost, easy operation and maintenance, and the many years of experience available with tipping-bucket instruments are the main reasons for their large-scale exploitation. Weighing gauges are mainly used in regions where solid precipitation is expected, but their cost is higher and maintenance is not easy, although the absence of mechanical moving parts is an advantage. Non-catching-type gauges are the new frontier of precipitation measurements and, notwithstanding their high cost, are particularly well suited for automated weather stations, and provide additional valuable parameters such as particle size distribution, precipitation type, and visibility (Table 12.3).

The minimum list of technical parameters provided below should be included in the user manual of each instrument, and sufficient advice on the choice of output values should be provided to the user to meet different applications:

- Measurement range
- Delay time
- Linearity
- Instrumental measurement uncertainty, for the whole measurement range
- Resolution
- Step response time
- Threshold
- Time constant for those instruments classified as first-order response instruments
- Internal calculation cycles (if any) and data reporting interval.

Further recommendations apply to specific instrument technologies. Tipping-bucket rain gauges should be corrected to compensate for the inherent underestimation and the sampling error at high and low precipitation rates, respectively. Software correction algorithms using the time stamp of each tip and applying dynamic calibration curves provide the best results [12.19]. The internal clock (or the clock of the data logger) must be checked and possibly adjusted automatically on a daily basis, at least to the nearest tenth of a second.

For weighing gauges, in the case of precipitation intensity measurements, the time constant should be less than 1 min. Therefore, any filtering algorithm used to reduce the noise in processing the data produced by the weighing device should not increase the response time of the instrument. It is important that the information provided about precipitation intensity and total accumulation be consistent (accumulated precipitation is obtained by integrating precipitation intensity over time), and both values reported separately.

In any case, information about the achievable measurement accuracy must be provided in the technical documentation. For operational rainfall intensity measurements, the achievable accuracy is indicated by WMO [12.1] in the following terms:

- Under laboratory, constant flow conditions: 5% above 2 mm h^{-1} and 2% above 10 mm h^{-1}
- In field conditions: 5 mm h^{-1} up to 100 mm h^{-1} and 5% above 100 mm h^{-1} .

A calibration certificate from an independent third party (possibly a certified or WMO-recognized laboratory) should be included with each individual instrument. The certificate must include a description of the calibration procedure and results to check compliance with the relevant recommendations, and should document the traceability of the reference used, the environmental conditions (such as temperature, humidity, etc.), and the time frame used for averaging the precipitation signal.

In order to reduce the wind-induced undercatch of precipitation particles, the aerodynamic shape of the gauge should minimize the deformation of the wind field above the gauge orifice, as suggested by WMO [12.1] and supported by [12.49] using numerical simulation. The use of windscreens is advisable, especially for solid precipitation, but the positive effect of the shield should be documented by means of wind tunnel measurements or computational fluid dynamics simulations. Correction of the wind-induced undercatch can be applied according to the precipitation intensity, wind speed, and environmental temperature, as sug-

gested by [12.50] and [12.51], but the raw data should be preserved as well.

Precipitation intensity at 1 min should be measured and used for further analysis only if all 1 min data are transmitted and used (1 min intensity should not be used in a temporal sampling scheme, i.e., one synoptic measurement every hour or 3 h, as a single 1 min value is not representative of a longer period of time).

12.5.2 Specifications for Non-Catching-Type Gauges

At the time of writing, no specification for non-catching-type gauges has been provided by WMO. However, the following additional specifications are recommended. The minimum list of technical parameters provided below should be included in the user manual of each instrument, and sufficient advice on the choice of output values should be provided to the user to meet different applications:

- List of the measured quantities, (precipitation particle diameter, terminal velocity, precipitation intensity, etc.)
- Measurement range of each measured quantity
- Delay time of each measured quantity
- Linearity of each measured quantity
- Instrumental measurement uncertainty, for the whole measurement range
- Resolution of each measured quantity
- Step response time of each measured quantity
- Threshold of each measured quantity
- Time constant for those instruments classified as first-order response instruments
- Internal calculation cycles (if any) and data reporting interval of each measured quantity.

Precipitation intensity should be expressed in the usual measurement units (mm h^{-1}), and any classification by intensity intervals should not replace the numerical value. The measurements of the precipitation particle diameter, counting, terminal velocity, precipitation intensity, and the total accumulation should be consistent, and reported separately.

12.6 Quality Control, Uncertainty, and Calibration

The increased need for traceability and comparability of precipitation measurements collected from various sites and monitoring networks worldwide demands greater attention to their overall quality and accuracy. Quality control is the ultimate tool to prevent the propaga-

tion of errors and to ensure the traceability of precipitation measurements to international standards, so that precipitation data from different sources can be soundly compared and used in a variety of applications.

12.6.1 Precipitation Measurement Biases and Uncertainties

Both instrumental and environmental factors may cause biases and uncertainties in precipitation measurements (e.g., the systematic mechanical bias of TBRs, the dynamic response of WGs, the wind-induced undercatch). Calibration and correction may overcome instrumental and environmental measurement biases, but they themselves are subject to uncertainties.

Further sources of uncertainty arise from the field operation of precipitation measurement instruments and can hardly be quantified unless undertaking suitable instrument intercomparison campaigns. In order to support network managers in evaluating the quality of their installations in the field, the Siting Classification for Surface Observing Stations on Land was developed as a common ISO/WMO standard. It was published as ISO standard 19289:2015 (EN) [12.52], and by WMO in the *Guide to Instruments and Methods of Observation* [12.1] (Volume I, Chapter 1, Annex 1.D). The siting classification allows the user to assess how well the siting of an instrument meets the siting recommendations provided in the Guide.

Instrumental Biases

Instrumental biases affect all types of precipitation gauges, with different characteristics depending on the specific measurement principle adopted.

Tipping-bucket gauges are known to suffer from systematic mechanical biases; they underestimate rainfall, especially at high precipitation intensities, because of the amount of water that is lost during the tipping movement of the bucket. Although this can be remedied by dynamic calibration (performed over the full operational range of precipitation intensity values as described below), usual operational practice in hydro-meteorological services and instrument manufacturing companies relies on single-point calibration (obtained at a single reference intensity as described below). This derives from the assumption that dynamic calibration has little influence on the total recorded precipitation amount, although it is essential to reflect the actual pattern of precipitation intensity over time. The related biases, known as systematic mechanical errors, result in an overestimation at lower intensities (depending on the single-point calibration operated) and underestimation at the higher precipitation intensities. To ensure that this bias is independent of the rainfall intensity, some tipping-bucket gauges are equipped with a siphon able to deliver water to the bucket at a constant rate during tilting. This would imply that the bucket is always operated at the same flow rate but with different frequencies depending on the rainfall intensity. In this case, single-point calibration is sufficient to limit the bias.

Tipping-bucket gauges are also subject to the unbalancing of the buckets that can be corrected by reproducing a constant flow rate for a sufficient duration in laboratory conditions and by recording the time between consecutive tips (inter-tip time). If the inter-tip time is not regular, the two buckets are not balanced, and the volume collected in the two buckets is not the same. By acting on the stop screws, the bucket position is adjusted until accurate balancing is obtained.

Finally, tipping-bucket gauges are affected by sampling errors due to the discrete nature of the measurement principle. The hypothesis at the basis of the measurement principle is that precipitation is constant between consecutive tips. Sampling errors strongly influence the assessment of light precipitation events, which commonly results in recording many isolated tips, resulting in substantial overestimation of the precipitation rate at the corresponding time step and underestimation in the contiguous steps. The presence of a certain amount of water previously stored in the bucket before the start of a new event and the amount that remains inside the bucket at the end of the event may affect the measurement of the precipitation rate.

A fundamental characteristic of weighing gauges when measuring precipitation intensity is the response time, which leads to measurement errors (systematic delay due to the filtering algorithm adopted to reduce the signal noise). The response time is of the order of 6 s to a few minutes depending on the gauge design and model. The actual sensitivity of weighing gauges can be very different from gauge to gauge and depends on the transducer resolution.

Catching-type drop-counting gauges are subject to biases due to the changing size of drops generated by the nozzle with precipitation intensity, while the counting system assumes a fixed volume of the droplet. The volume actually varies in a nonlinear fashion with precipitation intensity, and a corresponding bias arises in measurements that may reach 10–20% depending on the instrument design [12.40].

Catching-type rain gauges are affected by so-called catching errors related to wetting and splashing. The associated losses are about 2–10% and 1–2%, respectively, as reported by [12.32]. Wetting losses depend on the geometry and material of the gauge collector and container, the amount and type of precipitation, and the number of events during the time needed to dry the container. For solid precipitation, the loss is smaller than for liquid precipitation, because the collector is usually wetted only once during snowmelt.

The WMO Guide no. 8 [12.1] recommends that the collector be designed to prevent precipitation from splashing in and out. This can be achieved if the vertical wall is sufficiently deep and the slope of the funnel is sufficiently steep (at least 45%).

Environmental Factors

Catching errors also include the effects of evaporation and wind on precipitation measurements.

The first measurements of evaporation losses started in the nineteenth century, as reported by [12.32]. They were based on the difference between the amounts of precipitation simultaneously measured in two storage gauges: one observed daily and the other observed monthly. The annual accumulation was corrected using the difference between the two measures, but the wetting losses from daily emptying of the container were also included; therefore, the method could not be used to single out the evaporation losses. Also, differences in readings from a pit gauge (with the orifice located at the level of the surrounding ground) and an elevated gauge occur due to differences in the temperature of the collected water, and thus the pit gauge is not a good reference for estimating evaporation losses.

Since the end of the nineteenth century, the method employed to assess evaporation losses has involved measuring the evaporation rate of simulated precipitation during precipitation-free periods. As an alternative, comparing the total accumulation from a storage gauge with the time integral of precipitation intensity measurements from a weighing gauge provides a good estimate of the evaporation losses. Weighing gauges may provide measurements of evaporation as negative precipitation values should the weight of the water collected in the container decrease.

Evaporation losses are season-dependent and usually quite low, especially for rain intensity measurements: according to the WMO Guide no. 8 [12.1], they may account for less than 5% of the total precipitation amount. The [12.1] also suggests that, in storage and weighing gauges, errors associated with evaporation are minimized by using an oil surface layer in the container.

Wind is the main environmental factor affecting precipitation measurements. The effects of the immediate surroundings of the measurement site on the wind field can give rise to local variations in precipitation. To reduce the effect of wind on the measured precipitation, the choice of the measurement site, including the location of precipitation gauges within the area of interest, is important. The WMO Guide no. 8 [12.1] reports that objects should not be closer to the gauge than a distance of twice their height above the gauge orifice, and sites on a slope or the roof of a building should be avoided. In general, the best sites are in clearings among trees or where other objects act as an effective windbreak for winds from all directions. The effects of the wind, and of the site on the wind, can be reduced by using a pit gauge for liquid precipitation, or by making

the airflow horizontal above the gauge orifice using homogeneous dense vegetation kept at the same level of the gauge orifice or appropriate fence structures, or by using windscreens around the gauge.

Furthermore, the wind effect on precipitation measurements is due to the interaction between the gauge body and the airflow. Indeed, the airflow surrounding any precipitation gauge is deformed by the presence of the gauge body, resulting in the acceleration of wind above the orifice of the instrument, which deflects the hydrometeors away from the collector, usually resulting in precipitation undercatch. The main factors of influence are the gauge shape, the wind speed, and the type of precipitation. The resulting measurement error is considered the most significant cause of environmental or *catching* bias, and quantification of this error is essential to obtaining accurate measurements. For rainfall and snowfall, the losses relative to the total amount are about 2–10% and 10–50%, respectively [12.32]. At high wind speed ($8\text{--}10\text{ m s}^{-1}$), collection losses of up to 40% and 80% have been reported by [12.53] and [12.51] for liquid and solid precipitation, respectively.

12.6.2 Laboratory Tests and Field Experiments

Counting errors are related to the ability of the instrument to correctly quantify the amount of water that is collected or detected by the instrument. They can be experienced both in catching and non-catching types of instruments, although in the latter case the assessment of such errors is very difficult, and is hard to perform in controlled laboratory conditions. Laboratory calibration is needed to obtain high-quality measurements and may provide a classification of catching-type measurement instruments based on their laboratory performance.

The laboratory calibration is performed under constant equivalent rainfall intensity, obtained by means of steady water flow generation (e.g., using volumetric pumps or gravimetric methods).

The operational status of precipitation gauges can be verified in the field by means of portable calibration devices in order to detect malfunctions, output anomalies, and calibration drifts. Field calibration tests are based on the same principles as laboratory calibration, using the generation of a few constant equivalent precipitation rates within the range of operational use of the instrument.

Catching errors are detectable in the field by comparison with a reference gauge, and intercomparison campaigns lead to their quantification.

Fig. 12.9 The response time of a weighing gauge: 63.2% of the reference equivalent intensity is measured in less than 1 min

Calibration of Catching-Type Gauges

The CEN/TR 16469:2013 *Hydrometry—Measurement of the Rainfall Intensity (Liquid Precipitation): Requirements, Calibration Methods and Field Measurements* [12.46] reports the procedure for performing the calibration of catching-type gauges as follows. The calibration is performed in a certified laboratory, and a constant water flow, equivalent to a reference precipitation intensity, is conveyed to the funnel of the instrument. The constant flow regime is obtained from a suitable hydraulic device for different precipitation intensity values (dynamic calibration) within the range of operational use declared by the instrument's manufacturer. The flow is measured by weighing the water over a given period after passing through the rain gauge. The output of the instrument under test is recorded when a pulse occurs at regular intervals. The two measurements are compared in order to assess the difference between the actual flow of water conveyed through the instrument and the precipitation intensity measured by the instrument itself. The relative percentage error can be expressed as follows

$$e_{\text{rel}}[\%] = \frac{I_m - I_r}{I_r} \times 100, \quad (12.1)$$

where

I_m is the measured liquid precipitation intensity,
 I_r is the reference equivalent precipitation intensity.

In the case of weighing gauges, the performance is also based on the step response, expressed in terms of the time constant, i.e., the amount of time that is

required by the instrument to measure 63.2% of the reference intensity value (assuming a first-order type of response). Figure 12.9 shows the response time of a weighing gauge for different equivalent precipitation intensity values.

The calibration procedures described above are in agreement with Annex 1 of the report of the fifteenth WMO/CIMO session, where a standardized procedure for laboratory calibration of catching-type gauges is recommended. The result is a calibration certificate presenting the results of the calibration including corrections as required. The Italian standard [12.54] describes the same calibration procedure and, in addition, classifies precipitation gauges into three classes of performance, as follows, according to the calibration results:

- Class A: the maximum deviations are less than or equal to $\pm 3\%$ against the reference precipitation intensity at the temporal resolution of 1 min. Weighing rain gauges shall also have a step response time within the same time interval.
- Class B: the maximum deviations are less than or equal to $\pm 5\%$ against the reference precipitation intensity at the temporal resolution of 1 min. Weighing rain gauges shall also have a step response time within the same time interval.
- Class C: the maximum deviations are less than or equal to $\pm 10\%$ against the reference precipitation intensity at the temporal resolution of 1 min. This also applies to weighing rain gauges where the step response time is less than or equal to 1 min. Where the weighing rain gauge step response is greater than 1 min, the maximum deviations shall be within $\pm 5\%$.

Fig. 12.10a,b Relative percentage errors at various equivalent reference intensities and correction curves for a tipping-bucket gauge (a) and a weighing gauge (b)

If the precipitation gauge tested has a maximum deviation greater than $\pm 10\%$ in measuring the reference precipitation intensity at the temporal resolution of 1 min, it cannot be classified according to this standard.

The same instrument can be assigned to different classes of performance over different measuring ranges.

The calibration certificate must contain the average value and the 10° and 90° percentiles of the percentage relative error distribution e_{rel} (%), for each value of the tested reference precipitation. This is presented in the form of a table. The dynamic calibration curve, obtained by fitting to the relative errors of tested precipitation intensities, must be reported in the certificate to enable correction of the readings. Figure 12.10 shows the performance of a tipping-bucket and a weighing gauge in terms of relative errors e_{rel} (%).

The standard also requires consistency of information. Any inconsistency between the precipitation intensity output at 1 min resolution and other quantities provided by the instrument (e.g., the precipitation amount) must be declared.

Although less efficient, hydro-meteorological services and instrument manufacturers often rely on the single-point calibration. In this case, only one reference precipitation intensity is checked, and the associated adjustment is applied mechanically by operating on the stop screws, so that the error becomes zero at that particular intensity. For any other precipitation intensity, some underestimation or overestimation persists. This is equivalent to assuming a conventional measure for the amount of water associated with each tipping of the bucket, which is different from the actual bucket size.

Calibration of Non-Catching-Type Gauges

No relevant international standard yet exists to define rigorous methods and procedures for calibration of non-catching-type gauges and for the evaluation of the associated uncertainty. As there is no funnel/container to collect precipitation, the calibration and uncertainty evaluation is more difficult than in the catching-type gauges, and the use of an equivalent reference flow rate is not possible. Instead, the actual characteristics of precipitation must be reproduced, including the drop size distribution, drop frequency, and fall velocities.

Laboratory and field tests were used by [12.55] to evaluate the measurement capabilities of an optical disdrometer. In the laboratory tests, high-precision spherical lenses made of silica and sapphire, with known refraction indices, were generated with diameters of 0.5, 1, 3, and 5 mm. These tests provided information on the maximum percentage errors in the diameter measurements. Free-falling water drops of different sizes were also generated using needles connected to a tank maintained at a constant water head. These were collected in a graduated cylinder, and the total volume of the collected water was compared with the cumulative volume of the drops measured by the instrument.

Other authors (e.g., [12.56]) reported that the calibration of optical disdrometers is essentially based on spheres with known diameter falling through the measuring area. A similar principle, based on the fall of small spheres on the sensor membrane, is used to calibrate impact disdrometers.

12.6.3 Correction Methods

Systematic instrumental and environmental biases must be corrected either in real time or in post-processing using calibration curves and suitable algorithms able to maximize the efficiency of the correction. Two examples are reported in detail in this section regarding the correction of systematic mechanical errors of tipping-bucket rain gauges and the wind-induced undercatch.

Correction of Systematic Mechanical Errors

Systematic mechanical biases are corrected using a suitable calibration curve obtained from dynamic calibration tests, as the best-fit regression function. Figure 12.11 shows the performance of the same tipping-bucket and weighing gauges of Fig. 12.10 after correction is applied, thus reporting the residual errors e_{res} (%).

Dedicated post-processing algorithms must be employed to achieve sufficient accuracy and to minimize the impact of sampling errors and the discrete nature of the measurement. Various algorithms have been proposed to this end, as are discussed in the literature [12.19, 57, 58]. However, the operational practice of most users, including national weather services, still relies on the trivial counting of the number of tips occurring in the desired period. The number of tips counted in each 1 min interval (the WMO-recommended time resolution for rain intensity measurements) multiplied by the nominal volume of the bucket provides the 1 min precipitation intensity record.

This method (as already observed by [12.57]) results in a general underestimation of precipitation in-

tensity figures and a high level of uncertainty, due to the random nature of the number of tips per minute within any real-world, highly variable event. Moreover, the correction of systematic mechanical biases is not optimized with this method, since it would be applied to the averaged values only, and most tipping-bucket gauges show a nonlinear correction curve after laboratory calibration [12.29].

A better method employs the inter-tip time algorithm (see, e.g., [12.19, 57]), which is based on the assumption that the nominal volume of each bucket is equally distributed over the inter-tip period. The calculation of precipitation intensity for each minute accounts for the portion of the inter-tip period actually falling into that minute. In this way, the calibration is also the most effective, since the correction applied to the volume of the bucket at the variable inter-tip scale is precisely the one corresponding to the measured precipitation intensity.

The performance of different post-processing algorithms employed in the calculation of rainfall intensity from tipping-bucket gauges is compared and discussed by [12.59] using data recorded at a field test site. Two tipping-bucket gauges using different mechanical designs were compared with a catching-type drop-counting gauge used as the working reference due to its high resolution in both time and volume for the investigated rainfall intensities. The comparison highlights the benefits of employing smart algorithms in post-processing of the raw data and their ability to improve the accuracy of precipitation intensity measurements.

In particular, the results allow comparing the performance of the inter-tip time algorithm with the more

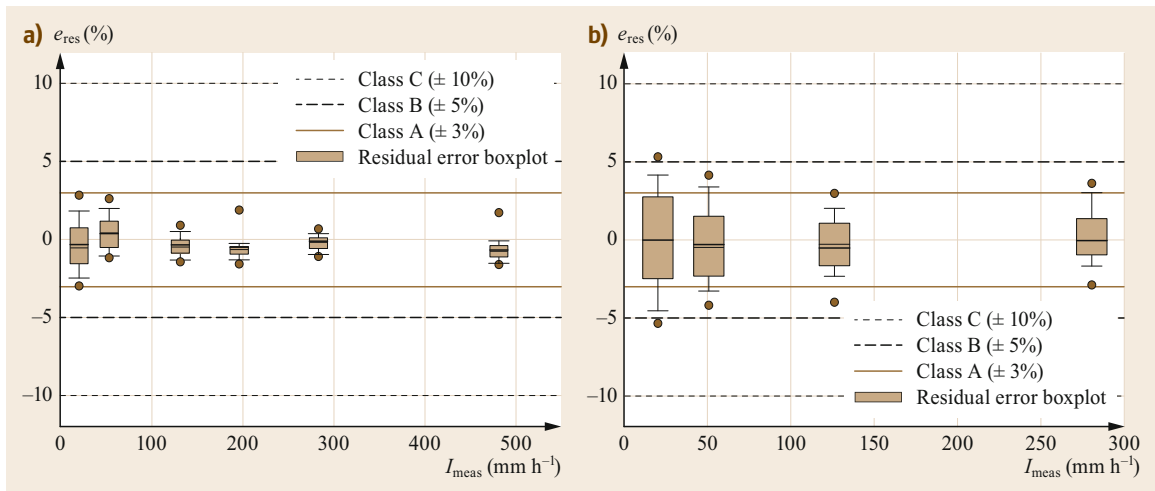

Fig. 12.11a,b Residual errors for a corrected tipping-bucket gauge (a) and a weighing gauge (b). After the correction, the TBR (tipping-bucket rain gauge) falls in Class A, while the WG is in Class B for RI less than 50 mm h^{-1} and in Class A for RI higher than 130 mm h^{-1}

Fig. 12.12a,b The realization of the reference rain gauge pit at Vigna di Valle, Italy (2007) (WMO field intercomparison of rainfall intensity gauges, 2009; photo © Emanuele Vuerich) (a) and a DFIR equipped with a Geonor T-200B weighing gauge located at the experimental site in Marshall (Colorado) (b) (after [12.62] © American Meteorological Society. Used with permission)

common tip-counting method. The main benefit of adopting the inter-tip time method to calculate rainfall intensity resides in a better representation of the inner variability of rainfall events. The measured rainfall intensity series shows an improved correlation coefficient and a lower root-mean-square error (RMSE) with respect to the reference, closely approaching the performance of an ideal gauge, which is not affected by mechanical biases.

Correction of the Wind-Induced Undercatch

The wind-induced undercatch can be approached by using correction curves obtained as a function of wind speed, gauge geometry, type of precipitation (rain or snow), precipitation intensity, and particle size distribution. Correction curves can be derived using data from experimental sites equipped with different precipitation gauges in operational conditions and a reference one. The WMO recommends as a reference for liquid precipitation a gauge placed in a pit (Fig. 12.12a) with the gauge orifice at ground level, sufficiently distant from the nearest edge of the pit to avoid in-splashing. A strong plastic or metal anti-splash grid with a central opening for the gauge should span the pit. Because of the absence of wind-induced error (see e.g., [12.60]), they generally show more precipitation than any elevated gauge. The reference installation for solid precipitation (Fig. 12.12b) is known as the double fence intercomparison reference (DFIR). It has octagonal vertical double fences surrounding a storage or automatic gauge, which itself has a particular form of wind-deflecting shield known as the single Alter shield. Note that this field reference gauge is itself not free

from measurement biases, and its construction could be improved [12.61].

At an experimental site in Haukelisetter (Norway), two Geonor T-200B gauges, one unshielded and one equipped with a single Alter shield, were installed together with the DFIR. Temperature measurements and anemometers at a height of 10 m and at the gauge collector height were also available.

Figure 12.13 shows the catch ratio between the single Alter-shielded gauge and the reference obtained at that site for different temperature classes. For temperatures above 2°C, where the precipitation is mainly

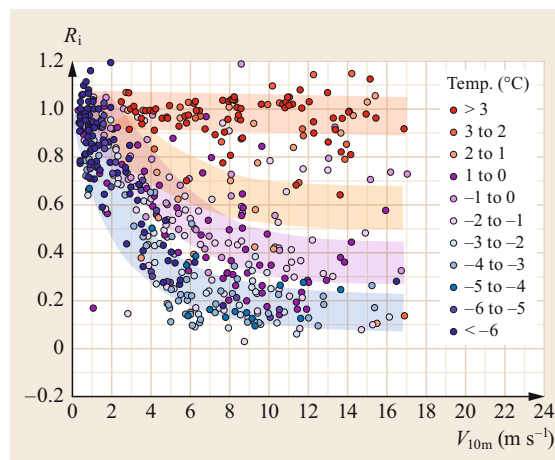

Fig. 12.13 Catch ratio of the Geonor gauge equipped with a single Alter shield when compared with the DFIR for different wind speeds (10 m height), classified according to the air temperature (after [12.63])

Fig. 12.14 (a) Observed and adjusted accumulation from one precipitation event compared with the accumulation observed by the DFIR. Temperature and wind speed during the event are shown in (b) and (c), respectively

falling as rain, the catch ratio is less influenced by the wind. For temperatures below -2°C , the precipitation is falling mainly as snow, and the catch ratio has a characteristic rapidly decreasing pattern with wind speed. For temperatures between -2 and 2°C , where rain, snow, and mixed precipitation occur, increased scatter appears, depending on the precipitation type. The four temperature classes highlighted as color bands in the figure suggest a continuous change from higher to lower temperature consistent with a gradual change in the distribution of liquid and solid precipitation particles during a mixed-phase event. Based on a three-year data set from the Haukelisetter test site that contains a number of concurrent observations of the catch ratio (R_i), the following correction curve was formulated [12.63]

$$R_i = \left[1 - \tau_1 - (\tau_2 - \tau_1) \frac{e^{\left(\frac{T_i - T_\tau}{s_\tau}\right)}}{1 + \exp\left(\frac{T_i - T_\tau}{s_\tau}\right)} \right] e^{-\left(\frac{V_i}{\theta}\right)^\beta} + \tau_1 + (\tau_2 - \tau_1) \frac{e^{\left(\frac{T_i - T_\tau}{s_\tau}\right)}}{1 + e^{\left(\frac{T_i - T_\tau}{s_\tau}\right)}} + \sigma(T_i) \epsilon_i, \quad (12.2)$$

where β and θ are two fitting parameters, T_τ is the threshold temperature and defines the transition between the two limits above, while s_τ indicates the fuzziness between rain and snow, and $\sigma(T_i)$ is a parameter governing the variance in the measurement error.

The equation was derived from the assumption that the catch ratio is a function of wind speed (V) and air temperature (T) in the form

$$R = f(V, T) = [1 - \tau(T)] e^{-\left[\frac{V}{\theta(T)}\right]^\beta} + \tau(T). \quad (12.3)$$

The parameter $\tau(T)$ goes from one limit, dry snow, to another, mixed precipitation, when the temperature increases/decreases. A sigmoid function fits experimental data reasonably well, yielding the parametric function as follows

$$\tau(T) = \tau_1 + (\tau_2 - \tau_1) \frac{e^{\frac{(T - T_\tau)}{s_\tau}}}{1 + e^{\frac{(T - T_\tau)}{s_\tau}}}. \quad (12.4)$$

An application of the correction curve is shown in Fig. 12.14. Some difference between the adjusted accumulation (brown line) and the reference one (black line) remains, which is probably ascribable to the actual (unknown) particle size distribution.

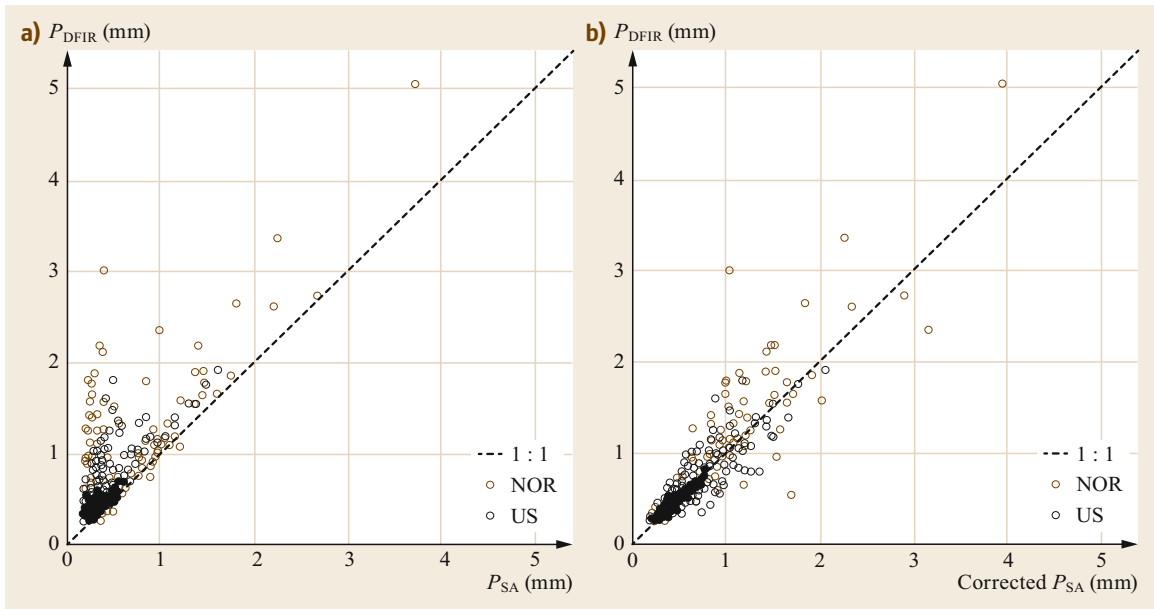

Fig. 12.15a,b Uncorrected (a) and corrected precipitation (b) from a Geonor T-200B weighing gauge equipped with a single Alter shield (P_{SA}) versus the DFIR (P_{DFIR}) for snow events (after [12.64] © J. Kochendorfer et al.)

Fig. 12.16a,b The relationship between the catch ratio R_i (TBR/double fence automatic reference) and wind speed V for accumulation periods of (a) 1 h and (b) 3 h. The mean temperature during each accumulation period is color-coded (after [12.66] © S. Buisán et al.)

Data from the 2010 winter in the two experimental sites of Marshall (USA) and Haukeliseter (Norway) were analyzed by [12.64]. The authors proposed a correction function with exponential shape

$$R = e^{-a(U)(1 - [\tan^{-1}(b(T_{air}) + c)])}, \quad (12.5)$$

where the experimental parameters a , b , and c vary with the height of the anemometer and the type of instrument (unshielded, single Alter-shielded, etc.).

The effect of the correction is shown in Fig. 12.15, where the uncorrected and corrected precipitation is compared with the DFIR measurements in Fig. 12.15a and Fig. 12.15b, respectively. After the correction, a significant scatter of the residuals persists, which is probably due to the effect of noise, the spatial variability in precipitation, and the spatial variability in crystal type that are not fully taken into account in this study. With the aim of deriving correction curves that could be extended to other sites, data from eight experimen-

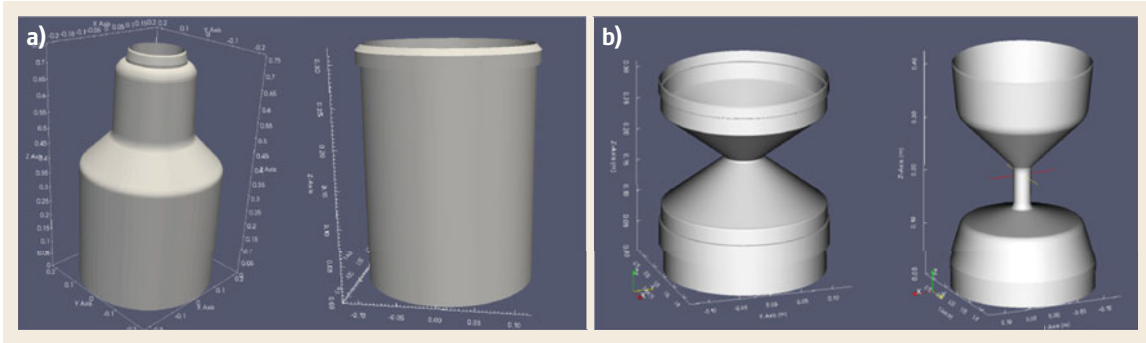

Fig. 12.17a,b 3-D models of the OTT Pluvio2VR weighing gauge and the Casella tipping-bucket rain gauge (a) and models of the EML ARG100VR and the EML SBS500VR tipping-bucket rain gauges (b). The orifice diameters are 160, 228, 254 and 254 mm; their heights are 757, 320 310 and 425 mm. The models are not to scale (after [12.49] with permission from John Wiley and Sons, © American Geophysical Union)

tal sites were analyzed by [12.65]. The study provided the parameters of (12.5) for single Alter-shielded and unshielded chimney-shaped weighing gauges, by separating mixed and solid precipitation, and for wind speed measured at 10 m or at the collector height.

The data set obtained by [12.66] at the Formigal (Spain) experimental site was divided into two samples, and the correction curves derived for TBR rain gauges at 1 and 3 h accumulation scales are shown in Fig. 12.16. For 1 h accumulation, the authors propose (12.6), where a contribution of the melting of snow during the previous hour of accumulation is also included.

$$\text{TrueAcc (1 h)} = \frac{\text{Acc}}{\text{CR}} - 0.095 \frac{\text{Acc}}{\text{CR}} + 0.095 \text{Acc}(\text{prev h}), \quad (12.6)$$

where the catch ratio CR is a function of wind speed and air temperature.

The wind-induced undercatch of precipitation gauges is also addressed in the literature by means of numerical simulations to calculate the flow velocity and turbulence around the gauge collector and the consequences of the aerodynamic disturbance on the hydrometeor trajectories.

This is obtained by performing finite-volume computational fluid dynamics (CFD) simulations based on the solution of Reynolds-averaged Navier–Stokes (RANS) equations or large-eddy simulations (LES) to obtain the airflow patterns close to the gauge collector (e.g., by [12.67, 68]). The computation of the particle trajectories is conducted with a Lagrangian method assuming no influence of particle motion on the airflow [12.69].

CFD simulations based on the RANS model allow for an Eulerian description of the air velocity com-

ponents over the three-dimensional spatial domain in time-averaged terms. The LES simulations allow the time-dependent airflow patterns to be described down to the computational mesh dimension that represents the detached scale.

Particle trajectories are simulated by solving the equation of motion that depends on the relative velocity between air and particles ($v_p - v_a$), the drag coefficient (C_d), and the gravitational contribution, as follows

$$V_p \rho_p \mathbf{a}_p = -C_d A_p \rho_a 0.5 (\mathbf{v}_p - \mathbf{v}_a) |\mathbf{v}_p - \mathbf{v}_a| + V_p (\rho_p - \rho_a) \mathbf{g}, \quad (12.7)$$

where \mathbf{a}_p is the particle acceleration vector, \mathbf{v}_p is the particle velocity vector, ρ_a is the air density, and ρ_p is the particle density.

The physical shape of a gauge has a significant impact on the aerodynamic effect and on the collection efficiency. It has been shown that appropriate *aerodynamic* shapes are able to reduce the deformation of the airflow [12.49]. The authors employed computational fluid dynamics simulations to evaluate the time-averaged airflow realized around *aerodynamic* rain gauge shapes (Fig. 12.17b) when impacted by wind. The results are shown in terms of comparison with the aerodynamic response of two *conventional* rain gauge shapes (chimney and cylindrical shapes, Fig. 12.17a).

Figure 12.18 shows the nondimensional magnitude of velocity (normalized with the undisturbed wind speed) on a stream-wise vertical plane for gauges of different shapes. The white band displayed for all gauges represents the shear layer; the wind speed here equals the undisturbed wind velocity. This layer separates the strong airflow regime above the collector (red shaded colors) from the recirculating airflow zone inside the gauge (blue shaded colors). In the case of aerodynamic

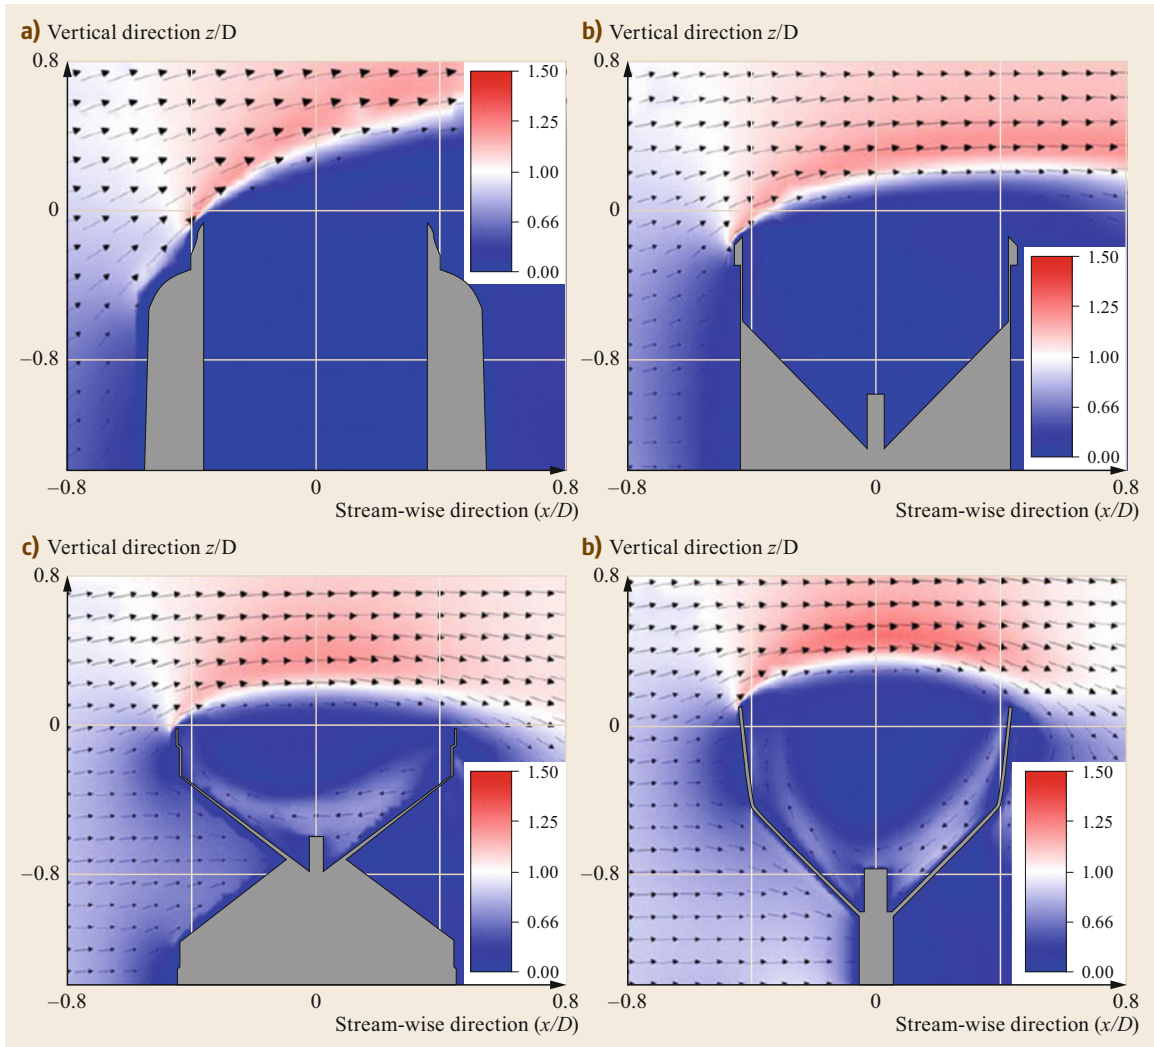

Fig. 12.18a–d Color plots of the vertical stream-wise section of the airflow nondimensional magnitude of velocity for the (a) OTT Pluvio2, (b) Casella, (c) EML ARG100, and (d) EML SBS500 gauges. The velocity fields were computed by executing RANS $k-\omega$ simulations with a horizontal wind speed U_w equal to 2 m s^{-1} . The arrows represent the time-averaged magnitude and direction of the airflow (after [12.49] with permission from John Wiley and Sons, © American Geophysical Union)

rain gauges (Fig. 12.18), the shear layer spans all over the orifice and touches the downwind edge of the collector.

The Lagrangian model of hydrometeor trajectories was improved by dynamically updating the drag coefficient estimation along each trajectory according to the computed particle Reynolds number [12.51, 70]. Figure 12.19 presents a comparison of the simulated collection efficiency for an unshielded (Fig. 12.19a) and a shielded (Fig. 12.19b) gauge for three different particle size distributions of solid precipitation based on field observations.

The impact of wind on the accuracy of non-catching-type gauges is still poorly understood and depends on the specific geometry of the gauge. While for catching-type gauges, three main geometry classes can be easily identified (cylindrical, *chimney*, and *champagne glass* shape), non-catching-type gauges show a broader variety of design and geometric solutions. Most important, they generally lack the axial-symmetric features of catching-type gauges, therefore introducing a new dependence of their measurement accuracy on the wind direction, in addition to wind velocity. Detailed studies are needed to quantify

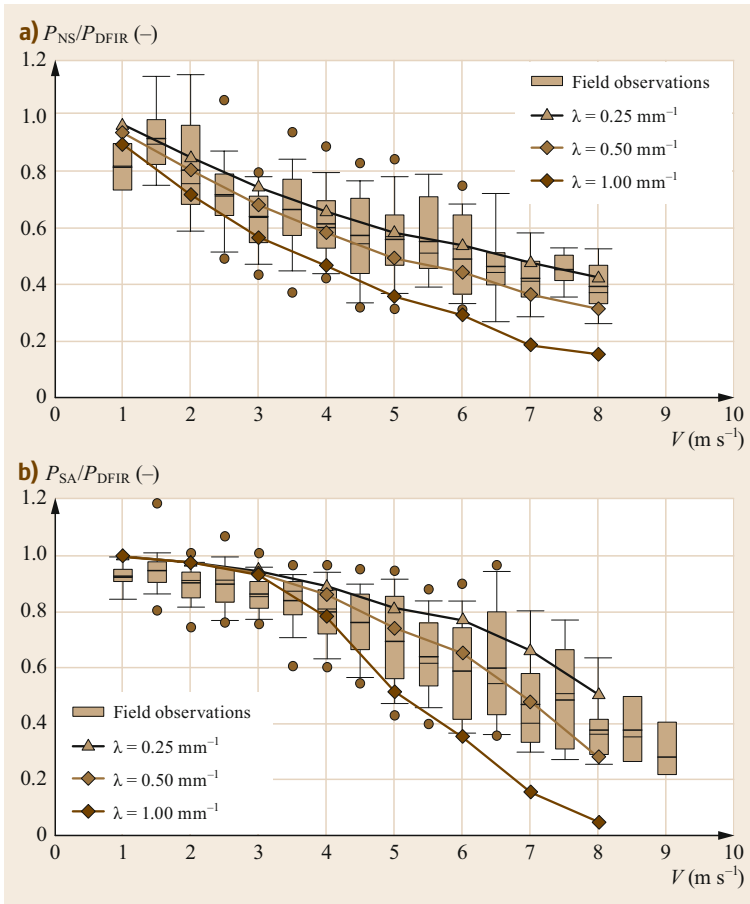

Fig. 12.19a,b Collection efficiency versus horizontal wind speed V (m s^{-1}) for an **(a)** unshielded and **(b)** single Alter-shielded Geonor T-200B gauge computed using a dynamically updated C_d (after [12.51]). Three different particle size distributions for snow are simulated according to the slope parameter λ (mm^{-1}) of the assumed inverse exponential distribution. Experimental data from the Marshall field site are shown in the boxplots (after [12.71] © American Meteorological Society. Used with permission)

such errors and to derive a possible correction curve to account for the aerodynamic performance of the gauge.

12.6.4 Measurement Uncertainty

The measurement result MR can be described as the sum of the raw measurement M , the correction of systematic errors C , and the uncertainty contribution $\pm U$

$$MR = M + C \pm U . \tag{12.8}$$

The measurement uncertainty, which produces the dispersion around the mean value of rainfall intensity measurements (see boxplot in Figs. 12.10 and 12.11), must be estimated. The uncertainty is due to random factors; some sources of uncertainty are observed in the field (wind, evaporation, splashing, etc.), while others may occur during the laboratory calibration [12.72, 73].

The uncertainty of experimental measurements can be synthetically described by (12.9), where the total uncertainty U_T is equal to the sum of field uncertainty U_F , specification uncertainty U_M provided by manufacturer,

and laboratory uncertainty U_L

$$U_T = U_F + U_M + U_L . \tag{12.9}$$

The field uncertainties are estimated to be about -1% for evaporation, $+0.5\%$ for adherence, -0.5% for the inclination of the sensor, $+1\%$ for splashing, and from -5% to $+80\%$ for wind and 0.5% for other sources [12.74]. For U_M , some contributions must be taken into account at the time of calibration, such as drift and nonlinearity. The U_L component varies according to the calibration system. For liquid precipitation, the measuring ranges and the associated uncertainties are reported in Table 12.4, as published in [12.1].

The calibration methods can be classified as input (volumetric) or output (gravimetric) methods. The input method consists in using a calibrated device to drain water into the rain gauge (RG), thus simulating rain with a known amount of water and then verifying the amount of rain measured by the rain gauge under test. The device can be a measuring cylinder, a peristaltic pump, dispensers with interchangeable orifice, etc. The output method consists in using a calibrated weighing to determine the volume of precipitated water after it

Table 12.4 Typical characteristics of precipitation measurements according to WMO Guide no. 8, Volume 1, Chapter 1, Annex 1.A [12.1]

Variable	Range	Required measurement uncertainty	Achievable measurement uncertainty
Rainfall depth (<i>RA</i>)	0–500 mm	0.1 mm for <i>RA</i> ≤ 5 mm 2% for <i>RA</i> > 5 mm	The larger of 5% or 0.1 mm
Snow depth (<i>SA</i>)	0–25 m	1 cm for <i>SA</i> ≤ 20 cm 5% for <i>SA</i> > 20 cm	1 cm
Precipitation intensity (<i>RI/SI</i>)	0.02–2000 mm h ⁻¹	n/a for 0.02–0.2 mm h ⁻¹ (trace) 0.1 mm h ⁻¹ for 0.2–2 mm h ⁻¹ 5% for > 2 mm h ⁻¹	In laboratory: 5% above 2 mm h ⁻¹ 2% above 10 mm h ⁻¹ In field: 5 mm h ⁻¹ 5% above 100 mm h ⁻¹

Note: EN 17277:2019 [12.75] recently published by CEN defines three classes of catching-type instruments based on their measurement uncertainty: ±3%, ±5%, and ±10%.

drains off the rain gauge; the control device is a precision balance.

The uncertainty sources during the calibration can be summarized as follows:

- Repeatability of measurements of air temperature, air relative humidity, atmospheric pressure, and water temperature
- Calibration certificate of thermometer (for air and water), hygrometer, barometer
- Repeatability of measurements of calibrated caliper, resolution of caliper, intra-laboratory measurement with caliper
- Repeatability of measurements of calibrated weighing, calibration certificate of weighing, specification of weighing, calibration certification of standard weight
- Only for input method: repeatability of measurements of calibrated graduated cylinder, resolution of measures of calibrated cylinder, calibration certificate of graduated cylinder, error of parallax and/or meniscus reading using measuring cylinder, specification of measuring cylinder.

The rainfall intensity is obtained indirectly using a rain gauge and a data acquisition system or a data logger to record the times when pulses occur. During a laboratory calibration, the data logger must be calibrated in time and frequency in the pulse channel used for acquisition of the signal from the instrument under calibration, because physical and electrical factors can influence the stability and accuracy of the data logger. The largest contribution to the uncertainty budget may be due to the internal clock of the data logger. Another source of uncertainty for tipping-bucket rain gauges is the repeatability of the time interval between tips (balancing of the buckets).

12.6.5 Specific Quality Control Methods

Quality control (QC) of data is a fundamental component of the measurement chain, used to verify the reliability of data obtained by the user and to prevent the propagation of errors. General guidelines are described in the WMO Guide no. 8 [12.1]. These procedures can be applied in both real time and non-real time for data quality assurance. QC consists of all processes that are used to generate confidence and ensure that the data produced will have the required quality. They also include the examination of data at stations and data centers to verify that the data are consistent with the goals of a quality management system, and to detect errors so that the data can be flagged as unreliable, corrected, or—in the case of gross errors—deleted.

The formal procedures for quality management and quality assurance prescribed by the International Organization for Standardization (ISO) are appropriate for meteorological data. The ISO 9000 [12.76] standard was developed to assist organizations in implementing and operating quality management systems, and describes the fundamentals of quality management systems and gives definitions of the related terms. The ISO 9001 [12.77] standard specifies the requirements for a quality management system that can be certified. The ISO 9004 [12.78] standard gives guidelines for continuous improvement of the quality management system. The ISO 19011 [12.79] standard provides guidance on auditing the quality management system.

In the case of precipitation measurements, suspicious data (doubtful, missing, value beyond the expected limits, etc.) are flagged with a specific number to identify the type of problem and are never deleted.

Typical test criteria for precipitation measurements are summarized in Table 12.5. An example of a suitable

Table 12.5 Typical test criteria for precipitation measurements

Method	Error	Reason
All instruments	Missing data. Value exceeding admissible range	Instrument malfunctioning, power outage, or data transmission error (see instrument diagnostic information)
Tipping-bucket gauges	Low constant value for long periods No value during liquid precipitation No value during solid precipitation	Water storage in the funnel Clogging of the nozzle Snow capping, ice formation (heating failure if present)
Weighing gauges	Spurious values in no-precipitation periods No value during solid precipitation	Vibrations (wind) or temperature induced algorithm error Snow capping, ice formation (heating failure if present)
Non-catching-type gauges	Anomalous number of occurrences in the no-precipitation particles class	Dirt accumulation on the optics (e.g., spider webs, dust). Beam obstruction

quality control procedure for 1 min precipitation data may include the following control actions:

- Number of samples and missing data: for the same sensors the data logging system acquires the raw data on a timescale of less than 1 min. If the number of samples collected in 1 min is less than the expected minimum for each instrument that minute is tagged and the flag is coded.
- Native errors and doubtful/erroneous data: 1 min data can be identified as doubtful or erroneous according to the corresponding diagnostic parameter reported in technical manuals.
- Plausible value check and doubtful/erroneous data: the operational range is declared by the manufacturer; if is not declared or is declared unlimited the 1 min data is assumed plausible if less than the WMO upper limit (2000 mm h^{-1}). A different and bespoke upper limit, related to the local climate conditions, can be assumed. Therefore, if the *RI* value on 1 min exceeds the upper limit it is flagged as doubtful. If the 1 min *RI* value is negative it is flagged as erroneous.
- Data collected during the maintenance actions are flagged to exclude them from data analysis.

Ancillary data can also be controlled by means of a QC procedure. The QC takes into account the working limits of ancillary sensors and the plausible values related to climatic conditions. The maximum and minimum limits for air temperature, relative humidity, atmospheric pressure, wind direction, wind speed, wind gust, and global solar radiation are fixed. Also, the maximum and minimum variability of data in 1 min is checked.

12.6.6 Intercomparison Results

The main objective of the WMO Laboratory Intercomparison of Rainfall Intensity Gauges was to test the performance of catching-type rainfall intensity gauges

of different measuring principles under documented conditions. The involved rain gauges were divided into three groups and were tested in three different laboratories (the Royal Netherlands Meteorological Institute, Netherlands; Météo France, France; University of Genova, Italy) during a period of about 3 months, and the instruments were then rotated from one laboratory to another. Seven fixed reference intensities were tested ($2, 20, 50, 90, 130, 170, 200 \text{ mm h}^{-1}$), and if the maximum declared intensity was larger than 300 mm h^{-1} , further reference intensities were tested between 300 and 500 mm h^{-1} .

The manufacturers of the majority of the tipping-bucket rain gauges did not apply any correction based on dynamic calibration. For some instruments, a single-point calibration was applied at a single rain intensity around $30\text{--}50 \text{ mm h}^{-1}$. On a smaller group of instruments, a correction based on dynamic calibration was applied. Results were presented in the form of two graphs, which report the relative percentage error and the response curve.

Figure 12.20a shows the overall response curves for the uncorrected tipping-bucket gauges, derived by averaging the measured data obtained at all three laboratories for the two identical instruments when applicable. Each curve is therefore representative of the observed behavior of one particular instrument. The deviation from the reference value increases with the equivalent reference rainfall intensity. As for corrected instruments, the correction proposed by the manufacturer and implemented in the data logger was able to reduce the errors in most cases to fall within the limits $\pm 5\%$ defined by WMO for the required uncertainty of rainfall intensity measurements. The performance of instruments after correction is shown in Fig. 12.20b.

For weighing gauges, the bias in terms of relative errors is less than uncorrected tipping-bucket rain gauges over the entire range of intensities. Nevertheless, for this type of instrument, the delay in detecting the variation in the rainfall intensity is sometimes relevant. An assessment of the step response was therefore per-

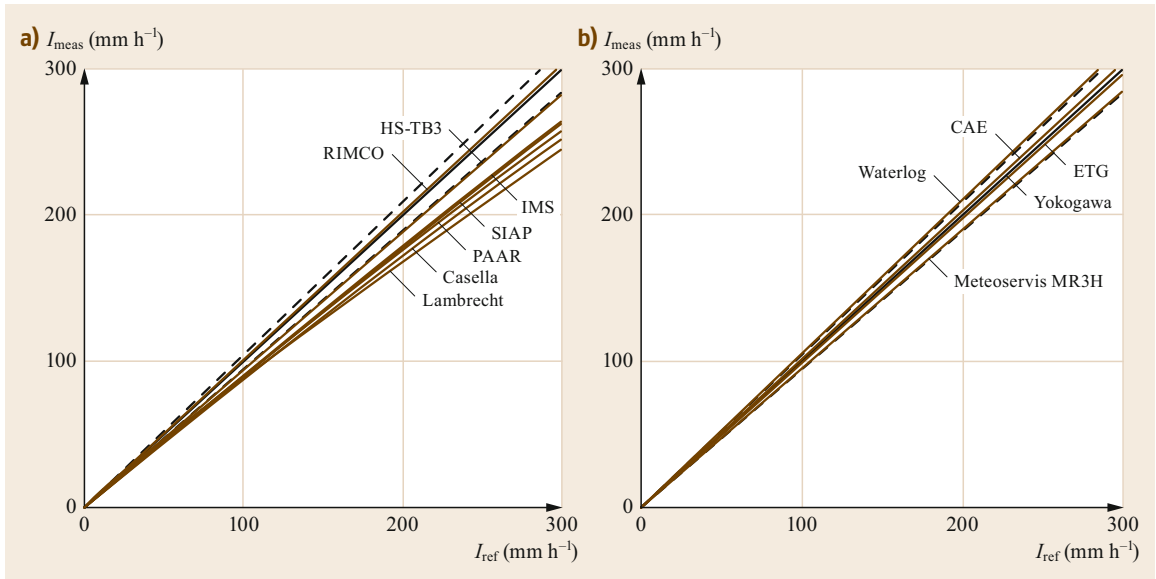

Fig. 12.20a,b Ensemble of response curves for the uncorrected TBRG (a) and those applying some correction for systematic mechanical errors (b). Dashed lines indicate $\pm 5\%$ (after [12.4])

Fig. 12.21 Nonparametric distribution of relative deviations from the reference for all instruments involved, with sample size (number of rainy minutes) indicated in gray background (after [12.28] with permission from Elsevier)

Fig. 12.22 Comparison between relative deviations in the field (dark brown boxplot) and laboratory test results (light brown boxplot) for catching-type gauges. The sample size and the observed frequency distribution are shown at the top and bottom of the graph, respectively

formed by switching the flow rate from 0 to 200 mm h⁻¹ and then back to zero, with the duration of the input flow being determined based on the time needed for stabilization.

The WMO Field Intercomparison of Rainfall Intensity Gauges was carried out in Vigna di Valle, Italy from October 2007 to April 2009. The main objective was to compare the performance of in-situ rainfall intensity instruments of different measuring principles under high rainfall intensity. This experiment enabled the influence of the operational conditions on precipitation measurements to be assessed (e.g., wind effect on precipitation collection, variability of rainfall intensity). Preliminary laboratory tests were carried out on the catching-type rain gauges involved in the field experiment.

Both catching and non-catching types of gauges were involved in the field test, and ancillary instruments were installed (anemometers, wetness sensor, temperature and relative humidity probes, atmospheric pressure

sensor, global irradiance pyranometer). Based on the results of the WMO Laboratory Intercomparison, only some corrected TBRs and WGs with short step response and low residual errors were used as working reference instruments.

The results are summarized in Figs. 12.21 and 12.22. In the first graph, the performance of all instruments (catching and non-catching) are reported in terms of relative deviations, with the associated sample size (number of 1 min rain data). The results show that all catching-type gauges have similar performance in terms of both biases and dispersion (with some outstanding cases), while the non-catching types of gauges have much larger biases and dispersion against the reference. Figure 12.22 shows a comparison between the laboratory and field performance for catching-type rain gauges only. The relative deviations in the field are larger than in laboratory tests, where in some cases the instruments comply with the WMO recommendations of ±5%.

12.7 Maintenance

Although maintenance procedures may be rather expensive and time-consuming, high-quality measurements can hardly be performed in the absence of periodic maintenance and verification of the possible degrading of the instrument performance over time. This is especially true in harsh environments and for instruments employing moving mechanical parts or small orifices that are prone to clogging, such as many catching-type gauges.

12.7.1 Periodic Checks and Maintenance Procedures

The operational status of precipitation gauges in the field is periodically checked in order to detect any malfunction, drift, blockage, etc. Suitable maintenance procedures are adopted to keep the instrument clean and ready to detect and report as soon as precipitation occurs. The frequency of periodic checks and the most suitable maintenance operations depend on the technology and the physical principle exploited to perform the measurement (Table 12.6). Maintenance practices are recommended by WMO [12.1] for the most widely used types of gauges and are reported below. Additional or extraordinary maintenance could be required in the case of different technologies or in locations where the characteristics of the surrounding environment may accelerate ageing or blockage (presence of dust, foliage, ice, etc.).

For any gauge, maintenance and periodic checks should be performed in the absence of precipitation and high wind gusts, and by annotating the period when maintenance is performed and indicating it with a suitable code in the record. For catching-type gauges, checking the conditions of the funnel is a typical maintenance operation and consists of two parts:

- *Clogging*
The maintenance procedure consists in a preliminary visual inspection of the state of the funnel. In case of obstacles, or leaves or sediment accretion along the funnel walls, the operator should remove

the funnel from the gauge and manually clean the walls. In order to verify the conditions of the narrow funnel outlet, the operator could perform one of the following operations. The first is a visual inspection of the funnel outlet, and it may be not possible if the manufacturer applies filters or a sophisticated design of the funnel outlet. The second is pouring a limited amount of water into the funnel and verifying that the water flows through the funnel outlet without accumulating inside the funnel. In any case, the operator should be equipped with a proper pipe cleaner or small brushes in order to clean the narrower parts of the funnel without deformation of the surfaces.

- *Leveling*
The leveling of the funnel orifice should be verified with the help of an electronic or spirit level. If the status is unsatisfactory, the operator can adjust the mounting screws to restore the leveling. Particular attention should be paid to the stability of the supporting pole that must remain in a perfectly steady position; otherwise the operator should plan the execution of a new installation of the supporting pole.

For storage gauges,

the outer container of the gauge and the graduated cylinder should be kept clean, both inside and outside, by using a long-handled brush, soapy water, and a clean water rinse. Worn, damaged, or broken parts should be replaced, as required. The vegetation around the gauge should be kept trimmed to 5 cm (where applicable). The exposure should be checked and recorded. The operation and maintenance of storage gauges in remote areas poses several problems, such as the capping of the gauge by snow or difficulty in locating the gauge for recording the measurement, which require specific monitoring. Particular attention should be paid to assessing the quality of data from such gauges [12.1].

Table 12.6 Maintenance of precipitation instruments

Maximum interval	Water level	Tipping bucket, weighing, and drop counter	Optical	Thermo	Microwave
6 months	Check for clogging and leveling		Sensor cleaning and check of leveling		Check of leveling
1 year	Check of the graduated scale	Field verification of the dynamic calibration curve	No standard calibration procedure available		
3 years	Volumetric calibration	Dynamic calibration in the laboratory	No standard calibration procedure available		

After every extreme/high-precipitation event—check of the instrument status

For weighing gauges, the WMO suggests that routine maintenance be conducted every three to four months, depending on precipitation conditions at the site:

Both the exterior and interior of the gauge should be inspected for loose or broken parts and to ensure that the gauge is level. Any manual read-out should be checked against the removable data record to ensure consistency before removing and annotating the record. The bucket or catchment container should be emptied, inspected, cleaned if required, and recharged with oil for rainfall-only operation or with antifreeze and oil if solid precipitation is expected. The recording device should be set to zero in order to make maximum use of the gauge range. Both the digital memory and power supply should be checked and replaced, if required. Timing intervals and dates of record must be checked [12.1].

Weighing gauges with no automatic emptying devices require regular maintenance in order to maintain the level of the water accumulated in the container below the total capacity. For this reason, the operator must continuously monitor the water level in the gauge and be prepared for a timely intervention according to the magnitude of the precipitation.

Typical checks and maintenance procedures should cover the following aspects:

- Antifreeze solution: every time the operator discharges the container, a minimal amount of liquid must be preserved in a solution of water and antifreeze agent (usually a propylene glycol mixture with alcohol in the quantity specified by the manufacturer) to permit the operation of the gauge when the environmental temperature decreases to -40°C .
- Anti-evaporation agent: every time the operator discharges the container, a given quantity of oil must be added to the solution of water and antifreeze agent (in the quantity specified by the manufacturer). The role of the oil is to reduce the evaporation of volatile antifreeze solutions and precipitation and to reduce splashing, while allowing solid precipitation to penetrate the anti-evaporation film.
- Snow capping and bridging: when long periods of low environmental temperature and solid precipitation occur, the gauges should be monitored regularly in order to detect possible snow accumulation on the gauge orifice rim. Modern gauges are equipped with heating systems to reduce snow capping, but the low electrical power of such devices

does not ensure efficient snow melting in the case of very low temperature. The operator should monitor the power consumption of the heating system (in cases where the information is provided by the data logger) or perform technical inspections to remove any snow/ice residual on the gauge orifice rim.

For tipping-bucket gauges, routine maintenance should include:

cleaning the accumulated dirt and debris from funnel and buckets, as well as ensuring that the gauge is level. It is highly recommended that the tipping mechanism be replaced with a newly calibrated unit on an annual basis. Timing intervals and dates of records must be checked [12.1].

The annual replacement of the mechanism may not be necessary, and is subject to careful checking and/or field verification as detailed below.

The checking of mechanical elements is aimed at verifying the absence of debris inside the buckets and ensuring that the small counting balance rotates without abnormal friction. If the first check fails, the operator should clean the buckets with a small brush. This operation must be performed with great care for the delicate mechanical elements, since the balancing of the bucket could be easily compromised. In the case of abnormal friction during the rotation of the buckets, the operator should return the gauge to the laboratory for an in-depth cleaning of the mechanical components and follow the manufacturer-prescribed procedures if provided, or just replace the bucket assembly. While the verification of the counting performance of the mechanical sensor is not part of the routine maintenance operations, it is good practice to perform a complete field verification after performing any manual intervention on the tipping-bucket balance system.

The characteristics of non-catching-type gauges may differ significantly according to the measuring principle and the design adopted by the manufacturer. It is difficult to provide general maintenance procedures for such gauges; however, many non-catching types of gauges adopt optical elements such as lenses, mirrors, or light/radiation beam orifices that are often subject to occlusion caused by the presence of dirt/dust. The operator should perform periodic checks at intervals depending on the sensor characteristics (usually specified by the manufacturer). In the case of occlusion, the debris must be carefully removed using soft brushes, or the specific products occasionally provided by the manufacturer, in order to prevent damage to the lenses or optical elements of the sensor.

12.7.2 Field Calibration/Verification

For catching-type gauges, the WMO [12.1] suggests that:

a proper field calibration, and field calibration check or field inspection should also be conducted on a regular basis as part of the routine maintenance and check, taking into account site and operational constraints.

For catching-type gauges, a recommended procedure using a portable device to generate reference flow rates is given by WMO [12.1].

The main purpose of the field verification is to detect calibration drifts during operational use, as described by [12.46]. This calibration also provides valuable insights into data analysis and interpretation. The field calibration should be performed using a portable field calibration system (Annex B of [12.46]) based on the same principle as the laboratory calibration, using the generation of constant equivalent rainfall rates within the range of operational use (steady water flow). From the operational viewpoint, the portable field calibrator should permit rapid tests and should not contain any sophisticated components, in order to provide a cost-effective solution. The repeatability of the field calibrator (and its accuracy) should be assessed in a laboratory before operational use and its (expanded) uncertainty determined.

During the WMO Field Intercomparison of Rainfall Intensity Gauges, a dedicated portable calibrator was designed and used for calibration and verification. Its performance and results are described in the final report [12.4].

The field calibrator designed at the University of Genova is a modified Mariotte bottle composed of a cylindrical water container of suitable capacity (about 2 L), a combination of air intakes and output nozzles for generating different rainfall intensities, and an electronic system to detect the emptying time. A suitable combination of air intakes and nozzles can be selected based on the gauge collector size and the reference intensity chosen for the calibration. By opening the top

tap and bottom nozzle, a constant flow is conveyed to the funnel of the gauge, and the reference intensity is determined according to the emptying time and the conversion table (volume–time–intensity). Air intakes provide the pressure compensation, thus maintaining a constant push. The field verification should be performed in operational conditions, in the absence of precipitation or fog and at low wind speed.

12.7.3 Metrological Confirmation

Metrological confirmation is defined as a set of operations required to ensure that measuring equipment conforms to the requirements for its intended use, according to [12.80]. Once the instruments are calibrated and their accuracy certified by an independent third party so that measurements are traceable to the international standards, it is the duty of the station manager to periodically check that the instruments still preserve their original characteristics. This is the role of field inspection, i.e., the practice of testing the performance of an instrument in the field and sending it back to the laboratory for recalibration if needed. Indeed, the instrument performance is subject to deterioration over time due to aging, operating conditions, the surrounding environment, and other random or unexpected events.

For example, in the case of catching-type gauges, a typical procedure would involve periodically checking the performance of the instrument using a suitable field calibrator. The results of the field test are then compared with the expected performance of the gauge, such as from the calibration certificate, and deviations from the expected behavior are calculated. If deviations remain within a satisfactory margin (say $\pm 1\%$), the instrument is still suitable to operate. When deviations are larger, the instrument is either replaced with a new one or sent back to the laboratory for recalibration. The period between two successive field inspections can be set to an initial value (e.g., 1 or 3 years) and then expanded or reduced depending on the results of the first test (if the instrument performance is close to the original behavior, the next inspection can be delayed, and vice versa).

12.8 Application

The use of liquid and solid precipitation measurements covers such a broad spectrum of applications that compiling any detailed list would inevitably fail to be comprehensive. Most of these are based on the observation and investigation of typically measured characteristics of precipitation such as the rainfall

amount, intensity, and duration, in addition to the frequency of intense rainfall events [12.73]. The most common ones include precipitation climatology studies, statistics of extreme events for engineering design, meteo-hydrological warnings and flood protection, optimization of irrigation for agriculture, water resources

management and potable water supply, pollution control, among others.

Since liquid and solid precipitation are the forcing input of the land phase of the hydrological cycle, the knowledge of precipitation, its variability, and the observed patterns of precipitation events in both space and time are of paramount importance for most hydrological studies. The consequences of such studies for the engineering practice are exploited in everyday technical operations for the design, management, and maintenance of any man-made structure that interacts with water in the natural landscape. The *design rainfall* is indeed a common variable used in civil engineering for the realization of urban drainage networks, bridges, levees, erosion control structures, and many other civil works. The design rainfall is obtained from the statistical analysis of long time series of rainfall observations and describes the amount of rain that is expected with a given probability of occurrence at a given location and over a predefined time window.

Measurements of precipitation intensity, and especially long records of measurements extending into the past, are of foremost importance in the management of flood hazard, since the return period of extreme events is derived from the statistical analysis of such time series. Analogously, in water resources management, precipitation measurements are essential for evaluating the availability and variability of freshwater resources (springs, aquifers, etc.) and the management of reservoirs. In addition, precipitation is one of the most important sources of renewable energy, as it releases large amounts of water over high-elevation landscape, providing the potential energy exploited by hydropower plants to obtain sustainable energy.

Agriculture is a major user of precipitation measurements, given the need for adjusting the amount of water provided to crops in order to optimize the growth rate and maximize harvests, especially in regions characterized by a scarcity of precipitation. In addition, the protection of crops from hail and other intense precipitation events requires the availability of direct in-situ observations.

Climatological studies should be based on reliable and accurate data sets of precipitation measurements in order to estimate possible long-term trends and cyclical patterns. The correct measurement of precipitation and other meteorological and hydrological variables, as well as the correct interpretation of historical data, will be of foremost importance in the future for the prediction of changes in weather patterns affecting the earth's climate.

In light of the large demand for precipitation measurements, national or regional agencies in most countries are in charge of deploying, maintaining, and man-

aging precipitation monitoring networks in order to supply the measured data to various types of users. Each application, however, has its own specific requirements in terms of both the measured quantities and the sensitivity, resolution, and accuracy of the measurement instruments.

For example, real-time control of urban drainage networks may require precipitation intensity measurements at a fine temporal resolution (1 min) and with high accuracy, while irrigation control for agricultural purposes may require measurements of the precipitation depth at the daily or weekly scale, with lower accuracy. Measurements used to calibrate precipitation estimates provided by remote sensing tools (e.g., radar or satellite-borne sensors) may require highly accurate knowledge of the particle size distribution and type of hydrometeors at the timescale of minutes. For some users, the accuracy of precipitation measurements is not as crucial as timeliness, and thus amateur networks of low-cost/low-accuracy instruments are successful in that they provide real-time access (within minutes) to the measured data over the Internet.

This broad range of requirements is precisely the reason why the national and international standards on the accuracy of rainfall intensity gauges aim at defining the required performance of measurement instruments according to a small number of classes. Each instrument is assigned to a class based on specified and certified performance, so that the user may decide which class of instruments is required for the application in hand. Once the instrument's class is declared by the station manager, with the associated third-party certification, assessing the suitability of measurements thereof for a specific application would be straightforward.

Although a single station or a small network can be easily developed as a fit-for-purpose technical solution, and instruments thus selected according to the most suitable technology and specifications, measurements from national meteorological networks are made available to the general user with little awareness of the intended use. Adhering to a fit-for-purpose philosophy is therefore very difficult in the case of large networks, which are rather multipurpose services. There is a danger that national agencies may interpret their mission as that of fitting a single purpose (e.g., civil protection), or may try to meet the requirements of one category of users alone (especially if this is the least demanding one). Instead, given the complex nature of the targeted phenomena, for precipitation monitoring networks to provide optimal service they should ideally meet the most demanding requirements of fine temporal resolution and high accuracy, allowing users to possibly degrade the information to the scale they actually need for each application.

12.9 Future Developments

The results of the recent WMO intercomparison initiatives and the ongoing accurate lab/field tests within the activities of the WMO/CIMO Lead Centre B. Castelli on Precipitation Intensity, Italy [12.81], enable the following considerations to be highlighted on the achievable accuracy of currently available instruments for in-situ precipitation measurements.

For liquid precipitation, conventional tipping-bucket rain gauges have the potential to achieve reasonable to high accuracy over the medium to upper range of rainfall intensities. In order to achieve such a high level of accuracy, suitable dynamic calibration is required, and appropriate software corrections for both sampling and mechanical errors must necessarily be applied. Note that the common statistics derived from precipitation intensity records are particularly affected if corrections are not applied (see, e.g., [12.20]). In addition, the catching performance of the gauge is affected by the interaction of the gauge body with the wind, and correction or the use of instruments with an aerodynamic shape are recommended.

Weighing-type gauges are the second most widely employed class of instruments currently in operation for precipitation measurements. Advantages include the absence of mechanical parts, better conveying performance because of the absence of the funnel, and suitability for solid precipitation measurements (snow). However, test results indicate that the influence of the dynamic response (time constant) of the measuring system on the accuracy of time-varying precipitation intensities (including the smoothing algorithm used to deal with the noise) is significant for this kind of instrument and must be taken into account accordingly. Otherwise, the overall accuracy of the weighing gauge can be even lower than that of traditional tipping-bucket rain gauges [12.82]. Again, the statistics on precipitation extremes are particularly sensitive to the associated errors [12.30].

For solid precipitation measurements, the catching performance of the gauge is the key issue, and environmental error sources (especially wind) are the most influential factors. The shape of the gauge body is critical in determining its aerodynamic response when impacted by the wind, and correction curves (either empirically or numerically derived) must be applied to account for the associated undercatch. The use of wind-screens or the practice of burying the instruments with the orifice at the level of the surrounding ground may attenuate this effect.

Non-catching-type instruments are the emerging class of in-situ precipitation gauges. For these

instruments, rigorous testing is more complicated, since rain droplets, crystals, and snowflakes of various size and density should be produced—instead of an equivalent water flow—to provide the reference precipitation. Even the calibration of such instruments is still a problem [12.83], and based on the results of the recent WMO intercomparison of rainfall intensity gauges in the field, caution should be exercised in using the information obtained from non-catching instruments in any real-world application, and even in assessing the results of scientific investigations based on such measurements [12.4].

However, the development of highly accurate non-catching gauges for both liquid and solid precipitation is an increasingly relevant and pressing requirement in the atmospheric and hydrological sciences and their applications. Indeed, national meteorological services and other organizations in charge of the management of monitoring networks over large regions generally prefer such kinds of instruments. This is because of their potential for reducing maintenance costs (by eliminating any moving part or containers to be periodically emptied), the high temporal resolution, and their suitability for use as part of a fully automated monitoring network. Drawbacks can be easily identified in the higher complexity of the exploited technology, such that the user's ability to correctly maintain and calibrate the instrument may be limited.

Whatever the instrumentation employed, the actual requirements for precipitation monitoring networks are primarily their accuracy and reliability. Therefore, the measuring principle alone is insufficient in discriminating between the various types of gauges. Rather, the performance of each instrument over the measuring range of interest for the application in hand should be the focal point, based on well-documented procedures for the assessment and certification of such performance in fully controlled conditions, as well as on the traceability of the measurement to the international standards of mass and time.

This philosophy was the basis for the development of the WMO recommendations on the accuracy of rainfall intensity measurements [12.1], which indicate a range of $\pm 5\%$ as the maximum admissible error (in the laboratory) for *RI* measurements at the time resolution of 1 min. Based on such indications, national standards on the accuracy of precipitation measurements are appearing (e.g., [12.54, 84, 85]), and the standardization process within CEN and ISO has already begun.

Arianna Cauteruccio

DICCA – Dep. Civil, Chemical and Environmental Engineering
University of Genova
Genova, Italy
arianna.cauteruccio@edu.unige.it

Arianna Cauteruccio, PhD in Civil, Chemical and Environmental Engineering – Fluid-Dynamics and Environmental Engineering at the University of Genova, and Collaborator of the WMO-CIMO Lead Centre “B. Castelli” on Precipitation Intensity. Graduated in Civil and Environmental Engineering (University of Genova, 2016). Research fellow since 2019, conducts research on the uncertainty of precipitation measurements, urban hydrology and flood risk assessment and mitigation, with both numerical (Computational Fluid Dynamics simulations) and experimental (Wind Tunnel and field tests) approaches.

Matteo Colli

DICCA – Dep. Civil, Chemical and Environmental Engineering
University of Genova
Genova, Italy

now at ARTYS s.r.l.
Genova, Italy
m.colli@artys.it

Matteo Colli (M'18) was born in Genova, Italy, in 1983. He received the B.S. and M.S. degrees in Water and Soil Defence Engineering from the University of Genova, Italy, in 2010 and the Ph.D. degree in Fluid Dynamics and Environmental Engineering Processes from the University of Genova, Italy, in 2014. From 2014 to 2017 he was a Research Assistant with the Dep. of Civil, Chemical and Environmental Engineering, University of Genova. Starting from 2017 he is a Research Assistant with the Dep. of Electrical, Electronics and Telecommunication Engineering and Naval Architecture, University of Genova. His research interests include atmospheric measurements, fluid dynamics numerical computation and hydrology.

Mattia Stagnaro

DICCA – Dep. Civil, Chemical and Environmental Engineering
University of Genova
Genova, Italy
mattia.stagnaro@unige.it

Mattia Stagnaro is Research Assistant with the Department of Civil, Chemical and Environmental Engineering, University of Genova. He received the M.Sc. degree in Water and Soil Defense Engineering, and the Ph.D. degree in Fluid-dynamics and Environmental Engineering from the University of Genova, in 2010 and 2014, respectively. Since 2015 he started collaborating with the WMO/CIMO Lead Centre “B.Castelli” on Precipitation Intensity. His research interests include precipitation measurements techniques, numerical simulation to evaluate environmental effects on the measures, and hydrological processes.

Luca G. Lanza

DICCA – Dep. Civil, Chemical and Environmental Engineering
University of Genova
Genova, Italy
luca.lanza@unige.it

Luca G. Lanza is Professor of Hydrology and Hydraulic Structures at the University of Genova, and Scientific Director of the WMO-CIMO Lead Centre “B. Castelli” on Precipitation Intensity. Graduated in Civil Engineering (University of Genova, 1991) with a Ph.D. in Hydro-dynamics (University of Padova, 1995) conducts research on urban hydrology, flood risk assessment and mitigation, environmental monitoring and water resources management, and authored about 400 papers in peer reviewed journals and conference proceedings. He provides technical and technological advisory services for landscape management bodies and private companies.

Emanuele Vuerich

Italian Air Force
Rome, Italy
emanuele.vuerich@aeronautica.difesa.it

Emanuele Vuerich received his M.Sc. Degree of Physics at the University of Roma Tre and the M.Sc. Degree in Leadership and Strategic Analysis at University of Florence. He obtained the qualification in Atmospheric Science and Meteorology and the title of WMO qualified weather Forecaster (Italian Air Force Training Centre in Pratica di Mare – Rome). Chairperson of The WMO CIMO Expert Team in Instrument Intercomparisons (WMO, 2010–2018).

Visibility Sen

13. Visibility Sensors

Martin Löffler–Mang, Klaus Heyn

The main application fields of visibility sensors are traffic safety (air, road, and sea) as well as air quality control. For measurements of the visibility of the atmosphere, a variety of techniques have been used in the past. More recently, optical technologies that utilize transmittance and scattered light measurements have dominated the commercially available instruments, and these are presented in the following. Of special interest are the extinction theory and the deduction of the meteorological optical range. Furthermore, the most important technology limitations are discussed. Besides technical data, the necessary maintenance associated with each method, as well as the methods of quality control and calibration, are presented. Finally, some research developments are described as possible devices for the future.

Visibility is a complex psychophysical phenomenon, governed mainly by the atmospheric extinction coefficient associated with solid and liquid particles held in suspension in the atmosphere; the extinction is caused primarily by scattering rather than by absorption of the light. Its estimation is subject to variations in individual perception and interpretative ability, as well as the light source characteristics and the transmission factor. Thus, any visual estimate of visibility is subjective [13.1].

When visibility is estimated by a human observer (see Chap. 22) it depends not only on the photometric and dimensional characteristics of the object which is, or should be, perceived, but also on the observer's con-

trast threshold. At night, it depends on the intensity of the light sources, the background illuminance and the adaptation of the observer's eyes to darkness and the observer's illuminance threshold [13.1].

Consequently instrumental methods are utilized to measure the extinction coefficient from which the meteorological optical range (MOR) may be calculated. These measurements are based on the assumption that the extinction coefficient is homogeneously distributed and the result of the point measurement can be applied to the entire distance. Some instruments measure the light attenuation directly and others measure the scattering of light to derive the extinction coefficient.

13.1 Measurement Principles and Parameters

Visibility is an optical phenomenon and, therefore, all estimates and measurements of visibility in the past and today use optical methods. Table 13.1 gives an overview of the utilized and measured parameters for visibility. Furthermore, in Table 13.2 the current relevant parameters for visibility measurements are summarized. Air turbidity measurement using the methods listed in this chapter is suitable for air quality monitoring over prolonged periods, e.g., for trend investigations in clean air regions or conurbations.

Basically two categories of instruments for the determination of MOR must be differentiated:

- Instruments that measure the attenuation of the light due to scattering and absorption by particles in the air along a horizontal cylinder of air (transmittance measurement).
- Instruments that measure the intensity of light scattered in specific directions by a small volume of air. From the measured scatter signal (scatter coefficient) the extinction coefficient is directly derived. The absorption of light is often negligible and the scatter signal strength may be considered to represent the extinction coefficient.

Both instrument categories utilize a light transmitter that comprises a collimated light source generating a light beam and a light receiver that comprises a photo detector with lens system to measure the scattered with respect to attenuated light beam.

The typical field of application for transmissometers is along runways in order to provide a precise MOR information for the calculation of the runway visual range (RVR). However, for meteorological stations and/or road or harbor sites the available space does typically not allow to install a transmissometer with 50 or even 100 m baseline length.

The introduced types of instruments that estimate the scatter coefficient require only limited space (1 to 2 m in general). Since the measurement relates only to a very small volume of air, the representativeness of measurements for the general state of the atmosphere at the site may need to be improved by averaging of a number of samples or measurements. In the past the use of this kind of instrument has often been limited to specific applications (for example, highway visibility measurements, or to determine whether fog is present) or when less precise MOR measurements were adequate. However, state-

Table 13.1 Parameters used and measured by visibility sensors

Utilized parameters			
Parameter	Description	Unit	Symbol
Wavelength-dependent spectral radiance (radiant flux)	Radiance of a surface per unit wavelength. This is a directional quantity, sometimes also called <i>spectral intensity</i> .	W sr ⁻¹ m ⁻³	$L_{e,\Omega,\lambda}$
Wavelength		m	λ
Solid angle		sr	Ω
Measured parameters			
Parameter	Description	Unit	Symbol
Spectral directional attenuation coefficient	The attenuation coefficient describes the extent to which the radiant flux of a beam is reduced (absorbed and scattered) as it passes through the atmosphere. It is direction and wavelength-dependent. $\mu_{\Omega,\lambda} = -\frac{1}{L_{e,\Omega,\lambda}} \frac{dL_{e,\Omega,\lambda}}{dz}$	m ⁻¹	$\mu_{\Omega,\lambda}$
Atmospheric transmittance	$T = e^{-\mu l}$ The equation relates the measured atmospheric transmittance to attenuation (extinction) coefficient under consideration of the path length l . In practice the spectral directional transmittance is measured, see below	%	T
Spectral directional transmittance	Transmitted spectral radiance, divided by the received spectral radiance. It is direction and wavelength-dependent. $T_{\lambda,\Omega} = \frac{L_{e,\Omega,\lambda}^t}{L_{e,\Omega,\lambda}^i}$ $L_{e,\Omega,\lambda}^t$ is the transmitted spectral radiance, $L_{e,\Omega,\lambda}^i$ is the received spectral radiance	%	$T_{\Omega,\lambda}$

Table 13.2 Other relevant parameters for visibility measurements

Parameter	Description	Unit	Symbol
Extinction coefficient	Extinction coefficient is an older term for the attenuation coefficient (see Table 13.1) but is still used in meteorology and climatology. In practice the spectral directional attenuation coefficient $\mu_{\Omega,\lambda}$ is measured	m^{-1}	μ
Standard visibility (<i>Normalsichtweite</i>)	Visibility definition by Koschmieder $V_N = -\frac{\ln 0.02}{\mu}$ The distance at which the contrast of a black object against the bright background has reduced to 2%	m	V_N
Meteorological optical range	Operationally used visibility definition incorporates internationally agreed upon contrast safety margin $\text{MOR} = -\frac{\ln 0.05}{\mu}$ The distance at which the contrast of a black object against the bright background has reduced to 5%	m	MOR

of-the-art forward scatter meters are now being used in increasing numbers in automatic meteorological observation systems because of their ability to report MOR over a wide range and their relatively low susceptibility to contamination of optical surfaces compared with transmissometers (see Sect. 13.3.3 for more details).

The siting of visual measuring equipment should be representative; therefore, it should be chosen with the specific measurement task in mind. For aeronautical

purposes, e.g., measurements are to be representative of conditions at the aerodrome or along the runway. In any case the instruments should be installed in accordance with the directions given by the manufacturers and the accessibility for servicing and repairs have to be ensured. The optical axis of a transmissometer with respect to the volume of air in which the extinction coefficient or scatter coefficient is measured should approximately be at the eye level of an observer; 2.0 to 2.5 m above ground level is usual.

13.2 History

For meteorological purposes visibility has traditionally been defined as a quantity to be estimated by a human observer, and observations made in that way had been and are still widely used. However, the human observer estimation of visibility is affected by many subjective and physical factors. The essential meteorological quantity, which is the transparency of the atmosphere, can be measured objectively and nowadays is represented by the MOR. Measurement devices that determine the transparency of the atmosphere have a long history; they have been developed and used since meteorologists started to observe and record visibility.

13.2.1 Telephotometric Instruments

A number of telephotometers have been designed for daytime determination of the extinction coefficient by comparing the apparent luminance of a distant object with that of the sky background. As an example for a historical relevant device a schematic drawing of the

Löhle telephotometer after [13.2] is shown in Fig. 13.1. This relative telephotometer had the advantage that the angular separation of the observation fields could be varied. The last version of this device was produced by Zeiss. Two telescopes F_h and F_z are directed at the horizon sky and the distant object, respectively. A hinge at D permits the adjustment of the separation. There is an adjustable diaphragm in front of the objective of F_h which makes it possible to equate the luminance of the two fields and so measure the ratio B/B_h [13.2].

13.2.2 Visual Extinction Meters

A very simple instrument for use with a distant light at night takes the form of a graduated neutral filter, which reduces the light in a known proportion and can be adjusted until the light is only just visible. The meter reading gives a measure of the transparency of the air between the light and the observer, and from this the extinction coefficient can be calculated. The overall ac-

Fig. 13.1 Schematic drawing of the Löhle telephotometer (after [13.2])

curacy depends mainly on variations in the sensitivity of the eye and on fluctuations in the radiant intensity of the light source. The error increases in proportion to MOR.

The advantage of this instrument is that it enables MOR values over a range from 100 m to 5 km to be measured with reasonable accuracy, using only three well-spaced lights, whereas without it a more elaborate series of lights would be essential if the same degree of accuracy were to be achieved. However, the method of using such an instrument (determining the point at which a light appears or disappears) considerably affects the accuracy and homogeneity of the measurements [13.1].

13.2.3 Early Analog Visibility Sensors Allowed First Observation Automations

By the 1950s, the continuous development in electronics, data distribution and registration technologies had already allowed for the design of the first transmissometers and compact backscatter measurement devices (*F. Friängel*, SKOPOGRAPH and VIDEOGRAPH). Since computer technology at that time was not yet advanced for implementation in customer products (the first 8-bit microprocessor was available in 1975), the measurement, data distribution and recording only had access to analog electronics (analog current data output, chart recorder). Figures 13.2 and 13.3 illustrate the appearance of some exemplary historical devices.

Fig. 13.3 Analog backscatter sensor VIDEOGRAPH (Impulsphysik, 1960s and 1970s), photo © Impulsphysik, Hamburg, Germany

13.2.4 First Integrating Nephelometer for Visibility Measurement

In theory, an integrating nephelometer will give a better estimate of the scatter coefficient than, e.g., a backscatter device like that introduced above. However, in practice it turned out that it was very difficult to prevent the instrument structure from modifying the extinction coefficient in the sample volume. For example, the light beam barrier that is required to avoid optical short cuts between light transmitter and light receiver was located above the measurement volume and provided a significant shadowing for all kinds of precipitation. Consequently, the precipitation-related extinction coefficient was not representatively measured. In Fig. 13.4 a side view of the instrument without mounting pole is shown. Due to their complexity, intense maintenance

Fig. 13.4 Integrating nephelometer MS04 (AEG/FFM, 1965), photo © Wettermuseum e. V., Museum für Meteorologie und Aerologie, Lindenberg, Germany

requirements, and limitations to determine the extinction coefficient of precipitation particles, this kind of instrumentation achieved no practical relevance for the 24/7 visibility measurement.

13.3 Theory

The following deals with extinction theory, followed by Sect. 13.3.1 on the meteorological optical range (MOR). Furthermore, discussion of transmissometers and instruments determining the scatter coefficient will follow. Finally, details of forward scatter meters are presented.

13.3.1 Extinction

The turbidity of the air is caused by extinction of the visible part of the electromagnetic spectrum by the constituents of the air. Atmospheric air consists of gas molecules plus liquid and solid particles (e.g., cloud and fog droplets, aerosol particles) suspended in the atmosphere. The particles contain, inter alia, water-soluble substances, which give off or take up water vapor depending on the humidity of the surrounding air (evaporation or condensation) and as a result may experience size changes. The size range of the radius from 0.1 to ca. 1 μm is of special significance for the attenuation (extinction) of visible radiation (see Fig. 13.5). Fog typically consists of small water droplets with radii between 2 and max. 10 μm , depending on the fog type (see Fig. 13.6).

There is a relationship between atmospheric turbidity and the visible range. One option for describing the turbidity of the atmosphere is through the MOR, for which one measure is the extinction or attenuation coefficient [13.2–4]. The extinction depends on the wavelength of the radiation and on the thickness and composition of the traversed atmospheric layer. It can

be described by the Bouguer–Lambert–Beer law

$$I = I_0 e^{-b_{\text{ext}}(\lambda)s}, \quad (13.1)$$

where I is the luminous intensity at the end of the traversed atmospheric layer, I_0 the luminous intensity at the beginning of the traversed atmospheric layer, $b_{\text{ext}}(\lambda)$ is the extinction coefficient of the air for the wavelength λ , and s the traversed path length.

Equation (13.1) applies only for monochromatic light of wavelength λ . In practice, the extinction coefficient $b_{\text{ext}}(\lambda)$ is used for polychromatic light in the visible range with adequate accuracy. Equation (13.1) ignores the effect of multiple scattering, which however plays a part only in the case of high extinction values.

13.3.2 Meteorological Optical Range (MOR)

The MOR is the length of path in the atmosphere required to reduce the luminous flux in a collimated beam from an incandescent lamp, at a color temperature of 2700 K, to 5% of its original value [13.1]. The visual range formula proposed by Koschmieder [13.5] is used for an absolutely black visual target in daytime:

$$V = \frac{1}{b_{\text{ext}}} \ln \frac{1}{K'}. \quad (13.2)$$

Koschmieder defined a value of $K' = 0.02$ for the luminance contrast threshold of the eye of a trained observer with normal vision. The range obtained with this value

Fig. 13.5 Haze particle size distribution examples for different densities (*dashed lines*) and gamma distribution (*solid line*)

Fig. 13.6 Droplet size distribution examples for radiation (*dotted*), advection (*dashed*) and mature (*solid*) fog

is called the standard visual range V_N :

$$V_N = \frac{1}{b_{\text{ext}}} \ln \frac{1}{0.02} = 3.912 \frac{1}{b_{\text{ext}}} . \quad (13.3)$$

For aviation weather services, a value of $K' = 0.05$ has been recommended due to the special observation conditions. The range obtained with this value is called the meteorological optical range (MOR):

$$\text{MOR} = \frac{1}{b_{\text{ext}}} \ln \frac{1}{0.05} = 2.996 \frac{1}{b_{\text{ext}}} . \quad (13.4)$$

By definition, the standard visual range and the MOR apply only in daytime. It has become customary, however, to apply this relationship regardless of the level of

illumination, i.e., the terms *standard range* and *meteorological optical range* are also used to describe night time ranges. Table 13.3 shows the relationship between MOR, standard visual range, extinction coefficient and transmittance.

The maximum possible MOR in particle-free air is approximately 270 km, being limited by scattering of light by gas molecules (Rayleigh scattering). Since the lower atmosphere always contains water vapor and other pollutants, the extinction coefficient is never zero (or put another way, the MOR is never infinite). It is thus not meaningful to quote a single number for the detection limit, since it depends, inter alia, on the measurement task, the nature of the turbidity-producing particles and the length of the measuring path.

Table 13.3 Meteorological optical range, standard visual range, extinction coefficient and transmittance

Meteorological optical range MOR (km)	0.1	0.2	0.5	1	2	5	10	20
Standard visual range V_N (km)	0.131	0.261	0.653	1.31	2.61	6.53	13.1	26.1
Extinction coefficient $b_{\text{ext}}(\lambda)$ (km^{-1})	29.96	14.98	5.991	2.996	1.498	0.5991	0.2996	0.1498
Transmittance $\tau = e^{-b_{\text{ext}}(\lambda)s}$								
for $s = 100$ m	0.0500	0.2236	0.5493	0.7411	0.8609	0.9418	0.9705	0.9851
for $s = 50$ m	0.2236	0.4729	0.7411	0.8609	0.9287	0.9705	0.9851	0.9925
for $s = 10$ m	0.7411	0.8609	0.9418	0.9705	0.9851	0.9940	0.9970	0.9985

In contrast to human observers, instruments can only observe a small air sample in the direct vicinity of their installation site. This measurement always needs to assure that the determined extinction coefficient will be the same over the entire reported range. This assumption becomes more and more uncertain with increasing visibility range. Since it is possible to *look* in different directions and at very remote targets like a human observer can, camera-based observation systems like those discussed in Sect. 13.9.4 are not meant to replace (due to large uncertainties), but to support the MOR determinations that are naturally locally limited.

13.3.3 Transmissometer

The transmissometer is one of the most commonly used instruments. By measuring the transmittance it determines the mean extinction coefficient in a horizontal cylinder of air between a light transmitter and a light receiver. The light transmitter incorporates a modulated flux light source of constant mean power. The most frequently used light sources are halogen or xenon flash lamps and state-of-the-art transmissometers meanwhile use LED light sources [13.7]. The modulation of the light source prevents disturbance from sunlight and it is

generally recommended that polychromatic light in the visible spectrum should be used to obtain a representative extinction coefficient determination.

Since MOR determinations by transmissometers are based on the loss of light from a collimated beam, which depends on scatter and absorption, they are closely related to the definition of MOR. A good, well-maintained transmissometer working within its range of highest accuracy provides a very good approximation to the true MOR [13.1]. The extinction coefficient within the measurement baseline has to agree with the one within the relevant visual range. This being the case, we obtain the relative errors shown in Fig. 13.7 when determining the MOR for various absolute transmittance errors.

From a metrological perspective, however, the procedure of obtaining the transmittance is impaired not by a constant absolute error, but rather by a combination of a relative error (due especially to misalignments, incorrect calibrations and dirt deposits on the outer optical surfaces), which under some conditions may be of significant magnitude, and a small absolute error (due to the resolution and the signal-to-noise ratio).

Figure 13.8 shows the effect of the relative measurement error, which affects especially the large visual ranges. Limiting the relative transmittance error to, e.g.,

Fig. 13.7 Relative error of the meteorological optical range (MOR) for transmissometers at 1%, 0.5% and 0.2% absolute transmittance error (after [13.6] with permission from VDI e. V., Düsseldorf, Germany)

Fig. 13.8 Relative error of the meteorological optical range (MOR) for transmissometers at 1%, 0.5% and 0.2% relative transmittance measurement errors (after [13.6] with permission from VDI e. V., Düsseldorf, Germany)

0.5% allows the range to be determined with a relative error below 20% at meteorological optical ranges up to 100 times the baseline length. If the effects on the procedure of obtaining the transmittance can be reduced even further (to, e.g., 0.2%), measurements are possible up to 250 times the baseline length while maintaining a relative measurement error of 20% for the MOR. The illustrated decreasing measurement uncertainty of a transmissometer with decreasing MOR is an advantage for small meteorological optical ranges, in contrast with forward scatter meters. This is also the reason why one can calibrate a forward scatter meter in fog through transmissometer measurements.

The measurement uncertainties of transmissometers are largely negligible for small ranges, as long as the lower end of the measurement range is matched to the available measurement's dynamic range. The latter is determined by the signal-to-noise ratio, the resolution and any unwanted signal offsets. Figure 13.9 shows the

influence of the measurement error, which affects especially small ranges. A usable dynamic range of 1 : 1000 (60 dB) permits, e.g., a measurement down to 0.4 times the base length at a maximum relative error of 16% for the MOR.

With increasing transmissometer baseline length an increasing impact of the so-called forward scatter error needs to be taken into account. Since the transmitter and receiver optical systems of a transmissometer cannot provide an ideally narrow light beam with respect to field of view, unwanted stray light produces an additional receiver signal, which adds to the measured transmittance signal. The collection of forward-scattered light by the transmissometer receiver leads to a measurement error that is conveniently expressed as a fractional error in extinction coefficient (lower than the true extinction coefficient). The fractional error increases with the radius of the scattering particles but can be considered independent of the baseline.

Fig. 13.9 Relative error in the meteorological optical range (MOR) for transmissometers in the presence of different transmittance measurement errors dependent on the dynamic range (DYN) (after [13.6] with permission from VDI e. V., Düsseldorf, Germany)

Fig. 13.10 Transmittance measurement value increase due to forward scatter error @ MOR = 0.766 times the baseline length depending on the transmitter and receiver half angles, based on data (after [13.8])

However, the final conversion into the MOR needs to consider the utilized baseline length. Therefore, the resulting MOR error will naturally increase with increasing baseline length. For particles much larger than the wavelength of light, the error is roughly proportional to the particle radius and to the angular width of the receiver. For a particle of $10\ \mu\text{m}$ (i.e., the largest particle radius typically in fogs) and $0.55\ \mu\text{m}$ wavelength (peak in response of human vision), the error will be less than five per cent if the receiver half angle is less than 1 mrad [13.9]. Figure 13.10 illustrates the increase factor for the measured transmittance when different transmitter divergences and receiver fields of view are utilized [13.10].

13.3.4 Instruments Determining the Scatter Coefficient

The attenuation of light in the atmosphere is due to both scattering and absorption. The presence of pollutants in the vicinity of industrial zones or dust may make the absorption term significant. However, in general, the absorption factor is negligible and the scatter phenomena due to reflection, refraction, or diffraction on water droplets constitute the main factor reducing visibility. The extinction coefficient may then be considered as equal to the scatter coefficient, and an instrument for de-

termining the latter can, therefore, be used to estimate MOR. Measurements are typically taken by concentrating a beam of light on a small volume of air and by determining the proportion of light that is scattered in those directions where scattering provides the best estimate of the scatter coefficient in all conditions. Due to the flux modulated light source, an instrument of this type can be used during day and night. The scatter coefficient b is a function that may be written in the following form

$$b = \frac{2\pi}{\Phi_V} \int_0^\pi I(\theta) \sin \theta d\theta, \quad (13.5)$$

where Φ_V is the flux entering the volume of air V and $I(\theta)$ is the intensity of the light scattered in direction θ with respect to the incident beam [13.1]. The accurate determination of b requires the measurement and integration of light scattered out of the beam over all angles. However, practical instruments measure the scattered light over a limited angle range and rely on a high correlation between the limited integral and the full integral (see Sect. 13.4 for further details). Instruments that determine the scatter coefficient use three main measurement methods: backscatter, forward scatter, and scatter integrated over a wide angle.

Fig. 13.11 Schematic diagram of a backscatter sensor

Backscatter

In these instruments a light beam is concentrated on a small volume of air in front of the light transmitter. The light receiver is located in the same housing and detects the light that is backscattered from the light beam in the sampled volume of air, see Fig. 13.11. Due to the significantly different response strengths for fog, rain and solid precipitation that cannot be corrected for by conventional backscatter sensors, this technology has up to now been limited to simple fog warning applications with respect to applications that allow larger measurement uncertainties in precipitation.

Forward Scatter

The amount of light scattered by small particles (aerosols, small droplets) is angular-dependent and varies with the chemical composition (e.g., salt concentration), type of nucleus (sand, dust), size and shape of the particles. As a consequence, a scattering angle should be chosen so that the angular dependence is minimal and representative for the scatter coefficient. Instruments determining MOR based on the forward scatter principle are generally called forward scatter sensors or forward scatter meters, see Fig. 13.12.

Scatter over a Wide Angle

Such an instrument, which is usually known as an integrating nephelometer, is based on the principle of measuring scatter over as wide an angle as possible, ideally 0° to 180° , but in practice about 10° to 120° . The light receiver is positioned perpendicularly to the axis of the light transmitter which provides light over

Fig. 13.12 Schematic diagram of a forward scatter sensor

a wide angle, see Fig. 13.13. Although, in theory, such an instrument should give a better estimate of the scatter coefficient than an instrument measuring over a small range of scattering angles, in practice it is more difficult to prevent the presence of the instrument from modifying the extinction coefficient in the air sampled. Integrating nephelometers are not widely used for measuring MOR. This type of instrument is more often used for measuring pollutants.

13.3.5 Forward Scatter Meter

A transmissometer measures the fraction of light (transmittance) that has not been absorbed or scattered out of a light beam after it has travelled a certain distance through the atmosphere. The study of human vision has shown that the transmittance (or the extinction coefficient which is easily computed from transmittance) is the correct parameter to characterize the degradation of vision by precipitation or aerosols. In contrast to the transmissometer, a forward scatter meter measures a small portion of light scattered out of a light beam into a relatively narrow range of scattering angles. The forward scatter meter measurement is then used to estimate the extinction coefficient; the scattered signal is assumed to be proportional to the extinction coefficient.

Fig. 13.13 Schematic diagram of an integrating nephelometer

Fig. 13.14 Relation between extinction coefficient σ and MOR according to (13.6)

The validity of the estimate depends upon the physical properties of the scattering particles [13.9]. Since both the forward scatter meter signal and the extinction coefficient are proportional to the particle density, variations in particle density cannot affect the validity of the forward scatter meter measurement.

The response of a forward scatter meter depends upon the fraction of light scattered into the detected range of angles. Since particles of different type have different scatter functions, the ratio of scattered signal to extinction coefficient (i.e., the forward scatter meter calibration factor) can depend upon the type of scattering particles. One way of addressing this problem is to select a scattering angle where scatter function is as closely proportional as possible to the extinction coefficient for the weather phenomena that reduce visibility. Several authors have shown that the best angle is between 20° and 50° [13.10–13]. Another approach is to identify the weather phenomena and apply a different calibration to different weather types.

Particle absorption can be a problem, since a forward scatter meter cannot detect absorption. However, if the amount of absorption is proportional to the amount of scattering, the effect of absorption simply changes the proportionality between scattered signal and total extinction coefficient. Generally speaking, forward scatter meters exhibit larger measurement uncertainties than transmissometers, but due to the smaller effect of deposits on the optical apertures, they are better suited for large ranges than transmissometers. Especially where vision is restricted by precipitation, haze and mist, however, there may occur further particle-type-dependent measurement uncertainties (Mie scat-

tering which depends on the angle, the wavelength and the phenomenon involved).

Influence of the Calibration and the Window Dirt Contamination

The optimal forward scatter angle range was found to be in the range of 40° – 45° when infrared light is utilized. The forward scatter measurement evaluates the light scattering properties of the atmospheric particles but not the absorption by solid particles. It is based on the assumption that the scattered light under the utilized angle range corresponds to the total amount of scattered light and is therefore proportional to the extinction. As a result the following basic aspects apply:

- The forward scatter instrument evaluates the extinction coefficient directly.
- The received signal increases proportional with increasing particle concentration.
- Without any atmospheric extinction, the received signal approaches zero.

Equation (13.6) describes the relationship between the evaluated forward scatter signal (extinction coefficient) and the MOR, as illustrated in Fig. 13.14,

$$\text{MOR} = -\frac{\ln \varepsilon}{\sigma} = -\frac{\ln 0.05}{\sigma}, \quad (13.6)$$

where MOR is the meteorological optical range in meters, σ the extinction coefficient in m^{-1} , and ε the perceptibility contrast threshold (0.05 for MOR).

Due to the inverse proportionality between the measured forward scatter signal (extinction coefficient) and

Fig. 13.15 Scatter phase function examples for fog and haze, based on data (after [13.13])

the reported MOR, measurement inaccuracies (e.g., uncorrected window dirt contamination that reduce the measured forward scatter signal or wrong calibration) have the same relative impact (same error percentage) throughout the entire measurement range. These impacts need to be seen as an *unwanted factor* on the extinction coefficient. The target of the calibration for a forward scatter meter is to keep this *unwanted factor* as small as possible.

As already illustrated, the received signal of a forward scatter meter represents the extinction coefficient if the forward scatter angle is selected such that the strength of the scattered light under this angle can represent the entire extinction coefficient,

$$\begin{aligned} \text{FSS (forward scatter signal@40°–45°)} \\ \propto \sigma \text{ (Extinction coefficient in m}^{-1}\text{)}. \end{aligned} \quad (13.7)$$

Depending on the measurement technology and the specific arrangement a sensor type specific conversion factor CF is required to convert the measured forward scatter signal into an extinction coefficient

$$\begin{aligned} \text{FSS (internal units)} \times CF \left(\frac{1}{\text{internal units} \times \text{m}} \right) \\ \propto \sigma \text{ (m}^{-1}\text{)}. \end{aligned} \quad (13.8)$$

Since the unit to unit deviations (including individual parameters like absolute transmitter light intensity with

regards to receiver sensitivity) need to be additionally considered, the forward scatter meter finally needs to be calibrated against a well-known extinction coefficient simulation σ_{CAL} . A fitting calibration factor (CAL) is evaluated

$$\text{CAL} = \frac{\sigma_{\text{CAL}}}{\text{FSS} \times \text{CF}}. \quad (13.9)$$

This calibration factor equalizes the sensor response with the extinction coefficient to be measured

$$\sigma = \text{FSS} \times \text{CF} \times \text{CAL}. \quad (13.10)$$

An unwanted additional influence on the forward scatter signal (FSS), like uncorrected window dirt contamination needs to be seen as an error factor which directly influences the found sensor calibration factor CAL, leading to a proportional under- or overestimation of the true extinction coefficient σ .

Influence of the Scatter Phase Function

So-called scatter phase functions are utilized to describe the relation between scatter angle and scatter strength. The response of a forward scatter meter for different aerosols and droplets can be estimated by utilization of the scatter phase functions. The value of a scatter phase function describes the portion of light that is expected to scatter in a certain direction. To allow direct

Fig. 13.16 Measurement wavelength impact on relative extinction coefficient (EXCO/EXCO @ 550 nm) for different particle radii

Fig. 13.17 Wavelength impact on the extinction coefficient (EXCO), 785 nm example

value comparisons, a scatter phase function is normalized with respect to the integral value below the curve and the represented extinction coefficient.

One commonly used set of phase functions are contained in LOWTRAN, which is a *low* spectral resolution (20 cm^{-1}) band model radiative transfer algorithm developed by the Air Force Geophysics Laboratories, now the Air Force Research Laboratories (AFRL). LOWTRAN incorporates different aerosol models that are based on measurements and investigations from various sources [13.13]. Figure 13.15 illustrates exemplarily the different expectable scatter signal strengths for some visibility phenomena models over the scatter angle. The response differences between fog and types of hazes are obvious.

Measurement Wavelength Impact

The utilized measurement wavelength also has an impact on the scatter measurement. Due to different scatter

properties, the small non-liquid particles in haze will generate less scattering and will therefore be underestimated. Figure 13.16 illustrates the measurement wavelength impact on the relative extinction coefficient measurement for different particle radii. For smaller particles larger deviations must be expected when other wavelengths than the nominal 550 nm are used.

The general wavelength impact on the extinction coefficient can be described with Ångström's equation

$$\sigma_{\lambda} = \sigma_{550 \text{ nm}} \left(\frac{550 \text{ nm}}{\lambda} \right)^{\text{EXP}} \quad (13.11)$$

In [13.2] different typical exponents EXP are defined to be used with the equation for different high visibility ranges:

- EXP = -1.3 for 30 km standard visibility
- EXP = -1.6 for 90 km standard visibility

- EXP = -2.0 for 150 km standard visibility
- EXP = -4.0 for Rayleigh atmosphere

Figure 13.17 illustrates well the resulting deviation of the measured extinction coefficient at 785 nm versus the true extinction coefficient at 550 nm.

Combined Wavelength and Scatter Phase Function Impacts

For the MOR measurement range beyond 10 km (haze), both the impact of the measurement wavelength and the scatter phase function need to be taken into account, and which fortunately partly compensate for each other when an infrared wavelength is chosen. The combi-

nation of the measurement wavelength and the scatter phase function impact represents the aerosol-dependent measurement uncertainties that need to be taken into account for all forward scatter meters. Depending on the most dominant haze phenomenon (dictated by the installation site) the resulting reporting deviations must be expected to exceed 30% in some cases. Up to a MOR of 10 km, a measurement uncertainty of approximately 10% can be achieved in the best case. Depending on the utilized forward scatter angle and measurement wavelength, the uncertainty can easily become 20% up to more than 30% if all the range-limiting phenomena are taken into account and the entire measurement range up to MOR > 70 km is covered.

13.4 Devices and Systems

Nowadays, MOR can be measured using methods relying on either transmitted or scattered light. Whichever one is applicable depends first and foremost on the type of atmospheric pollutants, which measurement range will be covered and what level of measurement uncertainty is acceptable. The measurement methods described here are applied in visual range measuring instruments which are used predominantly for securing air, road and shipping traffic and for meteorological forecasting. They are commonly calibrated in units of MOR. They can, however, also be used and calibrated accordingly to determine the extinction coefficient, and transmissometers also to determine the transmittance.

13.4.1 Transmissometer

The light from a suitable source is collimated and sent down the required path. It is detected by a photoelectric sensor either directly or after reflection from a triple mirror (see Fig. 13.18). The consistency of the properties of the light source and the sensor has to be ensured. In order to be able to measure in daylight, the interfering effect of the scattering of daylight along the measurement path must be eliminated. This is done by modulating the measured light. The photocurrent (AC) generated in the receiver by the measured light can be separated from the DC part of the daylight signal. In past designs, the transmitter and the receiver were com-

Fig. 13.18a,b Schematic diagram of a transmissometer. **(a)** Single path transmissometer, **(b)** double path transmissometer; b = baseline length (after [13.9] with permission from WMO)

bined into one unit (double path transmissometer) in order to avoid the challenging requirements for the consistency of the properties of the light source and the receiver.

Transmissometers are used preferably for MORs of 10 m to max. 10 km. Due to the principle involved, different baseline lengths might be needed for recording certain ranges. These lengths are typically around 50 to 100 m, and are even longer when dealing with greater ranges. Extinction measurement using the transmissometer principle has the lowest uncertainty. This applies first and foremost to the recording of smoke, soot and dust. In addition to the technical properties of the equipment, however, the MOR measurement uncertainty depends also on the baseline length in relation to the required MOR reporting range. Double path transmissometers (the measurement path is traversed twice) require a triple mirror at the end of the measurement path. Triple mirrors have the property that they reflect an incident light beam in parallel with themselves, without the need for precise adjustment when being setup.

13.4.2 Scattered Light Sensor

Scattered light sensors measure the scattering coefficient $b_{\text{sca}}(\lambda)$ in units of inverse meters. It is possible to determine the MOR directly with the help of scattered light sensors only if the absorption coefficient $b_{\text{abs}}(\lambda)$ is negligible. Otherwise, the results have to be corrected (at a wavelength of 550 nm, the ratio $b_{\text{abs}}/b_{\text{ext}}$ is 0.0 in clouds and in fog, approximately 0.1 to 0.2 in polluted

air)

$$\text{MOR} = \frac{2.996}{b_{\text{sca}}(\lambda)} \left[1 - \frac{b_{\text{abs}}(\lambda)}{b_{\text{sca}}(\lambda)} \right]. \quad (13.12)$$

Due to

$$b_{\text{sca}}(\lambda) = 2\pi \int_0^{180^\circ} p(\vartheta) \sin \vartheta d\vartheta, \quad (13.13)$$

where $p(\vartheta)$ is the scattering function, the measurement of $b_{\text{sca}}(\lambda)$ requires integrating the scattered light over the entire scattering angle range from 0° to 180° , which is not technically possible. Therefore, *integrating* scattered light measurements are restricted to integration over the largest technically feasible angular range (ca. 7° to 170°) and correct the measurement accordingly [13.15]. This concept is utilized in so-called *integrating nephelometers*. However, due to their complexity, high maintenance requirements and limitations to determine the extinction coefficient of precipitation particles, they achieved no practical relevance for the 24/7 visibility measurement. For these reasons the scattered light measurement is conducted exclusively within a selected and limited angle range.

The relationship between scattering and extinction depends on the scattering particles' size distribution and their chemical composition. The amount of light scattered by small particles (aerosols, small droplets) is angular-dependent. The chemical composition (e.g., salt concentration), type of nucleus (sand, dust) and

Fig. 13.19 Scatter phase function examples for fog (dashed/dotted lines) and rain (solid line), based on data (after [13.13, 14])

Fig. 13.20 State-of-the-art forward scatter meter example with look down geometry (after [13.16] photo © Vaisala Oyj, Helsinki, Finland)

size and shape of the particles influence the response strength. As a consequence, a scattering angle is chosen so that the angular dependence is minimal and representative for the scatter coefficient. The scatter phase function example in Fig. 13.19 compares the expectable scatter signal strength (logarithmic scaling) for advection fog, radiation fog and rain. The best correlation can be found between 20° and 50°

which is the typical angle range of forward scatter meters.

Compared with transmittance measurements, scattered light measurements have the advantage of compact equipment and a larger measurement range, up to > 70 km. However, they have the drawback of neglecting the absorption, and are therefore unsuitable for recording strongly absorbing particles in polluted air when the absorbing fraction $b_{\text{abs}}(\lambda)$ is unknown. Due to the relatively small measured volume, scattered light measurements in the presence of highly inhomogeneous atmospheric turbidity are representative only for a narrowly confined region. The typical forward scattering angles (Fig. 13.20) are 20° to 50°, preferably 40° to 45°. This angular range ensures the best possible agreement of the values of $b_{\text{sca}}(\lambda)$ for the various different visual range-restricting phenomena, and thus a minimum of any necessary phenomenon-dependent corrections.

Forward scatter meters can be calibrated by comparison with a highly accurate transmissometer, or through measurements with inserted defined scattering discs. However, the consistency of the properties of the light source and of the receiving apparatus has to be ensured (see Sect. 13.7 on maintenance for further reading).

Table 13.4 Advantages and disadvantages of the different measurement methods

Devices	Advantages	Disadvantages
Long baseline transmissometer (≥ 100 m)	Measurement up to MOR > 10 km possible Representative determination of the extinction coefficient for litho- and hydrometeors and all precipitation types	Separate transmitter and receiver units on stable foundations required Measurement down to MOR < 10 m not possible, cannot cover the entire RVR relevant MOR range MOR error due to uncorrected window dirt contamination and miscalibration increases with increasing MOR
Short baseline transmissometer (≤ 30 m)	Measurement down to MOR < 10 m possible Can cover the entire RVR relevant MOR range Representative determination of the extinction coefficient for litho- and hydrometeors and all precipitation types	Separate transmitter and receiver units on stable foundations required MOR error due to uncorrected window dirt contamination and miscalibration increases with increasing MOR
Backscatter meter	Very compact design possible, receiver and transmitter in one common enclosure Measurement volume remote from the instrument	Large measurement uncertainties especially for visibility reductions due to precipitation
Integrating nephelometer	Compact design Measurement under a wide range of scatter angles allows representative determination of the extinction coefficient for litho- and hydrometeors	A disturbance of the measurement volume due to close-by mechanical parts cannot be avoided Shadowing of the measurement volume does not allow representative visibility determination in precipitation
Forward scatter meter	Compact design Optimal forward scatter angle allows visibility determination for fog, mist and precipitation with low uncertainties Large measurement range from < 10 m to > 50 km Internationally agreed measurement method as well for safety relevant air traffic applications (RVR determination)	Measurement uncertainties increase for visibility reductions due to lithometeors

13.4.3 Transmittance Versus Scattered Light Measurements

Compared with transmittance measurements, scattered light measurements have the advantage of compact equipment and a larger measurement range, up to > 70 km. However, they have the drawback of neglecting the absorption, and are therefore unsuitable for recording strongly absorbing particles in polluted air when the absorbing fraction $b_{\text{abs}}(\lambda)$ is unknown. Due to the relatively small measured volume, scattered light measurements in the presence of highly inhomogeneous atmospheric turbidity are representative only for a narrowly confined region. All practical operational instruments for the measurement of MOR sample a relatively small region of the atmosphere compared with that scanned by a human observer. Instruments can pro-

vide an accurate measurement of MOR only when the volume of air that they sample is representative of the atmosphere around the point of observation out to a radius equal to MOR. It is easy to imagine a situation, with patchy fog or a local rain or snow storm, in which the instrument reading is misleading.

Another factor that must be taken into account when discussing representativeness of measurements is the homogeneity of the atmosphere itself. At all MOR values, the extinction coefficient of a small volume of the atmosphere normally fluctuates rapidly and irregularly, and individual measurements of MOR from forward scatter meters, with respect to the short baseline of a transmissometer, might show considerable dispersion [13.1]. Finally, the advantages and disadvantages of different measurement methods are summarized in Table 13.4.

13.5 Specifications

For the measurement of atmospheric turbidity to be representative, bearing in mind the inhomogeneity of the atmosphere, the measuring equipment has to cover a particular minimum volume. The natural atmosphere itself (i.e., without anthropogenic pollution) can cause difficulties when deciding on a volume. In particular where there exist local or regional inhomogeneities or fog banks, the extinction coefficient can vary considerably in space and time, which may render it difficult to obtain a representative value. Generally speaking, in forward scatter meters the covered measurement volume is only a few to a few hundred cm^3 . The representativeness of the measurement results from the equipment's measurement volume and the heterogeneity of the visual range field. Caution is necessary, therefore, when extrapolating from point measurements to a large region. The measurement range of common forward scatter meters is ca. 10 m to 70 km.

Transmissometers always record a spatial average over their baseline length; this depends on the required measurement range and the permitted error magnitude (see Table 13.5). Baseline lengths between 10 and 100 m are common, corresponding to a measurement volume of 0.1 to 1 m^3 . The measurement range of common transmissometers is approximately 10 m to max. 10 km. Theoretically, assuming a constant 1% absolute error in the transmittance measurement, one can expect a relative error of less than 10% for the MOR from approximately 0.8 times to approximately 25 times the baseline length (Fig. 13.7). In case it is not feasible to reduce the error in the transmittance measurement below 1%, it is as well possible to extend the measurement range by using two-range or double-baseline transmis-

someters. In any case it has to be considered that the relationship between the measured transmittance and the reported MOR is not linear.

The measuring equipment is subject to the following general requirements:

- Ideal measurement range of the MOR (depending on the task): 10 m/100 m to 2 km/20 km (10 nmi)/70 km
- Resolution: 1 m according to the World Meteorological Organization (WMO) [13.1]
- Relative standard deviation $\pm 10\%$ (ignoring external influences) for MORs 10 m to 10 km
- Response time: approximately 1 min (for the entire system)
- Averaging time for the measurements: 1 min according to WMO [13.1]
- Data recording: interrogation cycle ≤ 15 s
- Eliminating the adverse effects of daylight, to ensure that the same results are obtained under constant meteorological and physical conditions during daytime and at night
- Independent of atmospheric temperature effects from -30 to 50°C
- The effects of self-heating and heating by solar radiation have to be eliminated
- Preventing the adverse effects of snow clogging, icing and birds/insects disturbances
- Long-term consistency of the light source, the receiver system and the electronics (six months without appreciable deviations), to the extent necessary for the measurement method
- Detecting and correcting for dirt deposits on the optical elements.

Table 13.5 Specification of different measurement methods for visibility. Note: The stated error and uncertainty percentages need to be understood as typical values; they might differ between different instrument types. The development of the MOR error due to uncorrected window dirt contamination over time depends significantly on the local conditions. Instruments with automatic window dirt contamination correction will reach the stated error borders after a much longer maintenance-free operation time. The transmissometers are assumed to be realistically calibrated within an uncertainty of $\pm 20\%$ @ MOR = 10 km. Additionally an uncorrected window dirt contamination of maximally 0.5% is assumed as an example for a 100 m and for a 30 m baseline transmissometer. For the scatter meters a larger uncorrected window dirt contamination of 10% as an example is assumed

Method	Calibration depending MOR error	MOR uncertainty hydrometeors	MOR uncertainty lithometeors	MOR uncertainty precipitation	MOR error due to uncorrected window dirt contamination
Long baseline transmissometer (≥ 100 m)	between 50 and 800 m $\pm 2\%$				-1.3%
	between 800 and 2000 m $\pm 5\%$				-3.2%
	between 2000 and 5500 m $\pm 12\%$				-8.4%
	between 5500 and 10 000 m $\pm 20\%$				-14%
Short baseline transmissometer (≤ 30 m)	between 10 and 800 m $\pm 2\%$				-4.3%
	between 800 and 2000 m $\pm 5\%$				-10%
Backscatter meter	$\pm 3-5\%$	$\pm 20\%$	$\pm 40\%$	$\pm 50\%$	+ 11%
Integrating nephelometer	$\pm 2-3\%$	$\pm 10\%$	$\pm 20\%$	Not usable	+ 11%
Forward scatter meter	$\pm 2-3\%$	$\pm 10\%$	$\pm 30\%$	$\pm 20\%$	+ 11%

13.6 Quality Control

The siting of visual measuring equipment should be representative, which leads to setup rules (Sect. 13.6.1). These are followed by some aspects of data quality control (Sect. 13.6.2). The quality of the reported MOR data from instruments like transmissometers or forward scatter meters are basically influenced by all parasitic drags that are described in the Sect. 13.6.3.

13.6.1 Setup Rules

Whereas in general, transmissometers and forward scatter meters used to determine the MOR are deployed so as to be free from locally limited inhomogeneities due to atmospheric pollution, e.g., smoke, industrial dirt, dusty streets, for the purpose of monitoring air quality they have to be deployed where they are representative for a particular vicinity. This applies especially to their height above ground level. If vertical inhomogeneities have to be recorded a number of vertically staggered instruments might have to be used. In general, it is advisable to avoid deployment at locations highly susceptible to fog, i.e., in the vicinity of bodies of water, streams or rivers or on very wet subsoil.

Particular attention should be paid to the correct alignment of transmissometer transmitters and receivers and to the correct adjustment of the light beam. The poles on which the transmitter/receivers are mounted should be mechanically firm (while remaining frangible when

installed at aerodromes) to avoid any misalignment due to ground movement during freezing and, particularly, during thawing. In addition, the mountings must not distort under the thermal stresses to which they are exposed. Some modern transmissometers can automatically adjust their alignment to compensate for this [13.7].

Furthermore, transmissometers and forward scatter meters should be installed in such a way that the sun is not in the optical field of view of the receiver at any time of the day. Forward scatter meters should also be aligned such that reflecting objects in the optical field of view of the receiver are avoided.

13.6.2 Data Quality Control

Any data quality control needs to be based on a deep understanding of all potential parasitic drags and their technology depending impact on the measurement uncertainty as described in Sect. 13.3.3 in order to find algorithms that can identify and separate unrealistic instruments readings.

Instrumental measurements of MOR must always be interpreted with caution. All practical operational instruments sample a relatively small region of the atmosphere compared with that scanned by a human observer. However, instruments can provide an accurate measurement of MOR only when the volume of air that they sample is representative of the atmosphere

around the point of observation out to a radius equal to MOR. Experience has shown that uncertain situations with patchy fog or local rain or snow events, in which the instrument reading might be misleading are not frequent and that the continuous monitoring of MOR using an instrument will often lead to the detection of changes in MOR before they are recognized by an unaided observer [13.1].

At all MOR values the extinction coefficient of a small volume of the atmosphere will normally fluctuate rapidly and irregularly and individual measurements of MOR from forward scatter meters and short baseline transmissometers will unavoidably show considerable dispersion. In order to obtain a representative MOR value it might therefore be necessary to take many samples and to smooth or average them. The analysis of the results from the *First WMO Intercomparison of Visibility Measurements* [13.17] indicates that, for most instruments, no benefit is gained by averaging over

more than 1 min, but for the *noisiest* instruments an averaging time of 2 min is preferable.

13.6.3 Parasitic Drags and Impact on the Measurement Uncertainty

When measuring MOR, the error sources and perturbations are not exactly quantifiable. The optical apertures (glass surfaces) are exposed to the risk of contamination by atmospheric pollutants. Depending on external conditions, significant transmittance errors can occur even within a few days in conventional transmissometers if the optical apertures are not cleaned regularly. This can, depending on the visibility, lead to considerable errors in the readings of the MOR. Measuring the dirt deposits on the optical apertures, with appropriate correction of the transmittance and/or regular automated recalibration of the transmittance measurement, can reduce the measurement errors. Even with long cleaning intervals,

Table 13.6 Major parasitic drags and countermeasures for transmissometers (after [13.1])

Transmissometers	
Parasitic drag	Countermeasures
Atmospheric pollutants deposited on optical surfaces	Contamination measurement and contamination correction in the frame of the sensor self-diagnostics Regular cleaning in accordance with manufacturer's instructions in the frame of preventive maintenance Reactive maintenance, cleaning only when needed
Instability of system electronics	Regular linearity and calibration check, using a graduated set of attenuation filters under stable, high visibility conditions Change/adjust instrument settings in accordance with manufacturer's instructions
Snow or ice build-up on surfaces near the optical measurement path	Sensor head heaters and hood heaters should be foreseen for instruments at installation sites that usually allow snow and ice conditions
Aging of transmitter light source	Light source intensity measurement and aging warning messages in the frame of the sensor self-diagnostics Replacement of the transmitter light source in the frame of preventive with respect to reactive maintenance
Insufficient rigidity and stability of transmitter and receiver mounting poles and effects of freezing or thawing of the ground	Regular calibration check under stable, high visibility conditions Change/adjust instrument settings in accordance with manufacturer's instructions
Calibration error due to calibration/adjustment being carried out when visibility is low or during unstable atmospheric conditions	Some modern transmissometers can provide automatic calibration corrections, based on the detection of stable high visibility conditions [13.7] Otherwise the calibration with respect to adjustment is to be carried out manually in accordance with manufacturer's instructions
Incorrect alignment of transmitters and receivers	Some modern transmissometers can provide an automatic alignment feature [13.7] Otherwise an alignment check with respect to correction needs to be conducted manually in accordance with manufacturer's instructions
Disturbance when sun is near horizon, or due to reflections from adjacent surfaces	In order to prevent sunlight disturbances, the installation and orientation must be carried out in accordance with manufacturer's instructions

Table 13.7 Major parasitic drags and countermeasures for forward scatter meters (after [13.1])

Forward scatter meters Parasitic drag	Countermeasures
Atmospheric pollutants deposited on optical surfaces	Contamination measurement and contamination correction in the frame of the sensor self-diagnostics A look-down geometry and weather protection hoods for the instrument windows provide a better protection for the optics and enable longer maintenance intervals Regular cleaning in accordance with manufacturer's instructions in the frame of preventive maintenance Reactive maintenance, cleaning only when needed
Instability of system electronics	Regular calibration check, using scatter plates that simulate defined fog conditions Change/adjust instrument settings in accordance with manufacturer's instructions
Snow or ice build-up on surfaces near the optical measurement path	Sensor head heaters and hood heaters should be foreseen for instruments at installation sites that usually allow snow and ice conditions
Aging of transmitter light source	Light source intensity measurement and aging warning messages in the frame of the sensor self-diagnostics Replacement of the transmitter light source in the frame of preventive with respect to reactive maintenance
Atmospheric conditions (for example, rain, snow, ice crystals, sand, local atmospheric pollutants) giving a scatter coefficient that differs from the extinction coefficient	An optimized scattering angle (40° to 45°) will reduce the related uncertainties [13.16] When a discrimination of the atmospheric conditions is possible, related corrections can be applied
Extra absorption by sand, dust and smoke giving a scatter coefficient that underestimates the extinction coefficient	When a discrimination of the atmospheric conditions is possible, related corrections can be applied for the forward scatter meter measurements
Incorrect procedures for calibration/adjustment, or use of incorrect or damaged scatter plates	Calibration and adjustment must be carried out in accordance with manufacturer's instructions Scatter plates must never be used in dense fog, drizzle or rain
Disturbance when sun is near horizon, or due to reflections from adjacent surfaces	In order to prevent sunlight disturbances, the installation and orientation must be carried out in accordance with manufacturer's instructions In the northern hemisphere the light receiver should ideally point toward the northern direction ($\pm 45^\circ$)
Disturbance by cobwebs or individual spider silk in the sample volume	Some modern forward scatter meter designs do not expose any supporting points that would allow a spider web to be placed inside or close to the measurement volume. The disturbance risk is significantly reduced [13.16] Regular cleaning in accordance with manufacturer's instructions in the frame of preventive maintenance Reactive maintenance, cleaning only when needed
Disturbance by flying insects in the sample volume	When a discrimination of the scatter signal that is generated by flying insects is possible, related corrections can be applied for the forward scatter meter measurements [13.16]

the resulting measurement uncertainty can be kept low in this way, including the upper end of the measurement range [13.7].

Rain, especially in conjunction with wind, can give rise to unwanted drops on the glass surfaces. In the case of drifting snow, the protective tubes in front of the optical apertures may become snowed up. Occasionally birds setup residence in these tubes. In order to counteract these effects, forward scatter meters (unlike transmissometers) can benefit from using a look-down

geometry. On the one hand, the downward-directed protective hoods reduce significantly the amount of dirt being deposited on the optical apertures; on the other, they prevent very effectively any kind of blocking of the instrument's optics, e.g., by wind-driven snow (see also [13.9]). Insects (midges), spiders and cobwebs can impair the measurement results of forward scatter meters. A suitable mechanical construction, however, can minimize the number of supporting points for spider webs in or near the measurement volume of forward

scatter meters. Interference by insects can be filtered out from the measured signals.

In transmissometers, mechanical loss of adjustment of the optical axis associated with changes in the state of the ground, ground movements or temperature effects have to be prevented. The possible distortion of transmissometer results, due to the increasing amount of forward-scattered transmitter light when the atmospheric extinction coefficient is very high, can be decreased by using small aperture angles in the transmitter's and receiver's optical systems, but never completely avoided.

In the presence of precipitation, transmissometers and forward scatter meters may produce different readings from the values estimated by an observer, since

these instruments perform point measurements whereas the observer examines a larger volume. Under some conditions, integrating nephelometers hardly respond (or do not respond at all) to precipitation, where due to their construction or deployment the precipitation is prevented from entering the measurement volume. In general, every visual range reduction has to be measured, including a reduction caused by precipitation. Forward scatter meters can be constructed in a way that even under unfavorable wind conditions only negligible shading of the measurement volume can arise [13.16]. A detailed quantification of the impact on the measurement uncertainty is provided in Sects. 13.3.3 and 13.3.5. Tables 13.6 and 13.7 summarize the parasitic drags and the potential countermeasures.

13.7 Maintenance

Systematic inspection and monitoring of the measurement system is required to ensure comparable data. Any contamination of the glass surfaces (light-transmitting areas) due to dirt or precipitation has to be removed before conducting measurements. Some range measuring equipment uses electric heating units and fans at the glass surfaces to guard against precipitation or other deposits. Transmissometers in particular require frequent cleaning or separate measurement of dirt on such surfaces, and appropriate correction of the result and/or automated adjustment of the calibration, since in the upper range they are far more sensitive to contamination of the external optical surfaces than forward scatter meters. Typical maintenance intervals of visibility measurement systems are summarized in Table 13.8.

In all cases of possible loss of adjustment of optical measuring sections, the equipment has to be checked.

Transmissometers in particular are sensitive to loss of adjustment, due to the required collimation of the light. In single path transmissometers (i.e., those without a triple mirror), the luminous intensity of the light sources has to be monitored. In double path transmissometers the individual consistency of the transmitter's luminous intensity and of the receiver's sensitivity is not essential since an internal optical comparison path can be applied in the transceiver that allows an automated compensation. Following any repair or replacement of light sources and other (mechanical, optical, electronic) components, careful adjustment is necessary to ensure that the equipment operates correctly and that the parameters are maintained over the entire measurement range.

For most transmissometers their optical surfaces must be cleaned regularly. Frequent servicing must be

Table 13.8 Maintenance of visibility measurement systems. Note: The above-stated window cleaning intervals are typical for instruments without automatic window dirt contamination correction and depend on the local conditions. For instruments with automatic window dirt contamination correction the cleaning intervals extend significantly and may be carried out exclusively on demand. If related warnings and/or alarms (e.g., window contamination alarm) are generated by the instrument, immediate action will take place independently from the scheduled maintenance interval

Typical interval	Transmissometer	Forward scatter meter Backscatter meter Integrating nephelometer
< 1 week	Immediate windows cleaning after wind driven precipitation contaminated an instrument window	
1 week	Regular windows cleaning	
2–4 weeks		Regular windows cleaning
6 months	General mechanical integrity check and general cleaning Calibration	General mechanical integrity check and general cleaning
1 year	Alignment check/re-alignment and calibration Linearity check with calibrated optical attenuation filters	Calibration check/calibration with scatter meter calibration units (SCU)

planned for, particularly at aerodromes. The instruments should be cleaned during and/or after major atmospheric disturbances, since rain or violent showers together with strong wind may cover the instrument windows with a large number of water droplets and solid particles resulting in major MOR measurement errors. The same is true for snowfall, which could also block the windows. Heating systems are often placed at the front of the optical systems and in the hood to improve instrument performance under such conditions. In some transmissometers air-blowing systems are used to reduce the above problems and the need for frequent cleaning [13.7]. Modern transmissometers and forward scatter meters monitor the contamination on the optical lens or window and produce warnings and errors when the contamination reaches a threshold. Some instruments make a correction for the window dirt contamination [13.1, 7, 16].

The MOR measurement of a forward scatter meter may be affected by cobwebs or even individual spider silk if the mechanical structure allows that these are placed in or close to the sample volume. Additionally, flying insects, which typically swarm around dusk in calm weather conditions can contribute to the scattered signal. Both cause the forward scatter meter to report artificially low MOR values. The reduction of the MOR of a forward scatter meter by cobwebs or flying insects can be very large, whereas these hardly affect a transmissometer measurement. Some forward scatter meters are capable to filter the raw signal for spikes induced by flying insects [13.1, 16].

Each turbidity measurement should be performed with calibrated equipment in accordance with the manufacturer's specifications. Usually the manufacturer specifies and supplies special calibration accessories. The manufacturer's recommended servicing intervals should be observed; they may have to be modified for particular sites. The calibration should be verified regularly (for transmissometers this is normally performed in very good visibility, i.e., over 10 to 15 km) and the instrument should be calibrated and adjusted if necessary. Atmospheric conditions resulting in erroneous calibration must be avoided. When, for example, there are strong up-draughts, or after heavy rain, considerable variations in the extinction coefficient are encountered in the layer of air close to the ground; if several transmissometers are in use on the site (in the case of aerodromes), dispersion may be observed in their measurements. Calibration should not be attempted under such conditions [13.1].

A transmissometer can be calibrated by direct comparison with the distance at which specified objects and lights of known intensity can be seen by an ob-

Fig. 13.21 Forward scatter meter with attached SCU (photo © Vaisala Oyj, Helsinki, Finland)

server. The observation should be as close as possible to MOR, as it is MOR which is used for conversion to obtain transmittance. The unavoidable incorporated observation uncertainties will generate a calibration error for the transmissometer, that decreases with increasing visual range. Instead of a calibration against human observations, the high visibility readings from a well known and maintained forward scatter meter can be utilized for calibration purposes [13.9]. Some state-of-the-art transmissometers conduct a calibration re-adjustment that is based on forward scatter meter readings automatically [13.7]. Additionally a linearity check using traceable optical neutral density filters should be regularly conducted.

The calibration check with regards to adjustment of instruments that measure the scattering coefficient cannot be carried out directly. The calibration has to be traceable and verifiable to a transmissometer standard, the accuracy of which has been verified over the intended operational range [13.9]. The calibration of a scatter meter involves the insertion of scatter plates (scatter meter calibration units, SCU), which simulates a defined MOR value, at a fixed position into the measurement volume. These SCUs are specific and provided by the instrument manufacturer, see Fig. 13.21. For a calibration of the scatter coefficient generally only a SCU simulation that corresponds to a low MOR value is required in combination with blocking the receiver (zero scatter coefficient, high MOR value).

At the visibility calibration facility (typically at the manufacturers premises), the SCU should be regularly checked on a known reference forward scatter meter, and if necessary recalibrated with a new coefficient. The known reference forward scatter meters are themselves regularly calibrated with a reference SCU and they are systematically checked against the reference transmissometers during low visibility episodes [13.1, 16].

13.8 Application

A variety of practical meteorological measurement tasks involve measuring the visual range, e.g., traffic route measurement stations, where the measuring section should be parallel to the road and as close to it as possible. For performing measurements in aviation and for determining various measures for the visual range, see [13.18]. The equipment manufacturer's data should also be adhered to. The temporal sequence of taking the readings should be matched to the relevant measurement task. Averaging intervals should not exceed 30 min, but typically a 1-minute gliding average is required for the MOR reporting according to the WMO and ICAO.

13.8.1 Climatology of Visibility Measurements

The customary representation methods, as used for other meteorological variables, should also be used here. In addition to averaging, however, for further processing only distributions over particular periods (e.g., day, month, year) or corresponding cumulative frequencies are meaningful. Often it is of interest to have information about the frequency distribution of the duration of particular steps of the MOR, especially below 1000 m (fog). In general, it is meaningless to quote extreme values and long-term averages. For the reporting of the MOR in the frame of aviation and roads applications the reporting resolution requirement of 1 m according to the WMO [13.1] needs to be considered. Small MORs below 1 km are of special significance. These should be, as far as possible, investigated for their causes (aerosols, precipitation, etc.), taking the relative humidity into account.

When dividing the MOR into classes for reasons of comparability, they should be chosen in a way that they correspond to the steps specified in the international meteorological codes or can be referred back to them (see Table 13.9 and Chap. 22).

13.8.2 Air, Street, and Sea Traffic

The three traffic types are treated in the following: air traffic (Sect. 13.8.2), street traffic (Sect. 13.8.2), and sea traffic (Sect. 13.8.2).

Air Traffic

The measurement and reporting of the meteorological optical range (MOR) and the runway visual range (RVR) is strictly regulated by the International Civil Aviation Organization (ICAO) with special respect to

installation sites, measurement range, allowed measurement uncertainties, averaging and reporting formats. However, some national Civil Aviation Authority (CAA) standards may modify the ICAO recommendations in a few aspects. Especially the Federal Aviation Authority (FAA) in the United States has defined slightly different requirements. The visibility information is typically required for the RVR calculation and for the reporting of the prevailing visibility. For both applications different visibility ranges, installation sites and/or observation practices are relevant. Whereas the RVR calculation requires MOR measurements up to 2000 m close to the runway, the prevailing visibility reporting requires a much larger observation (or measurement) range since the greatest visibility value which is reached within at least half the horizon circle or within at least half of the surface of the aerodrome needs to be reported.

The tolerable measurement uncertainty for MOR and RVR is specified in [13.1] and [13.19]. The following requirements for the *operationally desirable accuracy of measurement or observation* can be found:

Visibility:

- ± 50 m up to 600 m
- $\pm 10\%$ between 600 and 1500 m
- $\pm 20\%$ above 1500 m

Runway visual range (RVR):

- ± 10 m up to 400 m
- ± 25 m between 400 and 800 m
- $\pm 10\%$ above 800 m

According to ICAO the operationally desirable accuracy is not intended as an operational requirement; it is to be understood as *a goal that has been expressed by the operators*. These limits are only achievable under laboratory conditions but not in the operational practice where all environmental factors need to be considered.

For the operationally achievable measurement uncertainty the related WMO requirements apply. These are based on sensor performance under nominal and recommended exposure that can be achieved in oper-

Table 13.9 Meteorological optical range (MOR) steps to be used, according to the WMO [13.1]

MOR (km)	Steps
0.0–5.0	0.1 km steps
5.0–30.0	1.0 km steps
30.0–70.0	5.0 km steps
> 70.0	No further steps

Fig. 13.22 Achievable (solid lines) and desirable (dashed lines) MOR measurement uncertainty (based on numerical ICAO and WMO requirements according to (after [13.1, 9]))

ational practice. The achievable measurement uncertainty according to [13.1] is stated as follows:

MOR: The larger of 20 m or 20%
RVR: The larger of 20 m or 20%

Figure 13.22 illustrates the difference between the desirable and the achievable measurement uncertainties for the MOR measurement. For the RVR reporting even tighter desirable uncertainty borders are relevant (see Fig. 13.23). For the range up to MOR = 2000 m the RVR uncertainty requirements dictate the tolerable measurement uncertainties for a visibility sensor used to determine the RVR (case RVR = MOR). For the MOR range above 2000 m the uncertainty requirements for MOR apply directly.

Special attention needs to be paid on airports close to desert areas. Here the visibility is frequently reduced due to dust and sand. Conventional forward scatter meters will not be capable of reporting the correct MOR (see Sect. 13.3.3) since they are not capable of distinguishing between mist, haze, dust and sand and can therefore not apply any related corrections. For these application areas, transmissometers should still exclusively be used.

Street Traffic

Typically a MOR reporting up to maximally 2 km is required, since the road traffic safety relevant obscurations to vision are fog, dense snow and heavy rain, and therefore mainly the same range that applies for air traffic. Up to now there have not been international standards. Typically the local road authority will de-

fine the requirements. However, the European standard EN 15518-3:2011 [13.20] describes the measurement uncertainty requirements for stationary equipment for road traffic control and orientates on the achievable measurement uncertainty requirements set by the WMO (see above):

Visibility measurement range: 10 to 500 m
Resolution: 10 m
Accuracy: ± 10 m or $\pm 20\%$ of measured value, whichever is greater

Sea Traffic

Visibility information is relevant in all kinds of maritime operations like automatic fog signal and/or fog light control on lighthouses, port entrance marking and protection by harbor authorities, or to secure the vessel traffic in the navigable channel with, e.g., visibility measurements on moored buoys. The distance from which a light can be seen is strictly influenced by the MOR with respect to the atmospheric extinction coefficient. During the early 1970s, the definition of the luminous range was adopted in order to describe the visibility of maritime signal lights.

The luminous range is the maximum distance at which a given signal light can be seen by the eye of the observer at a given time, as determined by the MOR prevailing at that time. It takes no account of elevation, observer's eye level or the curvature of the earth. The luminous range value when the MOR is 10 nmi (18.52 km) is defined as nominal range. A light of an intensity of, e.g., 500 cd, provides a nominal range of approximately 8 nmi. It can be recognized at up to

Fig. 13.23 Achievable (solid lines) and desirable (dashed lines) RVR reporting uncertainty (based on numerical ICAO and WMO requirements according to (after [13.1, 9]))

12 nmi when the MOR is 20 nmi, but only at 3 nmi if the MOR is 2 nmi. Figure 13.24 illustrates the relation between the luminous range and the intensity of maritime signal lights for various MOR values.

13.8.3 Solar and Wind Power Plants

Visibility information (as well as the cloud coverage information) may be utilized to support the plant site selection in the planning phase as well as the solar power forecast in the operational phase. The atmospheric extinction between the heliostat field and receiver in solar tower plants is known to cause significant losses of reflected direct normal irradiance (DNI). This phenomenon puts a limitation on the size of the heliostat field and is included in some ray tracing and plant optimization tools. Usually, no detailed information about the local meteorological conditions is available for many sites that are now of interest for tower plant projects [13.22].

Wind turbines are usually equipped with two obstacle lights each. The data of a visibility sensor is used for controlling the intensity of these obstacle lights. The purpose of using the visibility sensor is to keep the disturbance to the neighborhood caused by these lights at a minimum level without risking the safety of air traffic. Related regulations exist in several (mostly European) countries, e.g., in Germany the regulations have been established since 2004 as a general administrative regulation for the marking and lighting of obstacles to air navigation (*Allgemeine Verwaltungsvorschrift zur Kennzeichnung von Luftfahrthindernissen* = AVV Kennzeichnung):

- Obstruction lights are mandatory for 100 m or higher turbines.
- One visibility sensor can observe a range of 1.5 km radius.
- Brightness of obstruction light can be reduced to 30% if the MOR is higher than 5 km and to 10% if the MOR is higher than 10 km.

13.8.4 Air Quality Control

For reasons of air quality control, both scientists and official authorities are displaying increasing interest in measuring the turbidity of the atmosphere due to air pollutants. The turbidity characterizes the atmospheric content of turbid extinguishing particles, and thus the pollution. It provides, therefore, information on long-term changes in air quality. The air quality control has become more and more important since the traffic density in large cities and the related exhausts have increased dramatically during the past years. It is especially important since the measurements of certain gases and the concentrations of small particulates (PM 2.5, PM 10, PM: particulate matter) play a significant role in health. Integrating nephelometers have a certain importance here since the response to small particulates can be expected to be less uncertain than for forward scatter meters (see Sect. 13.3.4).

However, in any case in-situ measurements with transmissometers or scattered light sensors incorporate the problem that they too are highly sensitive to water droplets from mist or fog, yet cannot distinguish between these and the particulates that are relevant for the air quality determination. For that reason the typi-

Fig. 13.24 Luminous range in prevailing visibility versus intensity of signal lights for different MORs (after [13.21] © Crown Copyright and/or database rights, reproduced by permission of the Controller of Her Majesty's Stationery Office and the UK Hydrographic Office (www.GOV.uk/UKHO))

cal optical particle concentration measurement devices do not measure directly in the free air like forward scatter meters, but instead utilize a pump in combination with a small measurement chamber in order to monitor the particle concentration for a defined volume of

air with regards to particle stream. One way to reduce the unwanted humidity influence on the particle concentration measurement results is to heat the air sample before it approaches the measurement chamber in order to remove the contained humidity.

13.9 Future Developments

Current developments utilize especially the forward scattering measurement method, but measurements at other scattering angles are used for optimization and correction purposes in order to take the characteristic scatter properties of different hydro- and lithometers into account. More reliable measurements and corrections for any dirt on the light-emitting apertures could allow virtually maintenance-free long-term deployment. New semiconductor light sources offer greater homogeneity of light propagation and longer service life. The sensors' dimensions and weight can be reduced, allowing for simpler operation. Even though its measurement uncertainty does not meet the ICAO and WMO requirements, the lidar (light detection and ranging) technology may be used in supporting applications. Remote measurements allow the detection of local visibility phenomena (like fog banks) in cer-

tain distances from the instrument location. The use of camera systems incorporates the potential for a phenomenon identification and a direct contrast determination of defined targets in order to estimate the MOR in supporting applications that do not need to fulfill the measurement uncertainty requirements according to ICAO and WMO.

13.9.1 Multiangle Technologies

New light scatter measurement arrangements and geometries and the evolving data evaluation techniques may in future allow a better differentiation of the visibility obscuring phenomena and the application of phenomenon-specific calibration corrections if needed. In contrast to conventional forward scatter meters the sample volume may be observed with more than

one receiver and under different optimized scatter angles in order to take advantage of the characteristic scatter properties of different hydro- and lithometeors [13.23, 24]. The different measurement angle-dependent scatter signal responses define a *scatter signature*, which can be beneficially utilized to distinguish between different particle types. As an example, the forward-to-backward ratio of scatter signal responses is significantly lower for solid precipitation particles than for liquid precipitation particles.

13.9.2 Multibeam Technologies

Like all conventional forward scatter meters, the above-mentioned multiangle technologies incorporate the need to correct for window dirt contamination of the transmitter(s) and receivers. There is some on-going research to expand the well-known four-beam technique towards an alternating multibeam technique. This alternating multibeam technique delivers an overestimated system of equations for the measured quantities and thus allows to mathematically reject the unknown parameters of the main disturbances. Consequently, this measurement arrangement and scheme incorporates the potential to automatically correct for window dirt contamination and variations of the transmitter light intensity without dedicated separate measurements.

13.9.3 Visibility Lidars

The lidar (light detection and ranging) technique may be used to obtain visibility when the beam is directed horizontally. The range-resolved profile of the backscattered signal S depends on the output signal S_0 , the distance x , the backscatter coefficient β , and transmission factor T , such that

$$S(x) \approx S_0 \frac{1}{x^2} \beta(x) T^2 \quad \text{where} \quad T = \int -\sigma(x) dx. \quad (13.14)$$

13.10 Further Reading

ICAO and WMO publications are seen as very basic information sources and are highly recommended for further reading. Especially the following two guides are of specific relevance:

- International Civil Aviation Organization, Manual of Runway Visual Range Observing and Reporting Practices (Doc 9328, AN/908), chapters 4, 7, and 8
- WMO, Guide to Instruments and Methods of Observation, WMO-No. 8, Volume I - Measurement

Under the condition of horizontal homogeneity of the atmosphere, β and σ are constant and the extinction coefficient σ is determined from only two points of the profile

$$\ln \left(\frac{S(x)x^2}{S_0} \right) \approx \ln \beta - 2\sigma x. \quad (13.15)$$

In an inhomogeneous atmosphere the range-dependent quantities of $\beta(x)$ and $\sigma(x)$ may be separated with the Klett algorithm [13.25]. As MOR approaches 2000 m, the accuracy of the lidar method becomes poor. More information on the requirements for performing visual-range lidar measurements to determine the direction-dependent MOR can be found in the International Organization for Standardization standard [13.18, 26].

13.9.4 Usage of Cameras

Camera systems are sometimes used as an aid for an observer in order to assess the visibility for an area that is blocked from view by buildings or to make visibility observations for a remote location. Automated determination of the presence of fog and the estimation of visibility from camera images is under development. This is not surprising given that the availability and quality of (web) cameras has increased, the costs of these systems decreased and the images can easily be made available on the Internet. Furthermore, image processing techniques are evolving and are now readily available. Various techniques have been implemented such as determining whether objects at known distances are visible by evaluating the presence of edges or contrast reduction. Other techniques use statistical parameters of an image such as gradients or Fourier analysis and relate these to visibility, or use the results of image enhancement methods such as de-hazing. Often the techniques are limited to daytime, and implementation needs to be tuned to the images/scenes for a specific site [13.27].

of Meteorological Variables. (World Meteorological Organization, Geneva, 2018)

Besides being very detailed description of the different technologies, these guides provide information about the best practices, procedures and the basic capabilities of instruments and systems for assisting Civil Aviation Authorities, National Meteorological and Hydrological Services and other interested users operating observing systems.

Klaus Heyn is an industrial expert for optical sensors in meteorological applications. In 1981 he gained his engineering degree in Hamburg, Germany and received a Diploma for his work on probability distribution and distribution density measurements of stochastic ergodic processes. He currently works as a Senior Scientist for the Weather Instruments Business Area of the Finnish company Vaisala and is responsible for current and future measurement technologies.

Electricity M

14. Electricity Measurements

Giles Harrison , Alec Bennett 

Atmospheric electricity concerns the transport of charge in the atmosphere and the resulting effects. Its measurement requires knowledge of several different quantities, each of which spans a wide parameter space. Examples are the range of electric fields present between fair weather conditions and thunderstorms, and the range of charges between that of a single molecular cluster ion to that carried by a hailstone. Methods for measurements of atmospheric electric fields were amongst the first quantitative measurements in atmospheric science, beginning in the mid-eighteenth century. Modern techniques extend to remote detection of lightning from satellites and local monitoring of lightning-induced electric field changes. The measurement of cluster ions is intimately linked to studies of cosmic rays and natural radioactivity and provides a sensitive method of detecting hazardous radioactive releases. Atmospheric electricity measurements have utility for lightning detection, warning, and associated weather forecasting, and in investigating the electrical changes in air associated with aerosol and radioactive pollution. They also have applications to studying electrical effects in the lower atmosphere resulting from changes in the space weather environment.

Atmospheric electricity is sometimes interpreted as solely concerning the study of lightning, but is more inclusively defined as the study of all electrical phenomena in the atmosphere, regardless of meteorological circumstances. For most purposes, atmospheric electricity can be considered a study of the transport of charge in the stratosphere and troposphere under

a range of meteorological conditions. Thunderstorms are in a sense the exception, as they occur in a restricted range of conditions and regions, in which large charges are separated in the presence of strong turbulent motions. Sufficiently large electric fields are generated to cause electrical breakdown as lightning and the release of acoustic energy as thunder.

Table 14.1 Parameters measured in atmospheric electricity

Parameter	Description	Unit	Symbol
Vertical electric field	Vertical electric force acting per unit charge	V m^{-1}	E_z
Potential gradient	Conventional description of vertical potential difference	V m^{-1}	F (or PG)
Conduction current density	Vertical current flowing per unit area due to conduction	pA m^{-2}	J_c
Air conductivity	Conductivity of air due to both negative and positive ions	fS m^{-1}	σ
Mean ion mobility	Drift speed of a cluster ion per unit electric field	$\text{m}^2 \text{V}^{-1} \text{s}^{-1}$	μ
Mean ion number concentration	Number of ions per unit volume	m^{-3}	n
Ion production rate	Rate of generation of bipolar ions per unit volume	$\text{m}^{-3} \text{s}^{-1}$	q
Space charge	Net concentration of charge per unit volume	C m^{-3}	ρ
Elementary charge	Modulus of the charge carried by an electron	C	e

14.1 Measurement Principles and Parameters

Measurements in atmospheric electricity extend across many different quantities but can be usefully divided into those made for disturbed weather (i.e., thunderstorm) and fair weather conditions. For disturbed weather purposes, a variety of measurement systems have been developed for detection of the lightning discharge itself, optically, electrostatically, or through use of radio frequency emission. In contrast, for fair

weather, when no appreciable charge separation occurs, the vertical electric field and the associated vertical current density are the principal quantities of interest. Fair weather atmospheric electricity has also traditionally included the conduction properties of air, such as the generation, concentration, and properties of the cluster ions it contains. The typical parameters considered are listed in Table 14.1.

14.2 History

Atmospheric electricity is amongst the oldest experimental topics in meteorology, with the globally iconic work of *Benjamin Franklin* (1706–1790) providing a useful date, 1752, with which to define the beginning of the modern era of work. Franklin's international reputation ensured his suggestions for experimental investigations were widely noticed [14.1].

Soon after Franklin's work became known, experimenters found that electrification remained present away from the immediate location of thunderstorms. The astronomer *Pierre Charles Le Monnier* (1717–1799) detected electrification in clear air in 1752 [14.2], and in June 1753, *Guillaume Mazeas* (1720–1775) showed that a silk-insulated 100 m horizontal wire suspended 10 m above the surface would nevertheless acquire charge in dry, nonthunderstorm conditions [14.3]. Later that year, electric charges in a cloudless atmosphere were detected by *John Canton* (1718–1772) [14.4]. Canton developed further apparatus to investigate charges associated with hail, snow, and rain. Remarkable studies were made with the early instrumentation, such as a series of continuous observations by *Giambattista Beccaria* (1716–1781) in Piedmont, north-west Italy [14.5], and 2 years of daily observations made by *John Read* (1726–1814), using a vertical rod mounted above his house in Knightsbridge, London [14.6, 7].

Early measurement instruments often used a flame connected to a mechanical electrometer as a method to acquire the local potential of the air. The need for a method of continuous measurement of the vertical atmospheric electric field was recognized by *Lord Kelvin* (born *William Thomson*, 1824–1907), who developed a continuous recording system based on a *water dropper* sensor for the atmospheric potential with a photographically registering electrometer. The spray of drops generated by the water dropper exchanged charge with its surroundings, ultimately equalizing the potential of the isolated pipe supplying the water spray, which was measured [14.8]. This continuous operation represented a significant advance over the flame probes. The Kelvin water-dropper potential equalizer was widely adopted internationally, including at the top of the Eiffel Tower [14.9], and for use on manned balloons [14.10]. Remarkably, a Kelvin water dropper equalizer is still in routine service at Kakioka Observatory in Japan (Fig. 14.1). Note that the magnitude of the vertical component of the atmospheric electric field E_z is commonly referred to as the *potential gradient* (PG), which is, by convention, regarded as positive in fair weather.

The widespread need for fair weather measurements at many international observatories led to more commonality in the technology used. Kelvin water drop-

Fig. 14.1a,b Potential gradient measurements made using the Kelvin water-dropper potential equalizer, at Kakioka Observatory, Japan. (a) Electrically isolated water-dropper header tank, with electrometer measuring tank potential and (b) water-dropper spray, falling from an electrically isolated tube emerging from the observatory wall. (photo: R.G. Harrison)

pers were used at some sites for PG, but they were superseded by radioactive probes (e.g., at Porto and Lerwick), which permitted continuous measurements without the need for a water supply and associated frost protection. In the second half of the twentieth century, *field-mill* instruments became increasingly commonly used for PG measurements. These avoid the regulatory issues arising from the use of ionizing radiation on radioactive probe sensors. Many commercial field mills exist and are now in use, and some have proved very durable in hostile atmospheric conditions.

Of particular importance for atmospheric electricity measurements was the lead given by the Carnegie Institution, which developed techniques for use on survey ships, and in particular, the *Carnegie*, an oceanographic and geomagnetic survey ship. The Carnegie's cruises between 1909 and 1928, when the ship was destroyed by fire, included routine measurements of air ion concentration, air ion mobility, and PG. The common diurnal variation in PG found across the planet in fair weather conditions is still known as the *Carnegie curve* [14.11, 12].

14.2.1 Early Measurement Technologies

Electrometers are devices designed to measure small amounts of charge. The earliest electrometers were a pair of pith balls, attached to each other by a thread hung centrally on a hook. When the balls became charged, they repelled by an electrostatic force, with a separation distance which was nonlinearly proportional to the charge carried. Absolute calibration is possible, if the arrangement is described in detail, for

example to allow retrieval of the potential from historical measurements [14.13]. Later designs of mechanical electrometers used gold leaf or straw as the sensing elements, again with the mechanical deflection under an electric force measured to obtain the charge. Using delicate bearings and sensitive torsion measurement, precise measurements of small charges could be made, e.g., in a device made by Kelvin, [14.8]. Attaching a mirror to reflect and move a light beam provided a method of amplification and recording for the small changes detected. This approach was used by the recording part of the Kelvin water-dropper system and for the PG measurements on the final cruise of the *Carnegie*.

During the early twentieth century new technologies were developed, and many geophysical observatories internationally adopted methods for atmospheric electricity measurements. The Nobel Laureate *Charles ("C.T.R.") Wilson* (1869–1959) devised a method to obtain regular measurement of the vertical current density and PG using a horizontal plate system, which was deployed at Kew Observatory from 1909, continuing in regular use for almost 70 years [14.14]. There has also been considerable longevity for the operating principles of a portable (*Gerdien*) device designed for air conductivity measurement [14.15], using an aspirated cylindrical capacitor instrument to determine the air conductivity by rate of decay of charge on an electrode exposed to air.

Some of the first sensors for lightning detection used the response of a capillary electrometer to < 20 Hz changes in atmospheric field, recorded on a photographic plate [14.16]. Wilson's investigations focussed

on determination of lightning charge moment, with the signal authenticity and range determined from acoustic methods, limiting the maximum range to less than 30 km. Similar techniques were used to investigate characteristics of the lightning electrostatic field change such as polarity and shape [14.17]. The arrival of early radio-frequency (RF) lightning detection methods in the mid-twentieth century, combined with an extended human weather observation network, were used to investigate lightning signals beyond audible range [14.18]. As instrumentation and techniques developed during the late twentieth century, the electrostatic field change associated with lightning could be used to estimate the location of charges neutralized by lightning in three dimensions [14.19]. Increased sensitivity of electronics and digital filtering enabled the electrostatic field change (below 50 Hz) associated with lightning to be used by commercial instrumentation to estimate thunderstorm range 100 km from the sensor [14.20].

14.2.2 Developments in Measurement Technologies

Developments in electronics provided alternatives to mechanical electrometers. Between about 1920 and 1960, thermionic valves provided the basis for measuring small charges, or measuring from voltage sources that were unable to supply current (i.e., high impedance voltage sources). The thermionic valve operated by deflecting a current from a heated electrode operating at low pressure, through the action of an electric field. By careful construction, the leakage current of the enclosing glass envelope was small, and the voltage to be measured caused deflection of the current with negligible current drawn. This leakage was further reduced by the use of coatings on the electrodes. Valve electrometers were durable electrically, although physically fragile, and well suited to fair weather measurements [14.21].

14.3 Theory

The description of quantities in atmospheric electricity requires consideration of the fair weather parameters and disturbed weather parameters separately. In the fair weather case, the quantities of electric field, conduction current density, and air conductivity can usually be related by Ohm's law, in the absence of turbulence. In the disturbed weather case, the lightning source position and the flash rate are the primary quantities to be determined for operational meteorology, but the lightning currents and surface electric field changes are important for research.

Transistors replaced thermionic valves in the second half of the twentieth century, with the properties of the semiconductor junction defining the usefulness of a device for measurements. In many ways, the field effect transistor closely replicates the operation of a thermionic valve, but its departure from ideal behavior, from, for example, the effect of leakage currents, restricts its use in electrometry. A major limitation is that the most sensitive semiconductor devices tend to be highly restricted in the dynamic range, which can render them badly damaged by overload conditions. For use in atmospheric electricity, when transient conditions can occur unexpectedly, this can be a severe disadvantage. The overall complexity of a semiconductor measurement circuit may, therefore, be dictated by additional protection devices, which must be included for reliability.

Semiconductor electrometers can be used for measurement of charge, current, and voltage. They typically use a standard integrated circuit element—the operational amplifier—which has been optimized to minimize the sensing current drawn, typically in the range of 1 to 10 fA. Operational amplifiers use feedback to provide close to ideal performance, and the feedback element is chosen for the quantity to be measured. If a capacitor is the feedback element, the device can typically measure charge, and if there is a feedback resistor, current can be monitored [14.22]. Voltage measurements and amplification can also be achieved [14.23], which can be extended over a wide range with additional circuitry [14.24, 25]. One important consideration in electrometry is the size of the feedback resistor required. To provide an output voltage of 1 mV from a 1 pA current, a 1 G Ω resistor is required. Generally, stable resistors in the range from 1 G Ω to 1 T Ω can be difficult to obtain. It is possible to synthesize these large resistor values using more standard components, but other disadvantages arise, depending on the circuit configuration.

14.3.1 Fair Weather Fundamentals

In this section, the fundamental measured parameters of fair weather atmospheric electricity are presented.

The *potential gradient* (PG) is essentially the primary quantity considered in fair weather atmospheric electricity. It is a determination of the vertical component of the atmospheric electric field. In fair weather conditions, the electric potential increases positively with height. If the potential is considered to be zero at the surface, the potential in fair weather at 1 m above

the surface is of the order 100 V. The PG near the surface is conventionally considered to be the difference in potential between a point at 1 m and the surface, i.e.,

$$F = \frac{\Delta V}{\Delta z}, \quad (14.1)$$

for F the potential gradient, Δz the difference in height, and ΔV the associated change in potential. A consequence of this convention is that the vertical electric field E_z differs from the PG by a minus sign, i.e.,

$$F = -E_z. \quad (14.2)$$

In fair weather, the PG is, therefore, positive, and the electric field negative. During disturbed weather, the PG can become large and variable, in magnitude and sign. In these cases, the PG responds to local charge separation and induced effects, whereas, in fair weather, it arises mostly from the conduction current passing through the finite conductivity of atmospheric air.

Atmospheric air has a finite electrical *conductivity* because of the presence of molecular cluster ions, formed by the combined effects of terrestrial radioactivity and cosmic ray ionization. Near the surface over the continents, cluster ions are generated by the ionization of air molecules from high-energy interactions, either from gamma emitting sources in the soil or alpha emitting isotopes of radon released through porous surface materials. There is also a small contribution from cosmic ray ionization, which increases with increasing height. Over the oceans, the principal source of atmospheric ionization is from cosmic rays. The typical surface ionization rate, found by an ionization chamber (a fixed volume device in which the rate of charge generation is measured), q is 10 ion pairs $\text{cm}^{-3} \text{s}^{-1}$, about 20% of which is due to cosmic ray ionization. Cluster ions have traditionally been categorized by their electrical mobility, which is their drift speed in a unit electric field. This has led, historically, to the distinction between small (or fast) ions and large (or slow) ions, and further categories have also been proposed. Small ions have a mobility of about $1 \text{ cm}^{-2} \text{ V}^{-1} \text{ s}^{-1}$, and they provide the greatest contribution to the electrical conductivity of air of atmospheric charged particles. Large ions would now be considered to be aerosol particles that have become charged, for example after a collision with a small ion.

The number concentration of small ions in atmospheric air determines the conductivity of air. If there are n ions per unit volume of mean mobility μ , the total conductivity σ is given by $\sigma = 2n\mu e$, where e is the elementary charge. The factor of 2 accounts for the contribution of the positive and negative ions, which are

assumed to have similar concentrations and values of mobility. If there is appreciable asymmetry in the ion properties, the individual contributions of the bipolar ions can be considered separately.

Air conductivity can also be considered in terms of an Ohm's law relationship for conduction, considering the vertical electric field E_z and vertical current density J_z , as

$$J_z = \sigma E_z. \quad (14.3)$$

This only applies if ohmic conduction occurs and will not be valid in other circumstances, for example if there is a turbulent component contributing to the charge transport. Note that, in this equation, the electric field convention is used: the conduction current density is found to be directed downwards in fair weather.

The air–Earth *current density* J describes the total vertical electric current flowing between the atmosphere and the Earth's surface. This current is measured directly using an electrode—often an isolated flat horizontal plate—exposed to the atmosphere. A sensitive and high impedance ammeter attached between the electrode and ground records the current.

In general, this current has four contributing components [14.2]. Firstly, there is the conduction current [14.26, 27]. This is the near-vertical current, which flows between the lower ionosphere and Earth's surface due to the action the global electric circuit [14.28]. The conduction current component can be found indirectly by measuring the air conductivity and electric field, with current inferred using Ohm's law [14.29, 30]. Turbulent motion of space charge within the atmosphere, charged regions in overhead cloud, and lightning transients combine to induce the second prominent component of the air–Earth current, called the displacement current. Whilst this component is induced on the sensing electrode rather than a flow of charge from the atmosphere, the continuous and broad spectra of variability of the atmospheric electric field means this current must be carefully considered in direct current measurements. The third component is that produced by turbulence, whereby ions and charged particles are transported by the movement of air. During disturbed weather, charged droplets, particles, or pellets falling on the electrode will produce the fourth component, referred to as the precipitation current. If the collecting electrode has sharp edges, an additional disturbed weather component may also be produced under a strong electric field, where point discharge (corona) is initiated. Point discharge can produce currents several orders of magnitude greater than the conduction current [14.19], so electrodes need to be smooth to avoid such contamination from additional current sources.

Of all these components, it is the conduction current (or rather the conduction current density) that is of most significance for the investigation of the global electric circuit, due to its origin from the potential difference between the ionosphere and surface. The small magnitude ($\approx 1 \times 10^{-12} \text{ Am}^{-2}$) of the currents brings with it a requirement for maintenance of extremely good electrical insulation between the electrode and ground under all weather conditions; the need to eliminate other unwanted current components makes the conduction current density a challenging parameter to measure.

14.3.2 Disturbed Weather Lightning Detection

In contrast with the fair weather current, the current that flows as a result of a lightning discharge is very many orders of magnitude greater. Methods of remote detection of lightning are discussed here, using radio frequency, optical and electrostatic techniques, as well as the acoustic energy generated.

The complete process of charge transfer during a single lightning discharge is called a *flash*. A flash neutralizes a portion of charge within a thunderstorm, which can be readily identified by a sharp change in the cloud's electrostatic field over a typical period of 0.2 s, followed by a much slower recovery of the order of 100 s, as electrification mechanisms within the cloud replace the neutralized charge. The complete discharge process during a flash does not produce a smooth current flow, but is, instead, composed of several discrete surges of current lasting a few tens of milliseconds, referred to as strokes. After the initial electrical breakdown of the air, a lightning channel is formed by a trail of electrons, called a leader. These leaders are only weakly luminous and will split and change direction after several meters in steps. These steps in channel propagation give rise to the name of the first stage in a lightning flash—the stepped leader. Once the lightning channel has been formed by the leader, current surges along it in discrete pulses or *strokes*. When the lightning channel is from the cloud to ground (CG), the initial stepped leader creates a pathway for the return stroke. This stroke is often very powerful, generating a typical peak current of the order of 10 000 A and occasionally exceeding 200 000 A. Currents of this magnitude produce a bright channel and quickly heat the air, producing the shockwave that is recognizable as thunder. More commonly, a lightning channel remains within the cloud, and the resulting strokes are termed intracloud (IC) or cloud-to-cloud (CC). Charge transfer between the cloud and nearby cloud-free air also occurs, as well as leaders, which originate from the ground, transferring charge to the cloud overhead and

are consequently termed *upward* or ground-to-cloud lightning. Lightning strokes can be of either positive or negative polarity. The polarity of a cloud-to-ground stroke is determined by the charge it lowers from the cloud to the ground. Since the base of a thundercloud is normally negatively charged, most CG strokes are of negative polarity (–CG). CG strokes with positive polarity tend to originate near the top of the cloud, where a large reservoir of positive charge is often found. A positive cloud to ground stroke (+CG) is, on average, the most powerful type of lightning stroke on Earth, responsible for significant damage and emission of radio signals that can be detected thousands of kilometers away. For radio detection of lightning, it is the stroke that is the fundamental property detected, so the location and count rate of radio-based detection systems will by default relate to strokes, not flashes. Since a single flash is typically composed of 2 to 5 (and occasionally more than 20) strokes, it is important to consider that other detection systems such as human observation or electrostatic techniques will consider lightning discharges in terms of complete flashes. This can, and often does, lead to confusion when comparing the output of different types of lightning detection techniques.

Radio Frequency (ULF to VHF)

Lightning emits a broad spectrum of electromagnetic radiation, which can be used for location and remote determination of the discharge properties [14.31]. Since different components of a lightning flash emit radiation with different effectiveness at different frequencies, researchers can optimize their radio receivers to have greatest sensitivity to bands within the spectrum according to their area of interest [14.31–33] with research on radio emissions spanning ultra low frequency (ULF) to very high frequency (VHF). For example, the initial ground-seeking leader stroke (stepped leader) and short, in-cloud leaders tend to emit most effectively in the VHF band, whereas the subsequent visible, high current surge along the leader's channel associated with the powerful return stroke emits the most strongly in the very low frequency (VLF) band [14.34]. Such differences are important factors in determining the maximum range and detection efficiency of radio-based lightning location instrumentation [14.32].

Whenever electrons are accelerated, electromagnetic radiation is produced. The greater the acceleration and number of electrons involved, the greater the energy radiated. The rapid acceleration of numerous electrons in a lightning channel at the start of a return stroke will, therefore, be expected to generate a signal of high power, albeit for a duration of only a few milliseconds [14.31]. The ionized lightning channel can be

Fig. 14.2 Reflection of VLF waves by the ionosphere

considered as an antenna, the length of which influences what frequency will be most effectively radiated. The ≈ 10 to 100 m steps in a channel of the downward-propagating stepped leader prior to a cloud-to-ground return stroke act as a set of similarly-sized antennas. Such antennas radiate energy most effectively at wavelengths twice their length, equating to typical peak emissions of order 10 MHz in the HF band. Steps energized by weak intracloud strokes can be even smaller, with length scales under 10 m and emitting the most strongly in the VHF band [14.35]. Once a return stroke is initiated by contact with an upward streamer near the ground, a surge of electrons propagate back up the ionized channel of the stepped leader. This channel can be several kilometers long, so will radiate most effectively at much lower frequencies than the stepped leader or intracloud stroke. These near-vertical, long channels act as monopole antennas above the conductive ground, emitting most effectively for wavelengths four times their length, typically around 10 kHz, in the VLF part of the radio spectrum [14.33, 36].

The ionosphere is an electrically conductive layer of the atmosphere beginning at an altitude between 60–90 km, depending on properties such as solar intensity. The ionosphere acts as an effective reflector of very low frequency radio signals such as those from lightning return strokes. Powerful VLF signals can propagate over thousands of kilometers through the atmosphere, since they are reflected between the ionosphere and surface instead of being strongly absorbed or lost to space (Fig. 14.2, [14.34, 37]). Such propagation properties and powerful emissions from return strokes are exploited by long-range lightning location networks, where VLF receivers are deployed across a large region and capable of locating lightning over continent-scale regions, or more [14.38–40]. Lightning is located by comparing the arrival time differences of the same signal received at multiple receivers, some-

times in combination with triangulation using magnetic direction finding (Fig. 14.2). The location accuracy of such long-range VLF arrival time difference (ATD) networks depend on the validity of their signal propagation model, receiver baseline (spatial density of receivers), and how accurate they can time the arrival of the same lightning signal arriving at the receivers (e.g., [14.38]). In reality, median location accuracies of 1–20 km are typical of this long-range location method, although higher density continental-scale networks with higher frequency upper limits (LF/VLF) can achieve median location accuracies of the order of 100 m. The necessity to use VLF for long-range lightning location means that such networks are normally strongly biased to CG lightning stroke detection, although most are also capable of locating strong intracloud activity as well. Shorter baseline, higher density networks incorporating the LF band have been demonstrated to detect, and discriminate between, both CG and IC/CC lightning strokes with peak currents as low as a few hundred amps.

In addition to accurate lightning location using VLF/LF networks, it is possible to detect the shape of individual lightning channels in three dimensions using a short-baseline (of the order of 10 km) network of VHF interferometers [14.35]. Such networks are tuned to the weaker components of the lightning discharge process and cannot exploit ionospheric reflection, so their range is little more than line of sight, at approximately 200 km. The VHF network technique does, however, allow exceptional detection efficiency and location accuracy (of the order of 10 m) over the relatively small area covered, making it popular with lightning research groups. In addition to scientific research, VHF interferometry is also used on some regional-scale lightning location networks for the purpose of total lightning (CG, IC, and CC) detection, especially when detection of weak IC strokes or initiation height is important. The short baselines required normally limit this tech-

nology to coverage of smaller countries or regions compared to the more continental-scale VLF/LF networks, although some near-global network providers incorporate VHF receivers, if they have the capability of deploying a suitably dense network of receivers over a wide geographical area. VHF signals from lightning can propagate through the ionosphere, where they can also be detected by space-based lightning detection instrumentation for scientific research.

The proximity and direction of lightning strokes using a single radio receiver is possible and can be a useful indicator of local thunderstorm activity. The range of such instrumentation is normally limited to a few hundred kilometers, and location accuracy is generally poor compared to using a network due to the assumptions required on lightning signal characteristics and propagation. False alarms can arise due to nearby anthropogenic sources of radio transients (e.g., [14.37]) and can be removed by requiring corroboration from multiple receivers in a network. The presence of ferrous material and conductive paths where currents can be induced at a site can generate systematic and angular-dependent errors in lightning direction estimation from single-site receivers of up to 30°, unless these errors are determined and accounted for by prior comparison with an independent method of lightning location. Range is normally estimated by comparing the amplitude of one or more radio frequency bands, although large uncertainties exceeding 10 km can result from the natural variability of lightning radio emission characteristics.

Given there are typically 2000 active thunderstorms on Earth at any time, the global atmosphere is subject to near-continuous excitation by lightning. Larger lightning strokes radiating strongly below VLF frequencies act to excite the waveguide between the surface and ionosphere, causing it to resonate. The fundamental frequency of this resonance is 7.8 Hz in the extremely low frequency (ELF) band, with six harmonics below 50 Hz [14.41, 42]. These near-continuous peaks are called *Schumann resonances*, and since they are a global signal, they can be measured from any location on Earth [14.43]. Their small amplitude can limit detection to sites with low background electrical noise, where the diurnal cycle of the resonance amplitude can be used to infer general characteristics of global lightning activity, such as diurnal and seasonal variability. Both electric and magnetic field components of Schumann resonances have been used for lightning, ionospheric, and radio propagation research (e.g., [14.37]).

Electrostatic

Neutralization of charge during a lightning flash occurs over a time period of approximately 0.2 s, producing a step-change in the electrostatic field of a thunder-

storm [14.17, 18]. This step is gradually removed as the cloud is re-energized, producing a recovery curve lasting for more than a minute (Fig. 14.3). Due to the image effect of the conductive surface below, the change in charge can be represented as a vertical dipole, of length twice the height of the neutralized charge region above the ground [14.16]. The total charge neutralized by a lightning flash can, therefore, be given in terms of charge moment when using quasi electrostatic measurements. Whilst the change in electric field measured at the surface can exceed 100 kV m^{-1} in the first second after a flash within a few kilometers, this dipole field quickly attenuates with distance, with magnitude proportional to the inverse cube of distance from the dipole. As a consequence, electrostatic lightning detection is usually limited to a range of less than 100 km before any signal is lost to background noise. Such a distance is, however, sufficient for warning of local thunderstorm activity around a site, with automatic electrostatic lightning detection and ranging instrumentation available commercially [14.44]. Every lightning flash will produce a step change of the thunderstorm electric field, so this method of lightning detection from a single sensor is capable of detecting all forms of lightning activity (CG, IC, CC) within a few tens of kilometers from the storm with very high detection efficiency. Providing that the electrostatic field is sampled at a rate of at least 10 Hz (ideally 100 Hz), it is possible to estimate the distance to the lightning flash using the maximum electric field change and an assumption of the charge moment. Note that such sampling frequencies limit the time resolution of the lightning discharge to the flash, not stroke, level. Higher sampling rates risk contamination from the electromagnetic component of the emission, and lower sampling rates risk undersampling of the signal, causing the true magnitude of electric field change immediately following the flash to be underestimated.

Whilst using a fixed value for lightning strength to estimate the distance to a flash based on signal amplitude would produce unacceptably large errors for a radio-receiver, such an assumption is more acceptable when using electrostatic detection. This is due to the inverse-cubed reduction of signal strength with distance for the electrostatic dipole field, which acts to limit the effect of natural variability in lightning charge moment on range uncertainty compared to radio peak amplitude, which reduces by a lower inverse power of distance (between 1 and 2 depending on propagation characteristics). For example, it is possible to estimate the distance of a 20 km flash with a typical uncertainty of 5 km using the electrostatic field change alone. The flash direction cannot be readily determined from the magnitude of the electrostatic signals alone.

Fig. 14.3 Potential gradient (PG) changes associated with lightning flashes approximately 10 km away, recorded by a JCI 131 field mill on August 25, 2005 (after [14.45])

Optical

In addition to qualitative lightning detection by human observation, optical sensors can be used to monitor lightning activity from the surface, atmosphere or space [14.46]. Selecting a wavelength of strong emission by lightning compared to sunlight allows optical observation of lightning even during the day. The wavelength of choice is at 777.4 nm. This corresponds to the optical emission of oxygen, excited in the plasma of the lightning channel. Optical detection is not generally used in isolation for automated ground-based thunderstorm warning systems but is instead used as an independent confirmation of nearby lightning for single-site detectors, where electric or radio noise can trigger false alarms. Obscuration of the optical signal by nearby objects and cloud limit the effectiveness of ground-based optical detection for distant lightning. An important use of optical lightning detection is on satellites, where the ability of an optical signal to pass through to space largely unaffected by the upper atmosphere is of benefit compared to lower frequency radio signals. Continuous optical lightning detection from polar-orbiting satellites has been available since the mid-1990s, with this proven technology being deployed on geostationary platforms as part of combined atmospheric monitoring missions from the late 2010s. The brightness of the 777.4 nm emission within thunderclouds can be mapped with high resolution cameras on board geostationary satellites to estimate lightning location in realtime over continent-scale regions at a spatial resolution of 5 km for low latitudes, although closer to 30 km at high latitudes due to the less favorable viewing

angle. An advantage of space-based optical detection of lightning is the ability to observe weak intracloud flashes near the top of the cloud, which can sometimes be a precursor for more intense lightning activity. However, the optical signal from strokes nearer the cloud base can be strongly attenuated by the cloud above, leading to the possibility of reduced detection efficiency of such events, especially during bright sunshine.

Acoustic

The explosive heating of air adjacent to the hot plasma within a lightning channel produces the shockwave that is familiar as the sound of thunder. The longest archive of thunderstorm activity extending over two centuries is provided by *thunder day* records, where the occurrence of thunder heard by a human observer was recorded by a weather service or a weather diarist. Thunder can only be heard within approximately 20 km of the lightning flash, if the site is quiet, and the observer is outside, with a maximum range of more like 10 km for indoor environments. Thunder day records are, therefore, of variable quality, depending on the observer's ability to perceive the thunder, but are nonetheless a valuable addition to long-term climatological records, especially prior to the commencement of automated lightning location networks in many developed countries during the 1980s. A particular feature, despite their simplicity, is that the detection sensitivity is constantly providing stable records for climatology, whereas lightning networks are generally regularly upgraded.

The lightning range can be estimated to within a few hundred meters by manually recording the time dif-

ference between the visible flash of lightning and the subsequent arrival of thunder, using the speed of sound in air for the environmental conditions, for example 343 m s^{-1} at 20°C . This range includes the height of the source too, so high-altitude intracloud flashes may be difficult to hear at ground level despite them occurring overhead. Sound propagation effects due to temperature gradients and echoes will introduce uncertainty in range estimation. The short range and difficulty in automatically discriminating between thunder and other sources of similar noise mean that this technique is not used for automatic lightning detection and ranging.

14.3.3 Precipitation Electricity

Convective precipitation is capable of producing strong and rapidly varying electric fields at the surface, due to charge carried to ground on precipitation. Although the total charge transferred between the cloud and ground by precipitation is small relative to other mechanisms, such as lightning and point (corona) discharge [14.47], it is considered as a possible mechanism for the triggering of lightning [14.48].

Raindrop Charging

The first continuous measurements of the electrical charge on rain were conducted over 100 years ago by *George* (later *Sir George*) *Simpson* (1878–1965) [14.49] in Simla, northern India, during the monsoon seasons of 1907–1908. Simpson's apparatus consisted of an electrically insulated rainwater collector connected to a recording electrometer, which registered the charge accumulated on the collector every 2 min. This was converted to a charge per cubic centimeter of rainfall by measuring the collected rainwater volume using a tipping-bucket rain gauge. Simpson reported that 71% of the rainfall associated with monsoon showers and thunderstorms was positively charged, at typically 300 pC cm^{-3} water, generating a typical current density to Earth of the order of 1 nA per square meter. These values are in accordance with more recent observations [14.50]. He also noted that although the heaviest rainfall during the storm was positively charged, there was no clear relationship between charge magnitude and rainfall intensity. The reason for this charge was considered by Simpson to be the result of droplet breakup in strong updrafts, with the falling raindrops retaining a positive charge and the liberated negative ions or smaller droplets traveling upwards in the updraft.

Simpson's explanation for the origin of charged rainfall was contested by C.T.R. Wilson, who instead proposed that the predominant positive charge on convective rainfall resulted from the selective cap-

ture of positive ions by the raindrops as they neared the ground [14.51]. According to Wilson, the negatively charged base of cumulonimbus clouds attracted an upward flow of positive ions. The raindrops falling below this cloud base were polarized by the negative charge above them, resulting in a negative charge on their lowest surface. The positive ions were attracted to the negatively charged drop's underside, causing the drop to acquire an overall positive charge by the time it reached the ground. The charged rainfall measured at ground level was, therefore, considered by Wilson to be the result of the charge distribution within the cloud, rather than the cause, as previously assumed. Nonetheless, Simpson explained his later finding of positively charged regions near thunderstorm cloud bases as being the result of raindrop breakup in strong updrafts [14.52]. The long-standing discussion between Wilson and Simpson on precipitation and thunderstorm charge structure presents one approach to summarizing the development of the subject [14.53].

Wilson's proposed ion-capture mechanism for raindrop charging was recognized by *Simpson* when he discovered that the charge on rainfall at the surface often mirrored that of the electric field, which, in turn, related to the charge near the cloud base [14.54]. This *mirror image effect* was thought to be due to the raindrops charging by scavenging of ions liberated from the surface as a result of point (corona) discharge during the strong electric fields experienced under a cumulonimbus. Since these ions would be of the opposite polarity to the charge of the cloud base and would increase in number with increased electric field, the raindrops they attach to would also be oppositely charged to the cloud base, but of proportionate magnitude. The mirror image effect has been verified by subsequent observations, including ones using modern sensors and techniques (e.g., [14.55, 56]). Although the effect is generally observed, local sources of space-charge can partially mask the inverse correlation under certain circumstances [14.57]. Recent studies indicate that raindrop charge is highly responsive to the ambient electric field, changing within seconds of a field polarity reversal. This calls into question the traditional explanation of selective ion capture by the raindrops as being the primary cause of the mirror image effect [14.54], since a drop is unlikely to scavenge sufficient ions in $\approx 1 \text{ s}$ to significantly affect its charge [14.55].

Precipitation current instrumentation has been based on a conductor shielded from external electric fields by a grounded wire mesh and connected to a sensitive ammeter [14.55, 56, 58]. A funnel-shaped conductor has also been used [14.55, 56], with an effective collection area of 0.2 m^2 . This instrument did not

contain any sharp protrusions to avoid contamination by corona discharge from strong electric fields during overhead thunderstorms. The current from the collector was logged at 50 Hz, with rainfall current, not individual drop charge, being reported. Rainfall intensity and drop size statistics were derived from a nearby distrometer. The direct measurement of precipitation current used by Simpson, and Soula and Chauzy, differs from the induction methods originally devised by [14.59] for measuring the terminal velocity of water drops in the laboratory and later applied to measuring the size and charge of rain drops in the atmosphere [14.60, 61]. The induction method requires the raindrop to pass through a loop conductor, where a current is induced and recorded by a sensitive ammeter. The drop charge is calculated from the induced current and has the advantage of preventing any effect of charge separation from drop breakup on the measurements [14.47].

As the number of charged rainfall observations increased throughout the twentieth century, it was apparent that although the expectation of positive charge during the most intense part of the storm was generally observed, the polarity of convective rainfall can show considerable variability between different rainfall events. This may be due to variability in the strength of updrafts, which have been linked to the polarity associated with graupel, an important charge carrier and common source of rainfall in convective clouds [14.50]. The close association between updraft speed and cloud electrification (and, therefore, precipitation charge) has been established by theoretical and experimental studies (e.g., [14.50, 55, 62, 63]), with heavy rain showers with weak updrafts producing significantly less precipitation current than similarly intense showers containing stronger updrafts.

A further complication in the assessment of rainfall charge is the question of how representative the sampling site is to the spatial distribution of rainfall intensity of the storm. This becomes especially important for complex, multicellular convective systems, with localized anomalies in rainfall intensity or hail shafts being easily missed during their passage over a sampling site.

14.4 Devices and Systems

Fair weather measurements seek to determine the conduction properties of air and the electric field, in the absence of local charge generation. The duration of fair weather conditions varies between sites, and, hence, some durability is required for the apparatus to be continually available for when the fair weather circumstances arise.

Snow Electrification

Early research by [14.64, 65] found that dry snowflakes were usually negatively charged, with rainfall and wet snow found to be generally positively charged. In both cases, increased precipitation rates produced large fluctuations in PG measured at the surface. Ice crystals below the -10°C isotherm height were reported by [14.50] to be of negative charge in the mature stage of a snow shower, with the graupel being positively charged. This is consistent with dry snowflakes reaching the surface with a negative charge. The polarity of ice crystals and graupel reversed at altitudes colder than -10°C .

Measurements of PG by [14.66] during a snow shower found that the PG increased during the heaviest portion of the shower, consistent with a lowering of negative charge to the surface by the snowflakes. Unlike during convective rainfall, the standard deviation of PG sampled at 1 Hz during the snow shower was low; [14.45] interpreted this as primarily due to the lower fall speed of the snowflakes, reducing short-period variability as the flakes moved slower past the sensor compared to raindrops, combined with a greater time for charge exchange with the air (and possibly each other), reducing the spatial and interflake charge variability.

As for sand and dust storms, wind-blown snow can acquire charge through triboelectrification, perturbing the fair weather electric field at snow covered sites, such as Antarctica [14.67].

14.3.4 Corona and Point Discharge

In strong electric fields, such as beneath thunderclouds, vertically-aligned rods and other objects may go in to corona, i.e., the air around the tip of the object may breakdown locally, allowing a large (microamp) current to flow. If the tip of the object is pointed, the electric field will be intensified, and breakdown will occur under a smaller applied field. The current produced can extend over a wide range, so a logarithmic response current ammeter is appropriate (e.g., [14.68]). For atmospheric conditions, temperature compensation is usually required or the possibility of comparison of two techniques [14.69].

14.4.1 Fair Weather Devices and Systems

For fair weather measurements, a typical atmospheric electricity station will include sensors and instruments for some or all of PG, air conductivity, and vertical current density. The PG is commonly obtained with a field mill device, but its calibration depends on having an-

other instrument for comparison. Often, a long wire (or *passive* wire, as there is no active method used to enhance its electrical coupling to the atmosphere) is used for this, as it presents minimal distortion of the electric field. A passive wire works by acquiring the local potential of the air through collision of air ions and falls into the general class of potential equalizer devices.

Potential Equalizers

Measuring the local potential of air requires exchange of charge between a measurement electrode and the air around it, ideally as rapidly as possible. Methods used historically for this include the flame probe, in which the good electrical conductivity of a flame is used to enhance the charge exchange, and the Kelvin water dropper (Sect. 14.2), which increases the area of charge collection by using a large number of small droplets. Radioactive potential equalizers are also effective in greatly increasing the local air conductivity and have been used extensively in the past but are now rarely used because of the radiological hazard they present.

The long or passive wire antenna is probably the most commonly used potential equalizer. In its basic form, it consists of a thin uninsulated horizontal wire stretched at about 1 m above the ground between insulators on two short masts (Figs. 14.4 and 14.5). The use of a thin wire and masts spaced well apart from each other ensures that the distortion of the atmospheric electric field is negligible, and, hence, the passive wire provides a reference method for calibration. For it to operate satisfactorily, considerable attention must be given to the quality of the insulation at each end, in order that the leakage from the antenna is considerably less than the current flowing onto the antenna; [14.70] estimated that the requirement on the leakage current is that it is about 2 fA. With a potential difference across the insulator of typically 100 V, this is a very demanding requirement. However, this can be achieved by using an additional insulator at each end with a short *guard* wire between the main insulator and the secondary insulator. If this guard wire is driven to have a potential close to the measured potential (e.g., to within a few mV), the potential difference across the main insulator is greatly reduced, by a factor of $\approx 10^5$. This approach requires a wide-range bipolar electrometer able to drive an external device to a measured potential, which the [14.21] and [14.70] designs implemented using thermionic valves, and for which the [14.22] design used transistors.

Ion Measurements

Measurements of atmospheric cluster ions typically operate using a deflecting electric field to collect the ions on an electrode and the current flow measured. If the rate of transport of air to the electrode is known, the

Fig. 14.4 Passive wire antenna. A length of uninsulated wire is stretched between two support masts, using good quality insulators. The potential on the wire is measured using an electrometer voltmeter. (Typical dimensions: length of long wire 20 m, support mast height 1 m)

Fig. 14.5 Passive wire apparatus showing the thin and long sensing wire emerging from a PTFE insulator. (photo: A.J. Bennett)

number concentration of ions can be obtained, under the assumption that the ions are singly charged, due to the difficulty in bringing an additional charge to an existing polarized region around the ion. A cylindrical geometry is well suited to this approach (Fig. 14.6), e.g., following the design of *Hans Gerdien* (1877–1951), as the air can be driven along the cylinder mechanically, with a radial electric field applied to drive the ions to a central coaxial electrode.

The bias voltage is chosen so that, for ions of the mobility required to be measured, an ion can be deflected to reach the central electrode within its transit

Fig. 14.6 Concept of the operation of a cylindrical ion collector, with the outer electrode grounded. A bias voltage is used to establish a radial electric field. Ion-laden air is driven through the system, and ions are deflected by the electric field and collected at the central electrode, and the integrated current measured

time through the system. Ions with mobility less than the critical value determined by the electric field chosen will also be captured. By switching the polarity of the bias voltage, either positive or negative ions can be collected. There are many variations on the basic principle, for example using a sheath of air to define the capture distance more precisely, or by using a segmented electrode with a range of local electric fields.

The programmable ion mobility spectrometer or PIMS [14.71], allows a range of bias voltages to be programmed to provide a sweep across the positive and negative ion mobility spectra (Fig. 14.7). From these, the bipolar ion concentrations can be determined. Continuous monitoring of the ion mobility spectrum can, therefore, be achieved. In this and many ion counters, it is necessary to compensate for temperature variations and the error currents from the impact of charged particles, which is independent of the deflecting field applied.

Air Conductivity

Air conductivity can be determined using charge relaxation methods or by direct ion counting and calculation. In the relaxation approach, the timescale τ of charging (or discharging) of an electrode exposed to air is related to the total conductivity by $\tau = \epsilon_0/\sigma$, where ϵ_0 is the permittivity of free space. Electrode configurations that have been used for this in the past include a passive wire, which is earthed and then allowed to acquire the local electric potential until it ceases to change, or the central electrode in an aspirated device. The classical device designed by *Gerdien* [14.15] used cylindrical geometry, a manually driven fan, and a mechanical electrometer, for which the charge relaxation time was determined. The PIMS instrument can operate in both conduction and voltage decay modes, allowing internal consistency tests.

Good agreement has been found between a PIMS instrument used to determine the air conductivity by an ion counting method and compared with the relaxation method for a passive wire antenna allowed to charge naturally [14.72, 73].

Current Density

The most direct measurement of the air–Earth current density measurement requires the electrical isolation of a portion of the ground and apparatus to measure the current flow to Earth [14.26]. In reality, the isolated surface can be emulated by a conducting plate electrode mounted flush with flat, open ground, so that the ambient electric field (and, therefore, the air–Earth current) remains unaffected by the presence of the apparatus (Fig. 14.8). The balance between sensitivity and practicality requires that the surface area of this plate is normally between 0.1 and 1.0 m².

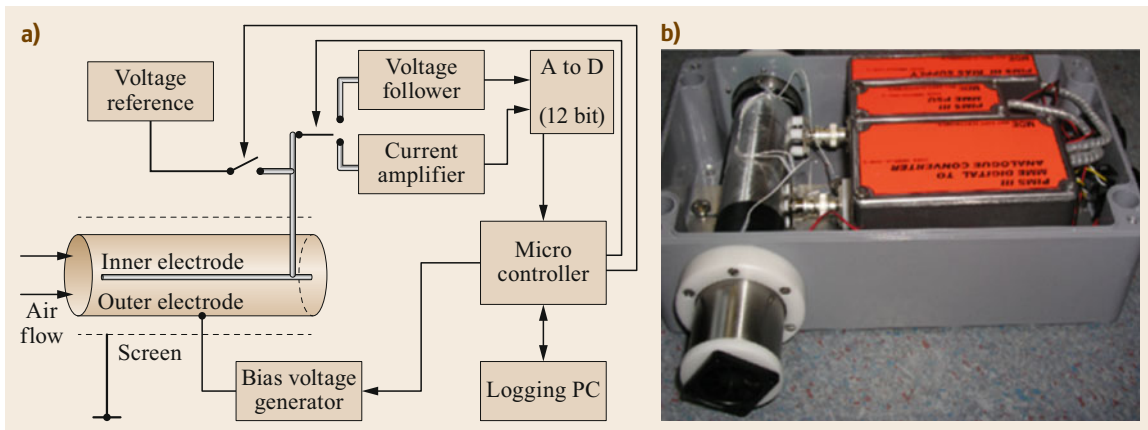

Fig. 14.7a,b Programmable ion mobility spectrometer (PIMS), (a) block diagram form (after [14.71] with permission of AIP Publishing); (b) the fan providing the forced ventilation is at the foreground end of the cylindrical sampling electrodes on the left (photo: R.G. Harrison)

Fig. 14.8 Concept of a plate electrode measurement for the vertical conduction current density. A horizontal plate is positioned slightly above the Earth's surface on insulators and the current flowing from it to the Earth's surface measured

A major challenge in continuous measurements of this current is the need to prevent leakage currents greater than a few tens of fA providing alternative conduction routes, especially in damp conditions. This requires high surface resistivity for all structures supporting the plate and the connection between the sensing electrode and the ammeter. Materials such as PTFE satisfy this requirement, although consideration must be made to the prevention of lower resistivity contaminants and moisture on the surface of the insulators. A guard ring surrounding the sensing electrode may also be used. The guard is electrically isolated from the sensing electrode it encloses but held at the same voltage to prevent leakage currents [14.26, 74]. A temperature-stable (or at least compensated) ammeter is required, which is sensitive to currents of the order of 10 fA, given the typical air–Earth current density of 1 pA m^{-2} . The current flowing can be measured by using a resistor to ground, but it is preferable to keep the plate itself at Earth potential, which can be achieved using a transimpedance amplifier with a high value feedback resistor, usually in the gigaohm range. Depending on the required temporal sensitivity of the measurement, a parallel capacitor may be added to provide passive low pass smoothing.

During fair weather, precipitation and often turbulent components of the air–Earth current density are insignificant, leaving the conduction and displacement components. Whilst the displacement current density is of use when investigating lightning or local variability in the boundary layer, it is the conduction component that is of greatest importance for the study of the global electric circuit [14.2, 26]. As a consequence, air–Earth current density instrumentation needs to eliminate or separate the displacement current component from conduction during fair weather. A method commonly used for continuous measurements due to its simplicity is to select the RC (resistor-capacitor) time constant of the sensor to that of the atmosphere (of order $1 \times 10^3 \text{ s}$) as first described by [14.75]. This allows the displacement current to pass to ground through the capacitor, whilst the conduction current passes through the input resistor

Fig. 14.9 Measurement of the conduction and displacement current densities using the combined two electrodes of different geometry in a GDACCS instrument. (photo: A.J. Bennett)

of the ammeter. Whilst simple to construct, a major disadvantage of this method is the required assumption of constant atmospheric relaxation time and, therefore, air conductivity. In reality, air conductivity varies significantly according to atmospheric aerosol concentration and ionization rate. An alternative method that does not require this assumption is to use two different sensing electrodes of different geometry ([14.72, 76], Fig. 14.9). The magnitude of the displacement current is proportional to the surface area of the electrode, whereas the predominantly vertically flowing conduction current is proportional to the electrode's horizontal cross sectional area. The conduction current component can, therefore, be isolated by subtracting the measurement made by two colocated electrodes of equal surface area but of unequal cross section.

In hostile conditions, it is important to ensure that the insulation is maintained, which is particularly difficult if there is blowing snow; *Burke and Few* [14.77] developed a suspended spherical sensor that allowed the conduction current to flow into its upper hemisphere and out of the lower hemisphere. The electrometer circuit was entirely self-contained within the sphere.

Long-wire (passive) antennas have also been used to measure the conduction current density, but the effective capture area must also be known, either by independent calibration or calculation (e.g., [14.78]).

Electric Field Machines

Electric field machines represent a class of measuring devices that use the motion of an electrode in some way to determine the electric field (Fig. 14.10). This approach is probably most commonly implemented in the electric field mill. A field mill operates by alternately exposing and covering an electrode mechanically. As the electrode is exposed, the change in the electric field

Fig. 14.10a–c Designs of an electric field mill: (a) Chilworth JCI131, (b) Boltek EFM100, (c) Campbell CS110. (photos: R.G. Harrison)

it encounters causes a charge to be induced. If the process is repeated rapidly, the current induced can be measured, which is related to the electric field to which the electrode is exposed. Furthermore, when the electrode is covered by the rotor, it is screened from the field and in a zero field environment. This gives a measure of the various offsets in the electronic system, which can be removed. Using a rotary geometry, a compact and durable instrument can be produced. Phase sensitive detection of the signal is usually employed, with the position of the rotor determined by optical or magnetic switches.

The induced current will be alternating at the frequency of the chopper's exposure to the atmosphere, and the magnitude of the signal is proportional to the atmospheric electric field. The necessity for moving parts makes this instrument relatively high powered compared to other sensors (a few hundred mA from 12 V supply for a rotating chopper) and subject to maintenance. The internal parts need to be kept electrically insulated, as the induced current to be measured is very small (of the order of 1×10^{-12} A). The field mill will measure the DC electric field of the atmosphere and will be sensitive to all variability at frequencies lower than the chopping speed, which is usually ≈ 200 Hz, although single rotations are normally averaged to reduce noise.

The alternate covering and uncovering of the sensing electrode (or stator) is achieved by mounting it beneath a rotating shielding electrode (or rotor), with sufficiently large gaps to prevent water from shorting out the electrode. The instrument can be used facing up or down. There are variations on the basic principle for specific applications, such as cylindrical electrodes rotating around an axis for dust sampling or rotating sampling spheres for use on balloons in thunderstorms,

to minimize instrument corona effects. Durability is improved by modern brushless design [14.79].

14.4.2 Disturbed Weather Systems

Methods for remote lightning detection developed during the later part of the twentieth century, which, through the use of networked systems, allowed the rapid dissemination of information about storm systems. Because a single sensor can detect remote lightning sources and monitor even greater areas in the case of satellite-carried instruments, regional lightning detection systems can be implemented relatively cheaply.

Meteorological Services

Almost all national meteorological services implement lightning detection networks or have access to the data provided by them. Forecasters find the additional information about convective storms useful, as the presence of lightning identifies active convection. For some specific circumstances, notably in Iceland, detection of lightning may provide the first information about the existence of an eruption plume from a volcano.

Stand-Alone Warning Systems

Where a situation requires local thunderstorm detection without the need for an internet connection or data provided by a third party, single-site, stand-alone warning systems are available. Aside from human observation, commercial stand-alone detectors use either radio or (quasi) electrostatic techniques, sometimes combined with an optical receiver.

Lightning is detected mainly by the strong radio-frequency pulse produced by the lightning channel. The pulse covers the entire radio frequency (RF) but has a peak emission at approximately 10 kHz in the

very low frequency (VLF) part of the spectrum. Depending on the frequency chosen, an RF detector may be biased to reporting only cloud-to-ground lightning flashes. A stand-alone RF detector will need to recognize the lightning pulse from background noise and, so, usually incorporates either crude filtering or a microprocessor to distinguish characteristics of the signal, such as pulse length, rise time, etc. The bearing of the emission can be reported using a magnetic induction loop. The simplest RF detectors simply report a suspected lightning pulse and use the signal-to-noise ratio, pulse characteristics, or dual frequency input to estimate the distance to the strike, with no information on bearing. The trend of lightning pulse amplitudes is used to estimate whether the storm is approaching or retreating. These sensors are generally inexpensive and highly portable, although of varied performance. Lightning flash distance estimates using a single site, stand-alone RF sensor are inherently inaccurate due to the natural variability of lightning peak currents and the power falling by only the inverse, or at best square, of distance. Pulse analysis and/or dual antennas of different frequency response provides an improvement to range estimation based on RF amplitude alone.

Sensors that incorporate orthogonal magnetic field antennas to estimate strike bearing from the site generally provide a reasonable estimate of bearing provided that they are located away from strong magnetic field/ferrous sources or not in complex terrain, which can distort the magnetic field of the signal. When magnetic direction finding from a single sensor is combined with the inaccurate distance estimates, the resultant storm location on the map tends to be scattered along the bearing line, making storm location from a single RF sensor rather ambiguous in these situations. RF sensors will always be subject to anthropogenic noise common in the radio spectrum, even down to VLF. Sources of noise originating from sparks from electric motors, power transmission, transportation etc., are particularly troublesome, as they can display similar characteristics to a lightning pulse or raise the noise floor to an unacceptable level. Lightning detectors measuring the magnetic field component (most commonly used) have the advantage that they can operate indoors and when covered, but they may be more subject to anthropogenic noise, as the magnetic component of the electromagnetic radiation will penetrate building walls more effectively than the electric field component. Even the signal from nearby computers and mobile phones has been found to produce false alarms in simple stand-alone RF detectors. Their key advantages over other systems are often related to price, ease of use, and portability rather than performance.

Electrostatic lightning detection is defined here as any measurement technique using variability in the

atmospheric electric field below 100 Hz, where the electromagnetic component of local lightning emission is small compared to the amplitude of the electrostatically generated field change. An electric field change resulting from lightning is the oldest method of quantitative lightning and thunderstorm electrification determination ([14.16, 26]), with its use in thunderstorm research and warning still used in the twenty-first century (e.g., [14.44, 80]). Stand-alone electrostatic methods exploit the large and rapid change in electric field produced by rapid transfer of charge by nearby lightning. The electric field is usually measured by an electric field mill. Except for very close flashes (within 5 km) the signal requires careful interpretation to detect a lightning flash, since lightning signals can appear similar to nonlightning sources of variability such as charged precipitation or even birds flying close by. Electric field mills can be combined with colocated sensors using a different method (e.g., optical) to verify the presence of lightning. As the electric field mill needs to be exposed to the atmosphere, it can only be installed where there is a clear view of the overhead sky (e.g., no overhanging tree branches, cables, etc.) and as far from taller objects as possible, as these will distort the electric field. Electric field mills are capable of detecting lightning to approximately 40 km, depending on their sensitivity, background noise at the site, and the lightning strength. This sensor will not be able to detect the bearing of the lightning, but when calibrated and sampled at a rate of at least 10 Hz will provide a greatly superior indication of distance to the strike compared to a single RF sensor using amplitude alone, as the electrostatic signal reduces by the inverse of the distance cubed. The primary use of an electric field mill is normally to warn of an increased DC atmospheric electric field magnitude indicative of electrified cloud overhead ([14.81]), rather than the detection and range of lightning itself.

An alternative to measuring the DC or slow-varying electrostatic field for stand-alone local thunderstorm detection is to use a displacement current sensor. These sensors work on a similar principle to the chopper in an electric field mill, where a current is induced in a conductor due to the variation of an electric field. Unlike the field mill, however, the sensor does not record the DC electric field but only the changes, so is in this respect the same as a radio receiver and does not require any moving parts. By constructing an antenna and suitable filtering to enable only changes in the atmospheric electric field resulting from lightning to be recorded (e.g., approximately 1–100 Hz) and avoiding the frequencies associated with the RF component of the discharge and artificial transmitters (< 1000 Hz), it is possible to produce an instrument that does not require the moving parts and unwanted slow variability

Fig. 14.11 Displacement current induced on the electrode of a BTD-300 thunderstorm detector by a lightning flash approximately 20 km away (recorded on March 21, 2017)

of the DC field characteristic of a field mill yet still retains the ability to detect the electrostatic change associated with a lightning strike ([14.20], Fig. 14.11). Like the field mill, only the distance to the flash can be derived, but again with a much greater sensitivity than RF due to the inverse distance cubed relation for electrostatic signals. A displacement current detector sampling between $\approx 1\text{--}50\text{ Hz}$ can also detect charged precipitation and the increased electric field variability produced by the production of corona ions during the strong electric field beneath a thunderstorm [14.20, 80]. Both signals can be used to warn of increased po-

Fig. 14.12 The Biral BTD-300 thunderstorm detector, with modeled lines of equipotential (*black*) compared to ground and electric field magnitude (*colors*) surrounding the three stainless-steel sensing electrodes. *Warmer colors* denote stronger field. (photo and model: A.J. Bennett)

tential for overhead lightning activity. Like field mills, single-site displacement-type detectors cannot be used indoors, are not usually highly portable, their electrodes require good electrical insulation from the ground to be maintained, and they cannot provide flash bearing (Fig. 14.12). Unlike their RF counterparts, they are more resistant to false alarms, very sensitive to all types of local flashes, and are able to detect nonlightning signals such as charged precipitation, which can be used to warn of potential nearby cloud electrification before the first lightning flash has occurred. A summary of the advantages and disadvantages of these detection methods is presented in Table 14.2.

Table 14.2 Comparison of different disturbed weather detection techniques

Technique	Advantages	Disadvantages
RF network	Excellent location accuracy (to a few 100 m) and good detection efficiency if the network is sufficiently dense. Sensor redundancy. Flash type and polarity discrimination. Can provide national or even global coverage.	Expensive to install and maintain. Requires multiple sites, sometimes in different countries. Method of rapid, long-range communication and central processing needed. Can only detect hazard after lightning is produced.
RF stand-alone	Only one sensor and site required. Can have good detection efficiency. Same signal used for range and direction. User-owned and operated.	False alarm rate can be high due to anthropogenic radio interference. Range accuracy can be poor, depending on method. Using VLF only can limit intracloud stroke detection efficiency. Can only detect hazard after lightning is produced.
Displacement current (< 50 Hz)	Only one sensor and site required. Very good flash detection efficiency within 100 km. User-owned and operated. Operates below most anthropogenic noise sources. Can warn of strongly charged cloud overhead before the first flash occurs.	Difficult to determine flash type. Requires exposure to the atmosphere whilst maintaining robust electrical insulation. Range accuracy low compared to RF network. Range limit of $\approx 100\text{ km}$.
Field mill	Only one sensor and site required. Very good flash detection efficiency within 10 km. User-owned and operated. Operates below most anthropogenic noise sources. Can warn of strongly charged cloud overhead before the first flash occurs. Quantifies DC field so can also be used for fair weather atmospheric electrical monitoring.	Cannot determine flash type. Contains moving parts, so liable to mechanical failure. Output can be difficult to interpret due to several sources of atmospheric field change during precipitation. Short range ($\approx 30\text{ km}$ for lightning) and usually unsuitable for flash range determination beyond <i>near</i> and <i>far</i> .

14.5 Specifications

In this section, the typical accuracies and connections for the different instruments are discussed.

14.5.1 Fair Weather Requirements

Generally, the fair weather PG is about 100 V m^{-1} and accurate measurements are possible to a few V m^{-1} , with a dynamic range of $\pm 500 \text{ V m}^{-1}$ usually being desirable to allow nonfair weather data to be identified. However, the limitation on fair weather data is largely that of the local environmental circumstances' exposure, as the surface PG is strongly affected by local meteorological conditions. If the object of the measurements is to obtain globally-relevant information rather than local information, the data has to be selected for that arising under undisturbed conditions. The conventional approach to this is to use data obtained under well-defined fair weather conditions, during which it is regarded that there are no local sources of electrical disturbance.

14.5.2 Automatic Recording

Typical modern field mill instruments provide an analogue output voltage or direct digital data (e.g., via a serial protocol such as RS232 or RS422 or Ethernet). This means that they can be used straightforwardly with data loggers. For fair weather data, sampling rates of 1 s are adequate, with averages computed at 1 or 5 min.

14.6 Quality Control

As with all instruments, the quality of the measurements has to be considered before they are used for a scientific analysis. This has to address the exposure of the instrument, and an assessment has to be made of the validity of the results obtained.

14.6.1 Fair Weather

Depending on the climatology of the site concerned, fair weather circumstances will generally only occur intermittently. The classification of the meteorological conditions is, therefore, an important consideration in determining which measurements to retain for further analysis. For accurate measurement of the electric field, calibration of the installation is required, through a combination of sensor characterization and knowledge of the correction factors to be applied to represent any local distortion of the electric field.

14.5.3 Disturbed Weather Requirements

For the detection of the strong atmospheric electric fields associated with disturbed weather conditions, it is necessary to measure the DC electrostatic field change of magnitude exceeding approximately 500 V m^{-1} , with an upper limit of at least 10 kV m^{-1} , ideally 100 kV m^{-1} , with a resolution and measurement uncertainty of at least 100 V m^{-1} , if quantification of the field is required. Alternatively, detection of electrical changes characteristic of strong electric field conditions, such as strongly charged precipitation (hydrometeors with individual charges typically in excess of 10 pC) and rapid electric field variability associated with wind-blown space charge (of order $10 \text{ V m}^{-1} \text{ s}^{-1}$ or more) or nearby lightning flashes (usually exceeding $1000 \text{ V m}^{-1} \text{ s}^{-1}$) require faster sampling to capture their detail, with a recommended sampling rate of order 100 Hz . As for fair weather measurements, sampling rates of 1 s are acceptable for disturbed weather monitoring, with a sampling rate of at least 20 Hz required to adequately capture electrostatic field changes associated with lightning flashes, using a field mill or displacement current sensor. Radio detection of lightning normally starts at VLF ($3\text{--}30 \text{ kHz}$) for long-range ($< 1000 \text{ km}$), predominately cloud-to-ground strokes, to LF and above (realistically $< 100 \text{ kHz}$) to ensure reasonable detection efficiency of weaker intracloud strokes at ranges exceeding a few 100 km .

Reduction Factor for the Electric Field

When a field mill or other measuring device is installed on a mast, the local electric field encountered will be distorted (Fig. 14.13). This affects the measurements, usually enhancing the field measured. It is necessary to determine a calibration for each installation individually, to allow it to be corrected (or *reduced*) to that of an open flat site with the measurement made flush with the surface. Determining the *reduction factor* to correct the measurements to that of an open surface is, therefore, required. This is achieved by comparison with a calibration measurement that is not affected by distortion, or, theoretically, by using an electrostatic model of the installation in which the distortion can be calculated.

The principle of the experimental approach to this is to run a second set of calibration measurements simultaneously in an undistorted situation and derive the ratio between the two instruments during the same interval,

Fig. 14.13 (a) Distortion of the electric field (solid lines, with dashed lines showing equipotentials) for a measuring instrument mounted on a vertical mast. (b) Removal of the electric field distortion by burying the instrument in the ground, with its sensing aperture flush with the ground. (c) A passive wire potential measurement is negligibly affected by the distortion effects (after [14.82])

which need not be very long (\approx minutes to hours), as long as the two instruments show well-correlated values.

One option to remove the distortion is to mount the calibrating instrument so that it is flush with the ground; another is to compare it with a passive wire antenna, which shows negligible distortion of the field because of its small geometry.

Conductivity from Relaxation Time

The air conductivity at the surface is typically in the range of 2 to 30 fS m⁻¹. To establish if an air conductivity measurement is reliable, it should be compared with that from another instrument, or a combination of techniques can be used, thus allowing a consistency check. The PIMS instrument, for example, can operate as a relaxation device as well as a current measurement device, allowing self-consistency checks [14.71]. It is also possible to compare two different techniques, e.g., the comparison of conductivity from an ion counter instrument with that derived from the relaxation time of a passive wire system [14.72].

Removal of Power Line Interference

With sensitive electrometers connected to exposed electrodes there can be difficulties with power line interference. This can be very local and vary with time of day, depending on the loading of the power grid. Corona ions can be generated from breakdown of high-voltage power lines and provide a direct source of interfering ions. For atmospheric electricity applications, when full screening is, almost by definition, impossible, it may be necessary to move the instruments to an electrically quieter site, or one in which saturation of the instruments by power line noise is sufficiently reduced that other filtering techniques become possible. Active com-

pensation of power line interference at 50 Hz has been found to provide some improvements for an exposed plate electrode [14.24], including embedded sharp digital FIR (finite impulse response) filtering stages to produce a low-pass filter below 50 Hz, such as that used by the Biral BTD-300.

Identification of Fair Weather

The selection of fair weather conditions is important in establishing which measurements are suitable for comparison with those from other sites. Various criteria have historically been used to identify fair weather conditions, but those of the UK Met Office (UKMO) originating in the 1950s have established themselves as capable of providing data in which global signals have been detected. The original UKMO criteria [14.83] for fair weather were:

1. The absence of hydrometeors
2. No low stratus cloud
3. Less than three-eighths cumuliform cloud
4. A mean hourly wind speed of less than 8 ms⁻¹.

The UKMO applied these criteria on an hour-by-hour basis to designate hourly PG data values as having *no hydrometeors* (i.e., no rain, hail, or snow), or being *fair weather* [14.83]. Daily and monthly averages were constructed from these hours.

Some refinements to these criteria were suggested by [14.82] to make use of modern automatic measurement systems. These refinements are to ensure that the visual range exceeds 2 km, that no extensive stratus cloud with cloud base below 1500 m is present, and that the surface wind speed is between 1 and 8 m s⁻¹. Taken together with original UKMO requirements, the revised fair weather criteria are:

- (FW1) no hydrometeors, aerosol, and haze, as apparent from the visual range exceeding 2 km
- (FW2) negligible cumuliform cloud and no extensive stratus cloud with cloud base below 1500 m
- (FW3) surface wind speed between 1 and 8 m s⁻¹.

This overall selection approach of identifying fair weather hours can now be implemented using automatic meteorological instrumentation at the same site. It has the merit over daily data selection that, even if the weather is often disturbed at a particular site, it is still possible to make the best use of the available values in forming climatological values.

14.6.2 Disturbed Weather Quality Control

Instruments used for disturbed weather measurements typically require less maintenance than those used for fair weather measurements, as the signals detected are usually larger. Nevertheless, there are quality and reliability considerations for accurate and consistent measurements to be obtained.

Detection Efficiency

The detection efficiency (probability of detection) of a lightning detection system quantifies the amount of lightning activity within a given geographical area that is expected to be detected by the system. The detection efficiency is normally expressed as a percentage and can relate to either lightning strokes or flashes, depending on the technology used. The detection efficiency (DE) is a function of receiver sensitivity, noise, lightning strength, and distance. It is, therefore, common to relate DE to a lower threshold of peak current, type (CG or IC/CC), geographical area (for a lightning location network), or as a function of proximity to individual stand-alone detectors. Reliable *ground truth* data

against which to determine the absolute DE of a system is challenging to obtain, given the challenge of detecting all lightning flashes in a known region during a comparison. The use of video evidence of lightning affecting known locations, lightning damage records, and short-range, high sensitivity VHF mapping arrays are examples of previously used methods to estimate DE from independent observations. Such independent verification has its limitations, especially with respect to weaker intracloud flashes, so DE relative to a high-performance lightning location network is sometimes quoted instead of absolute ground truth data. High-performance VLF/LF networks typically quote a DE of < 95% in their network center for CG flashes with peak currents exceeding a few kA.

False Alarm Rate

The false alarm rate (FAR), also known as the probability of false detection (POFD), of a lightning detection system is commonly expressed as a percentage of cases where an event is falsely detected compared to the total number of strokes or flashes. The false alarm rate is, therefore, sometimes confused with what is more properly determined as the false alarm ratio, since correct negatives are not accounted for. The FAR can also be expressed in terms of false alarms per unit of time (e.g., false alarms per day), which is more likely to be the correct determination of FAR but requires an appropriate time interval to be determined. Like DE, determination of absolute *ground truth* FAR is difficult to obtain due to lack of a reliable method of detecting every electrical discharge affecting an area. False alarm expectations quoted by manufacturers and operators of lightning detection systems are usually less than 2%, although it can be unclear whether the value relates to POFD or the false alarm ratio.

14.7 Maintenance

The operation of atmospheric electricity equipment requires regular attendance and maintenance, depending on the environmental conditions encountered (Table 14.3). Snow and ice, when present, must be removed if the apparatus is not specifically designed for those conditions.

14.7.1 Fair Weather Maintenance

Operation of fair weather equipment is particularly demanding, because of the great sensitivity of the instruments to leakage and degradation.

Insulators and Insulation

Due to the often picoampere currents and high impedances involved in the measurement of fair weather atmospheric electrical parameters, robust, highly resistive insulation is essential. The material used for insulation varies with application and availability, from amber, sulfur, and even heated sapphire in early twentieth century instrumentation, to polytetrafluoroethylene (PTFE) for modern instrumentation. PTFE has many desirable properties for this purpose, including a very high surface resistivity, it is hydrophobic with a low water absorption rate, low chemical and

Table 14.3 Maintenance schedule of instrumentation at mid-latitudes

Maintenance interval	Air conductivity sampling tubes	Plate electrodes	Field Mill	Electrostatic lightning detection
Daily	Surface cleaning and drying of insulators	Debris removal and drying of insulators		
Weekly	Partial dismantling and cleaning of insulators	Clear plants growing near electrodes	Inspect for dead insects	
Annual	Replace insulators. Rebuild and recalibrate	Rebuild electrometer	Clean and rebuild if necessary	Surface cleaning of insulators. Test and recalibrate

UV reactivity, resistance to residue accumulation, and is relatively inexpensive, mechanically robust (aside from creep under pressure), and easy to machine. Nonetheless, if an insulator is to operate reliably when exposed to environmental conditions, slight heating of the surface is normally required to prevent a lowering of surface resistivity in damp conditions, especially when hygroscopic impurities inevitably accumulate on exposed surfaces. The heat source can be placed inside the insulator, warming the surface from the inside (Fig. 14.14). However, as with other plastics, PTFE is a poor thermal conductor, so heater power and material thickness need to be considered to ensure effective surface heating. A rain shield can also be used to physically prevent precipitation from wetting the insulator, which would not be evaporated in sufficient time. Spider webs have always been a problem for very high impedance measurements, such as air–Earth current density, since they can introduce leakage currents to the sensing electrode. There is currently no clearly successful method of preventing spider-web accumulation on sensors, so instrumentation and fieldwork should be designed to minimize this risk. Maintenance for well-designed insulators is normally light, with the occasional (perhaps

6-monthly) check on heater effectiveness and removal of any spider webs and surface impurities.

14.7.2 Disturbed Weather Maintenance

Electrostatic lightning detection instrumentation will have similar insulation requirements for the sensing electrode to those for fair weather equipment (Fig. 14.15). The moving parts of field mill-type electrostatic sensors are subject to mechanical wear and jamming from foreign objects entering the chopper exposure slots. Initial startup may also be problematic in subzero temperatures or heavily contaminated environments if the chopper or motor becomes stuck. It must be ensured that the mechanism moves freely, is free from foreign objects (including insects), and that there are no objects preventing the chopper from being fully exposed to the atmosphere through the slots (e.g., by leaves, snow accumulation, or excessive coverage from spider webs).

For optical lightning detection, a primary requirement is that the optical window remains free from obscuration by opaque material (e.g., leaf debris, snow,

Fig. 14.14 Heated PTFE insulation of the geometrical displacement and conduction current sensor (GDACCS). Ultrahigh quality insulation is required continuously between the sensing electrode and ground (after [14.45])

Fig. 14.15 Electrical insulation method for the sensing electrode of a Biral BTD-300 thunderstorm detector, showing the shielded and heated PTFE insulator to prevent water-induced grounding during all weather conditions. (photo: A.J. Bennett)

mud, and spider webs) and gradual reduction of transmittance from accumulation of surface contaminants, including salt and algal growth. Dew and frost on the window will also reduce the window transmittance and, therefore, sensitivity to a lightning signal.

Lightning detection based on radio (RF) signals will generally require less maintenance than instrumentation requiring moving parts and fully exposed electrodes (since electromagnetic radiation is not greatly affected by electrically resistive weather shielding). The background noise should be periodically monitored for any significant increase in noise sources that may obscure or distort the lightning signals. If an increase in noise is detected, the addition of software-defined notch filters can be used to attenuate narrowband noise sources in the listening frequency, such as communication transmitters. Broadband noise sources, such as sparking of electrical equipment, are best avoided during site selection. Electrical shielding of the sensitive (preamplified)

parts of the receiver electronics will reduce noise issues, such as shielded coaxial cables and grounded, metallic shielding on circuit boards. Note that even if a receiver is designed for low-frequency signals, the geometry of the preamplified circuit board tracks may still permit significant interference from microwave signals if left unshielded. It is also important to maintain a good electrical ground on the RF receiving equipment for best performance, which may involve deep ground spikes for sites with low ground conductivity. Appropriate electrical impedance must be maintained for the antenna assembly and RF cabling to keep the standing wave ratio (SWR) as close to unity as possible, optimizing the power transfer. For VHF phase-sensitive radio detection (e.g., interferometry), relative cable length is an especially important consideration, with the short wavelengths involved requiring the maintenance of correctly matched cables to avoid errors in phase-shift calculation.

14.8 Applications

Surface atmospheric electricity measurements have a wide range of applications, including detecting charged clouds overhead and providing lightning warnings.

Atmospheric electricity measurements span a wide parameter space, and accordingly have many uses. The fair weather measurements are chiefly used for studies of the atmosphere's global electric circuit, through which current flows from tropical disturbed weather re-

gions around the planet. It is particularly influenced by space weather and pollution. Space-weather variations and their effects are an active area of study, which the atmospheric electricity data complements. In particular, the possible solar–terrestrial coupling mechanisms with the lower atmosphere can be explored, through, for example, electrical effects in fair weather clouds (Fig. 14.16). The effects of pollution are also sensitively

Fig. 14.16a,b Potential gradient (upper panels, red trace) measured under low stratiform cloud at Reading, observed using a colocated JCI131 field mill and Vaisala CL31 ceilometer (lower panels). **(a)** Effect of low clouds on the variability in the surface PG on May 9, 2017, showing the coupling between the cloud base charge and the PG, which ceases when the cloud dissipates at about 16:00 UTC. **(b)** Cloud base charge effect on the surface PG on May 15, 2016, which leads to a reduction in the PG as the negative charge in the cloud base is brought nearer to the surface with reducing cloud base height. (Ceilometer data are colored by the backscatter generated according to the color bar, the cloud base itself yielding the red color)

apparent in air conductivity; aerosol pollution decreases air conductivity, and releases of radioactivity increase the air conductivity. There are associated effects on the potential gradient, with a sharp decrease associated

with radioactivity and a steady increase with increased aerosol pollution. Disturbed weather effects, principally the detection of lightning, have immediate applications to weather forecasting and aviation meteorology.

14.9 Future Developments

Continued miniaturization of atmospheric electricity sensors makes measurements possible on airborne platforms, such as weather balloons and unmanned aircraft systems (UAS). This will allow investigation of the electrical environment within a range of clouds, and, further, regular measurements of the vertical profile of the electric field under fair weather conditions. The vertical integral of the electric field, known as the ionospheric potential, represents a global circuit parameter that has previously been difficult to monitor with continuity beyond that of individual investigators or projects. Improvements to the design of all-weather electrical insulation and cheaper, faster processors will allow more sophisticated and smaller sensors for electrostatic thunderstorm detection. Improved digital storage capacity combined with greater processing speed will

permit lightning monitoring, including raw data logging at higher frequencies, thereby capturing smaller and weaker components of electrical discharge. Continued characterization of the electrical conditions prior to lightning activity will be required to produce robust, reliable preflash warning devices, with associated benefits to lightning safety. Reduced price and increased sensitivity of CCD cameras and photomultipliers can widen the participation of transient luminous events (TLEs) monitoring, with more numerous, detailed, and full-color images of TLEs available across broader regions of the world. The advancement of near-global lightning and TLE monitoring from space will provide a significant addition to ground-based detection methods, especially for weak intracloud activity over the oceans.

Giles Harrison

Department of Meteorology
University of Reading
Reading, UK
r.g.harrison@reading.ac.uk

Giles Harrison is Professor of Atmospheric Physics at the University of Reading, UK, where he works on atmospheric electricity and scientific sensor development. His PhD is from Imperial College, ScD from the University of Cambridge and he is a member of the Academia Europea. In 2016 he was awarded the Appleton medal of the Institute of Physics, and he is the 2021 recipient of the Christiaan Huygens medal of the European Geosciences Union.

Alec Bennett

Biral
Portishead, UK
alec.bennett@biral.com

Alec Bennett is the Meteorological Products Manager at Biral, UK and a Visiting Research Fellow at the University of Bath. He works on commercial meteorological sensor development and thunderstorm detection research. His PhD is from the University of Reading, and he previously worked for the UK Met Office. In 2017, he was awarded the FitzRoy Prize by the Royal Meteorological Society.

Radioactivity

15. Radioactivity Sensors

Jacqueline Bieringer, Thomas Steinkopff, Ulrich Stöhlker

Radioactive substances in the atmosphere lead to exposure of humans and the environment to radiation. The purpose of monitoring these radioactive substances is to determine the magnitude of the exposure. The primary objective of the various methods of radiation monitoring is to quickly and reliably measure the levels of radioactive substances in the event of an (accidental) release. However, continuous analysis of trace amounts of radioactivity in the atmosphere is also needed to determine long-term trends and identify short-term, low-level increases in atmospheric radioactivity and their causes, for instance to provide proof of underground nuclear weapons tests. Radionuclides can be bound to particles or exist in the atmosphere in the gaseous state or as radioactive noble gases; thus various systems are used for their detection. Furthermore, the different types of radioactive decay require different measurement techniques. National, European, and international measurement networks and programs produce a multitude of data and, in combination with atmospheric transport modeling, enable dose prognosis and source term reconstruction. Here, different measurement techniques and their application are described, as well as methods for quality assurance.

The measurement of radioactive substances deposited on the ground and contained in the atmosphere is important for nuclear emergency preparedness, for verification of nonproliferation treaties such as the Comprehensive Nuclear-Test-Ban Treaty (CTBT), and in long-term monitoring of atmospheric radioactivity. Reliable mea-

surement results are essential for all applications: for early warning and implementation of countermeasures in case of a release of radioactive substances into the atmosphere, as part of identifying nuclear testing activity, and for the routine surveillance of atmospheric radioactivity levels. Data exchange at a global level re-

quires harmonized and precise measurement techniques and well-established quality control to enable the assessment and aggregation of available data.

In the following, the examples given are based on the European networks and the international measurement network for the verification of the CTBT.

15.1 Measurement Principles and Parameters

The measurement of radioactive substances in the air and deposited on the ground can be performed with different parameters using various techniques. In general, both the ambient dose/dose rate or activity concentrations in the air and specific activity deposited on the ground can be measured. Activity concentrations can be determined as gross activity concentrations (for alpha, beta, or gamma radiation) or for single radionuclides. Typical parameters of radioactivity sensors are listed in Table 15.1.

15.1.1 Monitoring Radioactivity in the Atmosphere

The primary purpose of continuously monitoring the activity concentrations of radionuclides in the atmosphere is to evaluate and possibly reduce radiation exposure to humans and the environment. For the protection of the population, comprehensive surveillance programs are required:

- To monitor activity concentrations of aerosol-bound and gaseous radionuclides in the atmosphere and to issue alerts in the case of elevated values
- To determine whether administrative and engineering measures for confinement of radioactive substances are effective under routine conditions.

The surveillance strategy chiefly relies on two general techniques:

- The first approach is online monitoring for emergency preparedness, in which activity concentrations and dose rates are monitored continuously and in real time in order to be immediately alerted in the event that a significant release of airborne activity may have occurred.

- The second is retrospective measurement (offline), in which constituents in the air or in precipitation are sampled for a given time span, after which the sample is taken to a radiation detection system and analyzed for radionuclides. Results for activity concentrations are then available after measurement. This is typical, e.g., for radionuclides which require radiochemical separation in the laboratory before analysis.

When implementing an effective surveillance program, it is important to achieve a proper balance between these two general approaches.

15.1.2 Principles of Sampling and Measurements

Locations for *air sampling* sites, in particular for sampling of aerosol-bound radionuclides, must be selected based on the guidelines of the World Meteorological Organization (WMO) [15.1] to ensure representativeness of measurement results for all sampling sites worldwide. In addition, synoptic observations should typically be representative of an area up to 100 km around the station, but for small-scale or local applications, the area may have dimensions of 10 km or less:

- Sampling is preferably conducted at a height between 1.5 and 5 m above ground level, in an undisturbed area so that air can be sampled without obstructions. The distance of the point of sampling to the nearest obstacle should be equal to at least ten times the height of the obstacle [15.2].
- If sampling and measurement equipment are placed in the surroundings of potential sources, e.g., as a part of the monitoring program of nuclear installations, they should be easily accessible for servicing and protected against unauthorized access.

Table 15.1 Measured parameters of radioactivity sensors for atmospheric measurements

Parameter	Description	Unit	Symbol
Ambient dose	Ambient dose equivalent	Sv	$H^*(10)$
Ambient dose rate	Ambient dose rate equivalent $\dot{H}^*(10) = dH^*(10)/dt$	$\mu\text{Sv/h}$ (mostly used)	$\dot{H}^*(10)$
Activity concentration	Activity concentration (activity per sample volume)	Bq/m^3	c
Deposited activity	Activity per area of the radionuclide r	Bq/m^2	$\alpha_{F,r}$

- Samplers are positioned such that their exhaust is directed downwind from the sample collector to avoid sampling their own exhaust air.
- If a sampler is operated on a horizontal surface (e.g., a roof), the exhaust air from the sampler should not be directed to the surface, where it could stir up dust and cause localized elevated activity concentrations from resuspended surface contamination.
- Ideally, 100% of the aerosol particles are deposited on a filter. Alternatively, the collection efficiency of the filter material needs to be accurately determined.
- The area of the filter should be correlated with the air flow, e.g., the sampling volume.
- The air flow and related sampling volume should correlate directly with the achievable detection limits.
- Gaseous components (noble gases, gaseous iodine) need special adsorbents for collection. Due to the limited capacity of the adsorbents, the required contact time between air and adsorbent, and the flow resistance, flow is generally lower than for particulate samplers.

Since buildings and walls in the vicinity of a *gamma dose rate probe* will influence the measured dose rates (e.g. through shielding, in the case of freshly deposited activity after an accidental release), it is recommended that probes be installed according to specific rules. In the *ideal site* approach, gamma dose rate detectors are installed at a height of 1 m on flat natural ground (grassland) without buildings within a distance of 20 m around the station [15.3].

15.2 History

The history of radioactivity measurements in the atmosphere is quite short relative to that of other atmospheric sensors.

15.2.1 History of Radioactivity Measurements in the Atmosphere

With the ignition of the first nuclear bomb, a long series of nuclear weapons tests began. From 1945 to 1962, a total of 345 nuclear weapons were detonated above-ground for experimental purposes. The United States and the former Soviet Union were responsible for the largest share of these, with 83 explosions in 1958 and 77 in 1962 [15.4, 5].

The tests also led to an increase in radioactive particles in the air and precipitation in Europe. Subsequently, monitoring techniques and instrumentation were developed in order to measure these fission products continuously and/or in a nuclide-specific manner. As the nuclear weapons race accelerated, these measurements became increasingly important. For example, the federal government of Germany expanded the area of responsibility of the German Meteorological Service (Deutscher Wetterdienst, DWD) by law in 1955. The DWD was commissioned to monitor radioactivity in air and precipitation and to provide meteorological forecasts of the atmospheric transport of radioactive particles.

The Partial Test Ban Treaty of 1963 banned nuclear testing for both military and peaceful purposes in the atmosphere, underwater, and in space. Although not all countries signed the treaty, it resulted in a significant reduction in radioactivity in the atmosphere,

but did not prevent nuclear testing overall, which moved underground. Underground nuclear testing was banned by the Comprehensive Nuclear-Test-Ban Treaty (CTBT) in 1996, which banned all nuclear explosions on earth [15.6]. For verification of compliance with the CTBT, a worldwide network consisting of seismic, hydroacoustic, infrasound, and radionuclide monitoring stations was installed for the detection and identification of nuclear testing activity. Radionuclide monitoring includes the measurement of both particle-bound radionuclides and the radioactive isotopes of the noble gas xenon [15.7, 8].

As an example, the nuclear weapons tests carried out in 1980 by the People's Republic of China were detected and verified by monitoring. After a test in 1976, a relatively undiluted radioactive cloud reached Central Europe from China, causing an increase in radioactivity levels in air and precipitation.

In order to implement the provisions of the Euratom Treaty of 1957 [15.9], and in the course of the large-scale peaceful use of nuclear energy, monitoring of radionuclides in the environment was extended and increasingly regulated by law.

In parallel with the networks monitoring aerosol-bound radionuclides, gamma dose rate monitoring networks have been established in Europe and internationally for the purpose of protecting people and environment against ionizing radiation. Some of these networks had been established during the Cold War period and were improved after the Chernobyl accident in 1986. Today, the German Federal Office for Radiation Protection (BfS), as an example, operates an early warning network with roughly 1800 ambient dose equivalent

rate (ADER) stations equally distributed over the German territory.

The gamma dose rate monitoring network and the aerosol monitoring network operated in Germany are both part of the German *Integrated Measuring and Information System for the Surveillance of Environmental Radioactivity* (IMIS) [15.10] and the German National Response Plan, which deals with the consequences of a possible large-scale radioactive contamination of the environment. The IMIS stores and distributes the results of predictive atmospheric transport models (in the case of an emergency) and atmospheric monitoring data (under routine conditions) as gamma dose rates, activity concentrations in air and precipitation, and deposited activity on the ground. In addition, data are transmitted to the European Radiological Data Exchange Platform (EURDEP) for aggregation to obtain a full picture of the radiological situation for European decision-makers and the public.

As a consequence of the Fukushima accident in 2011, strategies in Germany for (nuclear) emergency preparedness and monitoring were revised.

15.2.2 Measurement Methods

Radiation measuring devices have been developed to detect ionizing radiation and to determine the type, energy, and intensity of the radiation.

In the early days, only integrated monitoring devices existed for the measurement of gross radiation

15.3 Theory

In general, radioactivity—i.e., ionizing radiation—can be detected because of its interaction with the material of a detection device, which counts and amplifies electric charges. These charges are the result of ionization in the detector material, caused by the transfer of energy from the alpha or beta particles or from gamma radiation.

The measurement conditions must be accurately defined. Due to ionizing radiation emitted from natural radioactive elements (e.g., K-40, Rn-222 and its decay products), it is always necessary to determine the background caused by natural radioactivity.

Detectors must be calibrated for the specific measurement geometry so that measured pulse rates can be converted into activity. Activity concentrations are then determined by division with the amount (volume or mass) of the sample.

These did not discriminate between individual radionuclides and were based on ionization chambers (see e.g. [15.11] and references given therein), proportional counters, or Geiger–Müller tubes (Sect. 15.3.3), and various modifications thereof. One of the first systems able to distinguish between radiation from natural and anthropogenic radionuclides from measurements during sampling is described in [15.12]. NaI scintillation crystals were used from the late 1940s for the monitoring of radiation levels in the environment, but discrimination between individual radionuclides was still not possible. Air sampling and subsequent radiochemical separation was required to identify radionuclides present in the air.

Semiconductor detectors capable of detecting energy-resolved gamma and x-rays and coupled with multichannel analyzers allow real-time monitoring of radionuclide activity levels in air. In-situ liquid nitrogen-cooled high-purity germanium detectors (HPGe detectors) with high energy resolution have been used since the 1970s for the identification of radionuclides in air or deposited on the ground, and the development of new semiconductor materials with good energy resolution at room temperature has enabled the fabrication of compact spectrometric arrays. Today, automated air sampling systems coupled with high-resolution gamma or beta–gamma coincidence spectrometry allow for continuous monitoring of the activity concentrations of various airborne anthropogenic and natural radionuclides at trace levels [15.13–15].

The average activity concentration is determined by the following general equation (15.1)

$$C = \frac{A}{Q_s t_s \varepsilon_c} . \quad (15.1)$$

In this formula, C is the activity concentration given in Bq/m³, A is the activity, given in Bq. The volume flow Q is given in m³/h, and t_s , in h, is the sampling time span. ε_c is the collection efficiency.

In general, the activity at the time the sample was collected is given by equation (15.2). For short-lived radionuclides, corrections for their radioactive decay have to be applied.

$$A = \frac{R_N}{\varepsilon_r \varepsilon_S} . \quad (15.2)$$

R_N is the net count rate from the assay system, in s^{-1} ; ε_r is the counting efficiency of the assay system for a reference standard, in $Bq^{-1} s^{-1}$; and ε_S is the efficiency modification factor for counting (measuring) an actual sample as opposed to the reference standard (e.g., the dimensionless alpha self-absorption factor for particulate alpha on glass fiber filters).

Since temporal variations in activity concentrations during the period of sampling are not known, only average concentrations during the sampling interval can be determined. If individual radionuclides are measured, the radioactive decay during sampling and measurement can be corrected for.

Continuous automatic air monitoring requires more complex calculations of activity concentrations, detection limit, minimum detectable activity, and minimum detectable activity concentration. This is due to the nature of real-time data collection and analysis, in which activity concentrations of both the target radionuclides and interfering background can change over the course of the continuous operation.

Depending on the specific task, different detection devices are used:

- Typical devices for measuring the total amount of activity or the ambient dose rate include ionization chambers, Geiger–Müller tubes, proportional counters, and plastic scintillation counters. The total sum of radiation (alpha (α) and/or beta (β) and/or gamma (γ) radiation) is detected without discriminating between different radionuclides.
- Gamma-ray spectrometry is used for the detection and discrimination of different radionuclides according to the specific energies of their gamma emissions, expressed in kilo-electron volts (keV). This gamma energy can be measured using so-called room-temperature detectors based on semiconductors such as CdZnTe or scintillators such as LaBr₃ (both detector types provide energy resolution on the order of 2%) or thallium-doped sodium iodide (NaI(Tl)) with an energy resolution on the order of 7%. High-purity germanium (HPGe) detectors can be used, providing optimum energy resolution below 1%, but require cooling for operation.
- In laboratories, beta activity is typically measured using liquid scintillation spectroscopy (LSC) or proportional counters. Proportional counters cannot distinguish between different radionuclides. A distinction between certain isotopes is possible using LSC if the system is carefully calibrated and the quench of the sample solution is known. Powerful algorithms are able to distinguish not only between α and β emitters, but also individual radioisotopes.

The sample is mixed with an organic compound (the scintillator), which is stimulated by interaction with the beta (electrons) or alpha (He^{2+} -ions) particles emitted from the sample. The scintillator translates the energy that is transferred by this interaction into visible radiation. The visible radiation is detected by a photomultiplier.

- The measurement of single alpha-emitting radionuclides requires a radiochemical separation of the element. The element of interest is then deposited via electrolysis or auto-deposition on a metal planchet as a very thin layer. A thin layer is necessary to avoid the absorption of the alpha radiation in the sample matrix (self-absorption) and to achieve good energy resolution. The measurement by alpha spectrometry enables the detection of different isotopes due to the specific energies of the alpha particles.
- The sampling of aerosol-bound radionuclides is based on monitoring devices with filter tapes or filter plates. During sampling, the alpha activity can be simultaneously measured with a silicon detector, the beta activity with a GM-tube or plastic scintillation detector, and the gamma radiation by gamma-ray spectrometry, typically using LaBr₃, NaI(Tl), or HPGe detectors.
- The gamma radiation of the precipitation is measured with an in-situ gamma-ray spectrometry system facing downward and detecting the gamma radiation emitted from deposited radionuclides.

In order to reduce the minimum detectable activity and achieve results for very low-activity concentrations, pretreatment of the sample may be necessary before measurement. For example, the filter or the precipitation is measured following a short delay after collection so that the short-lived natural radionuclides (radon decay products) have decayed. The filter may also be charged and then diluted in acid, or precipitation evaporated to concentrate the radioactive material in the residue (e.g., for subsequent alpha and beta spectrometric measurements).

The sensitive measurement of tritium in precipitation requires a different sample preparation method. Separation procedures applied are distillation and electrolytic enrichment.

15.3.1 Gamma Dose Rate Measurements

The Geiger–Müller (GM) tube is the simplest type of measurement device for the detection of ionizing radiation. It consists of a cylinder filled with an inert gas. A high voltage is applied to two electrodes inside the cylinder. Ionizing radiation such as alpha and beta particles or photons interact with the gas inside the cylinder

and generate an electrical charge, which is collected and amplified. The inert gas allows the charged ions to be efficiently neutralized so that the counting of ionizing radiation can be continued. To characterize the performance of this type of detector, the number of output pulses generated by the tube is compared with the number of particles or photons reaching and interacting with the detector material. This depends on the efficiency of the detector, which is dependent on the volume of the cylinder and the pressure of the gas. Secondly, the dead time of the detection device has to be accounted for. This is the time required to collect the charges and neutralize the gas, before counting is continued. A third parameter is the energy response of the detector. Since GM counters detect ionizing radiation independent from the energy of incident particles or photons, the detector housing is designed such that it accounts for photons almost independently from energy.

Proportional counters are similar in design to GM tubes, with the main difference being that the electrical signal generated is proportional to the incident particle or photon energy.

Finally, the obtained count rate has to be converted to a radiation protection quantity. Since these quantities cannot be measured directly, so-called operational quantities are used, which in the case of monitoring external exposure to gamma radiation is the ambient dose equivalent rate ($H^*(10)$). GM tubes are frequently used for the detection of gamma radiation.

It should be noted that efficiency, dead time, and energy response are key parameters of all types of radiation measuring devices. In detectors with energy proportional readings, the energy resolution must be considered as an additional parameter.

Regardless of the type of detector, the operation of gamma dose rate detectors for environmental monitoring requires an understanding that the output of the instrument is the sum of four different components: the detector's inherent background, the natural terrestrial radiation, the secondary cosmic radiation, and the excess dose rate in the case of artificial radiation. The detector response, which is specific for each component, must be known. For this purpose, characterization experiments are required. One example are the intercomparison exercises performed by the European Radiation Dosimetry Group (EURADOS) on an almost annual basis [15.16].

A new development in gamma dose rate detectors in recent years has been initiated by the availability of room-temperature detectors (e.g., LaBr_3) with an energy resolution of approximately 2% at 662 keV. The gamma dose rate is calculated from the total spectrum, but these detectors are also able to determine individual nuclides contributing to the spectrum.

15.3.2 Gamma-Ray Spectrometry Using Semiconductors

Gamma-ray spectrometry measures the energy of gamma radiation emitted from a radioactive source/sample. As gamma rays have specific (discrete) energies characteristic of the respective radionuclide, gamma-ray spectrometry allows for the investigation of radioactive substances in a sample. Radionuclides can be identified, and specific activity or activity concentrations can be determined.

Because solid-state semiconductors and scintillators have much better stopping power than gas-filled ionization chambers, they are better suited for the detection of X- and γ -rays. The energy transfer of the gamma ray to the semiconductor material produces a difference in voltage that is proportional to the transferred energy. The electrical pulses generated by the detector are amplified and fed to a multichannel analyzer for acquisition of a pulse height spectrum.

There are essentially three different processes that can induce a detector pulse [15.17], and even gamma rays of a discrete energy result in a characteristic distribution of pulses across the spectrum. The most important effect is the photoelectric effect: the complete energy of the photon is adsorbed in the detector material. This results in so-called photo-peaks in the spectrum, which have characteristic energies for each radionuclide and are used to evaluate the activity of that particular radionuclide in the sample. The other two processes are e^+e^- annihilation and the Compton background, which comes from interactions involving only partial photon energy loss in the semiconductor material of the detector.

For analysis of the spectra, the system has to be calibrated for energy and detection efficiency. Energy calibration can be done using radiation sources with known radionuclides and energies. Efficiency calibration requires measurements of standards of known activity, ideally of the same geometry and matrix as the sample. Multinuclide solutions can be obtained from metrological institutions. An energy-dependent calibration curve can be obtained from the measured count rates at the various energies. Alternatively, detector responses can be modeled using Monte Carlo techniques.

15.3.3 Integrated Measurement of Alpha and Beta Decay

As a consequence of radioactive decay, a nucleus emits alpha particles (two protons and two neutrons, positively charged) or/and beta particles (electrons). In most cases this coincides with the emission of gamma radiation. For the measurement of the alpha and

beta particles, proportional counters can be used (see Sect. 15.3.1), with a thin entrance window at one end of the cylinder. Differentiation between alpha and beta particles can be achieved taking into account the different stopping power of alpha particles relative to beta radiation.

15.3.4 Measurement of Noble Gases

The activity of the noble gases krypton and xenon can be determined by measuring their beta decay (integrated method) without direct distinction between

the isotopes. They are measured inside a proportional counter (see Sect. 15.3.1), and the noble gas fraction is added to the counting gas [15.18, 19].

Other techniques for the nuclide-specific measurement of xenon use gamma-ray spectrometry (Sect. 15.3.2) or beta–gamma coincidence measurements. Beta–gamma coincidence measurement is based on the fact that a beta decay is accompanied by the emission of a gamma photon of a certain energy. Detecting beta particles in coincidence with gamma radiation enables the discrimination of different isotopes from background radiation [15.13].

15.4 Devices and Systems

The examples of methods, devices, and systems described above are by no means exhaustive. In Tables 15.2, 15.3, 15.4, and 15.5, the types of radiation measured, measuring methods, and sampling intervals and limits of detection are summarized. In addition, the table is divided into normal and emergency modes, respectively. The detection limits indicated are typical values that can vary with respect to the sampled volume, the efficiency of the detector, and the measuring time. For γ -radiation measurements, the detection limits given refer to Cobalt-60.

15.4.1 Gamma Dose Rate Probes

In order to cover an extended dose rate range, gamma dose rate probes are typically equipped with two GM tubes, for low dose (LD) and high dose (HD) rates, pro-

viding a measurement range from 20 nSv/h to 5 Sv/h. They include a high-voltage generation circuit, which needs to be stabilized electronically to cover a temperature range between -20 and $+60$ °C. In spectroscopy dose rate detectors, the LaBr₃ detector is connected to a multichannel analyzer forming a complete spectroscopy unit. Since the dose rate range is typically limited to 3 mSv/h, a GM tube is added to the spectroscopy detector to extend the dose rate range to Sievert per hour.

The probes are installed 1 m above ground level (Fig. 15.1). In the case of a fresh ground deposition, radionuclides deposited in four zones contribute approximately equally (25%) to the final measurement: from a circle of 3 m surrounding the probe, from a circular ring between 3 and 7 m, a circular ring between 7 and 20 m, and a circular ring between 20 and 100 m.

Table 15.2 Sampling and measuring devices for the measurement of radioactivity on aerosol-bound particulates: (a) routine mode, (b) emergency mode

Measured radiation/nuclides	Measurement method	Sampling and measurement interval	Limit of detection (Bq/m ³)
γ -Radiation	Monitoring system, filter tape	a) Daily b) 2 h	a) 0.01 b) 0.1
γ -Radiation	Laboratory method: γ -ray spectrometry after sampling	a) Weekly b) Daily	a) < 0.00001 b) < 1
Artificial α -activity concentration	Monitoring device with alpha spectrometry with a silicon detector	a) Daily/2 h b) 2 h	a) 0.1 b) 0.5
Artificial β -activity concentration	Monitoring device with silicon detector and algorithms to discriminate the count rates from the naturally occurring radionuclides	a) Daily/2 h b) 2 h	a) 1 b) 1
Strontium-89, Strontium-90	Laboratory method: liquid scintillation measurement or proportional counting after chemical separation	a) Monthly b) Daily	a) 0.000001 b) 0.1
Uranium-235, Plutonium-(239+240)	Laboratory method: α -spectrometry after chemical separation	a) Monthly b) Daily	a) 0.0000001 b) 0.1

Table 15.3 Sampling and measuring devices for the measurement of gaseous radionuclides: (a) routine mode, (b) emergency mode

Measured radiation/nuclides	Measurement method	Sampling and measurement interval	Limit of detection (Bq/m ³)
Iodine isotopes	Laboratory method: γ -spectrometry after sampling on charcoal (and molecular sieve)	a) Weekly b) Daily	a) 0.005 b) 1

γ -Radiation	Gamma dose rate	10 min	0.02

15.4.2 Alpha/Beta Particulate Monitors

These are automated monitoring devices for the simultaneous measurement of aerosol-bound alpha and beta activity concentrations and gaseous iodine.

Aerosol-bound radionuclides are collected on a filter tape with a typical air flow of about 15 m³/h and measured with a silicon semiconductor. The calcu-

lation of activity concentrations uses a mathematical compensation method, which differentiates between the artificial and natural alpha and beta activity. The sampling interval is adjustable, and after each sampling interval a fresh filter is available for the next measurement. A portion of the air is passed through activated charcoal with a reduced airflow rate of about 3 m³/h. In the activated charcoal the gaseous iodine is separated

Fig. 15.1 A probe of the German gamma dose rate network at a representative measuring site

from the air and simultaneously measured by gamma spectrometry using a NaI(Tl) detector.

15.4.3 High-Purity Germanium (HPGe) Detectors

For most gamma emitters with energies between about 50 keV and a few MeV, semiconductor detectors made of high-purity germanium (HPGe) are the most suitable. HPGe detectors are cooled with liquid nitrogen or electrically during operation to avoid the generation of background signals by thermal processes (*heat noise*). In order to reduce pulses from background radiation during the measurement, lead shielding with copper inlay is recommended.

Laboratory systems consist of an air (or precipitation) sampler that is operated continuously. Sample change is done manually; under routine conditions, sampling intervals of one week are commonly used. The charged filters are then placed on the detector and typically counted for several days. Laboratory detection systems generally consist of an HPGe detector, devices for signal processing—either as NIM (Nuclear Instrumentation Module) standard modules or as digital units—and a computer with control and analysis software. The size of the detector crystal is a benchmark for its efficiency. The combination of sampler and detector is the basis for the minimum detectable activity.

For *continuous monitoring of gamma radiation-emitting aerosol-bound radionuclides*, aerosol-bound radionuclides are collected on a filter tape with a typical volume flow of about 15 m³/h (Fig. 15.2). The gamma

radiation is measured simultaneously by gamma-ray spectrometry. A detection system with an HPGe detector is used. The filter tape is moved after a given sampling interval so that a fresh spot of the filter is available for each sampling interval. The different radionuclides are identified by their specific energies of gamma radiation. The calculation of the true activity concentrations in the given time interval has to take into account the new radioactive particles deposited on the filter during measurement, the decay of radionuclides on the filter, and buildup of their decay products [15.20].

Fig. 15.2 Automated system for aerosol sampling and measurement

Table 15.6 Advantages and disadvantages of the different methods

Measurement method	Monitor/ laboratory	Measured radiation/ nuclides	Advantage	Disadvantage
Dose rate probes	Monitor (network)	Ambient dose equivalent rate	Fast information, good time resolution (10 min), alarm function, robust	Integral measurement, background specific for each installation place, efficiency dependent on type of probe
Alpha/beta particulate monitors	Monitor	Artificial α -activity, artificial β -activity	Moderate time resolution (2 h), alarm function	Integral measurement, no nuclide-specific information
High-purity germanium detectors (HPGe)	Laboratory		Nuclide-specific measurement, high sensitivity	Time delay, well-trained staff needed
High-purity germanium detectors (HPGe)	Monitor	γ -Radiation	Nuclide-specific measurement, moderate time resolution (2 h), alarm function	Lower sensitivity, automatic evaluation needs to be proved
Nuclide-specific measurements after radiochemical treatment	Laboratory	Sr-89, Sr-90, U-235, Pu-(239+240), Am-241, H-3	High sensitivity	Time delay, established methods and well-trained staff needed
Gaseous iodine monitors	Monitor	I-131, I-132, I-133, I-135	Nuclide-specific measurement, moderate time resolution (2 h), alarm function	Adsorbent needs manual exchange
	Laboratory	Kr-85, radioxenon	Kr-85 accessible, established method	Time delay, well-trained staff needed, integral measurement, reduced distinction between different xenon isotopes
Noble gas measurement nuclide-specific measurement	Laboratory	Xe-133, Xe-135, Xe-131m, and Xe-133m	High sensitivity, mostly automated processing	Time delay, well-trained staff needed

15.4.4 Gaseous Iodine Monitors

Elementary iodine I_2 or gaseous compounds with iodine are adsorbed on charcoal and on special adsorption material. This material is either measured directly during sampling, as mentioned above, with a NaI(Tl) detector, or the sample is measured after a certain sample interval, usually with high-resolution gamma-ray spectrometry. With this method, I-131 and the short-lived isotopes I-132, I-133, and I-135 can be easily detected.

15.4.5 Noble Gas Measurement

Noble gases (krypton and xenon) are collected by adsorption on cooled activated charcoal at liquid nitrogen temperature (-197°C). Sampling of xenon only allows for higher temperatures of the activated charcoal, often in combination with other components such as zeolite, molecular sieves, or special membranes. Samples are enriched, purified, and measured using different techniques [15.21]. Since the amount of stable xenon and stable krypton per volume of air is constant worldwide, and the radioactive isotopes of xenon and krypton in the sample are processed along with their stable isotopes, the volume of stable xenon (and krypton) measured by the system can be converted to an effective volume

of air, and thus an activity concentration can be determined.

With *laboratory systems with proportional counters (krypton-85 and radioxenon)*, noble gas measurements in ambient air are performed in the following steps:

1. Sample preparation: enrichment, purification, and separation of the noble gas fractions by cryogenic adsorption and desorption, followed by gas chromatography
2. Measurement of the integral beta activity by gas counting in proportional counters and determination of the stable krypton and xenon volumes by gas chromatography.

In the krypton fraction, only one radioisotope (krypton-85) is present in the sample. For xenon, this counting method determines the integrated activity of all Xe isotopes present in a sample simultaneously, but in most cases originates mainly from the most abundant radionuclide of xenon observed in environmental samples, xenon-133, with a half-life of 5.24 days. Significant amounts of xenon-131m and xenon-135 can be calculated from the measured time-dependent decay rates of the xenon activity of the samples after the completion of counting [15.18, 19].

Laboratory systems with beta–gamma coincidence (xenon) use a different preparation and measurement technique:

1. Sample preparation: enrichment, purification, and separation of the xenon fraction by molecular sieves and activated charcoal
2. Coincidence measurement of beta and gamma radiation with a plastic scintillator (beta) and NaI detector (gamma). Analysis of gamma energy and beta energy spectra.

The energies of the electrons and gamma rays produced in the decay of Xe-133, Xe-135, Xe-131m, and Xe-133m are detected simultaneously. The coincidence technique reduces the ambient background and thus increases the sensitivity of the measurement. The recording of the beta energy allows for high-sensitivity measurement of the meta-stable states [15.20].

Laboratory systems with high-energy-resolution gamma-ray spectrometry (xenon) use a different measuring technique:

1. Sample preparation: enrichment, purification, and separation of the xenon fraction by molecular sieves and activated charcoal
2. Measurement of gamma radiation with a high-energy-resolution HPGe detector. Analysis of gamma energy spectra.

The energy of the gamma rays produced in the decay of Xe-133, Xe-135, Xe-131m, and Xe-133m is detected and resolved with a high-energy-resolution HPGe detector. The xenon isotopes are identified from the known decay energies, and the peak heights in the spectrum are converted into activity. The minimum detectable concentrations are typically around 0.2 mBq/m³ [15.20].

Table 15.6 presents some of the advantages and disadvantages of different devices and methods.

15.5 Specifications

In the following Tables 15.6 to 15.10, the general specifications for different measuring systems are given. They refer to the detection limits given in Tables 15.2 to 15.5, which strongly depend on different parameters as described in Sect. 15.4.

The collection of aerosol particles with an aerosol effective diameter up to 10 μm must be ensured by using filters with corresponding specifications, for example by choosing a glass-fiber filter with a high degree of separation. The choice of the filter medium

Table 15.7 Specifications of typical measuring systems—aerosols

Measured radiation/nuclides	Measurement method	Detection	Sampling medium
γ-Radiation	Automatic system: γ-ray spectrometry	HPGe detector 15%	Filter tape
γ-Radiation	Laboratory method: γ-ray spectrometry after sampling	HPGe detector ≥ 20%	Filter
Artificial α-activity	Monitoring system: alpha spectrometry	Silicon detector	Filter
Artificial β-activity	Monitoring system: integral measurement	Plastic scintillator	Filter
Strontium-89, Strontium-90	Laboratory method: LSC	Photomultiplier	Filter
Alpha-emitting radionuclides	Laboratory method: α-spectrometry	Silicon detector	Filter

Table 15.8 Specifications of typical measurement systems for gaseous radionuclides

Measured radionuclides	Measurement method	Detector	Sampling medium
Iodine isotopes	γ-Ray spectrometry	HPGe detector	Charcoal
Iodine-131	Automatic system: NaI(Tl) monitoring device	NaI(Tl) detector	Charcoal
Krypton-85,	Laboratory method: Beta-counting	Proportional counter	Cryogenic enrichment on charcoal
Xenon isotopes	Laboratory methods: Beta-counting γ-Ray spectrometry Beta–gamma coincidence	Prop. counter, HPGe detector, plastic scintillator	Enrichment on charcoal
Carbon-14 in Carbondioxide	Laboratory method: LSC	Photomultiplier	Enrichment of CO ₂ in NaOH

Table 15.9 Specifications of typical measurement systems in precipitation

Measured radiation/radionuclides	Measurement method	Detector	Sampling medium
γ -Radiation	γ -Ray spectrometry	HPGe detector	Precipitation
Strontium-89, Strontium-90	LSC	Photomultiplier	Precipitation
Uranium-235, Plutonium-(239+240), Americium-241	α -Ray spectrometry	Silicon detector	Precipitation
Tritium	LSC	photomultiplier	Precipitation
β -Activity	Integral beta-counting	Geiger-Müller tube	Precipitation
γ -Radiation	In-situ γ -ray spectrometry	HPGe detector	In-situ; ground

Table 15.10 Specifications for the measurement of ambient dose rate (for GM tubes used in the German gamma dose rate network)

Detector type	Count rate per dose rate ($\text{min}^{-1} \mu\text{Sv}^{-1} \text{h}$)	Intrinsic background rate (min^{-1})	Dose rate range ($\mu\text{Sv h}^{-1}$)	Energy range (keV)	Quantity
Low dose	1000 ± 20	< 15	0.02–1000	$35-1250 \pm 20\%$	$H^*(10)$
High dose	1.0 ± 0.2	< 0.20	20–5 000 000	$60-2000 \pm 20\%$	$H^*(10)$

should also take into consideration that it might need to be suitable for radiochemical processing subsequent to gamma spectrometric analysis, for example for the

identification of alpha and beta emitters. Examples are glass-fiber, cellulose, polypropylene, and PVC filters with cotton support.

15.6 Quality Control

Quality control (QC) for measurement systems is critical for providing reliable results, especially in the event of nuclear emergencies. Internal quality control is conducted by repeated measurements of radioactivity standards and calibration sources. In addition, external quality control is performed through participation in national and international intercomparison and proficiency tests [15.22].

15.6.1 Calibration

Detection systems need to be calibrated with respect to the type and quantity of radiation measured. Calibration sources require well-known composition and activities. Their energies should cover the energy range needed for the measurements. They should be traceable to national standards. Best practice is to use a calibration source in the same measuring geometry and matrix as the samples to be analyzed. If a different medium is used for calibration, corrections for the density and composition of the material must be applied. For γ -ray spectrometry, in some cases a simulation of the detection efficiency is possible using Monte Carlo techniques.

For measurements applied after radiochemical separation, the determination of chemical recovery is necessary. This is done by adding a tracer of another isotope of the same element with known activity to each sample.

Spectrometric systems also need energy calibration to determine the relation between spectrum channel and energy of the radiation. This is done with radiation

sources with radionuclides emitting energies covering the desired energy range.

15.6.2 Specific Quality Control Methods

To ensure high-quality functionality for *gamma dose rate probes* and to uncover possible failures, initial performance tests of newly delivered or repaired probes should be performed. Probes are irradiated at different dose rate levels e.g., 10, 1000 and 100 000 $\mu\text{Sv/h}$, and the observed dose rate is compared with reference values. Initial tests must be complemented by periodic quality assurance tests. Typically these test are performed every 5 years. In these tests, the long-term responses of the probes are compared with their initial parameters.

For *spectrometric measurements*, significant deviations in energy calibration, efficiency, and peak shape may be observed during the measurement. Recurrent measurements of radioactivity standards and calibration sources are used to control the stability of the system with regard to energy calibration, energy resolution, and efficiency. Periodic measurements of the background ensure that possible contamination of the measuring system is identified at an early stage. The time intervals for these checks depend on the tasks of the specific laboratory and vary from daily to semiannually.

For *laboratory filter measurements*, it is also important to measure a blank filter in each new batch to identify potential interfering radionuclides on the filter material.

15.7 Maintenance

Preventive maintenance is recommended to avoid technical failures. The frequency and types of procedures depend on the type of device.

15.7.1 Gamma Dose Rate Probes

Defects in electrical systems and equipment carry an increased risk of accidents and fire. Together with other maintenance tasks, specialists regularly check the safety of the measuring systems, at least every 4 years. Observed failures are removed immediately. Electrical safety tests according to the German Statutory Accident Insurance (DGUV) regulation part 3 and DIN VDE/EN industry standards [15.23–28] are required by law in Germany. These tests improve the electrical safety of the measuring systems and also reduce electromagnetic interference, thus leading to improved overall station performance.

15.8 Application

The described methods and devices are used for nuclear emergency preparedness as well as for environmental monitoring and the verification of the CTBT. In addition, these measurements are used for scientific studies. Measurement are exchanged on an international level to allow for a (more or less) complete assessment of the radiological situation.

15.8.1 Emergency Preparedness

Consistent and appropriate protective measures must be in place before, during, and after radiological emergencies. This requires information about the affected areas, the level of contamination, and the actual and future exposure. For this purpose, online air monitoring and gamma dose rate networks are required, with stationary probes equally distributed over the national territory. In emergency mode, data from all stations will be accessed in almost real time, enabling the population to be informed in an efficient and timely manner.

The operational status of monitoring devices is monitored by experts on a daily basis. For maintenance, technicians are trained to complete repairs as quickly as possible in the case of failures. In both routine mode and emergency mode, all relevant data are transferred to a central location. In the case of offline sampling, the filter and the precipitation samples are collected and transported to central laboratories where measurements (following radiochemical separation procedures, if needed) are conducted.

Along with electrical safety tests, the site conditions of the gamma dose rate stations are checked, and batteries have to be changed every 8 years.

15.7.2 Aerosol Sampler

For aerosol samplers, it is recommended that volume flow and pumps be checked at least semiannually.

15.7.3 Spectrometric Systems

In general, a specific maintenance regime is not necessary. Required maintenance or repair will be identified with the QC measurements. As an example, for HPGe detectors, a continuous degradation of the energy resolution might be caused by a loss of vacuum in the system and will be detected with internal QC measurements.

15.8.2 Environmental Monitoring

Measuring devices used for the detection of radionuclides in the atmosphere are operated in automatic mode. In the case of an emergency, the results for aerosol-bound radionuclides and radioactive iodine isotopes and for ground-deposited radionuclides are available in less than 2 hours.

High-volume filter samples and samples of precipitation have to be collected manually and transferred to a laboratory for further investigation. Sensitive measurements of these filter samples (trace analysis) enable the observation of long-term trends in activity concentrations and investigation of increased activity concentrations in the range of micro-becquerel per cubic meter [15.29]. Possible sources can be identified with information from different sampling sites by applying atmospheric transport models. This is based on a rapid exchange of measurement results between the laboratories performing such measurements with reliable quality.

Precipitation typically must be enriched to measure very low activity concentrations. In the normal mode, this is done by ion exchange systems used in automatic sampling devices. Automation of sampling systems requires precise organization of sample transport to the laboratory and maintenance.

One of the main functions of gamma dose rate networks is to provide immediate alerts if increased radiation levels are detected. If two neighboring stations

(distance less than 30 km) have detected increased radiation levels for a period of a minimum of 1 hour, an officer on duty is notified via cell phone, who then has to analyze the radiological situation within 1 hour [15.30]. Assuming a typical gamma dose rate of $0.08 \mu\text{Sv/h}$, the alert level is approximately $0.11 \mu\text{Sv/h}$. Independent from the alert mechanism, measurement results from the gamma dose rate network are provided every hour in routine mode and every 10 minutes in emergency mode.

The results of environmental monitoring provide continuous information about the present level of radioactivity caused by naturally occurring and man-made radionuclides. In Germany, 41 sampling and measuring sites for the collection and measurement of atmospheric activity concentrations and approximately 1800 stationary gamma dose rate probes are equally distributed over the German territory. The density is increased in the 20 km and 100 km emergency planning zones (according to new recommendations) around nuclear power plants.

All different types of networks provide an overview of the spatial and temporal variability of radionuclide levels deposited on the ground and in the atmosphere. An example of the sensitivity and selectivity of trace survey measurements is the observation of the radioac-

tive cloud from the accident at Fukushima–Daiichi by European networks [15.31].

15.8.3 Comprehensive Nuclear-Test-Ban Treaty

Apart from waveform technologies (seismic, hydroacoustic, and infrasound), continuous monitoring of radionuclides in the atmosphere is part of the worldwide International Monitoring System (IMS) for verification of the CTBT, which was established for the detection and identification of any nuclear test activity. Together with atmospheric transport modeling, the network is designed to detect all kinds of nuclear tests with strength of 1 kT or more at 95% certainty within 10 days. Radionuclide monitoring includes the measurement of both particle-bound radionuclides and the radioactive isotopes of the noble gas xenon, which is of special importance for the detection of underground testing. The radionuclides are detected after atmospheric transport from the source to the CTBT radionuclide stations. To meet the verification requirements, detection limits of $10 \mu\text{Bq/m}^3$ for Ba-140 (aerosol-bound) and 1 mBq/m^3 for Xe-133 (noble gas) must be achieved, along with data availability of 95% [15.7, 15, 32].

15.9 Future Developments

All types of systems used for radionuclide monitoring are under continuous development with respect to the main parameters, including sensitivity, time resolution, and reliability. For example, the CTBTO focuses on improvement in detection limits for the different xenon isotopes of noble gas systems operated in their network [15.14, 33, 34]. Because nuclear tests are not the only source of atmospheric xenon, the reliable determination of the ratio of the different xenon isotopes is important in order to distinguish between civil emissions and a nuclear test.

After the accident at the Fukushima–Daiichi nuclear power plant in March 2011, the application of mobile systems installed in vehicles and drones complemented by mobile gamma spectrometric measurements were found to be the most efficient techniques for monitoring contamination levels and the efficiency of decontamination measures in Japan [15.35]. These measurements were embedded in comprehensive measurement programs that were developed and implemented over a period of several years after the accident. From the lessons learned after the accident at Fukushima–Daiichi in Japan, the development of modern measurement

strategies taking into account recent developments, especially of mobile measurement equipment, will be the focus for improving radiation monitoring systems in the future.

The data exchange platform EURDEP collects and provides data from all European radiation monitoring networks in almost real time on behalf of the European Commission. Today, data are collected from 30 European countries, using a considerable number of different detector and measurement types and following different national policies. The comparability of these data is crucial for a meaningful interpretation, not only in the event of a nuclear accident with transboundary implications, but also for the correct interpretation of the data under natural background conditions. Furthermore, data assimilation techniques used in decision support systems like realtime online decision support system (RODOS) [15.36] strongly depend on harmonized data complemented by an appropriate uncertainty. Therefore, harmonized and metrologically substantiated radiation monitoring data are critical for adequate environmental radiation monitoring in Europe.

ustoehlker@bfs.de

Ulrich Stoehlker is responsible for the German external dose rate monitoring network, with 1800 gamma dose rate measurement posts and mobile equipment. This includes the organization and management of staff and laboratories at six different locations in Germany. From July 2010 until July 2013 he was Senior Radionuclide Officer at the International Data Centre (IDC) of the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) in Vienna.

16. Gas Analysers and Laser Techniques

Dwayne Heard , Lisa K. Whalley , Steven S. Brown 

A range of sensitive and selective analytical techniques are required to perform measurements of the gas-phase composition of the atmosphere, as the lifetimes and concentrations of trace gases in the atmosphere (the analytes) vary widely. This chapter describes in-situ methods where the analyte of interest is quantified either directly via the absorption or emission of radiation by the analyte or indirectly following chemical conversion or photodissociation to another species, which is subsequently detected via absorption or emission spectroscopy or chemiluminescence. Optical excitation is achieved using either a broadband light source or a narrowband laser source.

The techniques covered are differential optical absorption spectroscopy (DOAS), Fourier-transform infrared (FTIR) spectroscopy, cavity-enhanced spectroscopy (CES), tunable diode laser spectroscopy (TDLS), laser-induced fluorescence (LIF) spectroscopy (in particular, LIF at low pressure using fluorescence assay by gas expansion: FAGE), laser-induced phosphorescence (LIP) spectroscopy, and chemiluminescence. A technical description of each method and the underlying theory is presented, together with a discussion of instrument optimization and the parameters that control performance, for example instrument sensitivity and selectivity and possible interference-induced artifacts when operated in the field. Quality assurance is described, including the calibration and inter-comparison of instruments.

Finally, some examples of field measurements of the concentrations of key atmospheric gases (such as short-lived radical intermediates and longer-lived stable gases) using a variety of platforms are presented to illustrate applications of the methods described in this chapter.

In this chapter, techniques and instruments designed for the in-situ measurement of trace gases in the atmosphere using optical methods are described, together with some examples of their deployment in the field and the results they yield. The chapter covers methods suitable for ground-based measurements from fixed platforms and mobile measurements from ships and aircraft. These techniques can be divided into two main classes. The first involves direct optical excitation of the analyte and quantification via measurement of either the fraction of light absorbed (using the Bouguer–Lambert–Beer’s law) or the intensity of the ensuing emission from the excited state. The second involves the conversion of the analyte to another species via a chemical reaction with an added reagent, with the product being detected optically via its spontaneous chemiluminescence or through absorption or emission spectroscopy.

16.1 Measurement Principles and Parameters

Many trace gases are released directly into the atmosphere at the Earth’s surface from oceans or terrestrial environments via natural processes, or they are emitted during anthropogenic activities. Many others are generated following chemical transformations of those emissions (through the action of sunlight or reactions with a variety of oxidants) to secondary trace gases or aerosols with a very wide range of chemical functionality. With increasing aging of the air mass from the emission source, the oxidation products become less volatile and partition to the aerosol phase. A concern is whether anthropogenic emissions are causing a deterioration of the air that we breathe or are leading to a warming of the atmosphere, with associated impacts.

Gas-phase measurements performed using the techniques covered in this chapter are employed for many purposes. Some are used to monitor long-term trends in gas concentrations (e.g., for gases that have been phased out due to binding international treaties such as the Montreal Protocol) or to quantify human exposure to gases with an identifiable health impact. The resulting data are used by policy regulators. The lifetimes of trace gases span an enormous range, from a few milliseconds for the hydroxyl radical OH in a polluted environment to hundreds of years for some chlorofluorocarbons (CFCs). The lifetimes of short-lived gases such as radicals (which have an unpaired electron) are controlled only by the local in-situ chemistry, not by the transport of these gases. Hence, measurements made at specific times and locations are used as targets for atmospheric models that include our best knowledge of

This chapter is complementary to those on the ground-based sensing of gases (Chap. 1 on atmospheric measurements) and spectroscopic methods (Chap. 28 on spectrometers). Also, as the levels of many trace gases are controlled by solar radiation, this chapter is linked to those on spectrally resolved radiation measurements (Chap. 11 on radiation sensors, Chap. 40 on solar radiation sensors, and Chap. 28 on radiometers).

Local measurements can be made using these instruments at a fixed point in space, and regional measurements can be carried out on an aircraft or ship. Rather than being open-path detectors (like remote sensing instruments), the majority of the instruments described in this chapter have a dedicated inlet to sample the atmosphere.

the chemical mechanisms that transform gas emissions. The level of agreement between the measurements and the models quantifies how well the chemistry is understood. Verifying that the chemistry is understood and correctly represented in models leads to greater confidence in model-based predictions of how the air quality or climate will respond to changes in global emissions. Such predictions have driven policy to combat global warming and deteriorating air quality.

16.1.1 Measured Parameters of Gas-Phase Analyzers and Laser Techniques

The ultimate goal of the methods described in this chapter is to provide a quantitative measurement of the number density (or concentration) of a given trace gas, which can be converted into a mixing ratio if the total density of the air is known at the location of the measurement [16.1]. For a fixed concentration of a trace gas, the mixing ratio increases with altitude as the pressure decreases. One observable is the absorbance, which is a measure of the change in the intensity of radiation at a detector due to absorption by a sample, and is related to the concentration via the Bouguer–Lambert–Beer’s law. For example, the absorbance of a sample present in either a conventional absorption cell or an optical cavity can be measured using differential optical absorption spectroscopy (DOAS). Another observable is the intensity of emission from an excited state, measured either as an analogue voltage from a detector or the number of photons counted by a detector.

Table 16.1 Measured parameters of gas analyzers and laser techniques for trace gases

Parameter	Description	Unit	Symbol
Mixing ratio	Mole fraction of the trace gas in an ambient air sample, often quoted in parts per million (ppmv), parts per billion (ppbv), or parts per trillion (pptv) by volume	mol mol ⁻¹	χ
Concentration as a number density	Number of atoms or molecules of species X per unit volume of air	atom cm ⁻³ or molecule cm ⁻³	[X] or c_n
Concentration as a mass density	Mass of atoms or molecules of species X per unit volume	kg m ⁻³	c_m
Absorption cross-section	Inherent measure of the ability of a molecule to absorb light	cm ² molecule ⁻¹	σ_{abs}
Photodissociation quantum yield	Fraction of the molecules excited via photon absorption that dissociate to form a particular product	No unit	ϕ
Photolysis frequency	Rate of photolysis of a molecule integrated across the atmospheric range of wavelengths	s ⁻¹	J

Table 16.2 Key performance indicators for instruments that are used to measure trace gas concentrations

Parameter	Description	Unit	Symbol
Limit of detection	Lowest concentration or mixing ratio of a trace gas that can be measured, as defined for a given signal-to-noise ratio (or number of standard deviations of the noise) and signal averaging time	Molecule cm ⁻³ or mol mol ⁻¹	[], c_n , c_m , or χ
Precision	Concentration or mixing ratio corresponding to a particular number of standard deviations of the background signal	Molecule cm ⁻³ or mol mol ⁻¹	[], c_n , c_m , or χ
Accuracy	Accuracy of the calibration, cross-section, or path length, usually presented as a percentage of the derived quantity	%	
Degree of interference	Fraction of the observed signal that is due to an unwanted species (sometimes referred to as a bias)	%	

Detectors used in this context include devices such as photodiodes and photomultipliers in which a photocathode converts the emitted photons into electrons. If the path length and absorption cross-section are known, the Bouguer–Lambert–Beer’s law can be used to determine absolute concentrations without the need to perform a calibration, whereas emission methods require calibration (i.e., the signal from a known concentration of analyte is measured). Table 16.1 shows the parameters measured by absorption or emission instruments.

There are also a number of parameters that enable the detection performance of a particular instrument for a particular species to be quantified, as shown in Table 16.2. Which of these is most important depends on the desired application of the data. For example, when determining the trend in methane levels over several years or the emission flux of a given species from a surface, a precision to 1% of the measured concentration may be required. On the other hand, greater accuracy may be required in a comparison of instruments across a network or a comparison with a model [16.1].

It is useful to be able to convert a concentration (number density) [X] into a volumetric mixing ratio χ_X , as both of these quantities are commonly used when reporting abundances of trace gases. The relationships

used to interconvert these two quantities are

$$[X] = \chi_X \frac{p_{\text{air}} N_A}{10^6 RT} \quad (16.1)$$

$$\chi_X = [X] \frac{10^6 RT}{p_{\text{air}} N_A}, \quad (16.2)$$

where p_{air} is the local air pressure (in Pa or Nm⁻¹), N_A is Avogadro’s number (6.022×10^{23} mol⁻¹), R is the gas constant (8.314 J mol⁻¹ K⁻¹), T is the local temperature, and the units of concentration are molecule cm⁻³. In order to convert the mixing ratio into the commonly used units ppmv, ppbv, pptv, and ppqv (parts per million, billion, trillion, or quadrillion by volume, respectively), the mixing ratio is multiplied by 10^6 , 10^9 , 10^{12} , and 10^{15} , respectively.

16.1.2 Measurement Principles

The applications of the different types of measurements (absorption, emission, and chemical conversion with chemiluminescence) that are performed to quantify trace gases are given in Table 16.3. The flux of a gas is the number of molecules of gas that pass through a certain boundary plane (which may be a surface) per

Table 16.3 Principles and applications of gas analyzers

Type of sensor	Measurement principle	Applicability	
		Gas concentration	Gas flux measurements
DOAS, FTIR, CES, TDLs	Absorption	×	×
Laser-induced fluorescence	Emission	×	×
Laser-induced phosphorescence spectroscopy	Emission	×	
Chemical conversion with product detection	Absorption and emission (chemiluminescence)	×	×

unit volume per second. A negative flux corresponds to movement in a downwards direction, which could be due to the deposition of the gas on a surface, whereas

a positive flux corresponds to movement in a upwards direction, which could be due to the emission of the gas from a surface (e.g., a forest canopy).

16.2 History

In this section we provide a short historical account of the main analytical methods discussed in this chapter, mention some of the pioneers in this field, and mention some of the important molecules that can be quantified.

16.2.1 Differential Optical Absorption Spectroscopy (DOAS)

Differential optical absorption spectroscopy (DOAS) is a broadband (i.e., not monochromatic) ultraviolet and visible technique that utilizes the structured electronic absorption features of various small molecules to identify and separate multiple absorbing species. As such, it is often used in remote sensing applications, as described further in Chap. 26. Pioneering DOAS studies include measurements of ozone columns (the highest concentrations of ozone occur in the stratosphere) by *Gordon Dobson* (1889–1975). This technique is also commonly used to measure concentrations of absorbing trace gases over kilometer-scale open paths, in which case it can be considered an in-situ technique. The use of DOAS in closed-path optical cavities is described further in Sect. 16.2.4 below. The first demonstration of this method occurred in the 1970s. *Dieter Perner* and *Ulrich Platt* imaged a frequency-doubled dye laser beam over a 7.8 km path in Jülich, Germany, providing probably the first interference-free measurements of the OH radical [16.2]. Shortly thereafter, those authors used the same technique to measure CH₂O, O₃, NO₂, HONO, and NO₃ at sites in the US and Germany [16.3–5]. This method has since become a standard for measuring these and other trace gases such as halogen oxides [16.6, 7], SO₂, and glyoxal [16.8].

16.2.2 Fourier-Transform Infrared (FTIR) Spectroscopy

Interferometric techniques dating back to the work of *Albert Michelson* (1852–1931) in 1881 form the basis for broadband infrared spectroscopy. FTIR was initially applied as a measurement technique in ambient air in the mid-1950s [16.9], but was first used routinely for air monitoring in polluted regions in the 1970s [16.10, 11]. This method has the advantage of being versatile, as it can provide simultaneous measurements of numerous trace gases (e.g., O₃, H₂O₂, HNO₃, HONO, H₂CO, HCOOH, PAN, HCl, NH₃, NO, and NO₂) based on their mid-infrared absorption bands, but it also has the disadvantage of being less sensitive than other methods. A primary application of FTIR is in the study of biomass burning, as it is used in both laboratory and aircraft measurements of concentrated emissions from fires [16.12–14].

16.2.3 Tunable Diode Laser Spectroscopy (TDLs)

In contrast to DOAS and FTIR, spectroscopy based on tunable diode lasers achieves spectral selectivity through a narrowband light source rather than a dispersive or interferometric detector. This technique is most applicable in the mid- and near-infrared, where narrowband lasers can resolve individual rovibrational features of small, atmospherically relevant molecules. The history of this method is similar to those of the methods described above in that the first applications of this technology occurred in the 1970s and 1980s [16.15] and followed from the development of the laser sources themselves. As with DOAS and FTIR,

the method requires either a long, open atmospheric path or a multipass cell (more typically the latter for TDLS). Whereas White cell optics (invented by *John U. White* in 1942 [16.16]) are most commonly employed with the broadband source used in FTIR, Herriott cells (as demonstrated by *Donald R. Herriott* (1928–2007) in 1964 [16.17]) are appropriate for use with coherent light sources. The development of TDLS methods for atmospheric sensing has been facilitated by the development of these measurement cells [16.18].

16.2.4 Cavity-Enhanced Spectroscopy (CES)

The application of optical cavities to enhance the path lengths of optical detectors is a more recent development than the methods outlined above, although CES does share many attributes with those methods, depending on the specific implementation. In 1988, *O'Keefe and Deacon* [16.19] demonstrated an optical path equivalent to 2–13 km by measuring the decay of light from a pulsed laser light source based on an optical cavity constructed from a pair of visible, high-reflectivity mirrors. A year later, they applied this technique—known as cavity ring-down spectroscopy (CRDS)—to the NO₂ absorption spectrum in laboratory air [16.20]. In 1997, *Romanini et al.* [16.21] demonstrated the use of continuous-wave, narrow-band lasers in CRDS, a breakthrough that has since resulted in the utilization of CRDS and other CES methods in numerous applications, including greenhouse gas measurements. Among the first applications of CRDS (and other CES methods) in atmospheric sampling was the measurement of the nitrate radical NO₃, which has strong visible absorption bands that make it amenable to optical detection [16.22, 23]. It has also rapidly developed into a standard technique for measuring greenhouse gases using inexpensive near-infrared diode lasers [16.24, 25].

16.2.5 Laser-Induced Fluorescence (LIF) Spectroscopy

The hydroxyl radical OH, which is the primary atmospheric oxidant [16.26], was first detected by *James Anderson* in 1971 in the upper stratosphere and mesosphere using solar-induced fluorescence with a rocket-borne instrument. Anderson detected OH in the middle/lower stratosphere in 1975 using resonance fluorescence with gas discharge as a 308 nm light source. The development of LIF spectroscopy began after the invention of the laser in the 1960s [16.27], and measurements of atmospheric concentrations became more

common following the advent of the dye laser, which has a tunable wavelength [16.28]. One of the first attempts to measure tropospheric OH using LIF was undertaken by the Ford Motor Company [16.29]. Unfortunately, subsequent studies demonstrated that the observed signal mainly came from OH generated by the laser pulse itself, rather than from naturally occurring OH. A change of methodology in the 1980s led to the successful measurement of OH in the troposphere. Several other molecules, for example NO₂ and formaldehyde (HCHO), have also been detected directly via LIF at a range of wavelengths [16.30, 31]. Although a number of species have been detected by LIF following their conversion to another species either chemically (e.g., HO₂ → OH via the addition of nitric oxide, NO) or following photolysis (e.g., HONO $\xrightarrow{h\nu}$ OH), LIF is not used as widely as absorption methods to determine atmospheric compositions.

16.2.6 Chemiluminescence Methods

When an excited molecule is produced in an exothermic chemical reaction, it may subsequently spontaneously relax back to its ground state, emitting light in the process. The light emitted from the (usually electronically) excited molecule during this relaxation process is known as chemiluminescence. Detection methods based on chemiluminescence are popular and have been applied to a wide range of molecules, and a large number of commercial instruments that utilize chemiluminescence are in use worldwide. Some of the first atmospheric measurements performed via this method were those of ozone in the 1950s and 1960s; these involved reacting the ozone with a dye molecule [16.32, 33]. Owing to the lightweight nature of instruments that use this technique, chemiluminescence detection has been widely used on airborne platforms. NO is very commonly measured through its chemiluminescent reaction with ozone [16.34], as is NO₂ following its conversion to NO via photolysis or a catalyzed chemical reaction, and instruments that use this method are employed in air quality networks. Total reactive nitrogen (NO_y), which encompasses a number of species such as alkyl nitrates and nitric acid, has also been quantified. Measurement of NO_y is achieved through conversion to NO (usually by heating in the presence of a catalyst) followed by chemiluminescence [16.35], or specific NO_y species can be detected by heating the sample to a controlled temperature and measuring the NO₂ formed after pyrolysis using LIF [16.31].

16.3 Theory

We now outline some of the fundamental concepts and ideas that underpin the analytical techniques described in this chapter, such as the absorption and emission of light and the sensitivity (and therefore the limit of detection) of an instrument.

16.3.1 Optical Methods: Absorption Spectroscopy

Common to all optical absorption spectroscopy methods, regardless of the wavelength region considered or the specific technique used, is the application of the Bouguer–Lambert–Beer’s law. This law relates the change in intensity of a light source over a fixed path length l to the concentration N of an absorbing trace gas and its wavelength-dependent (or frequency-dependent) absorption cross-section $\sigma(\lambda, P, T)$ via

$$I(\lambda) = I_0(\lambda) \exp[-N\sigma(\lambda, P, T)l]$$

$$N = \frac{1}{\sigma(\lambda, P, T)l} \ln \frac{I_0(\lambda)}{I(\lambda)}. \quad (16.3)$$

This expression assumes a uniform gas concentration over the absorption path. If this is not the case, the argument of the exponent must be replaced by an integral over l rather than a product. The expression also assumes that all optical extinction occurs through absorption, which is generally not the case (see later). $I(\lambda)$ and $I_0(\lambda)$ are the intensities at the detector and incident on the sample, respectively, although the latter is often measured in practice as the intensity at the detector in the absence of absorbing trace gases or at a wavelength that is off-resonance with the target absorber. Depending on the type of transition (i.e., electronic, vibrational, or rotational), the absorption cross-section may be dependent on both temperature and pressure, as indicated by the equation. The absorber concentration N is normally given in units of number density (atoms or molecules cm^{-3}), meaning that the argument of the exponential function is unitless (σ is in $\text{cm}^2 \text{ molecule}^{-1}$ and l is in cm). This argument,

$$A(\lambda) = N\sigma(\lambda, P, T)l, \quad (16.4)$$

is referred to as the absorbance.

Absorbance is more commonly defined in terms of base 10 logarithms in the chemical literature, where it is also referred to as the optical density. In atmospheric science, the natural logarithm of the absorbance is considered. With the exception of radical species present at low concentrations, such as OH or Cl, atmospheric trace gas abundances are often expressed in mixing ratio units (pptv, ppbv, or ppmv). The mixing ratio $\chi =$

N/N_{tot} , where N_{tot} is the density of the air sample as a whole and N is the trace gas number density. A related quantity is the path-length-normalized absorbance, also referred to as the absorption or extinction α , which is given by

$$\alpha(\lambda) = \frac{A}{l} = N\sigma(\lambda, P, T), \quad (16.5)$$

and has units of inverse length.

For a typical range of molecular absorption cross-sections ($\sigma = 10^{-17}$ – $10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$) and trace gas mixing ratios of a few tens of pptv to a few ppbv (roughly equivalent to concentrations of 10^9 – $10^{11} \text{ molecule cm}^{-3}$), α is in the range 10^{-11} – 10^{-6} cm^{-1} . Thus, A is not appreciably large unless the optical path length is on the order of 100 m (10^4 cm) or greater. In other words, schemes that increase the optical path using long, open atmospheric paths, multipass cells, or optical cavities are essential when measuring atmospheric trace gases via absorption techniques.

Although the Bouguer–Lambert–Beer’s law is universally applied in optical absorption methods, its implementation varies depending on the technique, as outlined below. Note that each method has a different convention for wavelength or frequency. DOAS often uses the wavelength λ (in nm or μm), FTIR typically uses the wavenumber $\bar{\nu}$ (in cm^{-1}), TDLS commonly uses the frequency ν (in Hz), and CES may use any of these depending on the application. These units are easily interconverted via $\lambda = 1/\bar{\nu} = c/\nu$, where c is the speed of light.

Differential Optical Absorption Spectroscopy (DOAS)

As noted earlier in this chapter, DOAS is an ultraviolet (0.2–0.4 μm) and visible (0.4–0.7 μm) method that is used over long, open atmospheric paths, either in a remote sensing configuration or over a fixed path between an artificial light source and a spectrometer/detector. The application of the latter configuration—referred to as long-path DOAS (LP-DOAS)—for in-situ measurements is described in this section. The first and most obvious modification of the Bouguer–Lambert–Beer’s Law is that the change in intensity from light source to detector over a long open atmospheric path is non-negligibly influenced by Rayleigh (gas-phase) and Mie (particle-phase) scattering, as well as by aerosol absorption. Secondly, the method probes absorption from multiple species simultaneously, such that a sum over the absorbing species must also be included. Expressing (16.3) in terms of extinction and including these terms

yields

$$I(\lambda) = I_0(\lambda) \exp \left[- \left(\sum_i \sigma_i(\lambda, P, T) N_i + \alpha^{\text{Ray}}(\lambda) + \alpha^{\text{Mie}}(\lambda) \right) l \right]. \quad (16.6)$$

Here, $\sigma_i(\lambda, P, T)$ is the absorption cross-section due to trace gas i , while $\alpha^{\text{Ray}}(\lambda)$ and $\alpha^{\text{Mie}}(\lambda)$ are the Rayleigh scattering extinction in air and the Mie scattering extinction by particles, respectively. Rayleigh scattering cross-sections are proportional to the fourth power of the wavelength and thus increase rapidly toward the ultraviolet. For example, the Rayleigh scattering cross-section for dry air at 300 nm (σ^{Ray}) is $5.3 \times 10^{-26} \text{ cm}^2 \text{ molecule}^{-1}$, leading to a 13% attenuation for every 1 km of path length at sea level and 25 °C. Mie scattering by atmospheric aerosols is variable—it depends on the number, size distribution, and composition of the particles involved, but visible optical extinction can easily reach $\alpha^{\text{Mie}} \geq 10^{-6} \text{ cm}^{-1}$ in polluted urban areas.

As it is not possible to record the light intensity in the absence of trace gas absorption or scattering processes in an open path ($I_0(\lambda)$), DOAS separates the trace gas absorption cross-sections into structured (differential) and smoothly varying terms, i.e., $\sigma(\lambda) = \sigma^{\text{diff}}(\lambda) + \sigma^{\text{s}}(\lambda)$, and groups $\sigma^{\text{s}}(\lambda)$ together with Rayleigh and Mie scattering, which also vary smoothly. This separation results in a simplified description of the spectrum,

$$I(\lambda) = I'_0(\lambda) \exp \left[- \left(\sum_i \sigma_i^{\text{diff}}(\lambda, P, T) N_i \right) l \right] \quad (16.7)$$

$$I'_0(\lambda) = I_0(\lambda) \exp \left[- \left(\sum_i \sigma_i^{\text{s}}(\lambda, P, T) N_i + \alpha^{\text{Ray}}(\lambda) + \alpha^{\text{Mie}}(\lambda) \right) l \right]. \quad (16.8)$$

The term $I'_0(\lambda)$ can then be obtained from a smooth fit across the entire spectrum, while the differential structure can be fitted using known differential cross-sections for the target trace gases.

Fourier-Transform Infrared Spectroscopy (FTIR)

Fourier-transform spectroscopy is a common technique for performing broadband mid-infrared (mid-IR, 2.5–25 μm) measurements. Rather than using a dispersive element such as a diffraction grating to achieve

spectral resolution, FTIR records an interferogram by splitting the light from a broadband source and sending it along two paths, one to a fixed and the other to a movable mirror. The two beams are recombined on the same beam splitter and directed through a multipass sample cell to a detector. A scan of the movable mirror leads to sinusoidal variation in the detected light intensity due to alternating constructive and destructive interference of the two beams. The Fourier transform of this interferogram $I(\delta)$, where δ is the mirror displacement (or retardation, in cm), gives the spectrum $B(\bar{\nu})$ as a function of the frequency $\bar{\nu}$ in wavenumbers (cm^{-1}),

$$B(\bar{\nu}) = 2 \int_0^d I(\delta) \cos(2\pi\bar{\nu}\delta) d\delta. \quad (16.9)$$

The limit of spectral resolution (in wavenumbers) is given by $1/d$, where d is the maximum travel in the mirror.

A major advantage of FTIR is the ability to measure wide spectral regions and thus multiple trace gases simultaneously. FTIR instruments achieve this multiplexing at the expense of sensitivity, making the technique generally less applicable to the measurement of low-concentration trace gases. Depending on the spectral resolution and the species detected, analysis of FTIR spectra requires an understanding of spectral line shapes, as described in more detail in the next section.

Tunable Diode Laser Spectroscopy (TDLS)

Tunable diode lasers are typically used in the near-infrared (near-IR, 0.7–2.5 μm) and mid-IR to interrogate individual rovibrational features of small, atmospherically relevant molecules. The linewidths of these light sources are typically narrow compared to the target absorption lines, but their tuning ranges are limited to a single or at most a small number of absorption lines for the target analyte. The absorption cross-section in the Bouguer–Lambert–Beer expression (16.3) is then replaced with the line strength $S(\nu, P, T)$, which is in turn the product of an integrated line strength and a lineshape function. At low pressure, mid- and near-IR absorption lines are Doppler broadened due to the Maxwell–Boltzmann distribution of molecular speeds,

$$\Gamma_{\text{D}} = \sqrt{\frac{4 \ln 2}{\pi}} \frac{1}{\Delta\nu_{\text{D}}} \exp \left[-4 \ln 2 \left(\frac{\nu - \nu_0}{\Delta\nu_{\text{D}}} \right)^2 \right]. \quad (16.10)$$

In this Doppler lineshape function, ν and ν_0 are the frequency and the center of the line, while $\Delta\nu_{\text{D}}$ is the full width at half maximum, which is dependent on the

temperature and molecular mass. At higher pressures of a few hundred millibar or greater, pressure broadening dominates and gives the Lorentzian lineshape

$$\Gamma_L = \frac{1}{2\pi} \left[\frac{\Delta\nu_L}{(v - v_0)^2 + (\Delta\nu_L/2)^2} \right]. \quad (16.11)$$

In practice, the actual lineshape is a convolution of these two functions, referred to as a Voigt lineshape. The optimal sampling pressure is intermediate between the regime where Doppler and pressure broadening dominate, and is determined by the competition between linewidth sharpening and the decrease in analyte number density as the pressure is lowered. This regime is typically in the 50–100 mbar range.

Lineshapes are incorporated into the Bouguer–Lambert–Beer’s law to give a wavelength- or frequency-dependent absorption cross-section using the spectral line intensity, which is integrated over a given molecular rovibrational intensity at a given temperature. Spectral line intensities are available from databases such as HITRAN (high-resolution transmission molecular absorption database) [16.36].

Cavity-Enhanced Spectroscopy (CES)

If the multipass cell that is used to increase the path length and sensitivity for absorption spectroscopy is an optical cavity, the Bouguer–Lambert–Beer’s law still applies, but in a different form due to the lack of a single optical path length within the cavity. There are two methods of extracting an analyte concentration or mixing ratio from a CES signal. The first and most common is to perform time-domain measurements, which involves extinguishing the light source for the optical cavity and then measuring the characteristic time constant τ for single-exponential decay of the light intensity via

$$I(t) = I_0 \exp\left(-\frac{t}{\tau}\right). \quad (16.12)$$

This approach is known as cavity ring-down spectroscopy (CRDS). In the simple case of a two-mirror optical cavity, the time constant is related to the base path of the optical cavity (i.e., the mirror separation L), the speed of light c , and the mirror reflectivity R . Because the optical path lengths can be very long (in some cases in excess of 10 or even 100 km), the time constant is also limited by the Rayleigh scattering in the air at the sample pressure, as well as by Mie scattering by aerosols if an inlet filter is not used, i.e.,

$$\tau(\lambda) = \left[c \left(\frac{1-R}{L} + \alpha^{\text{Ray}}(\lambda) + \alpha^{\text{Mie}}(\lambda) + \sum_i \sigma_i(\lambda, P, T) N_i \right) \right]^{-1}. \quad (16.13)$$

Measurement of the time constants in the presence and absence of an absorber (τ and τ_0 , respectively) yields the absorber number density via

$$N = \frac{1}{c\sigma(\lambda, P, T)} \left(\frac{1}{\tau} - \frac{1}{\tau_0} \right). \quad (16.14)$$

A related time-domain technique, cavity-attenuated phase-shift spectroscopy (CAPS), measures the change in phase between a sinusoidal or square-wave modulated light source at the input and output of an optical cavity [16.37].

Intensity-domain measurements in which the optical cavity is continuously illuminated and the change in output intensity is measured as a function of wavelength or absorber number density are also common. These are referred to as integrated cavity output spectroscopy (ICOS), or simply cavity-enhanced spectroscopy (CES) [16.38], although the latter also refers to all methods that use an optical cavity for path-length enhancements in spectroscopy. In this case, the absorber number density (or densities) is related to the measured intensities at the detector in the presence and absence of the absorbing trace gas(es) via

$$N = \frac{1}{\sigma(\lambda, P, T)} \left[\frac{1-R}{L} + \alpha^{\text{Ray}}(\lambda) \right] \left[\frac{I_0(\lambda)}{I(\lambda)} - 1 \right]. \quad (16.15)$$

In the time domain (CRDS), the relationship in (16.14) is absolute so long as the absorption cross-section is known. In the intensity domain, measurements of I_0 and I are not sufficient to obtain an absolute measurement; the mirror reflectivity (or effective path length in the optical cavity) must also be known. This can be calibrated in laser-based experiments by measuring the ring-down time constant and determining $(1-R)$ from (16.13), or by measuring a known extinction in the case of a light source or detector combination that does not allow for time-resolved measurements. The difference in Rayleigh scattering between two pure gases (e.g., N_2 and He) with strongly contrasting Rayleigh cross-sections has been used for this purpose [16.39].

Cavity-enhanced methods are applicable to all of the wavelength ranges referenced above for the other techniques, from the ultraviolet to the mid-infrared. In the ultraviolet and visible, both CRDS and CES have been used with laser-based and broadband light sources, respectively. In the near- and mid-IR, both approaches have been used for small-molecule spectroscopy in much the same way as TDLS techniques employing multipass cells have. There are only a limited number of examples of the use of CES combined with FTIR.

Fig. 16.1 Schematic of a two-channel broadband cavity-enhanced spectrometer (BBCES) that uses LED light sources in the blue (455 nm) and near-UV (365 nm) to measure nitrogen dioxide (NO_2), glyoxal (CHOCHO), and nitrous acid (HONO) (after [16.40] © K.-E. Min et al., licensed under CC-BY)

This combination is not currently in common use in atmospheric sensing.

One other key aspect of the use of CES methods is the coupling between the light source and the optical cavity. Optical cavities are also referred to as optical resonators because they transmit light at discrete wavelengths or frequencies corresponding to the constructive interference that occurs when the cavity length is equal to an integral number of wavelengths. In the case of narrowband laser absorption spectroscopy in the mid- and near-IR, a frequency match between the laser and the optical cavity is required. This can be achieved by a variety of methods that tune the laser frequency and/or the cavity length into resonance with each other. In the visible and UV, it is common to use light sources with a bandwidth exceeding that of the cavity-free spectral range, thus ensuring the coupling of the light source to multiple cavity modes. These light sources may include pulsed lasers or visible diode lasers, or broadband light sources

such as LEDs and Xe arc lamps with emission spectra that span several tens to hundreds of nm. Figure 16.1 shows an example of a broadband cavity-enhanced spectrometer that uses LEDs as the light source.

16.3.2 Optical Methods: Emission Spectroscopy

This section focuses on fluorescence methods, describing the general principles of excitation and fluorescence collection schemes employed in atmospheric instruments. Apparatus design, the sensitivity and selectivity of each technique, and how the sensitivity can be maximized are discussed. Calibration methodology will be covered in Sect. 16.6.1, and examples of fluorescence spectroscopy devices are given in Sect. 16.4.2. All fluorescence instruments rely on an optical cell in which the sampled air, excitation light, and fluorescence detection intersect.

Laser-Induced Fluorescence (LIF) and Fluorescence Assay by Gas Expansion (FAGE)

The most commonly used excitation light source is a laser, although continuous lamps have found success in a number of applications, such as the detection of carbon monoxide [16.41]. Lasers, however, offer advantages in that they can be pulsed, allowing the fluorescence signal to be collected after the laser has been fired. This can greatly reduce the background signal from laser scatter, significantly increasing the signal to noise and the sensitivity of the instrument. The use of low pressures (1–5 Torr in OH and NO₂ cells) can help to extend the lifetime of the fluorescence beyond the duration of the laser pulse by reducing the number of collisions of the excited-state species with bulk gases (typically N₂ and O₂), as such collisions reduce the fluorescence signal through quenching. The fluorescence assay by gas expansion (FAGE) technique [16.42] refers to laser-induced fluorescence (LIF) conducted at low pressure. There is often an optimum pressure for FAGE instruments that balances the number density of the species of interest and the rate of quenching and thus leads to the maximum sensitivity [16.43].

A number of lasers (e.g., dye lasers, fiber lasers, and titanium sapphire lasers) have narrow spectral

linewidths. This property increases the selectivity of the apparatus by reducing the overlap with the excitation windows of other species. These lasers can be spectrally tuned away from an electronic transition, allowing the instrumental background signal to be determined, and making it possible to confirm the identity of the fluorescing species. Background signals originate from laser scatter, solar scatter that enters the cell through the inlet, and detector dark counts.

A single pass of the laser across the detection axis of the fluorescence cell may be performed, or multiple passes of the laser can be achieved using highly reflective mirrors. As the rate of excitation, and therefore the fluorescence signal, increases linearly with photon flux (provided the excited electronic state does not become saturated), multipass arrangements can improve the overall instrument sensitivity. However, the background laser scatter signal emanating from mirror surfaces increases with the number of passes, so the overall limit of detection of the device may be similar for both laser configurations. Also, multipass cells are more difficult to align than a single-pass setup and may increase laser-induced interference. A schematic of a multipass FAGE instrument is shown in Fig. 16.2 [16.43].

The detection of fluorescence may be on-resonance (i.e., excitation and fluorescence occur at the same wavelength) or off-resonance (the fluorescence is

Fig. 16.2 Cross-section of the FAGE instrument at Indiana University (after [16.43] © S. Dusanter et al., licensed under CC-BY)

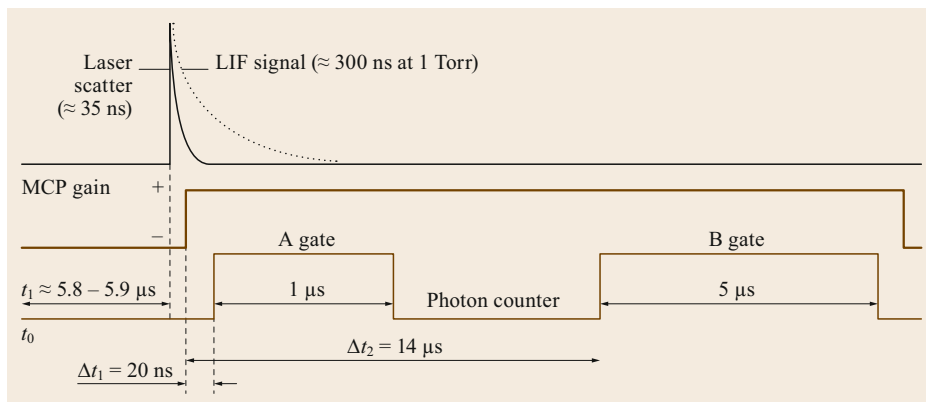

Fig. 16.3 Diagram of the University of Leeds FAGE instrument timings that are used to detect OH fluorescence following laser excitation (*top*). The microchannel plate (MCP) detector gain (*middle*) and photon-counting windows (*bottom*) relative to time zero (t_0) are presented for one 200 μs cycle. The second counter gate, labeled the *B gate*, is used to measure the sum of the photon counts from solar scattered light and detector thermal noise for subtraction from the first counter gate (after [16.44])

shifted with respect to the excitation wavelength). For off-resonance fluorescence, the light that reaches the detector can be optically filtered to distinguish the fluorescence from the laser scatter signal. Bandpass filters (long and short pass) are used. Bandpass filters offer high transmission at the desired wavelengths but considerable attenuation (on the order of 10^{-7}) at other wavelengths, which is sufficient to eliminate Rayleigh scattering and scattering from the cell walls. For on-resonance fluorescence applications, optical filtering to distinguish the fluorescence signal from the laser scatter is not possible. Instead, the detector must be temporally gated to observe the much weaker fluorescence signal once the intense laser scatter pulse has ended; this is the approach adopted for tropospheric OH detection utilizing LIF at 308 nm. On-resonance fluorescence measurements often still employ optical filters to minimize scattered light from other sources (e.g., solar scattered radiation or redshifted laser scattering from the chamber walls).

The gating of the detector from a low-gain state whilst the laser fires to high gain must be rapid in order to maximize the fluorescence detected and thus the instrument sensitivity. Figure 16.3 illustrates the timings used for OH detection with the University of Leeds FAGE instrument [16.44, 45].

LIF techniques include those that detect atoms and molecules directly by electronically exciting the species of interest and then detecting the subsequent fluorescence upon relaxation; examples of such species include OH, HCHO, NO, and NO₂. However, it is also possible to use LIF to detect molecules that do not fluoresce

following excitation by converting those molecules (selectively) into other molecules that do fluoresce. HO₂, for example, is detected using FAGE after it has been chemically converted to OH by reacting it with nitric oxide. Besides chemical conversion, thermal decomposition and photofragmentation techniques are also employed for the indirect detection of molecules using LIF.

16.3.3 Chemical Conversion Methods

In this section, we discuss techniques that permit the detection of atmospheric molecules through chemical conversion. We focus on the use of chemiluminescence, a process that involves the production of light following a chemical reaction. Chemiluminescence is the fundamental process that underpins the methodologies employed for the detection of a variety of atmospherically relevant species. Chemiluminescence can involve heterogeneous reactions between a target gas and a liquid or solid surface, or it can be homogeneous in nature, involving the production of light following a reaction between two gas-phase species. We also cover the process of liquid derivatization, which is used to facilitate the detection of a number of soluble gases by scrubbing the gases into a liquid solution and converting them to another species for detection by either liquid-based techniques such as liquid chromatography, chemiluminescence, or fluorescence detection. Due to the conversion step involved in these types of techniques, we will focus our attention on the sensitivity and selectivity of the chemical conversion methods discussed.

16.4 Devices and Systems

In this section, for each of the major classes of instruments that are used to measure gas-phase compositions, we describe practical aspects of the devices and how they are used in the field to make quantitative measurements. At the end of the section there is a comparison of the devices.

16.4.1 Absorption Spectroscopy Devices

We now introduce a number of examples of the more common applications of absorption spectroscopy devices for atmospheric measurements. The devices include single and multipass instruments and those that exploit optical cavities.

Differential Optical Absorption Spectroscopy (DOAS)

Long-path differential optical absorption spectroscopy (LP-DOAS) was described earlier in this chapter as a method that utilizes ultraviolet/visible absorption over long (typically kilometer-scale) absorption paths. Historically, the method used high-pressure Xe arc lamps as bright broadband light sources that emit across the UV and visible, albeit with some structure due to the presence of atomic emission lines in the source. More recently, light-emitting diodes (LEDs) have been utilized in LP-DOAS as spectrally bright light sources with emission spectra that cover a few tens of nanometers, enough to encompass the absorption bands of specific molecules. These light sources are small, inexpensive, long-lived, and consume barely any power; however, as previously noted, they only emit in specific wavelength regions. The light from the source is collimated by a spherical or parabolic mirror, sent to a retroreflector, and returned to a receiver. This receiver consists of a telescope, grating spectrometer, and detector—most commonly a charge-coupled device (CCD) camera. Situating the light source and receiver at the same location facilitates the recording of reference spectra from the light source. DOAS instruments may also be multiplexed by employing the same light source and receiver combination along multiple light paths and placing retroreflectors at appropriate locations. This arrangement has proven to be very useful for measuring the vertical profiles of trace gases in urban areas, especially for species such as HONO and NO₃ that exhibit characteristic gradients [16.46].

Fourier-Transform Infrared Spectroscopy (FTIR)

As noted above, FTIR spectrometers have the advantage that they can be used to measure multiple small

molecules via broadband measurements throughout the fingerprint region of the mid-IR, where nearly every molecular species (aside from homonuclear diatomics) has strong absorption lines from their fundamental vibrational transitions. Conversely, FTIR suffers from lower sensitivity than laser-based mid- and near-IR absorption spectroscopy. A multipass cell is required for measurements of atmospheric trace gases, and the most common configuration for FTIR instruments involves the use of the White cell [16.16]. White cell optics are appropriate for use with the broadband black-body emission sources used in FTIR instruments. This three-mirror design has the entrance (source) and exit (detector) holes at one end, with a mirror between them, and another two mirrors at the opposite end. Thus, the beam performs four passes through the cell from the source to the detector. This four-pass pattern can be repeated by directing the final pass back onto the second mirror instead, allowing for even more passes and path lengths of up to 100 m.

The strengths of FTIR are well matched to the sampling of biomass burning plumes (forest fires, agricultural fires), which exhibit a large number of trace gases at relatively high concentrations. *Yokelson et al.* have developed an airborne FTIR (AFTIR) system for this application [16.12–14]. The system uses a 0.81 m White cell with 120 passes for a total path length of 97 m. The spectrometer has a resolution of 0.5 cm⁻¹ and a scan time of 1.7 s, although the flush time through the large volume cell is 7–8 s, so sampling is not limited by the scan time. The 1 min limit of detection for absorbance (16.2) is $A < 10^{-3}$, equivalent to a detection limit in optical extinction (16.3) of $\alpha < 10^{-7}$ cm for the ≈ 100 m path length. This is sufficient to measure trace gases with a signal to noise in mixing ratio units of 5–20 ppbv, which permits the characterization of small molecules (CO, CH₄, CH₂O, CH₃COOH, HCOOH, CH₃OH, C₂H₄, NH₃) in fire plumes.

FTIR is also suitable for high-precision, high-accuracy measurements of greenhouse gases, which are present at higher mixing ratios (tenths to hundreds of ppmv) than other trace gases. *Griffith et al.* [16.47] describe a state-of-the-art FTIR instrument for this application that uses a 24 m White cell and a spectrometer with a resolution of 1 cm⁻¹. The 1 min precision (80 scans at 0.75 s each) in absorbance is $A \approx 2 \times 10^{-5}$, or $\alpha \approx 10^{-8}$ cm⁻¹ for a path length of 24 m. The 1 min precisions for CO₂, CH₄, N₂O, CO, and ¹³CO₂ are 20, 0.2, 0.1, 0.2, and 0.07 ppbv, respectively. These specifications meet or exceed standards established by the World Meteorological Organization.

Tunable Diode Laser Spectroscopy (TDLS)

Tunable diode laser spectroscopy measures small regions of the near- or mid-IR with high precision, allowing accurate and sensitive detection of small molecules with well-resolved individual rovibrational transitions. These instruments are typically not multiplexed (i.e., a single or just a few target analytes have transitions in the spectral range of the laser), but they generally yield much more precise measurements than FTIR. In the past, near-IR devices had the distinct advantage that they could make use of readily available, robust, and inexpensive laser sources developed for the telecommunications industry. However, the disadvantage of near-IR devices is that they probe relatively weak absorption lines associated with molecular overtone transitions. While mid-IR light sources that utilize lead salt diode lasers and difference frequency methods are also available [16.48], the recent development of quantum cascade lasers (QCL) and interband cascade lasers (ICL) has led to readily available inexpensive and robust mid-IR sources [16.49].

A common type of multipass cell used in TDLS applications for atmospheric science is the Herriott cell [16.17, 49, 50], which is appropriate for use with coherent light sources. This cell permits several hundred passes utilizing an alignment in which the beam enters through a hole in one mirror and is reflected between the mirrors in the cell. The beam wanders around the surfaces of the mirrors and produces a spot pattern, before eventually exiting through the entrance aperture. The number of passes can be increased through the use of astigmatic, rather than spherical, optics. A Herriott cell can provide path lengths of up to several hundred meters. With a typical precision in absorption of $A = 5 \times 10^{-6}$ for an integration time of 1 s, these instruments can achieve a precision in optical extinction of $\alpha = 5 \times 10^{-10} \text{ cm}^{-1}$, sufficient for the pptv-level detection of numerous atmospherically relevant trace gases in the mid-IR. Examples include CH_4 , N_2O , NO , NO_2 , NH_3 , HNO_3 , HONO , H_2O_2 , OCS , and isotope ratios of greenhouse gases [16.49]. For example, Richter et al. [16.51] report a precision for ethane (C_2H_6) and formaldehyde (CH_2O) of 15 and 40 pptv, respectively, at 1 Hz in airborne measurements.

Cavity-Enhanced Spectroscopy (CES)

Cavity-enhanced spectroscopy encompasses a wide variety of light sources, spectral regions, configurations of the optical cavity/measurement cell, and coupling schemes between the light source and the cavity resonances. Because the multiple passes can occur along a single optical axis, the cell volume can be much smaller in a CES instrument than in a Herriott or White cell.

Ultraviolet and visible CES instruments were originally developed with pulsed laser sources such as tunable dye lasers, but CES instruments based on visible diode lasers, light-emitting diodes (LEDs), and Xe arc lamps (among other sources) have also recently been demonstrated. The target molecules that can be probed in this region are effectively identical to those probed by DOAS and listed above. As an example, Wild et al. [16.52] have reported the measurement of NO_2 by CRDS at 405 nm using a broad-linewidth (0.5 nm) diode laser that passively couples to a 50 cm optical cavity with mirrors of reflectivity $R = 99.995\%$, giving a time constant $\tau_0 = 30 \mu\text{s}$ or an effective path length of 9 km. The precision in optical extinction for a 1 s integration is $\alpha = 2 \times 10^{-10} \text{ cm}^{-1}$, equivalent to a measurement precision of 15 pptv for NO_2 .

CES has found numerous applications in the near-IR due to the previously mentioned advantage of being able to use readily available telecommunications lasers with wavelengths of around $1.5 \mu\text{m}$. Instruments of this type have become a standard measurement technique for the major greenhouse gases CO_2 and CH_4 , which have overtones in that region. These instruments are commercially available. Crosson et al. [16.25] report a three-mirror cavity ring-down instrument with a $1.6 \mu\text{m}$ laser that gives $\tau_0 = 40 \mu\text{s}$ (an effective path length of 12 km) and a sensitivity to extinction of $\alpha = 1.6 \times 10^{-12} \text{ cm}^{-1}$ in 1 s. Application to CO_2 and CH_4 yields measurement precisions of 200 ppbv and 1 ppbv, respectively. Baer et al. [16.24] report an instrument based on an off-axis alignment that is essentially identical to a Herriott cell but does not have a hole through which the laser beam enters and exits. Using ICOS as the detection method and a laser with a wavelength of around $1.5 \mu\text{m}$, they achieved a precision similar to that quoted above of $3 \times 10^{-11} \text{ cm}^{-1}$ in 1 s and similar performance for CO_2 and CH_4 .

Mid-IR CES instruments are a relatively novel development, as robust light sources in that region have only recently become available. As an example, Richard et al. [16.53] demonstrated the measurement of NO to a precision of 20 pptv in 1 s using an interband cascade laser at $5.3 \mu\text{m}$.

16.4.2 Emission (Fluorescence) Spectroscopy Devices

In this section, we provide a number of examples of the more common applications of fluorescence spectroscopy devices for atmospheric measurements. The use of LIF to detect atmospheric molecules such as OH or NO_2 directly is discussed, and the section also includes a summary of how to use these direct techniques to detect nonfluorescing molecules.

FAGE for Tropospheric OH Detection

The hydroxyl radical (OH) is the most important daytime oxidant in the troposphere. OH controls the lifetimes of climate gases such as methane, and—through reactions with volatile organic compounds (VOCs)—governs the production of secondary pollutants such as ozone, acidic gases, and secondary organic aerosols.

Off-resonance fluorescence spectroscopy (excitation at 282 nm followed by fluorescence detection at 308 nm) can be employed for OH detection under dry conditions, such as in laboratory kinetic studies [16.54] or for stratospheric observations [16.28]. In the lower troposphere, however, owing to the high water vapor content, on-resonance detection (excitation and fluorescence at 308 nm) becomes necessary to minimize interference from OH generated during the laser photolysis of ambient ozone. At 282 nm, the ozone absorption cross-section and photolysis quantum yield of O¹D are approximately 25 times greater than those at 308 nm, so high concentrations of OH radicals can be generated along the laser detection axis of the fluorescence cell in the presence of ambient H₂O [16.26].

All current LIF instruments [16.45, 55–60] for tropospheric OH detection utilize low pressures (maintained at 1–4 Torr) achieved through the use of a critical orifice (\approx 1 mm) and a large pumping capacity. 1–10 kHz tunable light at 308 nm is employed, which is generated by a dye or Ti:S laser system operating at laser powers ranging from 1 to 20 mW. The background signal arising from laser scatter, solar scatter, or detector dark counts can be determined by tuning the laser away from a OH transition (typically by a few picometers) to a wavelength region where OH does not absorb. In recent years, however, a number of groups have reported interference from cell-generated OH [16.61, 62]—potentially from the unimolecular decomposition of ozonolysis products (e.g., the stabilized Criegee intermediate, sCI). Therefore, new methods of determining the instrumental background counts that involve the addition of propane or C₃F₆ above the inlet to chemically titrate ambient OH have been developed [16.60, 61, 63–65].

FAGE for Tropospheric HO₂ and RO₂ Detection

HO₂ can be detected by chemically converting it to OH, which is achieved by injecting nitric oxide into the detection cell just below the critical orifice. Although RO₂ radicals also react with NO and can eventually convert to OH in the presence of O₂, this conversion was originally considered to be too slow at the low pressures employed in FAGE cells. In 2011, however, *Fuchs et al.* [16.66] demonstrated that β -hydroxyperoxy radicals (formed following the addition of OH to unsaturated VOCs) could rapidly convert to OH in the

presence of NO within their residence time in a FAGE cell, implying that they could act as an HO₂ interference. Minimizing the FAGE cell residence time and limiting the concentration of NO can reduce this interference to acceptable levels (< 5%) for ambient HO₂ measurements. Alternatively, these RO₂ types can be measured by running under conditions that maximize the conversion [16.67].

The sum of the RO₂ radicals can be measured using LIF by adding a flow reactor that is differentially pumped (held at \approx 30 Torr) to the FAGE cell, in a method that is known as ROxLIF. At these higher pressures in the reactor, the addition of NO efficiently converts all RO₂ species with an extractable H atom to OH. CO is added in excess of the NO to rapidly convert OH to HO₂ and thus minimize radical losses at the walls of the reactor [16.68]. The sum of RO₂ and HO₂ has also been determined using the peroxy radical amplifier (PERCA), in which RO₂ and HO₂ are converted to NO₂ by adding NO and CO [16.33]. Following a chain reaction (which can involve a chain length of several hundred), NO₂ is detected using LIF spectroscopy [16.31]. The original version of the PERCA method detected NO₂ via its chemiluminescent reaction with luminol [16.33]. More recently, a PERCA has been developed that uses ethane instead of CO as the chain initiator [16.69].

Laser-Induced Fluorescence Detection of CH₃O₂ Following Conversion to CH₃O

Detailed atmospheric chemistry models predict that methyl peroxy radicals are the most abundant RO₂ radicals present in the atmosphere globally [16.70]. Daytime concentrations in remote regions are predicted to reach the high 10⁸ molecule cm⁻³ level, with the reaction of OH with methane acting as the dominant source of CH₃O₂ radicals. At present, CH₃O₂ is not detected specifically in the atmosphere; it is measured as part of the sum of RO₂ radicals using, for example, ROxLIF. However, *Onel et al.* [16.70] demonstrated that it is possible to sensitively detect CH₃O₂ using LIF by first converting the CH₃O₂ to CH₃O radicals by reaction with NO. The A²A₁($\nu_3 = 3$) \leftarrow X²E($\nu_3'' = 0$) CH₃O transition can be excited at 298 nm, and the resultant redshifted off-resonance fluorescence can be detected between 320 and 430 nm. Pulsed (repetition rate: 5 kHz, pulse width: \approx 25 ns) 298 nm radiation is generated by frequency doubling the output from a YAG-pumped dye laser (the dye DCM is used). Fluorescence is detected orthogonally to the gas flow, which is introduced into the detection cell (operated at low pressure: 2.6 Torr) via a critical orifice. A broad-bandpass filter (> 80% transmission in the region 320–430 nm) can be used to discriminate the laser scatter from the

fluorescence. However, background signals originating from redshifted scattered light from the detection cell walls must be minimized by delaying the fluorescence collection by ≈ 100 ns after the laser pulse. At the pressures employed, the fluorescence lifetime of CH_3O is 0.9–1.5 μs , so delaying the fluorescence detection was found to reduce the fluorescence collected by just $\approx 10\%$. The remaining background signal arising from laser scatter, solar scatter, or detector dark counts can be determined by tuning the laser away from the CH_3O transition to a wavelength at which CH_3O does not absorb (300 nm). The limit of detection for CH_3O_2 radicals using LIF is reported to be 3.8×10^8 molecule cm^{-3} for a 5 min averaging period at 2σ . Thus, LIF looks to be a promising methodology for specifically detecting ambient levels of CH_3O_2 , especially in regions of the globe where concentrations are predicted to be high.

Photofragmentation Laser-Induced Fluorescence Detection of Nitrous Acid

Nitrous acid (HONO) is found in a wide range of environments, ranging from remote oceanic regions to megacities. It plays a central role in tropospheric chemistry, as it is a major source of the hydroxyl radical in urban areas [16.71]. In marine regions, which account for more than 70% of the Earth's surface and are remote from anthropogenic emissions, HONO is one of the few sources of NO_x , which is a key precursor to secondary aerosols [16.72].

HONO is a nonfluorescent molecule, so it cannot be directly detected using fluorescence spectroscopy. However, HONO has a near-UV absorption band involving a $\Pi^* \leftarrow n$ type transition with a progression in the ν_2 stretch [16.73] with the most intense absorption at ≈ 355 nm, and previous investigators [16.74] have obtained a near-unity primary quantum yield for the process

The OH photofragment produced following the photolysis of HONO can readily be detected with high sensitivity and selectivity using either on-resonance (laser excitation at 308 nm) or off-resonance (laser excitation at 282 nm) LIF at low pressures [16.75]. Ambient measurements of HONO using PF (photo-fragmentation) followed by off-resonance LIF detection of the OH fragment were successfully performed by both *Rodgers and Davis* [16.76] and *Liao et al.* [16.75]. In both studies, tests were conducted to assess potential interferences that may arise from species that could photolyze at 282 nm or 355 nm. *Liao et al.* [16.75] report negligible changes to background signals with the addition of

1 ppbv of H_2O_2 , HNO_3 , CH_2O , and HO_2NO_2 . Ozone, however, is readily photolyzed by the 282 nm radiation, generating $\text{O}(^1\text{D})$. This then reacts with a H_2O molecule to give two OH radicals that are excited and detected in the same laser pulse. This is the same O_3 interference that prevents off-resonance LIF being used to make ambient measurements of OH in the troposphere [16.26]. The signal due to the O_3 interference can be accounted for and subtracted from the signal arising from HONO by modulating the photolysis laser on and off. However, the elevated background from the interference increases the limit of detection of the instrument and precludes the detection of ambient OH alongside that of HONO. On-resonance PF-LIF spectroscopic techniques have recently been developed for ambient HONO detection [16.77] as well as laboratory investigations of heterogeneous HONO production from various atmospherically relevant aerosol surfaces [16.78].

A single Nd:YAG laser system was utilized in early PF-LIF HONO instruments. The third harmonic (355 nm) was used to photolyze HONO to OH with typical pulse energies of 100 mJ, whilst the second harmonic (532 nm) was used to pump a dye laser system in order to generate tunable 282 nm radiation; ≈ 0.2 mJ/pulse of the 282 nm light was used for LIF OH detection. Dichroic mirrors were used to delay the OH probe laser by ≈ 14 ns with respect to the photolysis pulse. Both beams were directed into a detection cell along the same axis (orthogonal to the detection axis) in a single-pass configuration. More modern PF-LIF designs that perform on-resonance OH detection use two laser systems for 355 nm and 308 nm wavelength generation. The application of two lasers permits the use of different repetition frequencies, allowing OH to be probed at kHz resolution (at low pulse energies to minimize probe-induced interferences), whilst HONO can be photolyzed at 1–10 Hz (at energies of ≈ 10 –100 mJ/pulse).

Laser-Induced Fluorescence Techniques to Measure NO_2

The NO_2 molecule absorbs photons in the visible region between the $^2\text{A}_1$ and $^2\text{B}_2$ series in a continuum at wavelengths longer than 398 nm (the threshold for dissociation to NO and O), and fluoresces with red-shifted radiation at > 600 nm. Various wavelengths have been used for the LIF detection of NO_2 . *Thornton et al.* [16.79] used excitation of the $\text{A}^2\text{B}-\text{X}^2\text{A}_1$ band at 585 nm, where the NO_2 absorption cross-section is $\approx 1 \times 10^{-19}$ cm^2 molecule $^{-1}$, whereas *Matsumi et al.* [16.80] used 440 nm radiation, where the absorption is a factor of ≈ 6 stronger. Both of these wavelengths are in regions of the continuum where there is enough spectral structure to allow the laser

to be tuned to a peak and trough in the absorption cross-section, thus allowing background laser-scattered signal to be measured. The 585 nm and 440 nm excitation instruments have detection limits of 6 pptv and 30 pptv, respectively. A slightly different method that uses radiation from a single non-tunable laser has been successfully employed by *Matsumoto et al.* [16.81] and *Dari-Salisburgo et al.* [16.82]. These instruments use 523.5 nm and 532 nm radiation, respectively, to excite NO_2 , with the advantage being that only a single wavelength of laser light is required. The tunable sources used in Thornton's and Matsumi's instruments are complicated multilaser systems, meaning that they are expensive and often difficult to align and operate. Also, a large proportion of the laser energy is lost in a multilaser system. For instance, the Matsumi instrument produces $\approx 100 \mu\text{J pulse}^{-1}$ at 440 nm from a pump laser energy of $\approx 170 \text{ mJ pulse}^{-1}$. The disadvantage of the single-wavelength systems is that there is no way to obtain the laser background signal spectrally, so periodic scrubbing of the ambient air to remove NO_2 must be performed.

Thermal Desorption Laser-Induced Fluorescence (TDLIF) for HNO_3 , Alkyl Nitrates, and Peroxy Acetyl Nitrate (PAN)

Upon heating, most NO_y species dissociate to yield NO_2 ($\text{XNO}_2 \rightarrow \text{NO}_2 + \text{X}$, where $\text{X} = \text{RO}_2, \text{RC(O)OO}, \text{RO}, \text{OH}, \text{HO}_2, \text{NO}_3, \text{ClO}, \text{or BrO}$). *Day et al.* [16.83] showed that, for a residence time of 30–90 ms and a pressure of 1 atm, approximate gas temperatures for complete dissociation are as follows: 200 °C for compounds of the form RO_2NO_2 (PANs), 400 °C for compounds of the form RONO_2 (including both alkyl nitrates and hydroxyalkyl nitrates), and 650 °C for HNO_3 . Measured thermal decomposition rates of various compounds within the two organic nitrate classes RO_2NO_2 and RONO_2 exhibit little dependence on the R group.

Detection of Oxygenated VOCs Using Fluorescence Spectroscopy

As well as the detection of reactive small radical intermediates, LIF can also be used to study larger atmospheric intermediates that have a suitable absorption spectrum and a significant fluorescence quantum yield. In this section, we briefly discuss the detection of carbonyl species using LIF and the closely related technique of laser-induced phosphorescence spectroscopy.

Detection of HCHO by LIF. Formaldehyde (HCHO) is one of the most abundant oxygenated VOCs present in the troposphere. It is formed during the oxidation of VOCs that are primarily emitted, and is considered a good target species as it is indicative of recent VOC oxidation activity [16.84]. HCHO is also directly

emitted into the atmosphere from traffic or due to agricultural activities for example [16.84].

HCHO can be detected by fluorescence spectroscopy by exciting the $5_{0,5} \leftarrow 5_{1,4}$ rotational transition of the $4A^1A_2 \leftarrow X^1A_1$ vibronic band at 353.370 nm and collecting the resulting off-resonance broadband fluorescence (typically in the region 390–550 nm). Pulsed frequency-doubled Ti:sapphire lasers (3 kHz; 65 mW; White cell configuration) [16.85] or tunable fiber lasers (300 kHz; a few mW; single-pass configuration) [16.86] have been utilized to excite HCHO in LIF systems.

HCHO LIF detection cells typically run at pressures ≈ 100 –150 Torr; the excited-state lifetime of HCHO is ≈ 200 ns at these pressures. *Hottle et al.* [16.85] report a 3σ limit of detection (LOD) of ≈ 50 pptv for 1 s sampling using the Ti:sapphire HCHO system. A similar LOD (36 pptv, 2σ , 1 s sampling) is achieved with the fiber laser system when it is operated with a laser power of 10 mW [16.86].

The background signal from laser scatter, solar scatter, or detector dark counts can be determined in tunable HCHO LIF instruments by dithering the laser wavelength away from an HCHO rotational transition to a nearby minimum. This background determination ensures that there is no interference from any underlying broadband absorptions.

An UV industrial laser operated at 355 nm was recently developed by the *Hanisco group* [16.87] for the detection of HCHO via LIF. Although this laser system lacks tunability and the narrow linewidth necessary to select a single HCHO absorption feature, selectivity for HCHO can still be achieved through the use of a custom multibandpass optical filter that selectively transmits at the HCHO fluorescence wavelengths between 355 and 550 nm. A typical 1σ instrument precision of 150 pptv at ≈ 0 pptv HCHO can be achieved with 1 s of data collection [16.87].

Laser-Induced Phosphorescence Detection of Glyoxal. Glyoxal, one of the most abundant dicarbonyls in the atmosphere, is produced during the oxidation of acetylene, alkenes, aromatics, and biogenic species, including isoprene [16.88]. Primary emissions of glyoxal are negligible, so measurements of this compound can be used as a marker for oxidation processes involving both anthropogenic and biogenic VOCs [16.88]. Glyoxal also plays an important role in SOA (secondary organic aerosol) formation [16.88].

Away from urban areas, concentrations of glyoxal are typically low (< 200 pptv [16.88]), so techniques for detecting this molecule ideally need to be sensitive and selective. Laser-induced phosphorescence (LIP) detection of glyoxal in the atmosphere was first developed by the *Keutsch group* [16.89]. In their approach, the $8_0^{11}A_u \leftarrow X^1A_g$ transition to the $S_1^1A_u$ state is excited

near 440 nm by a doubled Ti:sapphire laser. The system undergoes complete conversion to the $T_1^3A_u$ state, which phosphoresces for $\approx 10 \mu\text{s}$ at 100 Torr. The design of the LIP detection cell is analogous to that of the NO_2 LIF instrument devised by the *Thornton group* [16.79]; it utilizes a multipass White cell that employs either 32 or 40 passes. The laser operates at 3 kHz and 80 mW of power is generated at 440 nm. Phosphorescence is collected from the 520 nm band, which offers a strong signal and sufficient spectral separation from the excitation wavelength to enable efficient filtering of the scattered laser light. Furthermore, high quantum efficiency detectors are available in this wavelength region. No interference from NO_2 is reported, and there is no requirement to filter the sampled air for particulates or water vapor prior to sampling. Periodically, a 490 nm bandpass filter that is designed to capture N_2 Raman scatter is used instead of the 520 nm bandpass filter to assess any changes in collection efficiency. To minimize the loss of glyoxal, the PTFE or PFA tubing used as the inlet and the detection cell are heated to 35 °C. The sensitivity of the instrument at 3σ was found to be 18 pptv/min during its first deployment on the BEARPEX (biosphere effects on aerosol and photochemistry experiment) field campaign [16.89].

The LIP technique has been developed further to allow the detection of methyl glyoxal alongside glyoxal through the Laser-Induced Phosphorescence of (methyl)GLyOxal Spectrometry (LIPGLOS) technique [16.90]. LIPGLOS exploits the difference between the phosphorescent lifetimes of these two dicarbonyl species, meaning that a single light source can be used to detect both. The method achieves 3σ LODs of 11 pptv and 243 pptv for glyoxal and methyl glyoxal, respectively, for a 5 min measurement point.

16.4.3 Chemical Conversion Devices

Some atmospheric trace gases that are difficult to detect directly using optical methods can be converted using a well-characterized chemical pathway into another species that is easier to measure. There are quite a few examples of the use of chemical conversion to detect atmospheric species [16.33], and in this section we provide a description of a limited selection of these in which the final detection is based on either the absorption or emission of light.

Detection of Nitric Oxide by Chemiluminescence

Reactive nitrogen species ($\text{NO} + \text{NO}_2 = \text{NO}_x$) are important in atmospheric science owing to their role in tropospheric ozone formation. NO_x is primarily emitted as NO, but quickly establishes a steady-state equilibrium with NO_2 during the daytime. By far the most common

detection technique for NO derives from the chemiluminescence reaction between O_3 and NO, which produces excited NO_2 molecules that fluoresce in the visible and IR and can be detected using red-sensitive photomultiplier tubes [16.91]. Interferences from metal carbonyls and ethylene in early NO instruments [16.92] were eliminated in later instruments by applying a red cutoff filter that blocks radiation in the wavelength region $> 648 \text{ nm}$, which is where the chemiluminescence from the interfering species predominantly occurs.

Excess O_3 is employed to maximize the sensitivity of chemiluminescence instruments used for the detection of NO, as the use of excess O_3 ensures that virtually all of the NO present in the sampled air reacts (with the O_3) in the detection region. The region in which the sampled air and ozonated air are mixed is highly reflective (it is often gold plated) to maximize the number of photons from the NO– O_3 reaction that are collected by the detector. Low pressures reduce the rate of quenching of the excited NO_2^* product, whilst slightly elevated temperatures increase the rate of the $\text{NO} + \text{O}_3$ reaction. The H_2O vapor level during ambient sampling can influence the quenching efficiency of NO_2^* and hence the sensitivity of the chemiluminescence instrument, so corrections for the water vapor level may be required in humid environments.

Alongside NO detection, commercial NO_x analyzers offer detection capabilities for NO_2 following its conversion to NO. Heated molybdenum converters are frequently used to carry out the conversion, which proceeds according to the equation

However, studies have highlighted that NO_y species such as PANs, nitrates, nitrites, and nitric acid are also converted to NO. *Winer et al.* [16.93] demonstrated that PAN was converted to NO with the same efficiency as NO_2 , whilst the conversion of nitric acid was less efficient but still significant.

That said, the tendency for NO_y species to convert to NO with similar efficiencies to NO_2 can be exploited to provide a measure of the total reactive nitrogen present. NO_y species have been shown to be efficiently ($> 90\%$) reduced by carbon monoxide on a heated gold catalyst [16.94].

Photolytic conversion of NO_2 using either a xenon lamp or UV-LEDs with an output centered on 395 nm offers a more selective way to convert NO_2 to NO for detection by chemiluminescence [16.95,96]. The conversion efficiency of NO_2 to NO using standard UV-LEDs with an output of 1 W and a sample flow of 1 L/min is up to 42%, which translates to a LOD of 2.5 pptv at 2σ (1 min average) [16.97].

Heat must be removed from the photolytic region to prevent the thermal decomposition of NO_y species such

as PAN, which could then be detected as NO₂. Photolytic cells are typically maintained below 50 °C by coupling heat sinks to cooling fans or Peltier cooling, and short residence times (< 1 s) are employed within the photolytic cell to minimize thermal decomposition. Ryerson *et al.* [16.96] report negligible PAN conversion using a Hg arc lamp converter. Laboratory tests on certain commercially available converters, however, have demonstrated that 8–25% of the PAN can decompose and contribute to the NO₂ signal under normal operating conditions [16.97]. This artifact can be significant, particularly in remote regions where NO_y : NO₂ ratios are elevated.

The spectral output of the UV-LEDs is sufficiently narrow (FWHM = 50 nm) to minimize the photolysis of other species that can yield NO directly or indirectly via NO₂. Reed *et al.* [16.97] demonstrated that there is no overlap of the wavelengths of UV-LEDs used in commercial Air Quality Design NO_x analyzers with the absorption spectrum of PAN. A small overlap of the lamp spectrum with the absorption cross-sections of HONO and NO₃ radicals suggests that these species could interfere with the NO₂ signal to a very small extent.

The use of LEDs with outputs shifted further into the UV (centered at 385 nm, a region where HONO absorbs more strongly) opens up the possibility of actively detecting HONO by photolytic conversion to NO [16.98]. Operating a photolytic cell in a switching mode, where the UV lamps centered at the two different wavelengths (385 nm and 395 nm) are switched on and off alternately, allows HONO to be differentially detected from NO₂ provided the efficiency with which each lamp converts HONO to NO (and NO₂ to NO) can be accurately determined. Reed *et al.* [16.98] determined a difference in HONO conversion efficiency between 385 nm and 395 nm of 6.5%. The back reaction in which OH + NO reforms HONO was noted as a source of uncertainty. Nevertheless, the prototype instrument offered promise, comparing reasonably well ($R^2 = 0.58$, $y = 0.82x$) with a LOPAP (long-path absorption photometer), an established HONO detection technique, during field deployment in a marine environment.

Villena *et al.* [16.99] demonstrated that photolysis of oxygenated VOCs (OVOCs) generates peroxy radicals within NO₂ photolytic instruments. The presence of OVOCs such as glyoxal, (HCO)₂, can lead to a negative artifact from the NO₂ produced in the reaction of NO with RO₂ within the photolysis region, i.e.,

These reactions cause the NO concentration within the photolytic converter to decrease relative to the NO concentration measured in the NO channel of the instrument that does not have a photolytic converter. In extreme situations where OVOC concentrations are high (e.g., at roadside locations), this effect can lead to negative NO₂ concentrations. Interestingly, close to roadside emissions, instruments that catalytically convert NO₂ to NO with molybdenum often suffer less from interferences, as NO_y concentrations close to the source tend to be low relative to NO₂. However, as the air ages and the NO_y : NO₂ ratio increases, the performance of molybdenum converters worsens. Given these reported artifacts for NO₂ instrumentation that rely on conversion to NO for detection, it is crucial to consider the sampling environment (roadside/urban background) when selecting instruments for atmospheric monitoring.

Liquid Derivatization Techniques for the Detection of Soluble Gases

Nitrous Acid Detection. The method most commonly employed to determine the HONO concentrations in ambient air is the long-path absorption photometer (LOPAP) technique, which was developed by Heland and coworkers [16.100]. This instrument was designed to be compact, cheap, and sensitive, making it applicable for long-term air-quality monitoring projects. As shown in Fig. 16.4, it utilizes two channels, with each channel consisting of a stripping coil to extract gaseous HONO into a liquid solution. The first channel extracts most of the gas-phase HONO and a small fraction of interfering species into the stripping solution. The second channel, which is run in series with the first, extracts a similar amount of interfering species, but there is little HONO left to extract. Subtraction of the calibrated signal of the second channel from the first channel provides an interference-free HONO concentration measurement.

The stripping solution used in a LOPAP contains sulfanilamide in HCl, which readily forms a diazonium salt with HONO. Applying a large excess of the sulfanilamide reagent ensures that only a short stripping coil and contact time (≈ 30 ms) between the air sample and stripping solution are required for near-complete (> 99.4%) extraction of gaseous HONO. The addition of *N*-(1-naphthyl)ethylenediamine dihydrochloride solution to this leads to the formation of an azo dye. The detection region of a LOPAP consists of an absorption cell made from Teflon tubing. Visible light is focused into the solution via fiber optics and undergoes multiple internal reflections within the tubing before being detected by a spectrometer. The logarithm of the ratio of the absorption intensities at the azo dye absorption maximum (at 544 nm) and at a wavelength where the azo dye does not absorb ($\lambda > 700$ nm) is linear with re-

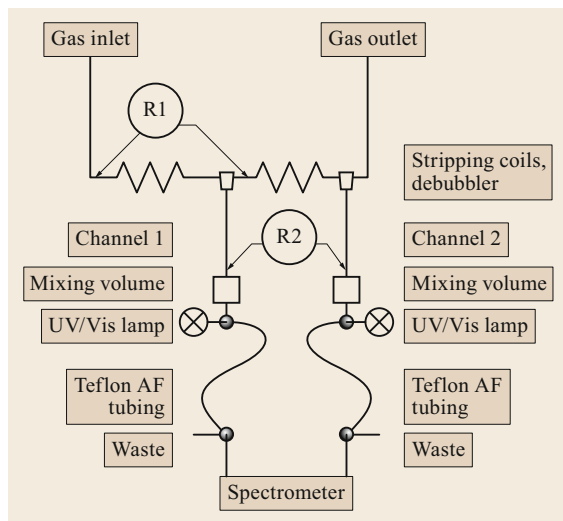

Fig. 16.4 Schematic of the setup of a LOPAP instrument (after [16.100] copyright American Chemical Society 2001)

spect to the HONO concentration present. The HONO concentration (c) can be determined (via the Bouguer–Lambert–Beer’s law (16.3)) using the equation

$$\begin{aligned} \text{Absorbance} &= \log \left(\frac{I_{\text{ref}}}{I_{\text{abs}}} \right) \\ &= \sigma \times l \times c + \log(\text{const}), \end{aligned} \quad (16.21)$$

providing the absorption path length (l) and the absorption coefficient of the azo dye at 544 nm (σ) are known.

The use of two channels in a LOPAP minimizes the occurrence of unknown interferences that are difficult to correct for and were previously observed using wet effluent denuder techniques. Furthermore, the low pH of the stripping solution (pH 0) minimizes known interferences from NO_2 and SO_2 [16.101, 102], NO_2 and phenols [16.103–105], and PAN hydrolysis [16.106], as does the short contact time within the stripping coil.

NO , NO_2 , O_3 , SO_2 , HNO_3 , PAN, a selection of hydrocarbons, HCHO, as well as mixtures of these com-

pounds have given no measurable interference during laboratory tests. However, an intercomparison between the LOPAP technique and DOAS conducted in a large outdoor smog chamber revealed that the LOPAP instrument gave measurements that were $13 \pm 5\%$ higher than DOAS on average [16.100]. Other intercomparisons conducted between DOAS and the LOPAP method under the complex conditions in the atmosphere demonstrated excellent agreement [16.107].

Recent measurements of HONO by a LOPAP at the South Pole highlighted that HO_2NO_2 , which was present at elevated concentrations owing to the low ambient temperatures, could be mistaken for HONO [16.108].

LOPAP is an extremely sensitive technique for HONO detection, with a LOD of 1–2 pptv for a 4 min sampling time [16.109]. The technique has also been extended to permit the detection of NO_2 [16.110] and HNO_3 [16.111].

Hydrogen Peroxide Detection. Hydrogen peroxide is a readily soluble gas and, as such, an important oxidant in the liquid phase. H_2O_2 plays a key role in oxidation processes that take place in cloud water, contributing significantly to secondary sulfate production in clouds and hence acid precipitation. Peroxides are formed in the gas phase in photochemical reactions and act as a temporary OH reservoir. Gas-phase photochemistry is the main source of H_2O_2 in the liquid-phase clouds [16.112]. Due to its high solubility, early attempts to detect H_2O_2 in the gas phase involved first extracting the gas into the aqueous phase by flowing an air sample and distilled water through a coil. The addition of luminol and copper ions to the solution containing H_2O_2 led to chemiluminescence at 450 nm, as detected using a blue-sensitive photomultiplier tube (PMT) [16.113]. Although no significant interferences from other gases such as NO_x , PAN, SO_2 , and O_3 are reported, the high detection limit of this technique (1 ppbv) limits its applicability to polluted regions only.

The reaction of *p*-hydroxyphenylacetic acid with peroxides [16.114] to form a fluorescent dimer that can

Table 16.4 Advantages and disadvantages of the different methods

Devices	Advantages	Disadvantages
Absorption spectrometers	Absolute measurement High specificity for molecular absorption lines Compact and lightweight construction is possible; reduced need for power and vacuum	Insensitive without substantial enhancement of the optical path length May be subject to instabilities and/or noise and drifts in the light source or from optical interference effects
Fluorescence/phosphorescence instruments	High specificity (narrow laser linewidth can excite a specific electronic transition); emission at specific wavelengths High sensitivity, allowing the detection of radical species (e.g., OH) present at very low concentrations	Nonabsolute (calibration is required to determine the ambient concentration of the fluorescing species) Expensive and highly technical instruments that require skill to operate
Chemiluminescence instruments	Compact and easy to operate Sensitive and selective	Nonabsolute (calibration required)

be excited at 320 nm, leading to fluorescence at 400 nm that is detected with a fluorimeter, offers a more sensitive means to detect H₂O₂ originating from the gas phase, with reported detection limits in the low tens of pptv. Much of the methodology outlined by *Lazrus et al.* [16.114] has been employed in all of the liquid derivatization instruments that have subsequently been used in the field to detect gaseous peroxides. An aqueous potassium acid phthalate solution is used to scrub peroxides from the gas phase. A conditioning agent containing formaldehyde and phthalate buffer is added to the scrubbing solution to prevent interference from SO₂, which can also form a fluorescent dimer. Any organic peroxides present also react with *p*-hydroxyphenylacetic acid to form fluorescent dimers. Therefore, to distinguish hydrogen peroxide from higher ROOH species, two-channel instruments are employed, with a H₂O₂-destroying catalase added to one channel to remove > 95% of the H₂O₂.

In more modern instruments, high-performance liquid chromatography (HPLC) is used to separate the peroxides in solution and thus enable speciated detection [16.115, 116]. Sampling resolutions of a few minutes and LODs as low as 5 pptv (for H₂O₂) make the airborne detection of peroxides as well as observations at remote ground locations feasible.

To quantitatively detect peroxides, the formation efficiency of the fluorescent dimer and the sensitivity of the fluorimeter must be determined through the addition of known aqueous-phase concentrations of peroxides. For gas-phase peroxide measurements, the scrubbing efficiency of the stripping coil must also be determined.

16.4.4 Comparison of the Methods

The advantages and disadvantages of the different methods are summarized in Table 16.4.

16.5 Specifications

The specifications for some key performance indicators in various measurement methods that use absorption, emission, or chemiluminescence are given in Table 16.5.

Table 16.5 Specifications for various measurement methods that use absorption, emission, or chemiluminescence

Method	Precision	Accuracy	Limit of detection	Time resolution
DOAS	Similar to LOD	Better than 10%	$\alpha = 1 \times 10^{-10} \text{ cm}^{-1}$ Single-pptv detection for UV/VIS-absorbing gases	10 min–1 h
FTIR		Better than 10%	$\alpha = 1 \times 10^{-7} \text{ cm}$ Single ppbv or tens of ppbv for multiplexed mid-IR-absorbing gases	1–10 min
TDLs		Better than 10%	$\alpha = 5 \times 10^{-10} \text{ cm}^{-1}$ Single pptv for mid-IR-absorbing trace gases Tenths to hundreds of ppbv for near-IR-absorbing trace gases and greenhouse gases	1 s
CES		Better than 10%	$\alpha = 10^{-11}–10^{-9} \text{ cm}^{-1}$, depending on the wavelength region and experimental approach Sub- or single-pptv detection is possible depending on the application	1 s
LIF:				
OH		20–40%	$2–8 \times 10^5 \text{ molecule cm}^{-3}$ (1 min)	1 s
NO ₂		Better than 10%	6–30 pptv	1 s
HCHO		25%	30–50 pptv	1 s
LIP:				
CHOCHO		Better than 10%	18 pptv (1 min)	1 s
Chemical conversion LIF:				
HO ₂		20–48%	$2–340 \times 10^5 \text{ molecule cm}^{-3}$ (1 min)	1 s
CH ₃ O ₂		15–17%	$3.8 \times 10^8 \text{ molecule cm}^{-3}$ (5 min)	1 s
PF-LIF:				
HONO		20–40%	15 pptv (1 min)	1 s
Chemiluminescence:				
NO		5%	7.2 pptv (1 s)	1 s
LOPAP:				
HONO		Better than 10%	1–2 pptv (4 min)	4 min
Liquid derivatization:				
H ₂ O ₂		Better than 10%	5 pptv (3 min)	3 min

16.6 Quality Control

In this section we consider two important aspects of quality control: calibration and intercomparison of instruments.

16.6.1 Calibration of Gas Analyzers and Laser Techniques

Standards can often be purchased for long-lived gases that are chemically stable. Flows of these gases, suitably diluted using a calibrated flow controller, are introduced at the inlet of the instrument. For some gases, the concentration of the gas standard can be traced to a national standard (see Chap. 5 on quality assurance and control).

Permeation Tubes

For other species with much lower vapor pressures, a permeation tube with a critical orifice from which a known quantity of material will effuse per second at a given temperature (often above the ambient temperature) is commonly used. The permeation device is weighed periodically to calibrate its effusion rate. An example of a molecule for which a permeation tube is used for calibration is formaldehyde, which can only be purchased in its trimeric form as a solid.

Short-Lived Species, Radicals, and Intermediates That Must Be Generated In-Situ

Unlike stable gases, short-lived radical species can neither be stored as a gas cylinder standard for calibration nor generated by a permeation tube, meaning that they must be generated in-situ. OH and HO₂ are typically generated by flowing humidified air past a mercury Pen-Ray lamp [16.55]. The 185 nm radiation from the lamp photolyzes water to OH and H (which reacts with O₂ to form HO₂) with a photolysis quantum efficiency of 1. The absorption cross-section of water at 185 nm is known, so if the photon flux F from the lamp and the time t that the air spends within the photolysis region are determined, it is then possible to calculate the generated OH (and HO₂) concentration via

$$[\text{OH}] = [\text{HO}_2] = [\text{H}_2\text{O}] \sigma_{\text{H}_2\text{O}} \phi_{\text{OH}} Ft. \quad (16.22)$$

The lamp flux can be determined using a calibrated photodiode [16.56], or the product Ft is often determined using chemical actinometry [16.55, 56, 117]. Many FAGE groups determine Ft offline using a flow of nitrous acid in either zero air or nitrogen [16.56, 117]. N₂O photolyzes at 185 nm to form NO, which can be detected using a commercial NO_x analyzer. Corrections are applied to account for the reduction in

sensitivity of the NO_x analyzer due to the presence of N₂O, which collisionally quenches a portion of the electronically excited NO₂^{*} molecules (produced in the reaction between NO and supplied O₃). Further corrections are also needed to account for the absorbance of the 185 nm radiation by N₂O. Despite these corrections, NO_x analyzers can sensitively detect just a few pptv of NO arising from the photolysis of N₂O. Applying N₂O actinometry generally permits the use of lower photon fluxes and shorter residence times in the photolysis region, which facilitates the generation of near-ambient levels of radicals (10⁷–10⁸ molecules cm⁻³). When N₂O actinometry is employed, turbulent flow reactors can be used to generate the radicals, which offers advantages over laminar flow reactors in that the flow profile and residence time of the air is better characterized. A faster flow rate also means that losses of radicals between the point of generation and FAGE sampling via radical–radical reactions or reactions with contaminants in the zero air are minimized. The disadvantage of this offline determination of Ft is that any change in the lamp output between actinometry determinations could be misconstrued as a change in the sensitivity of the FAGE instrument.

Ozone actinometry can be used to determine the lamp flux at the same time as a FAGE calibration [16.45, 55]. Oxygen present in the humidified zero air flow is photolyzed at 185 nm, yielding oxygen atoms that react with O₂ to form ozone, which can be detected using a commercial ozone analyzer. The limit of detection of ozone analyzers is ≈ 1 ppbv, which means that when ozone actinometry is employed, slower air flows are typically needed to ensure that sufficient levels of ozone are generated in the photolysis lamp region for detection. This requirement also implies that higher concentrations of radicals (often orders of magnitude higher than typical ambient levels) are generated when O₃ actinometry is used. A further complication arising from reducing the air flow and moving towards a laminar flow regime is that the air at the edges of the calibration tube spends more time passing the lamp than the air at the center. As FAGE instruments typically sample air from the center of the flowtube whereas ozone is typically sampled from the edge of the flowtube, the ratio of Ft at the center of the flowtube to Ft at the edges must be determined. In contrast to the absorption cross-section of H₂O or N₂O, the emission spectrum of the 185 nm Hg band overlaps with several features in the Schumann–Runge band of the O₂ spectrum, meaning that any change in the mercury lamp emission spectrum (e.g., as the lamp ages) can influence the absorption cross-

section. It is prudent, therefore, to determine the O_2 absorption cross-section regularly and for every lamp used [16.118].

Analogous calibration methodologies may be employed for HCHO LIF instruments, where H_2O vapor is replaced with methanol, which photolyzes at 185 nm to form HCHO [16.119].

To produce glyoxal in-situ, excess acetylene can be added to the humidified air flow in an OH calibration flow reactor. Acetylene reacts with the OH produced, generating a known yield of glyoxal [16.120]. Similarly, CH_3O_2 radicals can be generated by adding excess methane to a OH calibration flow reactor [16.70].

16.6.2 Intercomparison of Instruments

Examples of this will be given for the various techniques in relation to sampling the real atmosphere during field campaigns and sampling from within atmospheric simulation chambers. Intercomparisons between different techniques that detect the same chemical species offer a means to test instruments for interferences and assess the accuracy of the calibration method employed, thus increasing confidence in the reliability of those instruments. FAGE instruments used for OH and HO_2 detection have been compared to DOAS and chemical ionization mass spectrometry (CIMS), as well as to other FAGE instruments [16.121–123]. Given that FAGE instruments from around the globe differ significantly in terms of their optical cell designs,

a FAGE–FAGE intercomparison can yield valuable results. Atmospheric simulation chambers are often used for larger multi-instrument comparisons [16.121, 122]. Chambers ensure that instruments are sampling the same air mass and permit control over the chemical environment, thus offering advantages over ambient air intercomparisons. However, intercomparisons run in the real atmosphere offer the opportunity to compare instruments and techniques under more chemically complex conditions; e.g., in aged air masses or in environments where emissions are high and varied. Good agreement between measurements during ambient sampling can provide confidence in the technique and its applicability for use in the field. A drawback to ambient intercomparisons is that differences may arise due to the sampling of heterogeneous air masses.

HOxComp was the first formal blind intercomparison for HO_x measurements. It involved 4 LIF instruments, 1 CIMS, and 1 DOAS instrument [16.121–123]. The comparison took place in Julich, Germany in 2005 and involved 3 days of sampling ambient air and 6 days of sampling from the atmospheric simulation chamber, SAPHIR (Simulation of Atmospheric PHotochemistry in a large Reaction Chamber). All instruments were able to measure OH sensitively and at a time resolution that was sufficient for ambient measurements. However, the intercomparison did identify issues with the stability and accuracy of current calibration devices, and highlighted a potential nighttime artifact in some of the OH LIF instruments that took part [16.121].

16.7 Maintenance

The maintenance tasks for gas analyzers and laser techniques are given in Table 16.6.

Table 16.6 Maintenance of gas analyzers and laser techniques

Maximum interval	DOAS	FTIR	TDLS	CES	LIF	Chemiluminescence
Every measurement	Measure reference spectra	For some IR detectors, the liquid nitrogen typically needs filling every 8 h	Check laser power	Check zero time constant or intensity, align or clean optics as needed	Align laser/optimize power Perform visual check of laser optics Calibrate detection cell Calibrate photodiode against power meter Check cell pressures	Calibrate with known standard gas
Every field campaign	Set up and align retroreflectors	Purge the interior with dry N ₂ and replace desiccant	Align and clean optics Replace inlet lines	Align and clean optics Replace inlet lines	Replace fiber optics Clean detection cells and collection optics Replace nitric oxide cylinder and stainless steel delivery lines Change pump oil and filters Calibrate mass flow controllers used for gas delivery Replace laser chiller water and add fungicide Change dye	Replace inlet lines Calibrate mass flow controllers Replace charcoal trap Change particle filter
1–2 years		Replace the IR source as the intensity decays exponentially; may require alignment afterwards Replace internal HeNe laser if in continuous use			Change flashlamps or pump diodes for solid-state YAG lasers	

16.8 Applications

Some examples of applications are given in this section; please note that the selected examples reflect the interests and expertise of the authors to some extent.

16.8.1 Measurements of Short-Lived Radical Intermediates and Comparison with Model Calculations

One way to assess our understanding of the atmospheric chemistry that occurs in a particular environment is to compare the concentrations of short-lived RO_x radicals predicted by detailed chemistry box models to observations of radicals performed using FAGE instruments. As seen in the schematic provided in Fig. 16.5, OH, HO_2 , and RO_2 all play important roles in the oxidation of primary emissions and the production of secondary species such as ozone, NO_2 , and secondary organic aerosols.

When a model constrained by the concentrations of long-lived species such as VOCs, CO, and NO_x is able to accurately predict observed radical concentrations, it is likely that the radical sources and sinks present and the rate at which the chemical reactions occur are captured well by the model. Conversely, disagreement between a model and observed data can highlight chemical regimes or environments that are not sufficiently well understood. Under clean conditions, where NO_x and VOC concentrations are low and hence the atmospheric chemistry taking place is relatively simple, models tend to capture the observed OH concentrations well [16.125]. In chemically complex environments, however, such as in cities or forested regions (where
