Sonic anemometer with integrated open-path gas analyzer (compact system)	Minimal sensor separation Only cleaning of sensor required for maintenance Low power consumption	Disturbed by water droplets, ice, and dirt on the optical windows or within the measurement path Increased flow distortion
Sonic anemometer with enclosed-path gas analyzer (tube ≤ 1 m)	Reduced tube dampening compared to closed-path systems with longer tubes Can be used during times of precipitation or fog Less calibration drift due to dirt Considerably smaller number of technical data gaps in humid climates	Large tube and rain cap dampening compared to open-path sensors Requires regular checks of flow rate and exchange of filters for maintenance High power consumption due to the use of a pump Need to measure chamber temperature at high frequency
Sonic anemometer with closed-path gas analyzer (long tube)	Can be used during times of precipitation or fog Less calibration drift due to dirt No need for high-frequency temperature correction Considerably smaller number of technical data gaps in humid climates	Larger tube dampening compared to open-path and enclosed-path systems Requires regular checks of flow rate and exchange of filters for maintenance High power consumption due to the use of a pump

with increasing stability, the intermittent character of turbulence under stable conditions often requires an increased averaging time. Nevertheless, for practicality reasons and to facilitate an efficient data handling, a sampling time of 30 min is used over the entire day. This choice is always a tradeoff. For short sampling times, the low-frequency contributions to the fluxes are missed, and for long sampling times, the steady-state condition may not be fulfilled. Moreover, the high-pass filter correction can only compensate for a too-short sampling time under the assumption that heterogeneity-induced low-frequency contributions are negligible.

The choice of the measurement height depends on the vegetation height, the path length, and the separation between a sonic anemometer and an additional device to measure the scalars of interest (e.g., hygrometer). Devices with a path length of > 12 cm should not be used below 2 m, and devices with a path length of > 20 cm should be not used below 4 m [55.22, 50]. The minimum distance between a sonic anemometer and an additional device depends on the flow distortions caused by the devices and should be determined in a wind tunnel. Typically, for fine-wire temperature sensors, the minimum distance is 5 cm, and for hygrometers it is 20–30 cm. These additional instruments should be mounted downwind of the sonic

anemometers and 5–10 cm below the wind measurement path [55.133]. Therefore, to reduce the corrections of the whole system, the measurement height must be estimated, dependent on the path length of the sonic anemometer and on the separation of the measurement devices. Also, the measurement height should be twice the canopy height in order to exclude effects of the roughness sublayer. This is, however, often not feasible when measuring over tall vegetation. Flow distortion due to the measurement system can hardly be avoided [55.118]. Nevertheless, care must be taken that instrument mounts, tower elements, or other sensors are installed at a sufficient distance from the turbulence measurements (a distance that is five to tenfold of the dimension of the disturbing structure [55.134–137]).

55.4.6 Advantages and Disadvantages of the Different Trace Gas Sensors and Installations

The specific challenges and advantages of different types of gas analyzers used in eddy-covariance measurements have been investigated in several studies [55.138–140]. An overview is presented in Table 55.8.

55.5 Specifications

A general specification of flux measuring systems is difficult because the accuracy of the measurement depends not only on the sensor configuration but also on the turbulent conditions and, therefore, e.g., if the turbulence is fully developed and steady state [55.55,

141]. In Sect. 55.6.3 and Table 55.12, this connection of sonic anemometer type and data quality concerning the accuracy is shown. In Table 55.9, only some general specifications are given, see also the relevant chapters for the sensors: Chaps. 7–9 and 16.

Table 55.9 Specification of the sensors of eddy-covariance systems

Sensor	Range of measurements	Typical accuracy	Temperature range for application (°C)
Sonic anemometer, wind velocity, scientific instruments	0 to 60 m s ⁻¹	0.1 m s ⁻¹ for ≤ 5 m s ⁻¹ 2% for > 5 m s ⁻¹	–40 to 60 ^a
Sonic anemometer, sonic temperature	–40 to 60 °C	1 K	–40 to 60 ^a
Open-path gas analyzer, water vapor	0 to 60 ppt	1% of reading	–25 to 50 ^a
Open-path gas analyzer, carbon dioxide	0 to 3000 ppm	2% of reading	–25 to 50 ^a
Open-path gas analyzer, methane	0 to 30 ppm	1% of reading	–25 to 50 ^a
Closed-path gas analyzer, water vapor	0 to 60 ppt	1% of reading	–25 to 50 ^a
Closed-path gas analyzer, carbon dioxide	0 to 3000 ppm	1% of reading	0 to 50
Closed-path gas analyzer, methane	0 to 100 ppm	1% of reading	15 to 35
Closed-path gas analyzer, nitrous oxide	300 to 1500 ppb	1% of reading	15 to 35

^a Temperatures below 0 °C only in dry air or if the sensor is heated

55.6 Quality Control

A careful quality assurance (QA) and quality control (QC) process (Chap. 3) for eddy-covariance measurements is particularly recommended because of the very complex calculation procedure [55.57, 58, 75, 99, 142]. Such a procedure should include not only tests for instrument errors and problems with the sensors but also evaluate how closely the actual conditions agree with the underlying theoretical assumptions. Due to the variability of meteorological conditions, eddy-covariance quality control tools must comprise a combination of a typical test for high-resolution time series and an examination of the turbulent conditions. A second problem is connected with the representativeness of the measurements depending on the footprint of the measurement. The fraction of the footprint that is in the area of interest must be calculated (Chap. 1). A concise overview of quality control methods for eddy-covariance is summarized in Table 55.10.

55.6.1 Calibration of Turbulence Sensors

For the calibration of turbulence sensors, see the respective instrument chapters, such as Chaps. 7–9 and 16. However, it should be examined whether the calibration also holds under the measurement conditions in the field, with respect to e.g., temperature, pressure, and humidity.

55.6.2 Specific Quality Control Methods

Comprehensive and systematic procedures for quality control of eddy-covariance measurements were first developed in the 1990s [55.57, 58]. The corresponding tests are also summarized in several textbook chapters [55.99, 142]. An extension of these methods is presented in [55.75], with a special focus on long-term eddy-covariance measurements and their particular requirements with respect to automation and uncertainty assessment. Several instruments generate a specific error code or measure control parameters that can be used for data quality issues. Examples are shown in Table 55.11.

Steady-State Test

For the eddy-covariance method, steady-state conditions are required. Meteorological measurements fulfil this underlying assumption for short-time periods up to ≈ 1 h only roughly. There are several tests, which can be used directly or indirectly. For example, stationarity can be determined by examining the fluxes for different averaging times [55.56, 57]. In this way, the flux is determined over short intervals each of only ≈ 5 min duration, and then the average over the short time intervals is calculated. Steady-state conditions can be assumed, if this value does not differ by more than 30% from the

30 min-covariance. A gradation of the differences can be used as a classification of the data quality

$$\text{Stat} = \left| \frac{[\overline{x'y'}]_{5\text{min}} - [\overline{x'y'}]_{30\text{min}}}{[\overline{x'y'}]_{30\text{min}}} \right| \times 100\% , \quad (55.16)$$

where $[\overline{x'y'}]_{5\text{min}}$ is calculated as the average of six 5 min covariances within this 30 min-interval, see [55.57] for details.

Development of Turbulence

The development of turbulent conditions can be investigated with the flux-variance similarity [55.57]. In this case, the measured integral turbulence characteristics (ITC) are compared with the modeled characteristics given in the literature, e.g., [55.2]. Good data quality is suggested for differences < 30%.

$$\text{ITC} = \left| \frac{\left(\frac{\sigma_x}{X_*}\right)_{\text{Model}} - \left(\frac{\sigma_x}{X_*}\right)_{\text{Meas}}}{\left(\frac{\sigma_x}{X_*}\right)_{\text{Model}}} \right| \times 100\% , \quad (55.17)$$

where σ_x is the standard deviation of a quantity x , and X_* is its respective scaling parameter (Chap. 1).

Overall Data Flagging

An evaluation system for turbulent fluxes consists of two steps. The single tests should be evaluated according to the threshold values and corresponding data quality classes, and the overall quality of a measurement is expressed as an appropriate combination of the single tests [55.99, 142]. The highest priority should be given to the steady-state test. Note that for the test on integral turbulence characteristics for neutral stratification, the errors in the determination of the characteristics for scalars can be very high. This test should, therefore, not be overly interpreted, and the test on the characteristics of the wind parameters should dominate. In any case, the classification results of the single tests should be stored to have them available later in cases of doubt. For fundamental research, only data with highest quality should be used. Medium quality can still be used for long-term measurements of fluxes without limitations. Measurements with poor quality should only be used for ballpark estimates and should be discarded [55.75, 150, 151].

Footprint Climatology

The footprint analysis is a tool to estimate the source areas of the flux measurement [55.152–155] that is

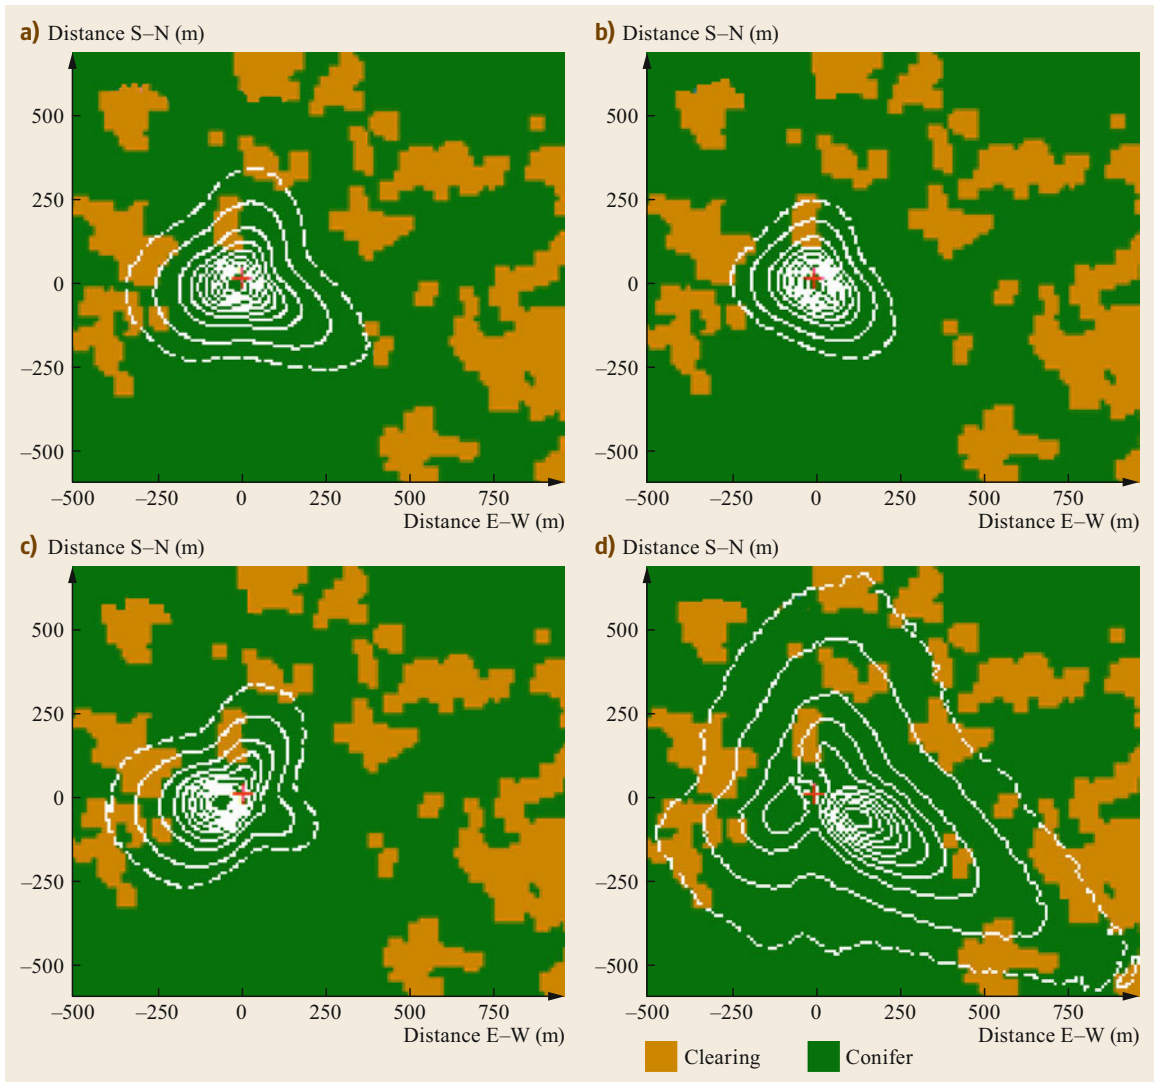

Fig. 55.6a–d Top-down view on footprint climatologies (*white lines*), accumulated for different regimes of atmospheric stability and obtained for the FLUXNET DE-Bay Waldstein–Weidenbrunnen site. Panels give footprint climatologies for all cases (**a**), unstable (**b**), neutral, (**c**) and stable (**d**) stratification. Values are in percentages of the integrated contribution around the peak of the function, with *solid lines* ranging from 90 to 10%, and the *dashed line* as 5% of the maximum. High values indicate a high relative contribution of the specific area to the fluxes measured in the given observation period. Colors in the background indicate land-cover classes. Distances to the tower position (*red cross*) are given in m. The analysis based on a nearly 3-month dataset in summer 2003 (after [55.152])

described in Chap. 1. An integral part of the footprint-based quality assessment approach is the average source weight function created over a longer measurement period, i.e., the footprint climatology [55.152, 156]. By means of 2-D footprint models [55.157, 158], it is possible to calculate footprint climatologies for individual grid cells rather than integrated over a wind direction sector [55.144, 145]. For such a more detailed analysis, each 30-min-source-weight function is projected onto

a gridded land-cover map, assigning a weighting factor to each grid cell that represents its relative contribution to actual measurements. The distribution of flux contributions from the different land-cover types can then be obtained by accumulating these weights arranged in different land-cover types. The application of footprint analysis to a larger dataset reveals patterns in the composition of the footprint that depend on wind sector and stability regime (Fig. 55.6).

Footprint-Dependent Data Quality Control

For data-quality assessment maps, any measured parameter (scalars and fluxes) can be linked to footprint analyses and data-quality flags. To ensure representative findings, footprint analyses for data-quality assessment should use a database of several months (at least 2–3) of meteorological measurements, so that several thousand half-hourly averaged observations are available. The correct interpretation of the findings relies on a good sample of the local wind climatology and sufficient coverage of different atmospheric stability conditions for all wind sectors. The analysis will be strengthened by choosing a database that covers a period of the year with high absolute values of exchange fluxes between surface and atmosphere.

A classic example of this application would be the visualization of spatial structures in the mean vertical wind component. Other examples include visualizing the flux fields for sensible or latent heat, which may indicate spatially variable sources for these parameters.

An additional, powerful way to apply footprints to eddy-covariance quality assessment is to link data quality to terrain features. In this scenario, the footprint results are then coupled to other approaches used to evaluate flux data quality. The choice of the method to assign flux data quality, as well as the definition and resolution of quality classes, can be chosen by the user and customized for each study, as long as the quality ratings are numeric to allow aggregation [55.145, 153].

55.6.3 Uncertainty Assessment

Besides qualitative information characterizing a flux measurement, i.e., quality flags, it is important to also provide quantitative information about the error or uncertainty associated with a specific flux estimate for proper interpretation and further use of the data. However, the discussion of the uncertainty of eddy-covariance measurements is not trivial because of the stochastic character of the input parameters. Therefore, different approaches are applied [55.159].

Results of Comparison Experiments

On the basis of long-term experience in sensor comparisons [55.141, 160, 161] as well as software comparisons [55.160, 162], some numbers for the possible accuracy of eddy-covariance measurements may be obtained according to the present state of knowledge. A significant dependency was found on the type of sonic anemometer with respect to their suitability for fundamental turbulence research and on the data quality (Sect. 55.6.2). The results are summarized in Table 55.12. To transfer these data to the carbon-dioxide

Table 55.12 Evaluation of the accuracy of the eddy-covariance method on the basis of the experimental results [55.141], data quality, and type of sonic anemometer

Sonic anemometer	Data quality class	Sensible heat flux	Latent heat flux
Selected open sector e.g., CSAT3	High quality	5% or 10 W m ⁻²	10% or 20 W m ⁻²
	Moderate quality	10% or 20 W m ⁻²	15% or 30 W m ⁻²
Omnidirectional e.g., uSonic-3	High quality	10% or 20 W m ⁻²	15% or 30 W m ⁻²
	Moderate quality	15% or 30 W m ⁻²	20% or 40 W m ⁻²

flux the results for the latent heat flux should be used with a threshold of $\approx 0.2 \text{ mg m}^{-2} \text{ s}^{-1}$.

Systematic Errors

After wide application of the eddy-covariance method including all corrections and storage terms, and after the availability of highly accurate net radiometers it became obvious that the energy balance at the Earth's surface could not be closed with experimental data [55.55], indicating a general systematic error (Sect. 55.9.1). The available energy, i.e., the sum of the net radiation and the ground heat flux, was in most cases found to be larger than the sum of the turbulent fluxes of sensible and latent heat. For many field experiments and also for the carbon-dioxide flux networks [55.60, 163], a closure of the energy balance of $\approx 80\%$ was found [55.164, 165]. The residual is defined as

$$\text{Res} = Q_S^* - Q_G - Q_H - Q_E, \tag{55.18}$$

with Q_S^* the net radiation, Q_G the soil heat flux at the surface, Q_H the sensible heat flux, and Q_E the latent heat flux. Over tall canopies, additional storage terms in the biomass and the air volume below the sensor should also be accounted for.

The problem cannot be described as only an effect of statistically distributed measurement errors because of the systematic underestimation of turbulent fluxes or overestimation of the available energy. In the literature, several reasons for this incongruity have been discussed [55.148]. The reason most often discussed is the heterogeneity of the land surface [55.166], which is not considered in the 1-D eddy covariance theory. The authors assumed that the heterogeneity in the vicinity of a flux-measurement site generates coherent structures, but such turbulent features generated by heterogeneities close to the measurement tower can be captured by the eddy-covariance method as long as their temporal extent is shorter than the sampling interval [55.167, 168].

As a first step, the energy exchange between the atmosphere and the underlying surface on scales larger than 1 km can be corrected with the Bowen ratio [55.148, 169–171]. With this approach, the residual will be distributed to the sensible and latent heat flux by preserving the Bowen ratio. However, this method is only valid if a similarity of both scalar fluxes is given even at larger scales, which is obviously not always realized. Some studies [55.105, 172] propose that a large part of the unclosed energy balance is related to the sensible heat flux and propose a correction with the buoyancy flux [55.2, 100].

Noise and Statistical Errors

Due to the very complicated algorithms of the eddy-covariance method, errors cannot easily be estimated according to the error propagation law [55.173]. Quite promising are statistical methods. Hereby, it must be noted that the time series used for eddy covariance are autocorrelated, and the usual statistical criteria for random numbers cannot be applied [55.54, 174, 175]. It is distinguished between:

Noise: error due to instrumental noise [55.75], see Chap. 2

Random error: statistical sampling error of a covariance measurement [55.75, 159, 175, 176], see Chap. 2.

The noise error is determined from the autocorrelation of the measurement signal, using the property of white noise being uncorrelated: a quantity x can be decomposed in its mean \bar{x} , deviations from that mean, x' , with a mean of $\bar{x'} = 0$, and a noise error term εx [55.177]

$$x = \bar{x} + x' + \varepsilon x. \quad (55.19)$$

The second-order autocovariance is then

$$C_{11}(p) = \overline{(x' + \varepsilon x)(x'_p + \varepsilon x_p)}, \quad (55.20)$$

where the subscript p denotes the same quantity as without the subscript but shifted in time by the amount p . If the noise εx is uncorrelated with the signal, then the noise term only appears at zero lag in the autocovariance. The variance of the noise error can, thus, be estimated as

$$\overline{\varepsilon x^2} = C_{11}(0) - C_{11}(p \rightarrow 0), \quad (55.21)$$

where $C_{11}(p \rightarrow 0)$ is $C_{11}(p)$, without $C_{11}(0)$, extrapolated to zero lag.

Thus, the noise of the errors of two time series εx and εy lead to an error of the covariance [55.75],

$$\sigma_{\text{covariance}}^{\text{noise}} = \sqrt{\frac{1}{N} \sqrt{\varepsilon x^2 y^2 + \varepsilon y^2 x^2}}. \quad (55.22)$$

Several authors determined the stochastic error of eddy-covariance fluxes based on raw data [55.175], while others determined an error estimate from final fluxes [55.176]. In general, the random flux error depends on the number of independent observations, which is not identical with the absolute number of observations n when time series are auto and cross correlated. The integral time scale is a measure for how long the variables are correlated and, therefore, not independent. The integral time scale is, therefore, often used to determine the number of independent observations. However, this metric is not always estimated reliably [55.54]. This problem is overcome by an algorithm [55.175] to determine the statistical variance of the covariance, which is a statistically profound and mathematically rigorous approach

$$\sigma_{\text{cov}(x,y)}^{\text{stoch}} = \sqrt{\frac{1}{n} \sum_{p=-m}^m (\overline{x'x'_p} \cdot \overline{y'y'_p} + \overline{x'y'_p} \cdot \overline{y'x'_p})}, \quad (55.23)$$

where $\overline{x'x'_p}$ and $\overline{y'y'_p}$ are the autocovariances with lag p , $\overline{x'y'_p}$ is the cross covariance with lag p on y , while for $\overline{y'x'_p}$, the lag p is on x . The summation bound m should be $n/2$.

55.7 Maintenance

Regular maintenance of eddy-covariance systems is critical for producing reliable flux data. In addition to site visits, online raw data surveillance is very useful to detect instrumental malfunctions as early as possible and to react swiftly to problems that may compro-

mise the data quality and continuous data acquisition. For specific maintenance issues of single sensors, see Chaps. 7–9 and 16. Some maintenance activities of the whole system are listed in Table 55.13.

Table 55.13 Maintenance of eddy-covariance measuring systems (site-specific intervals may be adjusted)

Maximum interval	Single sonic anemometer	Compact system	Sonic anemometer with open-path analyzer	Sonic anemometer with closed-path analyzer, short tubes	Sonic anemometer with closed-path analyzer, long tubes
1 day	Quick look on data or automatic data quality analysis				
1 week	–	Clean optical windows	Clean optical windows	Replace intake tube filter, clean rain-cap mesh	Check/replace intake tube filter, clean rain-cap mesh
1 month	Clean sonic transducers	Clean sonic transducers	Clean sonic transducers	Clean sonic transducers	Clean sonic transducers
1 year	Chamber test of the sonic anemometer [55.143], Chap. 9				
1 year			Replace scrubber chemicals and lab calibration	Replace scrubber chemicals and lab calibration	Replace scrubber chemicals and lab calibration

55.8 Application

The eddy-covariance method has been successfully applied to quantify the turbulent exchange of heat, water, CO₂, and other trace gases for numerous ecosystems in all climate zones of the Earth.

55.8.1 Intensive Measurement Campaigns and Process Studies

One of the earliest large-scale projects using eddy-covariance measurements was the Boreal Ecosystem–Atmosphere Study (BOREAS). Eleven flux towers were deployed during the intensive field campaigns of 1994 and 1996, representing the particularly climate-sensitive boreal ecosystem [55.178]. The primary objective of BOREAS was to collect the data needed to improve numerical climate models with a specific focus on biosphere-atmosphere exchange processes. Another important large-scale intensive measurement campaign using 13 eddy-covariance towers was the LITFASS-2003 experiment (Lindenberg Inhomogeneous Terrain—Fluxes Between Atmosphere and Surface: a Long-Term Study), which was part of the Evaporation at Grid-Pixel Scale (EVA-GRIPS) project [55.179]. Here, the study region was located in central Europe, and the objective was to provide data for investigating the effect of surface heterogeneity on the atmospheric water fluxes, leading to improved parameterization schemes for area-averaged evaporation. While the above-mentioned field campaigns aimed at

providing data for the development of weather and climate models, the Energy Balance Experiment (EBEX-2000) was conducted to work on methodological issues of the eddy-covariance technique. To this end, micrometeorologists from esteemed institutions around the world deployed 14 eddy-covariance towers at a carefully selected site in the Central Valley of California, where almost ideal conditions, such as surface homogeneity, high net radiation, and uniform weather conditions, were expected [55.127]. One of the most recent large-scale measurement campaigns using eddy-covariance measurements was Scale-X (Scale-Crossing Land Surface and Boundary Layer Processes in the TERENO-preAlpine Observatory), which took place in 2015 and 2016. This campaign went beyond the goals of the previously mentioned experiments, since it had a special focus on the transport processes above the eddy-covariance towers throughout the entire boundary layer, at the same time investigating methodological aspects such as advection in complex terrain and the energy balance closure problem [55.180].

55.8.2 Long-Term Measurements of Greenhouse-Gas Exchange Between Terrestrial Ecosystems and the Atmosphere

Long-term eddy-covariance measurements are usually conducted as part of ecological observatories aim-

ing to quantify the biosphere-atmosphere exchange of energy, water, and greenhouse gases, particularly CO₂. The main motivation for these measurements was the large uncertainty in the CO₂ sink strength of the terrestrial biosphere at the global scale and the ground-breaking opportunity for fundamental ecosystems research through observing ecosystems' responses to environmental conditions without any disturbance at the ecosystem scale. Two pioneering networks developed in parallel in Europe (EUROFLUX) and in northern America (AMERIFLUX). From these networks, a global initiative, FLUXNET, was founded and hundreds of long-term eddy-covariance stations have been established across most of the world's climate space and representative biomes [55.61]. These sites are not directly operated by FLUXNET, but it links across

a confederation of regional networks. FLUXNET provides a common infrastructure to archive and share flux and driver data from across the entire globe, it supports calibration, standardization, and intercomparison activities, and it enables global-scale synthesis studies on the terrestrial carbon, water, and energy cycle. Thereby, ensuring and improving intercomparability between sites is one of the main objectives. Since missing or poor-quality data are inevitable in a long-term time series of 30 min fluxes, a variety of gap-filling algorithms were elaborated in order to compute the desired annual estimates of CO₂ net ecosystem exchange and evapotranspiration [55.73, 74, 181]. A review of the scientific outcome of the first 20 years of FLUXNET, including future perspectives, is provided by [55.182] (Chap. 64).

55.9 Future Developments

Over the past 70 years, eddy covariance has become a mature method for measuring turbulent fluxes on the ecosystem scale. Nevertheless, there are still some unresolved issues related to certain details of the methodology, which need to be addressed in the future in order to further improve the accuracy of flux estimates.

55.9.1 Energy Balance Closure Problem

During the late 1980s it became obvious that the energy balance at the Earth's surface could not be closed with experimental data (e.g., [55.183]). In most cases, the available energy, i.e., the sum of the net radiation, the ground heat flux, and the rate of change of the sensible and latent heat storage within the air column underneath the sensor was found to be larger than the sum of the turbulent fluxes of sensible and latent heat. This was a main topic of a workshop held in 1994 in Grenoble [55.55], which resulted in the EBEX-2000 [55.127]. For various sites around the world, an average closure of the energy balance of $\approx 80\%$ was found [55.164]. This indicates a systematic underestimation of the turbulent fluxes, which has been mainly attributed to advection by the mean flow and horizontal flux divergence associated with secondary circulations impacting near-surface tower measurements [55.184, 185]. Current research on this topic investigates the partitioning of the energy balance residual between the sensible and the latent heat flux (e.g., [55.100, 171]) and the predictability of the magnitude of the missing flux [55.186]. It is still debated, whether the closure problem indicates a possible general underestimation also of other scalars, such as, e.g., CO₂.

55.9.2 Correction and of Probe-Induced Flow Distortion Effects and Sensor Optimizations

Probe-induced flow distortion, which is sometimes reduced to transducer shadowing effects, has been a topic of increasing interest over the past years, in part also related with investigations of the energy balance closure problem. Several studies suggesting that most of today's commercially available sonic anemometers are prone to a nonnegligible systematic underestimation of vertical velocity fluctuations and, consequently, velocity variances, covariances and, thus, flux estimates [55.110, 120]. The findings are, however, mostly based on field intercomparison studies, which are afflicted with the general problem that they do not have a clear reference measurement. This is only available in a wind tunnel, however it is questionable whether the flow-distortion effects can be transferred from these quasi laminar conditions to real-world boundary layer flows with very high Reynolds numbers [55.187]. To overcome these difficulties, the use of numerical simulations of the turbulent air flow around an anemometer was proposed [55.121]. Further development of this approach will probably allow us to obtain more accurate correction algorithms in the future and help to optimize the instruments' geometry.

55.9.3 Spatial Eddy Covariance, Eddy Covariance from Lidar Measurements

Another reason for the nonclosure of the energy balance can be the inherent high-pass filtering of any eddy-

covariance measurement on a single tower [55.81]. Even corrections to account for the missing low-frequency flux contribution cannot fully compensate for these losses, because all currently available methods are based on cospectra measured over homogeneous and flat terrain, so that any heterogeneity-induced circulations are not considered. In addition, secondary circulations often do not propagate with the mean wind and, therefore, cannot be captured by a temporal covariance [55.188]. A solution for this problem could be the calculation of a spatial covariance from multiple tow-

ers as proposed in the Large Eddy Simulation study of [55.189]. This principle has been partially tested under field conditions by means of airborne measurements [55.190] and multitower experiments [55.191, 192]. However, further field campaigns with a larger number of eddy-covariance towers are needed in order to fully explore the potential of a spatial eddy-covariance approach. Perhaps this will even be implemented by using a combination of wind, temperature, and water vapor lidars (light detection and ranging) in the future [55.193].

Matthias Mauder

Institute of Hydrology and Meteorology
Technische Universität Dresden
Dresden, Germany
matthias.mauder@tu-dresden.de

Matthias Mauder is a Professor in meteorology at the Technical University Dresden, Germany. Up to September 2021 he was the head of the group “Transport Processes in the Atmospheric Boundary Layer” at Karlsruhe Institute of Technology. He received his Doctorate in Micrometeorology from the University of Bayreuth (2006). As a postdoc, he developed new methods for the analysis of airborne eddy-covariance measurements and multitower measurements. His research aims to combine different observational techniques with numerical modeling to improve our understanding of turbulent transport processes and boundary-layer dynamics.

Andreas Ibrom is Senior Scientist at the DTU and Apl. Prof. at the Georg August University of Gottingen, Germany. Trained as Biologist in ecosystems research, he focuses on land–atmosphere exchange processes. His main scientific contributions are the development of the eddy-covariance technique and more than 30 site years of flux data that are available in international flux networks (FLUXNET, ICOS).

56. Alternative Turbulent Trace Gas Flux Measurement Methods

Janne Rinne , Christof Ammann , Elizabeth Pattey , Kyaw Tha Paw U ,
Raymond L. Desjardins 

The eddy-covariance (EC) method is the most direct micrometeorological approach to measure the surface-atmosphere trace gases under turbulent conditions. The measurement of trace gas fluxes by eddy covariance requires fast-response instruments (higher than 1 Hz) to measure the turbulent fluctuations of vertical wind velocity and trace gas mixing ratio. For many trace gas species, such fast-response analyzers are either not available or do not meet the required precision, long-term stability, and ease of operation under field conditions. Thus, a range of alternative flux measurement techniques have been developed to relax the requirement for fast response time and precision of analysis of the targeted trace gases. These alternative trace gas flux measurement methods are based on surface layer gradients, eddy accumulation, and disjunct eddy-covariance approaches. Of these, the two latter are presented in this chapter. In addition, the surface layer renewal approach, which can be used to understand turbulent exchange processes, and the nocturnal boundary layer Keeling plot approach for determination of the isotopic composition of emitted gases under stable conditions are also described.

The Earth's atmosphere is mostly composed of nitrogen (N_2), oxygen (O_2) and argon (Ar). However, several gases present in trace amounts have considerable effect on the functioning of the atmosphere, either via their radiative effects or due to their chemical reactions. For many of these gases, the terrestrial biosphere is either an important source or sink. Thus, the measurement of the surface exchange is crucial for our understanding

of atmospheric and ecosystem functioning. Turbulent fluxes of some trace gases, such as carbon dioxide and methane, can be measured by the standard eddy-covariance method (Chap. 55). However, for many trace gases, this is either not possible or is very expensive. Thus, this chapter gives an overview on alternative flux measurement methods.

56.1 Measurement Principles and Parameters

The trace gases for which no operational eddy-covariance system is available are a large group with varying characteristics and concentrations. Unlike the common greenhouse gases (H₂O, CO₂, CH₄, N₂O) some of these compounds interact heavily with surfaces, while others rapidly react in the atmosphere. Thus, the design of any flux measurement system needs to be adapted to the properties of the targeted compounds. The primary measurements of these flux measurement methods are typically trace gas concentrations and vertical wind velocity (Table 56.1).

The alternative flux measurement methods share the same basic assumptions as the eddy-covariance method:

- i) The measurement site must be horizontally homogenous for horizontal flux divergence to be negligible.
- ii) The flux is assumed to be constant between surface and measurement height, i.e., there is no vertical flux divergence.
- iii) Stationarity is assumed so that Reynolds decomposition is valid, and the time-dependent term in the average concentration is negligible.

While in the eddy-covariance, disjunct eddy-covariance, and eddy-accumulation methods, the turbulent fluxes are measured directly, the gradient and (hyperbolic) relaxed eddy-accumulation methods use more or less empirical parameterizations.

The most important assumption is the requirement of horizontal homogeneity, as it usually restricts the use of these methods, as well as the eddy-covariance method (Chap. 55), to locations with a relatively large flat and homogenous surface.

The alternatives for eddy-covariance flux measurements used nowadays can be classified either as gradient techniques, eddy-accumulation (or conditional-sampling) techniques, or disjunct eddy-covariance measurements. The gradient technique was already presented in Chap. 54, and thus is omitted from this chapter. In addition to the above-mentioned flux measurement methods, we will describe the surface-layer renewal technique, which can shed light on turbulent transport dynamics. Although the nocturnal boundary-layer Keeling plot method for determining the isotopic composition of emitted gas is not strictly a turbulent method, it will be presented here as an alternative flux measurement approach.

Table 56.1 Primary measurements (w is the vertical wind velocity (i.e., a vector)), with the usual convention of ascend being positive and descend being negative, and output of alternative flux measurement methods (EA: eddy accumulation; DEA: disjunct eddy accumulation; REA: relaxed eddy accumulation; HREA: hyperbolic relaxed eddy accumulation; DEC: disjunct eddy covariance; SR: surface renewal (H : sensible heat flux; LE: latent heat flux); NBL-K: nocturnal boundary-layer Keeling plot)

Method	Primary measurements (response time)	Output	Symbol	Dimension
DEC	Vertical wind velocity (0.1 s) Concentration of trace gas with 1–30 s intervals (0.1 s)	Mass flux	F_s	$\mu\text{g m}^{-2} \text{s}^{-1}$ $\mu\text{mol m}^{-2} \text{s}^{-1}$
EA	Vertical wind velocity (0.1 s) Average concentration of trace gas in updrafts and downdrafts (30 min)	Mass flux	F_s	$\mu\text{g m}^{-2} \text{s}^{-1}$ $\mu\text{mol m}^{-2} \text{s}^{-1}$
DEA	Vertical wind velocity (0.1 s) Average concentration of trace gas in updrafts and downdrafts (30 min)	Mass flux	F_s	$\mu\text{g m}^{-2} \text{s}^{-1}$ $\mu\text{mol m}^{-2} \text{s}^{-1}$

56.2 History

Before the advent of turbulent flux measurement methods, such as eddy covariance, most surface–atmosphere flux measurements were made by observation of the vertical gradients of the gas of interest, as well as the gradient of the horizontal wind with some assumptions made to derive turbulent mixing coefficients [56.1]. While this approach is still useful in a number of cases [56.2], new methods based on eddy covariance (Chap. 55), disjunct eddy covariance, and conditional sampling have supplemented our flux measurement toolbox.

Today, the most commonly used alternative flux measurement techniques are relaxed eddy accumulation, disjunct eddy covariance by mass scanning, and gradient techniques. However, there have also been other interesting methodological developments in the

Fig. 56.1 DEC system with two grab sampling inlets and intermediate storage reservoirs (white cylindrical containers) in operation at an alfalfa field near Fort Morgan, Colorado, August 2000 (after [56.3, 4]). The DEC sampling unit is positioned 0.6 m below the sonic anemometer at 3.2 m (photo © Janne Rinne)

past decades that may be of interest. The development of various techniques has been parallel in time. Thus, the order of the methods below is not chronological but reflects the ordering of the theories in the Methods section (Sect. 56.3).

56.2.1 Disjunct Eddy Covariance

The concept of deriving fluxes and other turbulence statistics from disjunct time series was first proposed by *D. Haugen* in 1978 [56.5], with early practical applications to overcome limitations of data storage and transfer at the Boulder Atmospheric Observatory in the early 1980s [56.6]. The first application of the disjunct eddy-covariance (DEC) method to measure trace gas fluxes was presented by *J. Rinne* et al. with a system using physical grab samplers (Fig. 56.1; [56.3]). In this application type, which was used mainly until about 2010, finite air volumes were sampled during typically 0.2 s into a reservoir at repetition intervals of 10–60 s [56.3, 4, 7, 8]. The grab air sample could then be analyzed during that interval with a trace gas analyzer having a slower response compared to conventional EC measurements. For the covariance flux calculation, the trace gas concentration of each grab sample analysis was combined with the vertical wind velocity measured at the respective air sampling time (Sect. 56.3.1).

A more feasible method of disjunct eddy covariance by mass scanning was introduced by *T. Karl* et al. [56.9]. This variant of the disjunct eddy-covariance method was commonly used for volatile organic compound (VOC) fluxes in the 2000s and 2010s.

56.2.2 Eddy Accumulation

In the early 1970s *R. Desjardins* [56.10, 11] developed the concept of accumulating air from up and down moving air parcels, or turbulent eddies, and then measuring the mean concentrations, with slow response gas analyzers, of the various trace gases in the air samples collected. This method was based on the same principle as the eddy-covariance (EC) technique, which was mainly being used for measuring the flux of water vapor and sensible heat. At the time, a technique that reduced the requirement for fast-response gas analyzers of EC was very welcome. The eddy-accumulation (EA) method, which involved the continuous separation of the sampled gas in two streams, depending on whether the vertical wind moved upwards or downwards, and with sample flow proportional to the vertical wind speed, solved the problem of the need for a faster response sensor than the state-of-the-art afforded.

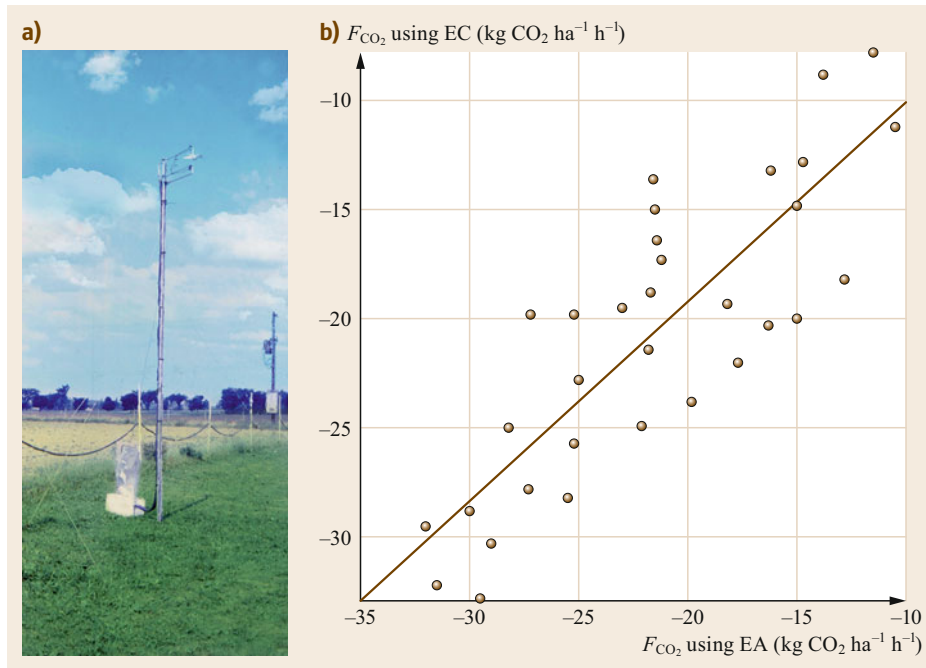

Fig. 56.2 (a) Eddy-accumulation system with bags as a sample storage system. Central Experimental Farm, Ottawa Canada, 1971 (photo © Ray Desjardins). (b) 10-minute mean CO₂ flux densities simultaneously obtained using eddy-covariance (EC) and eddy-accumulation (EA) measuring systems (after [56.12] with permission from Elsevier)

Fast sensing, followed by multiplication and averaging, was replaced by fast valve-controlled sampling and storage and measurement of the average concentration with a slow-response gas analyzer. For example, by measuring the difference of the mean concentrations of the up and downdraft air samples with a mass spectrometer, Desjardins demonstrated that one could measure the flux of many gas species simultaneously [56.10]. Figure 56.2a shows one of the first EA systems, which used fast-response solenoid valves situated in close proximity to a vertical axis propeller anemometer. Figure 56.2b shows 10-min mean CO₂ flux densities measured with a fast-response CO₂ analyzer and the EA bag sampling system. The 1 : 1 relationship between the results from the two sampling systems indicated that there were no systematic errors due to the different sampling techniques [56.12].

At the time, the fast-response valves were opened for about 25 ms for a preselected each 10 cm of vertical air travel. A decade later, proportional sampling valves with a frequency response of about 10 Hz were developed [56.13, 14]. Flow rates of up to 150 cm³ s⁻¹ were possible for a vertical wind of 1.5 m s⁻¹. These valves were ideal for the eddy-accumulation method because they could even correct for flow restrictions in the sampling line. However, soon after their development, J. Businger and S. Oncley suggested the use of constant sample flow [56.15]. This relaxation of the proportionality between the vertical wind velocity and sample flow rate led to the relaxed eddy-

accumulation (REA) method. Since this method gave fairly similar results to the EA and EC methods, the EA measurements using the proportional sampling valves was discontinued (see, however, the latest development [56.16]).

E. Pattey et al. developed an implementation of the density fluctuation correction WPL (Webb–Pearman–Leuning) specific to the REA method [56.17] according to the trapping media (i.e., using bags or traps as reservoirs). An independent verification of the REA method based on CO₂ fluxes by comparing them with EC shows that REA can be successfully implemented [56.18]. The same REA measuring system was used to determine isoprene fluxes over black spruce in the Boreal forest in 1994 during the BOREAS (Boreal Ecosystem–Atmosphere Study) campaign [56.19].

56.2.3 Surface Renewal

The origin of the surface renewal paradigm originates from chemical engineering and was developed to connect reactions occurring during molecular diffusion into turbulent parcels of fluid near a surface [56.20, 21].

From a micrometeorological perspective, K.T. Paw U et al. suggested that the turbulent coherent structures in plant canopies could be thought of as air parcels descending into a plant canopy and moving along horizontally through the canopy, while the scalar sources in the canopy increase scalar concentrations in the parcel (or sinks decrease the concentrations in a par-

cel) [56.22–24]. This process creates ramp structures in the high frequency time series of the scalar. The original micrometeorological surface renewal method involves

high-frequency measurement of scalar values to obtain fluxes and does not involve explicit transfer coefficients or mean scalar gradients.

56.3 Theory

In this chapter, we will briefly introduce the theory of the different alternative flux measurement methods to help the reader understand the technical requirements of measurement systems. These presentations are very brief, and the interested reader is encouraged to read the references given.

In the conventional eddy-covariance method (Chap. 55), the flux of a trace gas (or scalar quantity s) is determined as the covariance of the discretely recorded time series of the vertical wind velocity w_i and trace gas mixing ratio $\chi_{s,i}$ (equivalent to (55.4))

$$\begin{aligned} F_s &= \overline{\bar{\rho} w' \chi'_s} = \frac{\bar{\rho}}{N-1} \sum_{i=1}^N [(w_i - \bar{w})(\chi_{s,i} - \bar{\chi}_s)] \\ &= \frac{\bar{\rho}}{N-1} \sum_{i=1}^N (w'_i \chi'_{s,i}), \end{aligned} \quad (56.1)$$

where $\bar{\rho}$ is the average molar density of the air. It is assumed here that the time series w_i and $\chi_{s,i}$ are effectively synchronized in time (i.e., corrected for an eventual time lag; Sect. 55.3.2). Using a typical EC data sampling frequency of 10 Hz and a flux averaging interval of $T = 30$ min results in a total of $N = 18000$ data points for the flux calculation. In the ideal case, the *sampling interval* $\Delta = 0.1$ s between individual measurement recordings also equals the effective response time (or signal averaging time) τ_R of the w and χ_s sensors, leading to continuous nonoverlapping measurement series.

56.3.1 Disjunct Eddy Covariance (DEC)

The basic idea of DEC is that the flux may be calculated using (56.1) from a random-like subsampling ($n \ll N$ data points) of the full w_j and $\chi_{s,i}$ data series. Since well-developed turbulence in the surface layer is not periodic, subsamples taken at regular intervals can be considered random-like. In this case, the sampling interval $\Delta = T/n$ is increased to typically between 1 and 30 s, while the measurement response time τ_R is kept short at about 0.1 s. Accordingly, in the DEC approach the number of samples n taken over 0.5 h is reduced to between 1800 and 60. The principle is illustrated in Fig. 56.3a. In practice, the DEC concept can be applied in two different ways (Sect. 56.4.1):

- Disjunct air sampling (*grab sampling*)
- Continuous air sampling flow with disjunct detection of a certain trace gas.

The second application type is sometimes called *virtual disjunct eddy covariance* vDEC. However, this expression can be misleading because the described DEC principle equally applies for both application types [56.25]. The DEC method has been evaluated against the conventional EC method by data simulations and field experiments [56.7, 26–29]. The results confirm the theoretical considerations [56.5, 28] that the reduced sample number of the DEC method does not cause systematic error to the measured flux values but increases its random uncertainty. These main characteristics are explained in the following.

For conventional EC, as well as for DEC systems, the ability to detect the flux contributions of all relevant frequencies is limited by the response time τ_R of the measurement system, not the sampling interval Δ . The contribution of frequencies above the respective cutoff frequency $f_c = 1/(2\pi\tau_R)$ is mostly lost [56.30]. For DEC systems with grab sampling, τ_R is determined by the time it takes to fill the intermediate reservoirs (Sect. 56.4.1). For EC and DEC measuring systems with a continuous sample air flow, τ_R typically depends on the dimensions of the analyzer detection cell and its inlet tube, internal signal integration, or averaging time, as well as on the sample tube geometry and flow rate. Similarly to conventional EC systems, it has to be assured also for DEC systems that either τ_R is kept short (at typically 0.1 s) or the spectral loss of covariance has to be quantified and corrected for (Chap. 55). While in conventional EC systems, the sampling interval Δ is typically close to $0.5\tau_R$ to avoid aliasing when performing spectral analysis, it is considerably longer in DEC systems. The correspondingly reduced sampling frequency $f_s = 1/\Delta$ of DEC systems does not imply that frequencies above f_s (and below f_c) are lost, but they are aliased (mirrored) to frequencies below $f_s/2$ [56.25]. The integral of this aliased spectrum equals the integral of the full spectrum obtained from the nondisjunct time series, and thus no bias is introduced to the flux [56.25]. One drawback of DEC cospectra, however, is that the aliased and nonaliased contributions cannot easily be separated.

Fig. 56.3 (a) Disjunct subsampling of fast-response time series. The gray line represents the original continuous 10 Hz time series of the vertical wind speed w and the CO_2 mixing ratio χ_s , while the black dots are 0.1 s-long subsamples taken from these data at intervals $\Delta = 10$ s (after [56.25]). (b) Relative enhancement of DEC flux uncertainty compared to EC flux uncertainty ($\sigma_{\text{DEC}}/\sigma_{\text{EC}}$) as a function of the ratio between the sampling interval (Δ) and the integral covariance flux time scale (τ_f). For large x -axis values, the uncertainty increases like for statistically independent data points according to $1/\sqrt{n}$

The random uncertainty of fluxes measured by the EC and DEC methods was described as a function of T , Δ , and τ_f representing the integral timescale of the time series $w'c'$ [56.28]. This is illustrated in Fig. 56.3b. In the case when the sample interval is shorter than the integral timescale, the DEC flux uncertainty is very similar as for conventional EC. When the sample interval is longer than the integral timescale, the DEC flux uncertainty increases relative to EC approaching a simple $1/\sqrt{n}$ function that would be valid for full statistical independence of subsequent records of the $w'c'$ time series [56.7]. As the additional uncertainty of the DEC flux is random, it is decreased when fluxes are averaged over longer periods. The integral timescale is the $1/e$ -width of the covariance function peak and (besides wind speed and stability) mainly scales with the measurement height. As a rule of the thumb, one can assume τ_f (in units of s) similar to z (in units of m) [56.25]. Thus, especially for measurements over low vegetation, the sample interval is mostly longer than the integral timescale and the number of samples rather than the sample interval being the parameter controlling the uncertainty of the fluxes.

The DEC approach is generally used in combination with closed-path trace gas analyzers, which makes it necessary to account for the delay between the vertical wind velocity and mixing ratio measurements. The

time lag for synchronization is often identified empirically by the position of the peak (absolute maximum) in the cross-covariance function between w and the trace gas mixing ratio of interest [56.31]. In the case of DEC, the covariance function has to be calculated with the full w' time series (10 Hz) and the disjunct χ'_s time series that is gap-filled with zeros to the same time resolution. The time lag is best determined under conditions with well-developed turbulence and high fluxes.

56.3.2 Conditional Sampling Methods

Conditional sampling is the generic name covering the following methods:

- Eddy accumulation (EA)
- Disjunct eddy accumulation (DEA)
- Relaxed eddy accumulation (REA)
- Hyperbolic relaxed eddy accumulation (HREA).

The common requirements for conditional sampling approaches are as follows: 1) atmospheric turbulence is the dominant transfer mechanism in the surface layer, and 2) the vertical wind velocity is measured at high frequency in order to operate a conditional sampler that will separate air samples according to the vertical wind direction. Air needs to be sampled close to the

fast-response ultrasonic anemometer. The conditionally sampled air is then temporarily stored for further analysis on high-precision analyzers. Although conditional sampling methods are relatively easy to understand, and their theory is well-known, great care is required for their proper implementation. First, in order to sample the air conditionally, fast-response sampling valves are needed, which are under the control of unbiased high-frequency vertical velocity measurement. Second, conditionally sampled air needs to be kept in separate reservoirs, which can preserve the integrity of the trace gas samples of interest until their analysis. The analytical method requires high accuracy to measure precisely the difference between updraft and downdraft mixing ratios of the gas of interest. Third, several specifications need to be met. Turbulent flows need to be maintained in the intake, prior to conditionally separating the air samples. The lag between the wind velocity data and the air intake need to be accounted for. Any biases on the vertical wind velocity need to be removed in quasi realtime.

The theory of conditional sampling methods can be divided into two categories – eddy accumulation and relaxed eddy accumulation. In the former, the air is collected in up and downdraft reservoirs proportionally to the vertical wind velocity, whereas in the latter, the air is collected in the reservoirs at constant flow rate.

Eddy Accumulation (EA)

With the volume of air collected in the up and downdraft reservoirs proportionally to the vertical wind velocity (Fig. 56.4), the flux of the trace gas of interest can be calculated as

$$F_s = \overline{\rho \chi' w'} = \frac{\overline{\rho}}{T} \left[\chi^\uparrow \int_{t_1}^{t_2} w \delta^+ dt + \chi^\downarrow \int_{t_1}^{t_2} w \delta^- dt \right] - \overline{\rho} \overline{\chi} \overline{w}, \quad (56.2)$$

where χ^\uparrow and χ^\downarrow are trace gas mixing ratios in updraft and downdraft reservoirs, w is the vertical wind speed, δ^+ and δ^- are delta functions, and T is the length of the averaging period ($t_2 - t_1$). The values of delta functions are defined as

$$\begin{aligned} \delta^+ &= 1, & \delta^- &= 0 & \text{when } w > 0, \\ \delta^+ &= 0, & \delta^- &= 1 & \text{when } w < 0. \end{aligned}$$

Equation (56.2) can be mathematically derived from the eddy-covariance equation [56.10, 26, 32, 33].

If a sample representing the mean average mixing ratio, $\overline{\chi}$, is not collected separately, this can be estimated by the average of updraft and downdraft samples [56.10, 29]. If the vertical wind measurements are high-pass filtered at about 0.001 Hz, the last term in (56.2) can be neglected, as $\overline{w} = 0$, and w will correspond w' .

Fig. 56.4 Graph illustrating the sampling procedure of the eddy-accumulation method, in which the volume of air (10^{-3} m^3) collected in updraft and downdraft reservoirs is proportional to vertical wind velocity (m s^{-1}). Vertical wind velocity and sample flows are in arbitrary units

Disjunct Eddy Accumulation (DEA)

The fast and accurate control and adjustment of valve opening, which is required in the eddy-accumulation technique, has proven to be a challenging task. Thus, in disjunct eddy accumulation, sampling of air proportionally to vertical wind speed is realized using the disjunct eddy-sampling approach. This bypasses the challenge of fast flow control [56.26].

In disjunct eddy accumulation, sampling is conducted in two steps. First, the primary sampling is based on the same principle as in disjunct eddy covariance with grab sampling. The second step is the subsequent processing of air samples, which follows the principle in eddy accumulation. While in disjunct eddy covariance, the trace gas concentration in each air sample is measured separately, in DEA, air is accumulated in updraft and downdraft reservoirs from intermediate storage reservoirs (ISR, Sect. 56.4.2) for a duration proportional to the vertical wind velocity at the moment of the corresponding primary sampling, allowing the use of a constant flow rate. This leads to mathematical identity between disjunct eddy covariance and disjunct eddy accumulation.

While in the continuous sampling eddy-accumulation system, the sampling flow needs to be continuously adjusted to follow the variations in vertical wind velocity (Fig. 56.4), in DEA, the sample flow from ISR through an adsorbent cartridge can be kept constant while the sampling period is adjusted (Fig. 56.5). This is realized by adjusting the sampling time from the intermediate storage reservoir to the updraft or downdraft reservoir, as is shown in the two bottom panels in Fig. 56.5.

Fig. 56.5 Graph illustrating the sampling procedure of the disjunct eddy-accumulation technique. The air is sampled to intermediate storage reservoirs at times shown with *red dots* in vertical wind data (m s^{-1}). A volume (10^{-3} m^3) proportional to the vertical wind velocity at this moment is then transferred to either the updraft or downdraft reservoir. This is realized by integrating the quite constant sample flow from the ISR to the updraft or downdraft reservoir and terminating the sampling when the desired sample volume has been reached. Vertical wind velocity and sample flows are in arbitrary units

Relaxed Eddy Accumulation (REA)

The requirement of the EA method, which consisted of sampling air proportionally to the vertical velocity, was simplified by using a constant flow rate to collect the ascending and descending moving air samples separately ([56.15]; Fig. 56.6). The trace gas flux is proportional to the difference in the mean scalar mixing ratio (χ_s) of upward and downward moving air.

$$F_s = \bar{\rho} \overline{w' \chi'_s} = b \sigma_w \bar{\rho} (\overline{\chi_s^\uparrow} - \overline{\chi_s^\downarrow}) \quad (56.3)$$

Where b is an empirical constant, σ_w is the standard deviation of the vertical wind velocity, and $\bar{\rho}$ is the molar air density.

The value of the b coefficient in (56.3) is relatively constant when turbulence is well established, and fluxes are measurable [56.18]. Values are similar between different scalars at about 0.56 [56.18, 34, 35]. An analytical solution to account for the impact of the non-Gaussian nature of turbulence on the b coefficient by using the fourth-order Gram–Charlier functions has been derived [56.35]. The stability dependence of the b coefficient was also studied for various scalars [56.36]; for unstable conditions, no systematic dependence on

Fig. 56.6 Graph illustrating the sampling procedure of the relaxed eddy-accumulation method, in which the air is collected at a constant flow rate ($10^{-3} \text{ m}^3 \text{ min}^{-1}$) into updraft and downdraft reservoirs (*blue*), and when the absolute value of the wind velocity (m s^{-1}) is greater than the dead-band interval threshold (m s^{-1} , *red*). Vertical wind velocity and sample flows are in arbitrary units

stability is observed, and the value of 0.56 is confirmed, while for more stable conditions, a systematic increase of the b value is estimated using 10-min averaged fluxes. However, as for any measuring methods based on turbulence, the lack of turbulence at night limits the validity of the REA technique.

In order to enlarge the difference between the updraft and downdraft mean scalar mixing ratio, a deadband can be introduced into the REA measuring systems. A deadband is an interval of vertical wind velocities centered at zero, for which no air is collected in the updraft or downdraft reservoirs. The deadband also helps to extend the lifespan of the conditional sampling valves. The deadband could be a fixed interval or set to be proportional to the standard deviation of the vertical wind speed, σ_w . In the latter case, the actual deadband value could use σ_w calculated either from σ_w of the previous flux measurement period or from a running mean σ_w (dynamic deadband). By measuring the concentration of e.g., CO_2 in sample reservoirs together with eddy-covariance measurements of CO_2 fluxes, the b coefficient can be empirically calculated using (56.3). A robust model to predict the impact of the normalized deadband on the empirical coefficient b [56.18] shows that deadband intervals up to $0.2 \sigma_w$ could be used reliably because it is possible to predict their impact. To optimize the signal-to-noise ratio a larger deadband of $0.6 \sigma_w$ has been suggested [56.37]. Increasing the dead-

band is highly desirable for studying natural isotopes. By introducing a dynamic deadband of $0.5 \sigma_w$, it has been shown that the b coefficient has a relatively steady value equal to 0.42 [56.38].

The conditional sampling techniques require any bias on the vertical wind velocity to be removed in quasi realtime before activating the fast-response valves controlling the air collection. A relative bias of 20% on the vertical wind velocity will generate a 5% relative flux bias [56.18]. Several filtering approaches were successfully used to remove the bias on w , such as a digital high-pass filter [56.19] or a 5-min block averaging of the three wind velocity components [56.39]. At ideal sites (e.g., flat terrain, tall towers), when the bias on w is very limited, an unfiltered w signal provides good-quality REA fluxes [56.40].

The REA method had a high rate of adoption by the scientific community in cases when no fast-response gas analyzers were available or affordable.

Hyperbolic Relaxed Eddy Accumulation (HREA)

In order to maximize the difference between the updraft and downdraft sample mixing ratios of stable isotopes, the deadband was implemented differently [56.41]. Using the hyperbolic deadband, only the turbulent events contributing the most to the flux are sampled. The approach consists in excluding the values close to the mean using two hyperbolas, defined as follows

$$H = \left| \left(\frac{w'}{\sigma_w} \right) \left(\frac{\chi'_s}{\sigma_s} \right) \right|, \quad (56.4)$$

where H is the hyperbolic deadband defined as a function of the vertical wind velocity and mixing ratio of a scalar [56.41]. This requires knowing, at the time of sampling, the means and standard deviations of the vertical wind velocity and those of the relevant scalar for the stable isotope under consideration. These statistics can be obtained from digital recursive filters applied to the fast-response time series [56.42]. Poor scalar similarity can lead to considerably biased flux values by HREA [56.43]. This technique was marginally adopted by the scientific community.

56.3.3 Surface Renewal Methods (SR)

Surface renewal methods in micrometeorology [56.22–24] are conceptually based on a paradigm of turbulent coherent structures being the major flux-bearing eddies in surface roughness layers [56.44, 45], and that these turbulent coherent structures represent parcels of air interacting with surfaces (Figs. 56.7 and 56.8). The mass or energy balance of the surface renewal parcel can readily be written for this paradigm. As an example,

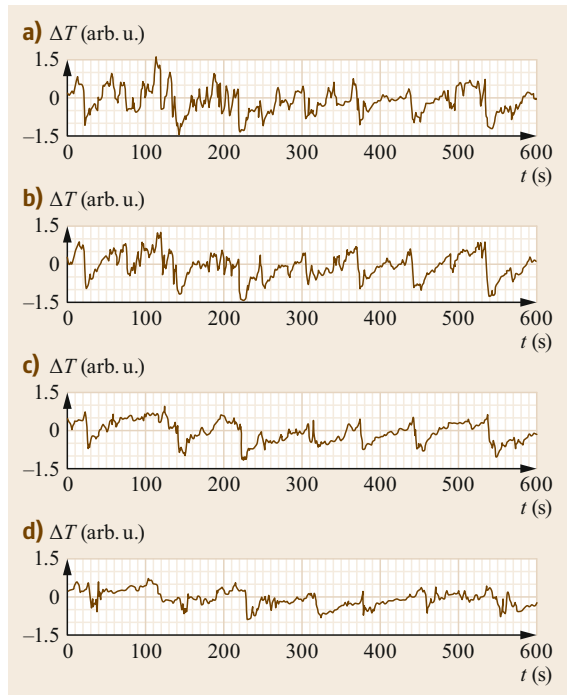

Fig. 56.7a–d Air temperature patterns at the canopy height z of 17.6 m (a) and below the canopy ($z = 15.4$ m (b), $z = 10.5$ m (c), and $z = 5.9$ m (d)), showing ramp shapes that are caused by turbulent coherent structure *sweeps* and *ejections* (after [56.44])

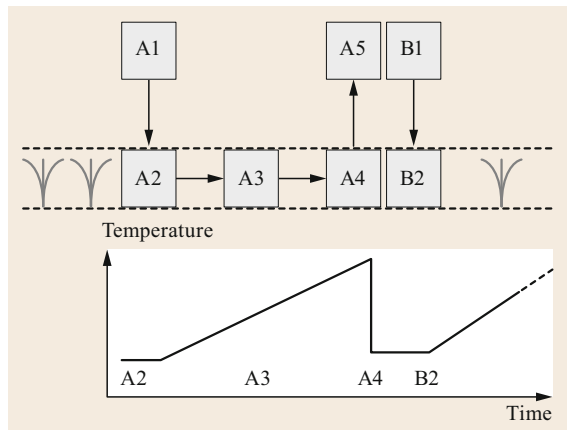

Fig. 56.8 Surface renewal paradigm of a turbulent coherent structure *sweep* entering a plant canopy (A2) from above the canopy (A1), accumulating a scalar (in this example temperature, phase A3), and then being ejected (A4) to above the canopy (A5), to be instantly replaced by another sweep from (B1) to inside the canopy (B2). The corresponding scalar pattern with time is shown in the *lower diagram* (after [56.23, 24])

the scalar heat energy balance (temperature), leading to measurements of sensible heat flux H can be written as

$$H = \alpha \rho c_p \frac{a}{d+s} h_c, \quad (56.5)$$

where ρ is the density of air (kg m^{-3}), c_p is the specific heat of air ($\text{J K}^{-1} \text{kg}^{-1}$), a is the amplitude of the ramp (K), d is the length of the ramp (s), s is quiescent time between ramps (s), and h_c is the height of the measurement (m), originally assumed to be the height of the plant canopy. Because one or more of the assumptions used in surface renewal, discussed later, may not always be valid, a calibration factor α is usually included in the equation.

For determination of the amplitude and duration for repetition of the ramps, Van Atta's structure function [56.46] has been used [56.23, 47]. The Van Atta method requires calculation of the second, third, and fifth-order structure functions, defined as

$$S^m(r) = \frac{1}{m} \sum_{i=1}^{i=m-j} [T(i+j) - T(i)]^m. \quad (56.6)$$

Using the assumptions of random turbulence contributions to structure functions, and with substitutions, one can derive these equations to solve for the ramp amplitude a and the ramp repetition interval ($d+s$) [56.46].

A cubic solution is used to obtain the ramp amplitude a for which Paw U and Su [56.23] used the standard analytical algebraic/polynomial-based cubic solution. Other researchers [56.47] used the trigonometric solution. For both methods, although there are up to three separate solutions to the cubic equation, typically one of them is the realistic solution that can be used.

The need for calibration of surface renewal against another independent measure of the scalar flux have been discussed because of several potential differences between the assumed idealized parcel exchange and reality [56.24, 48]:

- Equation (56.5) and its physical picture of turbulent coherent structures is based on a Lagrangian viewpoint, but measurements of the scalar change are made in a Eulerian framework. Therefore, the horizontal microadvection in turbulent coherent structures must be assumed to be zero for the Eulerian framework ramps to be used in place of the Lagrangian total derivative of the ramp structures.
- When the scalar change is measured at only one height, assumptions must be made about how the scalar change occurs at the other heights within the canopy.
- Like any vertical column-based model, mean horizontal and vertical advection divergence could

represent a significant portion of the canopy-atmosphere exchange process [56.49].

- Turbulent coherent structures may not represent 100% of the exchange.
- Multiple coherent structure sizes might be important in exchange processes, instead of a single size [56.50, 51].
- If the scalar is temperature and measured by thermocouples or other physical sensors, their response time, related to their size, may influence the characterization of the derivative dT/dt needed for surface renewal, and other possible issues [56.48].

Practical application of surface renewal depends on arriving at a value of alpha either by theoretical considerations or by direct calibration with other trace gas or scalar flux measurements, such as eddy covariance.

In the above theories, it is assumed that the ramps have an instantaneous change in the scalar at the termination of each ramp. Experimental data show that this is not strictly true, so equations accounting for this have been derived [56.52, 53], although with simplified paradigms such that there was no quiescent period.

It was hypothesized that modification of the original chemical engineering paradigms could be used, where the molecular diffusion from a surface into a parcel of fluid during the ramp phase of a coherent structure is replaced by a similarity-based turbulent diffusion paradigm [56.54]. It has been found that this method is relatively successful in arriving at the surface renewal calibration coefficient α [56.55–57]

$$\alpha = \begin{cases} \left[\frac{k(z-d)}{\pi z^2} \tau u_* \phi_h^{-1}(\zeta) \right]^{1/2} & (z-d) > z^* \\ \left[\frac{k z^*}{\pi z^2} \tau u_* \phi_h^{-1}(\zeta) \right]^{1/2} & h \leq (z-d) \leq z^* \end{cases}. \quad (56.7)$$

However, there are theoretical concerns about the application of similarity relationships, which are based on empirical results for idealized extensive horizontal surfaces and both large and small turbulent scales, to small-scale turbulence exchanging scalars within a coherent structure, and within the roughness elements of a plant canopy, during the relatively short ramp timescales.

One potential advantage of surface renewal, apart from its reliance on inexpensive sensors, is that it could require less fetch than eddy covariance. Its original theory envisions the sensor height at the canopy top, hence the fetch, if the processes are assumed analogous to conventional theoretical paradigms, would be something like 100 times the canopy height.

Fig. 56.9a–c Example of (a) one night of methane concentration and (b) $\delta^{13}\text{C-CH}_4$ data recorded at Mycklemossen peatland site, Sweden on 09.–10.07.2017, and (c) Keeling plot derived with the data. The blue line in (a) and (b) indicates the raw 1 Hz data and red circles the 10 min-averages. The intercept in (c) indicates a $\delta^{13}\text{C-CH}_4$ value of -81% . The online isotopic analyzer used here is Picarro G2201-i

Direct Surface Renewal of Trace Gases Such as Water Vapor and Carbon Dioxide

Several researchers have tested the ability to directly determine the fluxes of trace gases, such as water vapor and carbon dioxide, using surface renewal analysis of the ramp patterns seen in these trace gas scalars [56.55, 56.58, 59]. It should be noted that one of the main advantages of surface renewal is its relative simplicity and inexpensiveness compared to other methods, such as eddy covariance. This applies to derivation of water vapor flux, which can be calculated using the energy budget, for which SR requires only low-cost thermocouples and net radiation [56.60]. Direct surface renewal of trace gas scalars requires the usually expensive fast-response gaseous concentration sensors, such as infrared absorption gas analyzers (IRGAs), and, therefore, would not be as advantageous over eddy covariance.

56.3.4 Nocturnal Boundary-Layer Keeling Plot Method (NBL-K)

In the Keeling plot method for determining the isotopic signature of an emitted compound, e.g., $\delta^{13}\text{C}$ of respired carbon dioxide or emitted methane, we apply the so-called two-end-member mixing model [56.61–63]. This can be explained by considering a static chamber placed

at the surface to measure emission. At the beginning of the measurement, the mixing ratio (χ) and isotopic ratios inside the chamber equal those of the ambient atmosphere, considered as the first end member. During chamber closure the emission from soil increases the mixing ratio in the chamber, and the isotopic ratios approach those of the emitted gases, the second end member. Theoretically, the isotope ratios in the chamber reach the isotope ratio of the emitted gas as the mixing ratio approaches infinity. It can be shown that in such a case, the isotopic δ -value behaves linearly in relation to the inverse of the mixing ratio, following the equation

$$\delta = a_0 + a_1\chi^{-1}, \quad (56.8)$$

where δ is the isotopic composition, χ is the trace gas mixing ratio, and a_0 and a_1 are coefficients found by fitting the equation to the data (Fig. 56.9). Thus, the intercept, i.e., a_0 , gives us the isotopic signature of the emitted gas.

In the nocturnal boundary-layer Keeling plot method, the stable surface layer acts as the volume into which the two end members are mixed. Although the mixing is not as ideal as in a chamber with an internal fan, the use of the nocturnal surface layer data leads to similar Keeling plots to the chamber measurements. The footprint of the isotopic signature derived by the

nocturnal boundary layer is considerably larger than that of chamber measurement and depends on, e.g., stability and measurement height.

In order to derive a reliable δ value at the intercept, the measurements must cover the range on the

$1/\chi$ axis. The required range will depend on the variability of measured δ values around the linear $\delta-1/\chi$ line. Generally, the statistical uncertainty of the δ value at the intercept will decrease with the increasing range of mixing ratios.

56.4 Devices and Measuring Systems

The systems for measuring fluxes with the alternative methods presented here are mostly built in-house with very little standardization. Thus, each system is different. However, in the following, we describe typical measurement systems as references for readers aiming to design their own system.

56.4.1 Disjunct Eddy Covariance

Here, we describe the measurement systems for two variants of the disjunct eddy-covariance method. While the theory of these is largely similar, the practical approach is very different. In the first one, physically disjunct air samples are taken, while in the second one, disjunct measurement is a result of consecutive detection of different compounds with one analyzer. Disjunct eddy covariance can also be used to reduce the burden on data storage at remote sites [56.64]. In that case, the measurement system was a standard open-path eddy-covariance system (Chap. 55), which is not discussed here in detail.

Disjunct Eddy Covariance with Grab Sampling

A typical sampler design employs two intermittent storage reservoirs (ISRs), which can be evacuated by a vacuum pump and subsequently filled by opening a fast reacting high-flow conductance valve (S1, S2 in Fig. 56.10). The interval between the grab sampling is used to analyze the trace gas concentrations in the ISR and to evacuate it for the next sample. The alternating grab sampling in two reservoirs allows a parallel analysis of one ISR and the full evacuation of the other ISR. This way, the interval between consecutive grab samples can be halved, and the number of data points for covariance calculation can be doubled.

As inlet valves S1 and S2 (Fig. 56.10), direct-acting solenoid valves have to be used. They provide very short opening/closing times of only a few milliseconds in combination with a relatively large orifice to obtain a sufficient air sample volume (1.0–1.5 L) within the opening time of 0.1–0.2 s. The valves between the ISRs and analyzer need to be of suitable material to minimize surface losses. For example, for VOCs, Teflon-bodied valves have been used. Depending on the analyzer one can also direct the return gas from the analyzer back to

the ISR to prevent a pressure drop [56.7]. Also a system in which the ISRs are equipped with pistons to push all the air to the analyzer without pressure drop has been developed [56.65]. The typical sampling interval has been 20–40 s. In order to guarantee a fast sampling flow into the ISRs, no additional inlet tubing was used, and, thus, the somewhat bulky ISRs (with inlet valves) had to be positioned near the sonic anemometer to limit sensor separation effects (Chap. 55). However, this could lead to flow distortion effects around the sonic anemometer. The optimal position of the scalar sampler is below the sonic anemometer (Fig. 56.1), leading to minimal flux underestimation [56.66].

The flux underestimation due to vertical displacement of anemometer and sampler, when the sampler is below the anemometer, can be estimated by

$$\frac{F_m}{F} = \left[1 - 0.1 \left(\frac{z_w}{z_s} - 1 \right) \right], \quad (56.9)$$

where F_m is the flux measured by displaced sensors, F is the true flux, z_w is the height of the anemometer, and z_s is the height of the sampler [56.66]. Equation (56.9) shows that for a sonic anemometer at 3 m and a sampler at 2.5 m ($z_w/z_s = 1.2$), the flux underestimation is only 2%. For samplers 0.5–1 m below the anemometer on

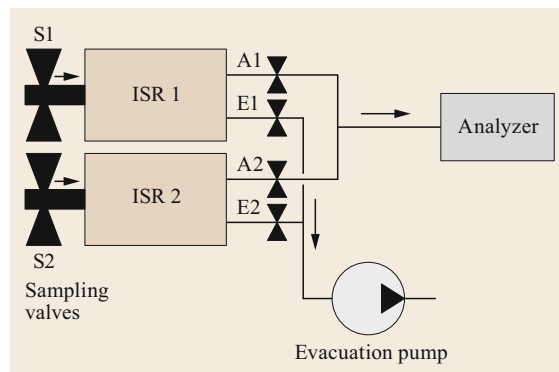

Fig. 56.10 A DEC system with two grab samplers. S1 and S2 are primary sampling valves, ISR 1 and ISR 2 are intermittent storage reservoirs, A1 and A2 are valves to the analyzer, and E1 and E2 are evacuation valves (after [56.3, 25])

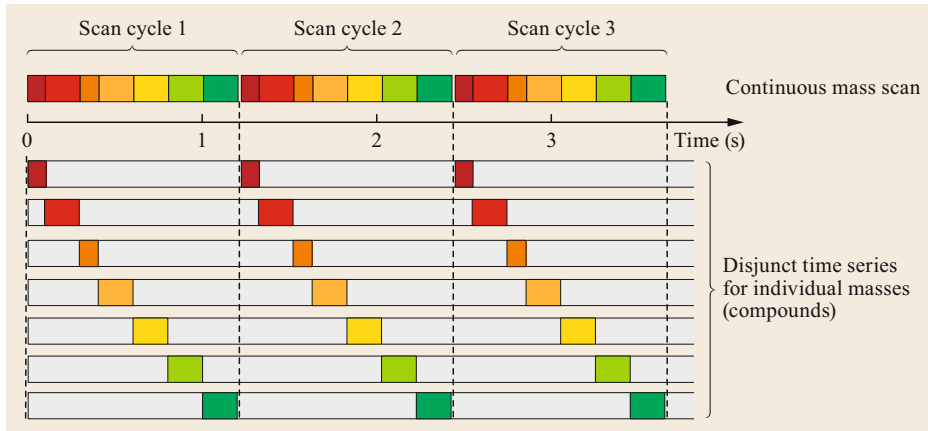

Fig. 56.11 Schematic example of a continuous mass scan covering 7 different masses/compounds (represented by different colors) with different dwell times on each mass (0.1 or 0.2 s) and the resulting disjunct time series for the individual masses. The cycle length corresponding to the DEC sampling interval Δ in this example is 1.2 s

tall towers, the resulting underestimation is, thus, negligible. The situation is not symmetrical with samplers above the sonic anemometer, which leads to a much larger flux underestimation. Other potential problems include a nonperfect evacuation of the ISRs prior to sampling leading to carry-over effects [56.67], and an alteration of reactive trace gases by the various inner-wall materials of the sampling system.

Disjunct Eddy Covariance by Mass Scanning

Up until now, the DEC approach has been applied predominantly for the measurement of volatile organic compounds (VOC) in combination with mass spectrometry detectors, like the PTR-QMS (proton transfer reaction quadrupole mass spectrometer) [56.68]. These instruments provide a relatively fast-response online measurement with a continuous sampling flow but can only detect one compound/charge-to-mass-ratio at a time. Thus, they can be used for conventional EC measurements of a single VOC species, like isoprene or methanol [56.69], but this way, their capability to measure a suite of different VOC species (with different molecular masses) is not exploited. Yet, with the DEC method, a simultaneous flux measurement for several compounds can be obtained by scanning through the respective masses [56.9], as illustrated in Fig. 56.11. This has been realized with typical mass scan cycle periods (representing the DEC sampling interval Δ , Sect. 56.2.1) between 1 and 10 s [56.70, 71]. These Δ values are commonly shorter than those used for grab sampling devices and are, thus, less prone to increased random uncertainty (Fig. 56.3b).

The measurement setup of a DEC system with mass scanning on a continuous air flow is simple (Fig. 56.12),

Fig. 56.12 Example schematic of a measurement system for disjunct eddy covariance with mass scanning [56.9]. The 32-meter long sample line (8 mm i.d.) had a flow rate of 10 L min^{-1} . The inlet was located near the sonic anemometer. The PTR-QMS sampled air (0.1 L min^{-1}) from the main sample line through a tube of 1.6 mm i.d. (after [56.71] © Authors)

as it does not require a complicated grab sampler. In many ways, the setup is similar to conventional EC systems with closed-path analyzers. Therefore, also many of the measurement issues are similar (Chap. 55). For example, the air flow in the sample line has to be fast enough to guarantee a high Reynolds number and, thus, a turbulent flow regime without strong streamwise mixing. In some cases, the response time of the PTR-QMS is slowed down either by the choice of longer dwell times for the signal to be above the detection limit or by physicochemical damping effects in longer inlet lines. If the effective response time is close to the DEC sampling rate Δ , also a conventional EC flux calculation can be applied by expanding (interpolating) the disjunct concentration time series to the 10 Hz resolution of the vertical wind measurements [56.70]. However, such procedures have to be applied with care, as they can lead to flux underestimation due to high-frequency loss [56.72].

For determination of the lag time due to the sample line of PTR-QMS (and potentially due to drifting computer clocks if sonic and mass scan data are recorded on separate logging devices), one can use the ion mass 37 (M37) water cluster signal. Since the water vapor flux is orders of magnitudes higher than the fluxes of VOC species, the peak in the covariance function between w and M37 signal is much clearer. Thus, one can first identify the peak position of the covariance function for the M37 signal and then apply it for the other masses, taking into account the scan sequence-dependent time shift illustrated in Fig. 56.11. However, wall sorption effects can cause the lag time to be different for compounds with different solubility or polarity [56.73].

56.4.2 Conditional Sampling

Many different EA and REA systems have been developed. In principle, these consist of sampling valves controlled by the vertical wind velocity measured by a sonic anemometer, mass flow controllers to ensure the proportionality between vertical wind speed and sampling flow, sample reservoirs for updraft and downdraft samples, and a slow analyzer or method to store the samples for subsequent laboratory analysis (Fig. 56.13).

The storage *bins* were initially aluminized polyethylene bags, but other types of storage techniques were also used. A sensible heat-flux detector made up of a fast-response thermocouple sensor for sensing temperature and two electronic bins for temperature measurements was also developed [56.74]. Electronic bins were also used to weigh the frequency of the concentration measurements from a fast-response CO₂ analyzer simultaneously with the air collected in bags.

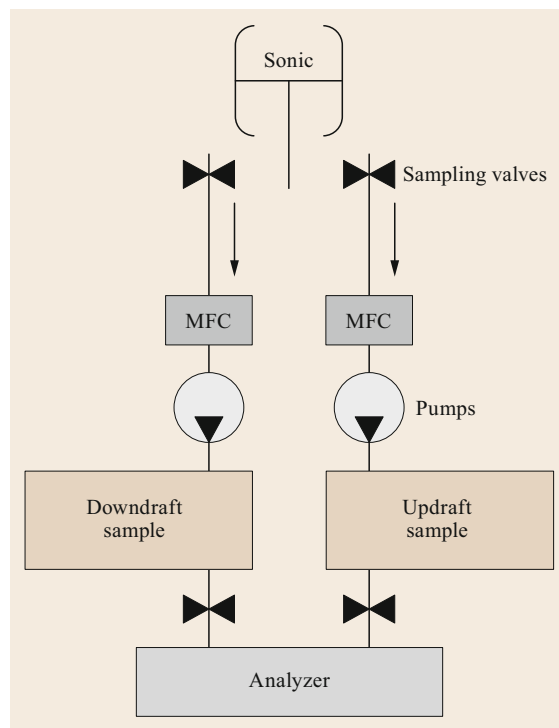

Fig. 56.13 Simplified schematic of an eddy-accumulation system. The analyzer can be replaced with a system to prepare samples for transportation and subsequent laboratory analysis

Recently, a new EA system development has taken place, utilizing digital mass flow controllers, leading to good correspondence with fluxes measured by EC [56.16]. Due to the difficulty of accurately controlling the fast variations in the sample flow, the eddy-accumulation method has not been extensively used.

Disjunct Eddy-Accumulation System with Adsorbent Sampling

A disjunct eddy-accumulation system [56.26, 75] consists of two intermediate storage reservoirs, each with its own primary sampling valve, a set of valves, pump, and flow meter for taking a known volume of air from the ISR to either the updraft or downdraft reservoir, and valves and a pump for evacuation of ISRs (Fig. 56.14). A sonic anemometer is used to obtain wind data that controls the sample accumulation. The updraft and downdraft reservoirs have been adsorbent cartridges used to collect volatile organic compounds. The disjunct sampling is realized by opening the high-conductance valve that lets the air rush into an evacuated intermittent storage reservoir. This is done at regular intervals and alternating the two ISRs. After air has been sampled in the ISR, a part of it is passed

Fig. 56.14 (a) Disjunct eddy-accumulation system (after [56.26] with permission from John Wiley and Sons). The sampling valves (α -valves), intermediate storage reservoirs, and subsequent six valves were situated in a sampler unit below the sonic anemometer, while the sample cartridges, three of the valves, pumps, and controlling electronics were situated at the tower. (b) Disjunct eddy sampler in the Niwot Ridge tower in Colorado, summer 1999. Note the vertical separation between sampler and sonic anemometer, the sonic anemometer being at 20.3 m and the sampler at 19.3 m (photo © Janne Rinne)

through the updraft or downdraft reservoir, depending on the sign of the vertical wind speed at the moment of the primary sampling. The volume passed through the cartridge must be proportional to the vertical wind speed. This has been achieved by integrating the flow rate measured by a flow meter and closing the accumulation valves when the required volume has been sampled. After the sampling, the ISR is evacuated for the next disjunct sample.

Critical design features of a disjunct eddy-accumulation system are the primary and secondary sampling. For the system to be able to resolve the contribution of high-frequency turbulence (Sect. 56.3.1; disjunct eddy-covariance theory), the primary sampling time must be as short as possible to obtain the short effective response time τ_R . This can be achieved by fast, direct-acting high flow-conductance solenoid valves. There should be as little dead volume upstream of the valve, excluding the use of sample tubing. This together with substantial volume of ISRs makes the sampler aerodynamically bulky. The ideal location of the sampler is below the sonic anemometer, as for DEC systems (Sect. 56.4.1). The challenge of the secondary sampling is to determine the sampled volume accurately. Thus, a good flow meter with little dead volume should be used, and its output read and integrated at sufficient frequency.

Finally, the materials used in the samplers should be such as to cause as small artifacts for the measurements as possible. The ISR with a low surface to volume ratio has been constructed from electropolished stainless steel or Teflon. Primary valves have commonly been stainless steel bodied, as large enough Teflon bodied valves have not been available. The tubing and valves for secondary sampling have commonly been Teflon.

Relaxed Eddy Accumulation

Several configurations of REA systems exist, mainly depending of the volume of air to collect and the kind of storage/trapping media used to collect the conditional samples.

At tower-based REA systems filling a pair of 10–20 L flexible bags can be done with a very small diaphragm pump located close to the ultrasonic anemometer pushing the air through the conditional valves and bags [56.18, 19, 41]. Also, adsorbent traps have been used as updraft and downdraft reservoirs [56.40, 76]. To automate the selection of reservoirs, either indexation of traps kept in carousels or selections of arrays of valves have been successfully implemented [56.76, 77].

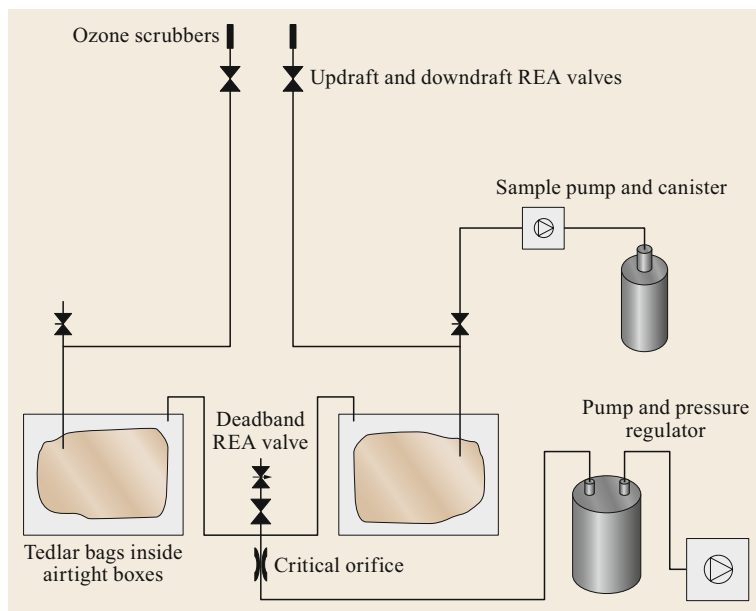

Fig. 56.15 REA system for measuring VOC fluxes (after [56.78])

Figures 56.15 and 56.16 show a schematic and a photo of a realization of another REA system [56.78]. This system is designed for measuring VOCs, thus the materials with which air is in contact are either Teflon or Tedlar. In this system, the two Teflon sampling valves on top are located next to the sonic anemometer used to control the sampling. In front of each valve, there is an ozone scrubber preventing ozone–VOC reactions inside the REA system and in subsequent air samples. Up and downdraft reservoirs are Tedlar bags, located inside rigid airtight boxes. The pump is located downstream and is used to create slight underpressure in these boxes. This design prevents the sample air from passing the pump, a potential source of contamination. The pressure regulator is a buffer volume that dampens the pressure fluctuations from the pump and reduces its effect on measured flow rates. There is an adjustable valve at the deadband line, creating flow resistance that is similar to sample lines. After a half-hour sampling period, a part of both the updraft and downdraft air is transferred to electropolished stainless steel canisters (Rasmussen canisters) by a dedicated valve and a sample pump. The analysis of these samples was subsequently conducted by gas chromatography. As the system required manual operations, it was suited only for short measurement campaigns.

Yet another REA realization does not collect samples for a set interval and then analyze them, but rather continuously samples through mixing reservoirs (Fig. 56.17; [56.39, 79]). In this system, which is de-

Fig. 56.16 Relaxed eddy-accumulation system as presented in Fig. 56.15 (after [56.78]) in the Siikaneva wetland in Finland, summer 2005. The conditional sampling valves are situated in the blue box next to sonic anemometer and the sample bags inside the gray boxes (photo © Janne Rinne)

signed to measure size-resolved aerosol fluxes or VOC fluxes, the aerosol or VOC concentrations in sample reservoirs are measured in an alternating pattern with a single analyzer. A CO_2 analyzer measuring the concentrations in the reservoirs, together with EC measurements of CO_2 fluxes, can be used to calculate the values of b coefficient. With this system, automated long-term measurements are feasible.

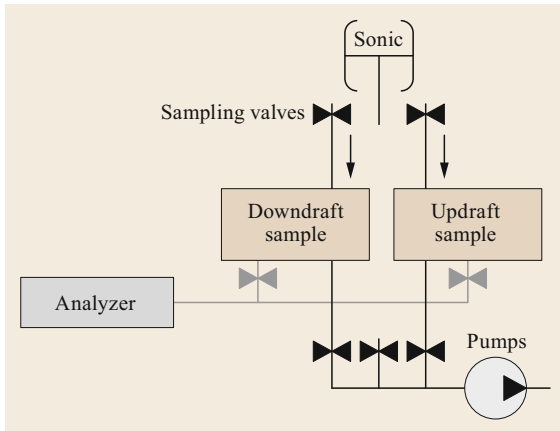

Fig. 56.17 An REA system with flow-through reservoirs, see also [56.39, 79]

Hyperbolic Relaxed Eddy Accumulation

The sampling system for HREA measurements is, in principle, very similar to that for REA measurements. The most significant difference is the need for a fast-response scalar sensor alongside the sonic anemometer to control the conditional sampling. Here, for example, temperature, CO₂, H₂O, or O₃ can be used [56.80, 81].

56.4.3 Surface Renewal

The major gas for which the surface renewal has been used is water vapor. The water vapor flux has been obtained by using surface renewal for the sensible heat flux density and then using the energy budget residual equation to obtain the latent heat flux and, thus, the water vapor flux.

The basic instrumentation needed is a fine wire thermocouple (to measure the surface renewal-based sensible heat flux density H), a net radiometer to measure R_n , ground heat flux plates and one or more soil temperature sensors to measure G , and a data-logging device that can not only record data but analyze the structure functions and calculate H on the fly. All of these can be obtained for relatively low cost compared to a direct eddy-covariance system for water vapor exchange (which requires at least an ultrasonic anemometer and a fast-response gas analyzer in addition to a data logger). If custom built, the system can be even less expensive.

The thermocouple size is an important issue because the accuracy of structure functions depends on the high frequency response of these sensors, linked to narrow wire diameters. Practically, the thermocouple size needs to be large enough to be physically sufficiently robust to withstand the stresses of field deployment, especially related to arachnids and insects. A related solution is to use two relatively fine wire thermocouples,

such that at least one of them will be operational even if the other is broken by the elements.

For measurement of trace gas fluxes with the surface renewal method, a fast response gas analyzer is needed, while a sonic anemometer is not. Thus, this method does not considerably ease the instrumental requirements for trace gas flux measurements, as the fast trace gas analyzer is commonly more expensive than the sonic anemometer.

56.4.4 Nocturnal Boundary-Layer Keeling Plot Method

The aim of the measurements is to cover a large mixing ratio range with corresponding isotopic ratios during an individual night. In principle, any system resolving isotopic ratios and mixing ratios from the same air mass can be used for the nocturnal boundary-layer Keeling plot method. These can be either methods in which air is sampled to be later analyzed in the laboratory, or online measurements. As the analytical techniques for stable isotopes are described in Chap. 17, here only the sampling systems are described.

A system for collecting air samples for subsequent laboratory analysis can consist of sample bags (e.g., Tedlar), a pump for filling up the bags, and tubing to reach the selected sampling height. For example, in an experiment in Finnish mires, air was sampled from heights of 42 and 280 cm above the peat layer. Samples were 4 L in volume and taken at 1 h intervals to 5 L Tedlar bags with 2 L min⁻¹ sample flow, flushing them before [56.82].

In an online measurement system, air is drawn from the selected measurement height to the analyzer. As analyzers need to be protected from elements, they are typically placed 10 to 30 m from sampling tower. As sample flow into the analyzer can be low (< 100 mL min⁻¹); one can use a pump to have a reasonable flow rate in the sample line and take a sample into the analyzer as side flow in an analogous way to that shown in Fig. 56.12.

56.4.5 Comparison of the Methods

While the eddy-covariance method is the preferable method for turbulent flux measurements, there is a need for the above-described alternative methods when fast-response analyzers for a certain trace species are not easily available. It may also be that the existing fast-response analyzers do not operate well in field conditions or are not suitable for field use due to, e.g., high power consumption. In this case, the methods in this chapter or the surface-layer gradient techniques introduced in Chap. 54 may be considered. Table 56.2 gives an overview of the pros and cons of these methods.

Table 56.2 Table summarizing pros and cons of different alternative turbulent flux measurement methods

Measurement method	Advantages	Disadvantages
Disjunct eddy covariance with grab sampling	Theoretically sound and direct method Enables direct flux measurements with slow analyzers (1–60 s)	Bulky and complicated inlet (compared to EC and DEC with mass scanning)
Disjunct eddy covariance with mass scanning	Theoretically sound and direct method No bulky and complicated sampler needed	Requires fast analyzer (< 1 s)
Eddy accumulation	Theoretically sound and direct method	Complexity of fast sample flow control
Disjunct eddy accumulation	Theoretically sound and direct method No need for fast sample flow control	Reduced number of samples lead to increased random uncertainty Bulky sampler Typically needs line power
Relaxed eddy accumulation	Feasible as sample flow is kept constant Low-power system possible	Theoretically less direct than EA but still proven robust
Hyperbolic relaxed eddy accumulation	Feasible as sample flow is kept constant Low-power system possible Higher concentration difference than in REA	Theoretically less direct than EA Needs high-frequency measurement of another scalar, with no time lag
Surface renewal	Based on theoretical turbulent transport mechanisms Simple, inexpensive and low power	May require field calibration Theoretically less direct than EC
Nocturnal boundary-layer Keeling plot	Feasible way for obtaining isotopic signatures of emitted gases	Poor time resolution

56.5 Specifications

The ability to measure fluxes of trace gases typically depends mostly on chemical analysis. We can estimate the accuracy of the chemical analysis needed for EA, REA and HREA measurements by inverting the equations used for calculating the fluxes (Table 56.3).

For DEC, we can estimate the magnitude of uncorrelated noise in the concentration signal that can be

allowed [56.25] for a certain flux level with a 95% confidence interval

$$\sigma_{n,\text{noise}} = \frac{\Delta F \sqrt{n}}{2\sigma_w}$$

This is presented in Table 56.4 for sample intervals of 10 and 30 s, within a measurement period of 0.5 h.

Table 56.3 Required precision of concentration measurement to achieve flux measurements of $1 \mu\text{mol m}^{-2} \text{s}^{-1}$ with conditional sampling systems at $\sigma_w = 0.6 \text{ m s}^{-1}$. Equations obtained by deriving the flux error using standard error propagation for the equation in the given reference and inverting this to solve for error in the concentration measurement

Measurement method	Equation to estimate the required accuracy/noise level	Required precision/noise level
Eddy accumulation	$\Delta c = \frac{\Delta F \sqrt{2}}{\sigma_w}$ [56.83]	2.4
Relaxed eddy accumulation, no deadband	$\Delta c = \frac{\Delta F}{b\sigma_w \sqrt{2}}$ [56.38]	2.1
Relaxed eddy accumulation, dynamic deadband of $0.5\sigma_w$	$\Delta c = \frac{\Delta F}{b\sigma_w \sqrt{2}}$ [56.38]	2.8
Hyperbolic relaxed eddy accumulation, with deadband of 1.0	$\Delta c = \frac{\Delta F}{b_{\text{HREA}} \sigma_w \sqrt{2}}$ [56.40]	5.4

Table 56.4 The level of uncorrelated noise in the concentration measurements allowed to achieve a flux measurement of 1 using the DEC method with different sample numbers

n	180	60
$\sigma_{c,\text{noise}}$	11	6.5

56.6 Quality Control

The quality of the measured fluxes depends on three parts:

- Turbulence statistics
- Trace gas concentration measurement
- Functioning of the flux measurement system.

In principle, for turbulence statistics, similar criteria apply as for the eddy-covariance method (Chap. 55). However, the alternative flux measurement methods provide no or only limited data on high-frequency variations of the trace gas. Thus, these tests can only be applied to vertical wind speed or by using e.g., CO₂ as a proxy.

Each trace gas analyzer has its own parameters for quality control of measured trace gas concentrations, and these should be referred to for the quality of the concentration measurement. Below, the quality control parameters typical for each flux measurement method are discussed.

56.6.1 Sample Volumes in Conditional Sampling Systems

In conditional sampling systems (EA, DEA, REA, HREA), the volume of air collected into updraft and downdraft reservoirs during an averaging period should be roughly equal. Any major deviation from this would indicate that either the average wind deviates considerably from horizontal wind, the sonic anemometer is badly misaligned, or there is some technical problem in the system. Therefore, the sample volumes provide a feasible check for proper functioning of the measurement system.

56.7 Maintenance

As there exists such a variety of different designs, general rules of maintenance cannot be readily given. Most of the flux measurement systems described above require either extensive maintenance or are designed for manual measurements, with an operator on site (Table 56.5). The conditional sampling systems can be automatized but then require maintenance of valves, pumps, and analyzers. In systems

56.6.2 Disjunct Eddy Covariance

In principle, similar quality control as for conventional eddy covariance is applicable for disjunct eddy covariance. However, some quality control tests, such as the stationarity test, can be challenging due to the reduced sample number leading to noisier statistics. Also, spectral analysis is affected by low sampling frequency and aliasing effects [56.25].

In a DEC system with grab samplers (Fig. 56.10), a systematic difference between the trace gas concentrations obtained from the two ISRs can indicate contamination in the sampler. In such systems, it is also advisable to record the ISR pressures, as anomalies may reveal malfunctions of the primary sampling valves or the evacuation system. Continuous-flow DEC systems work much the same way as conventional eddy-covariance systems.

56.6.3 Linearity and Statistics of the Keeling Plot

For the intercept of the Keeling plot to have low uncertainty, the concentration data should have a sufficiently large range. The assumption of two-end-member mixing leads to linearity of the δ -to- $1/\chi$ plot. Thus, the tests for linearity of the data, the correlation between δ and $1/\chi$ can be used to assess the quality of the data collected. Furthermore, statistical tools calculating the confidence intervals for a fitted line can be used to derive the confidence intervals for intercept values, i.e., the isotopic signature of emitted gas.

employing online analysis, the analyzer may require frequent attention. For example, in disjunct eddy-covariance systems, proton transfer reaction mass spectrometer (PTR-MS) analyzers typically need calibration several times per month. The systems for automated isotope measurements and the surface renewal method are at the lower end of maintenance requirements.

Table 56.5 Generic list for maintenance items for different measurement methods. As designs differ from each other, so does the actual maintenance procedure for each individual system design

System	Maintenance
Disjunct eddy covariance with grab sampler (DEC)	Check the valves Check the pump Monitor flow rates and ISR pressures
Disjunct eddy covariance with continuous sample flow (DEC)	Cleaning the tube at intervals Check pump Check the flow in the main tube
Conditional sampling systems (EA, DEA, REA, HREA)	Check the valves Check pumps Check sample reservoirs, especially in automated systems Monitor flow rates in system
Surface renewal	Follow the maintenance protocols of sensors
Nocturnal boundary layer Keeling plot	Check the flow in the main sample tube Check the pump

56.8 Application

As many trace gas flux measurement systems described in this section are experimental and mostly developed and built in-house for specific research questions, a comprehensive account for their applications is elusive. In Table 56.6, we give some examples of the applications of each measurement method discussed in

this chapter. Some techniques, such as eddy accumulation, have barely been used, while, for example, there have been many diverse applications of relaxed eddy accumulation. Unfortunately, the less successful developments, from which we could also learn, are rarely reported in the scientific literature.

Table 56.6 Compounds for which alternative flux measurement techniques are used. For details, see the text below

Method	Compound/Parameter	Analyzer	References
Disjunct eddy covariance, with grab samplers	VOCs	Proton transfer reaction mass spectrometer	[56.3, 4, 8]
Disjunct eddy covariance, with continuous flow	VOCs	Proton transfer reaction mass spectrometer	[56.2, 9, 70, 71, 84]
Eddy accumulation	Aerosol particles	Electric low pressure impactor	[56.85]
Disjunct eddy accumulation	C ₆ H ₆ , pesticides	Mass spectrometer	[56.76]
Relaxed eddy accumulation	VOCs	Gas chromatography	[56.26, 75, 86]
	NO _x	Chemoluminescence	[56.87]
	NH ₃	Ion chromatography	[56.88–90]
		Colorimetry	[56.89]
	VOC	Gas chromatography	[56.19, 40, 78, 79, 91]
	Mercury	Cold vapor atomic fluorescence spectrophotometry	[56.92–94]
	Herbicides	Gas chromatography	[56.76, 95, 96]
	Aerosol particles	Differential mobility particle sizer, Hygroscopicity tandem differential mobility analyzer	[56.39, 97, 98]
Hyperbolic relaxed eddy accumulation	$\delta^{13}\text{C}$ in CO ₂	Gas chromatography	[56.41, 99]
	Peroxyacetyl nitrate	Gas chromatography	[56.80]
Surface renewal	H, LE		[56.24, 60, 100]
	CO ₂		[56.58, 101]
Nocturnal boundary layer Keeling plot	$\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ in CO ₂	Gas chromatography	[56.102–104]
	$\delta^{13}\text{C}$ in CH ₄	Gas chromatography	[56.82, 105, 106]

56.9 Future Developments

The eddy-covariance method is the most direct micrometeorological method for measuring turbulent fluxes and does not require complicated samplers. Thus, the development of novel fast-response analyzers usually leads to the use of the EC method over the more indirect methods described in this chapter, as it is the preference of most researchers [56.107]. This has been observed, for example, in the case of methane, for which the development of cavity ring-down laser spectroscopy has led to proliferation of eddy-covariance measurements [56.108].

However, there will always be compounds for which analyzers that are suitable for eddy-covariance measurements do not exist or can not be suitably operated in the field environment. For those compounds, the micrometeorologist's toolbox includes methods such as gradient methods, conditional sampling methods, and disjunct eddy-covariance methods. Due to the large variety of gases and aerosols of interest and their different chemical and physical properties, the method used has to be tailored separately for each application.

Janne Rinne

Department of Physical Geography and
Ecosystem Science
Lund University
Lund, Sweden
janne.rinne@nateko.lu.se

Janne Rinne is Professor of Physical Geography at the Department of Physical Geography and Ecosystem Science at Lund University in Sweden. He received his PhD in Meteorology in 2001 from the University of Helsinki. His research interest is the effect of the biosphere on the atmospheric composition, which he has been studying especially using a variety of micrometeorological surface-layer flux measurement methods. He teaches courses in meteorology and physical geography.

Christof Ammann

Climate and Agriculture
Agroscope Research Institute
Zürich, Switzerland
christof.ammann@agroscope.admin.ch

Christof Ammann is Senior Scientist at the Swiss Federal Research Institute Agroscope, and leads a research team on agricultural greenhouse gas emissions. His interdisciplinary research focuses on field measurements of the exchange of reactive/nonreactive trace gases between the biosphere and the atmosphere using various measurement techniques. Since 2011, he has been a member of the Swiss Federal Commission on Air Hygiene—the clean air advisory board of the Swiss Government.

Kyaw Tha Paw U is a Professor of Atmospheric Science and Biometeorologist in the Department of Land, Air, and Water Resources at the University of California, Davis(USA). He received his PhD in Biometeorology from Yale University. His areas of interest are biometeorology, turbulence theory, applications of turbulence analysis to measurements, such as evapotranspiration and carbon dioxide fluxes, and bioaerosol transport, from both a modeling and an experimental perspective.

Raymond Desjardins

Science and Technology Branch
Agriculture and Agri-Food Canada
Ottawa, Canada
ray.desjardins@canada.ca

Raymond Desjardins is an Emeritus Scientist at the Ottawa Research and Development Centre, Central Experimental Farm, Science and Technology Branch, Agriculture and Agri-Food Canada. He received a PhD in Micrometeorology from Cornell University in 1972. He is a Member of the Order of Canada, Member of the Order of Ontario, and a Fellow of the Royal Society of Canada. He develops techniques to quantify mass and energy exchange over a wide range of ecosystems using tower and aircraft-based systems. Some of his recent research is focused on improving estimates of the carbon footprint of Agricultural products and helping Canadian farmers compete on the international markets.

57. Evapotranspiration Measurements and Calculations

Richard Allen , Thomas Foken , Ayse Kilic , Ricardo Trezza , Samuel Ortega-Farias 

Actual and maximum rates of evaporation (E) and evapotranspiration (ET) are important to the operation of atmospheric process models and for hydrologic and agricultural modeling. Because rates of evapotranspiration are limited by both the available energy at the surface and the availability of water, a variety of techniques can be used for estimation. The near-maximum ET under nonlimiting water availability can be closely approximated by the reference ET concept using near-surface observations of air temperature, humidity, wind speed, and solar radiation via the Penman–Monteith or a similar method. The determination of actual rates of ET when water is limiting demands a more complex approach, and often requires daily (or even more frequent) water balance data for the upper soil layers. An alternative is to measure the actual ET using micrometeorological techniques such as the eddy-covariance and Bowen ratio methods. The application of standardized calculations for the reference ET is discussed, as are iterative surface energy balance–aerodynamic combinations, which are useful in conditions where water is limiting.

Evapotranspiration is a highly relevant parameter in agriculture, hydrology, and weather and climate prediction and forecasting. Water vapor is not only the most important greenhouse gas; it is also responsible for weather phenomena, including cloud formation and

precipitation and atmospheric vapor transport. In contrast to estimating evapotranspiration, measuring evapotranspiration is not a simple task. It often requires the use of parameterizations, which are also discussed in this chapter.

57.1 Principles of Evapotranspiration Determination

Evaporation is one of the steps in the hydrological cycle. It is defined as the transport of water via various flow paths into the atmosphere [57.1]. If the path is through the stomata of vegetation, it is called *transpiration*. Because it is not easy to distinguish between transpiration and direct evaporation from water or soil, especially during measurement, the two processes are often considered together; this combined process of evaporation and transpiration is generally called *evapotranspiration (ET)*. The evaporation of ice is referred to as *sublimation*. *Interception evaporation* is the water vapor flux from, e.g., wet leaves and plant canopies after rain or dewfall. These terms are often prefixed with the word *actual* to indicate that the ET represents the true rate or depth of evaporation at a certain time and location. *Potential evaporation* is the maximum rate of evaporation (limited by surface energy availability) from a large area that is completely covered with a free-water surface or

by actively growing vegetation with adequate moisture at all times. Multiplying the evaporation rate—usually given in millimeters per time interval—by the heat of vaporization yields the *latent heat flux*. This latent heat is used to transform liquid water to vapor, and is expressed in units of W m^{-2} (i.e., it is an energy density flux). A daily average of 1 W m^{-2} is equal to a water column of 0.0347 mm d^{-1} at 0°C or 0.0353 mm d^{-1} at 20°C (the latter is recommended in [57.2]).

Evaporation is difficult to measure in the environment directly. Only a few methods are able to measure the loss of water from an evaporating water surface or soil volume, or the associated latent heat flux (Table 57.1). Most of these are indirect methods that use a parameterization approach. Many indirect methods only require classical measurements, such as those of temperature, humidity, wind speed, solar or net radiation, and soil parameters.

Table 57.1 Parameters measured by evaporation sensors

Parameter	Description	Unit	Symbol
Depth of evaporation over time	Change in the water level due to evaporation (e.g., Class A pan; see Sect. 57.4.2)	mm	h
Weight of evaporated water	Loss of mass of water from a volume (of soil with plants; see Chap. 58)	$\text{kg m}^{-2} = \text{mm}$	m
Fluctuations in vertical wind and humidity	Latent heat flux with the eddy-covariance method (Chap. 55)	W m^{-2}	Q_E
Near-surface gradients of air temperature and humidity	Latent heat flux with the Bowen ratio method (Sect. 57.3.2)	W m^{-2}	Q_E

57.2 History

Many of the instruments that were developed to measure evaporation directly, such as the atmometer and evaporation pan, are no longer widely used. Because of the difficulty involved in measuring evaporation directly, several indirect methods based on standard meteorological parameters have been developed. These conventional developments are covered in this section too.

57.2.1 Measurement Devices

There has been an awareness of evaporation, as a process through which wet surfaces dry, since ancient times. The first techniques for measuring humidity were proposed by *Leonardo da Vinci* (Chap. 8), and were based on determining the change in weight of a material as it dried. The first devices that were actually used to determine evaporation were constructed in the seventeenth century [57.3]. In 1687,

Edmond Halley (1656–1742) constructed a pan with a thermometer to investigate the evaporation from the ocean [57.4]. In St. Petersburg, *Georg Wilhelm Richmann* (1711–1753) built an evaporation gauge in which variations in the weight of a vessel were balanced by the buoyancy provided by supports located in lower tanks [57.5, 6]. He named this instrument an atmometer. This name was also used, along with the term *atmidometer*, for instruments developed by *John Leslie* (1766–1832) and *Horace Bénédicte de Saussure* (1740–1799) (Chap. 8). Several atmometers that were generally based on a vessel filled with water were subsequently constructed; these instruments used various construction techniques to weigh the mass of the evaporated water [57.3, 7].

Significant progress in atmometer or evaporimeter design was made by *Albert Piche* [57.8], who used absorbent paper as the evaporating area and surface (Fig. 57.1). A glass cylinder was filled with water and

Fig. 57.1 Atmometer or evaporimeter developed by Piche [57.8] (after [57.9])

sealed with a disk of filter paper that had a pinhole in the middle. Piche found that the measured evaporation was nearly identical to the ventilation term E_a of the Penman equation [57.10] (see (57.18) in Sect. 57.3.7). Ceramic material has also been used for the evaporating surface instead of filter paper. A mechanical system for measuring evaporation depth was developed. In this system, the vessel from which the water evaporated is connected to another water tank containing a float that registers the

Fig. 57.2 Evaporimeter developed by Czeratzki (photo © Adolf Thies GmbH & Co. KG, Göttingen, Germany)

water loss from the system. This instrument was widely used in agrometeorology and is still available. A version of this sensor that employed a ceramic evaporating surface was modified by Czeratzki and used with a mechanical registration system [57.11], Fig. 57.2. Also, the ETgauge—which uses a canvas cover—was developed by Altenhofen [57.12, 13] in the US.

57.2.2 Concept and Development of a Reference Evapotranspiration

The terms *potential evaporation* (E_p) and *potential evapotranspiration* (ET_p) have taken on a number of meanings over the past century. E_p is defined here as the quantity of water that is evaporated per unit area and per unit time from an idealized extensive free-water surface under existing atmospheric conditions. Three primary methods of estimating E_p or ET_p have been used during the past century: pan evaporation measurement; estimation of the potential evapotranspiration based on weather data; and the reference evapotranspiration approach. Among these, reference evapotranspiration (ET_o) has been found to be the most practical. The term ET_p was widely used from the 1940s to the 1970s, when it was defined as the maximum evaporative index (from which estimates of the actual ET from vegetation were derived). However, there have also been several other important and contrasting definitions for ET_p . One of the primary definitions of ET_p is the rate of evaporation and transpiration from a saturated (free-water) vegetated surface such that the evaporation process occurs at the potential level. However, while this is a theoretically attractive definition of ET_p , the difficulty involved in sustaining a saturated surface and obtaining simultaneous weather data makes it rather impractical. Standardized parameterizations of the Penman–Monteith equation for calculating ET from nonsaturated grass and alfalfa surfaces are described later in this chapter. The reference evapotranspiration approach, despite some shortcomings, can be a consistent and reproducible method of assessing weather-based potential evaporation.

Although practically challenging, the potential evaporation from a large open water surface can be measured using relatively small evaporation pans, and the resulting measurement presents relatively consistent relationships to the available energy, aerodynamics, and surface temperature. In contrast, as well as the difficulties involved in maintaining a saturated soil or vegetation surface to sustain ET_p , another challenge when measuring ET_p is that its magnitude varies with surface characteristics such as the aerodynamic roughness of the vegetation (although the magnitude of ET_p

depends primarily on the atmospheric conditions and surface albedo). Thus, ET_p should actually be defined for a specific vegetation type (in terms of height, leaf area, and roughness). This can be done using a predictive equation such as the Penman–Monteith relation (introduced later; *Howard Latimer Penman* (1909–1984), *John Lennox Monteith* (1929–2012)), where the surface resistance is taken to be very small or zero and aerodynamic and radiative properties that fit the vegetation are employed. However, this dependence of ET_p on the vegetation type considered makes its application and measurement very challenging, and it is less relevant to hydrological and weather processes due to its assumption of a saturated surface.

A second definition of ET_p relaxes the free-water surface (i.e., a saturated vegetation surface) requirement and sets ET_p equal to the rate of ET expected from disease- and stress-free, relatively tall, dense, leafy vegetation in the presence of a relatively high soil-water content and dry leaf surfaces, implying that the vegetation is transpiring at a rate governed by near-maximum leaf and boundary layer conductances and energy availability. The advantage of this definition of ET_p is that it gives values that are closer to the upper bound on ET expected from vegetation on days without rain. This second definition was used in papers and equations developed by Penman [57.14], where ET_p was taken to be the measured ET from clipped cool-season grass. However, one issue with this definition for ET_p is the need to define the specific characteristics and aerodynamic structure of the vegetation represented by ET_p . Another problem is that, when determining the upper bound for ET_p for a specific type of vegetation, it is necessary to identify appropriate values of the surface (leaf and canopy) conductances, which vary with environmental factors such as the solar radiation, relative humidity at the leaf surface, leaf temperature, soil water potential, and carbon dioxide concentration. In some ways, the use of a reference ET_{ref} (as discussed later) is more consistent and convenient. Also, the feedback between the characteristics of the defined potential surface and the associated weather measurements should be considered. It is important not to *mix and match* the ET_p from tall forest vegetation, for example, with weather data collected over a surface covered with short grass.

A third definition of ET_p , and perhaps the best one for process modeling, is the potential ET expected from any specified type and condition of vegetation or other terrestrial surface when soil water is sufficient not to limit transpiration. This definition even applies to vegetation with a relatively low leaf area, such as very

young plants, and is therefore synonymous with what is often termed the potential *crop ET* in agricultural applications [57.2]. The value of ET_p is strongly governed by the relative leaf area over the surface and the leaf conductance. When this definition of ET_p is used, it is sometimes assumed that the soil surface between plants is relatively dry, meaning that the soil evaporation component is small. Other works [57.2] include a soil evaporation component that can change daily as the soil dries; the actual ET can then be modeled as being equal to ET_p unless the soil-water availability in the effective root zone falls to a level that can no longer supply water to the plant at the rate assumed for this definition of ET_p [57.2].

57.2.3 Concept and Development of Reference Evapotranspiration

The term *reference evapotranspiration* (ET_{ref}) was first defined and used in the 1970s [57.15, 16] to resolve ambiguities associated with the definition and interpretation of the potential evapotranspiration (as discussed in the previous section). The inclusion of the word *reference* implies the use of a specific type of vegetation or a specific definition of vegetation properties to define the evaporative index. *Wright* and *Jensen* suggested that the maximum ET in unsaturated conditions may be approximated by the ET from a well-watered reference crop of alfalfa (also called lucerne) at least 0.2 m high. *Doorenbos* and *Pruitt* defined their ET_{ref} (denoted ET_0) as

the rate of evapotranspiration from an extensive surface of 8–15 cm tall, green grass cover of uniform height, actively growing, completely shading the ground and not short of water.

Subsequently, this definition specified that the grass cover should be a cool-season grass with roughness, density, leaf area, and canopy resistance characteristics that are similar to those of perennial ryegrass (*Lolium perenne*) or alta fescue (*Festuca arundinacea* Schreb. Alta), since warm-season grass varieties such as Bermuda (*Cynodon dactylon*) exercise considerable control over transpiration and have relatively low ET_{ref} rates. The FAO [57.2] later narrowed the definition of ET_0 in terms of the Penman–Monteith equation (introduced in Sect. 57.3.8) as the rate of evapotranspiration from

a hypothetical reference crop with an assumed crop height of 0.12 m, a fixed surface resistance of 70 s m^{-1} and an albedo of 0.23,

and where the reference surface

closely resembles an extensive surface of green grass of uniform height, actively growing, completely shading the ground and with adequate water.

One benefit of using the reference concept is the ability to readily measure and validate the reference ET using living, standardized vegetation. In addition, because the stomatal control of the reference surface

is intended to approximate that of most agricultural vegetation, ET_{ref} is generally closer than E_p or ET_p to the actual ET. Another advantage of using ET_{ref} is that weather data are commonly or preferably measured above standardized weather surfaces such as grass or other short growing vegetation, so the predicted ET flux is synchronized with the temperature, humidity, and wind measurements taken over the weather station surface, and reflects the impact of feedback mechanisms between the vegetation and overlying boundary layer.

57.3 Theory

Several methods of measuring evapotranspiration are available. These methods are described in other chapters of this Handbook. The most direct methods are the eddy-covariance method (Chap. 55) for measuring evapotranspiration in the footprint of the sensor (Chap. 1) and lysimetry (Chap. 58) for measuring the evapotranspiration from a small sample (i.e., the size of the lysimeter). Chamber measurements can also be used (Chaps. 59 and 60). The aerodynamic and modified Bowen ratio methods, which are similar to the Bowen ratio method (Sect. 57.3.2), are used to determine dry deposition (Chap. 54). Measurement methods (Sects. 57.3.1–57.3.4) and calculation methods (Sects. 57.3.5–57.3.10) are described in the following sections.

57.3.1 Evaporation Pans for Potential Evaporation Measurements

Evaporation pans are still used, especially in hydrological networks. In the US, the main pan used is the Class A evaporation pan [57.17], which is round and has a water surface area of 1.14 m². The evaporation is calculated by measuring the water loss in the pan, and complicated corrections [57.18, 19] for the wind velocity, atmospheric moisture, and water temperature are needed. A reliable but much simpler method for determining the total daily evaporation [57.20] uses the change in the height (h) of the water in the evaporation pan corrected for the precipitation, i.e.,

$$ET_p = k_p (h_{\text{day before}} - h_{\text{measurement day}}) \tag{57.1}$$

(in mm d⁻¹), where the values of the pan factor (k_p) [57.15] listed in Table 57.2 are correction coefficients to include when estimating ET from a clipped grass reference surface or the evaporation from shallow water bodies. These coefficients take into account the effects of the upwind fetch on pan evaporation (both

dry and moist), the mean relative humidity, and the total daily wind [57.2, 15, 21–23].

There is no general theory for all evaporation pans, and all recommended methods of transforming pan evaporation data into estimates of ET_p or E_p are based on empirical methods. However, some rules must be applied. The evaporation from the pan depends on the wind velocity as well as the water vapor pressure deficit between the water surface (saturated vapor pressure of water) and the air. Both of these terms are strongly affected by the distance between the water surface and the edge of the pan, as this distance influences the wind velocity at the surface and because water vapor can accumulate in the small volume from the water surface to the edge of the pan. Therefore, standard calculation procedures are only valid when the range of possible

Table 57.2 Values of the coefficient k_p in (57.2) that are applied when using the Class A pan to determine the grass reference ET of meadows or cereals (or bare soil: *values in parentheses*) in the vicinity of the device (mean wind speed and minimum relative humidity on the day of measurement) [57.20, 24]

Mean wind speed	Extension of results to the area in the surrounding (m)	Coefficient k_p for the minimum of the relative humidity	
		> 40%	< 40%
≤ 2 m s ⁻¹ (low)	1	0.65 (0.80)	0.75 (0.85)
	10	0.75 (0.70)	0.85 (0.80)
	100	0.80 (0.65)	0.85 (0.75)
	1000	0.85 (0.60)	0.85 (0.70)
2.1–4.4 m s ⁻¹ (moderate)	1	0.60 (0.75)	0.65 (0.80)
	10	0.70 (0.65)	0.75 (0.70)
	100	0.75 (0.60)	0.80 (0.65)
	1000	0.80 (0.55)	0.80 (0.60)
≥ 4.5 m s ⁻¹ (strong)	1	0.50 (0.65)	0.60 (0.70)
	10	0.60 (0.55)	0.65 (0.65)
	100	0.65 (0.50)	0.70 (0.60)
	1000	0.70 (0.45)	0.75 (0.55)

distances from the water surface to the edge of the pan has been clearly defined. Furthermore, the water vapor pressure of the air above the pan depends on the ET flux and the conditions near the surface of the surrounding area. It is therefore necessary to use recommendations for the vegetation in the surroundings and the soil moisture. However, the latter is not generally measured or documented. Any calculation of evaporation pan data depends on these criteria and is only valid for these circumstances. Evaporation from a pan is also strongly influenced by the water surface temperature, which is in turn influenced by the absorption of solar radiation by the shallow water body as well as the absorption or reflection of radiation by the bottom and sides of the pan.

When pan evaporation data are used to estimate the evaporation from large water bodies, E_{pan} tends to overestimate the total amount of open water evaporation and distort the seasonal distribution due to differing thermal and aerodynamic characteristics between the pan and open water. Thus, E_{pan} can often peak several months before the peak evaporation from deep lakes. Early studies in semiarid to arid climates in the US revealed a very significant influence of pan size on E_{pan} , but it is now clear that this is primarily due to a decreasing effect of local advection as the water surface area increases [57.15]. A good discussion of the issue of accounting for the influence of the local pan environment on the estimated evaporation from a lake is presented in [57.25]. Subsequent studies in India [57.26] and in Prosser (WA, USA) and California [57.27–29] have clearly demonstrated that unless the local environment of the pan is taken into account, the estimated ET (or evaporation from a lake) can be subject to errors of up to 35%.

Whereas the US Class A pan is elevated above the ground surface, other pan designs, such as the Colorado sunken pan, the Russian GGI-3000 sunken pan, and the Russian 20 m² tank, have rims that are almost level with the ground or grassed surface [57.30]. These pans bypass some of the aerodynamic and solar radiation issues associated with the Class A pan but are more difficult to maintain.

57.3.2 The Bowen Ratio Method for Determining the Actual Evapotranspiration

The Bowen ratio method is one of the most popular methods of determining the sensible and latent heat fluxes from a land or water surface. The method is based on Bowen ratio similarity and the energy balance equation [57.31]

$$\text{Bo} = \gamma \frac{\Delta T}{\Delta e} \quad (57.2)$$

$$-Q_s^* = Q_H + Q_E + Q_G, \quad (57.3)$$

where the psychrometric constant $\gamma = 0.667 \text{ hPa K}^{-1}$ for $p = 1013.25 \text{ hPa}$ and $t = 20^\circ\text{C}$ (Chap. 8). ΔT is the temperature difference between two heights and Δe is the water-vapor pressure difference between two heights, with the value at the upper height subtracted from that at the lower height in each case. $-Q_s^*$ is the net radiation, Q_H is the sensible heat flux, Q_E is the latent heat flux, and Q_G is the ground heat flux. From both equations, the sensible and latent heat fluxes can be determined as

$$Q_H = (-Q_s^* - Q_G) \frac{\text{Bo}}{1 + \text{Bo}}, \quad (57.4)$$

$$Q_E = \frac{-Q_s^* - Q_G}{1 + \text{Bo}}. \quad (57.5)$$

In addition to the net radiation (Chap. 11), the ground heat flux (Chap. 61) must be determined along with the temperature and humidity at two levels (Chaps. 7 and 8) according to (57.2).

An advantage of the Bowen ratio method is that the equations do not require the wind speed and do not prescribe that the measurement heights must be separated by a certain distance. However, to ensure that a sufficiently turbulent regime is present, it is recommended that only measurements where the wind speed at the upper height is greater than 1 m s^{-1} and the difference of the wind speed at the two heights is greater than 0.3 m s^{-1} should be used [57.31]. This can require additional instrumentation with anemometers, which is typically ignored. Even though the height difference between the measurements (Δz) is not required in the equations, increasing Δz also increases the differences in temperature and humidity between the two heights. Consequently, the influence of measurement error decreases as Δz is increased, so it is recommended that the ratio of measurement heights should be greater than 4–8 [57.31]. In practice, these recommendations are rarely followed because the aerodynamic height ratio is limited for practical reasons to about 1.5 for measurements over high vegetation [57.32, 33]. Fetch size requirements, which increase with increasing Δz , also come into play.

Equations (57.4) and (57.5) are singular for $\text{Bo} = -1$. Consequently, the estimated energy fluxes for early morning and evening hours are often unrealistic. Therefore, the range $-1.25 < \text{Bo} < -0.75$ should be excluded from further analysis. To overcome this problem, an hourly Penman equation was used in [57.34] to derive the ET for periods when $\text{Bo} \rightarrow -1$. To obtain ET estimates for these problematic periods, the ET_{ref} from the Penman equation is multiplied by a reference ET fraction $\text{ET}_r F$ that is determined during daylight periods before or after the periods with unstable Bowen

ratio energy balance (BREB) estimates by dividing the measured ET by ET_{ref} . In 1967, Tanner suggested that simple combination equations could be substituted for BREB estimates during these problematic periods. This approach requires the use of instrumentation for measuring wind speed.

To determine the correct sign of the flux when $Bo < 0$, the decision criteria

$$\begin{aligned} \text{if } (-Q_s^* - Q_G) > 0 & \text{ then } (\lambda \Delta q + c_p \Delta T) > 0, \\ \text{if } (-Q_s^* - Q_G) < 0 & \text{ then } (\lambda \Delta q + c_p \Delta T) < 0, \end{aligned} \quad (57.6)$$

where c_p is the heat capacity at constant pressure, should be applied [57.35]. If these criteria are not fulfilled, the fluxes should be omitted from the analyses.

The crucial disadvantage of the Bowen ratio method is that, due to the unclosed energy balance [57.36, 37] (Chap. 55), any residual is either added to the net radiation or distributed according to the Bowen ratio to the sensible and latent heat fluxes. In general, the fluxes determined with the Bowen ratio method are larger than those determined with the eddy-covariance method. By definition, the Bowen ratio method fulfills the energy balance equation, but the quantitative accuracy of the fluxes may be limited by uncertainties or systematic error in the measurement of $-Q_s^*$ and Q_G .

The Bowen ratio method is often superior to the direct use of turbulent transfer equations to estimate the water vapor transport above a surface. This is primarily due to constraints on the estimates obtained using the Bowen ratio method, which arise from the inclusion of the radiation balance in the method. Errors in the estimates of temperature/humidity gradients are not directly related to the estimates of Q_E or Q_H , in contrast to strictly aerodynamic methods. In some situations, however, the net radiation or heat transfer below the surface is not easily measurable. For forests, brushlands, or orchards, it can be important to account for changes in the heat storage of the canopy over periods shorter than 24 h. For water bodies, it is difficult to accurately measure $-Q_s^*$ and Q_G . In these situations, one should consider using aerodynamic methods, as described in Chap. 54.

An overall evaluation of the method is given in Sect. 57.5. The error associated with this method is gauged under the assumption of accurate net radiometer measurements (Chap. 11). Furthermore, the heat storage in the soil should be calculated very accurately to reduce the influence of the residual of the energy balance closure (Chaps. 55 and 61).

57.3.3 Evapotranspiration by the Residual in the Energy Balance

Solving (57.3) makes it possible to determine the evapotranspiration as the residual when the sensible heat

flux, the net radiation, and the ground heat flux are known, i.e.,

$$Q_E = -Q_s^* - Q_G - Q_H. \quad (57.7)$$

The advantage of this approach is that there is no need for the expensive instrumentation required to measure the latent heat flux (evapotranspiration). Eddy-covariance systems may be used to measure Q_H and the low-cost surface renewal method may be employed to measure Q_H [57.38], see Chaps. 55 and 56. However, this method has two disadvantages. Measuring the sensible heat flux with the eddy-covariance method may not lead to sufficiently accurate values for Q_H , meaning that the energy balance equation may not be adequately closed due to methodical problems [57.36]. Assumptions must be made to correct for this (Chap. 55). Furthermore, sonic anemometers are used to measure the buoyancy flux, which must then be converted into the sensible heat flux using the latent heat flux [57.39, 40]. Therefore the equation should be solved iteratively. Surface renewal methods that require only a fine-wire thermocouple and estimates for the net radiation and Q_G can provide an empirical approximation for Q_H , and thus for Q_E , based on surface heat ramping and exchange theory, but they must be calibrated for the surface type and the vegetation conditions present and are generally less accurate than using eddy-covariance techniques. Furthermore, the results of the energy balance residual method can be affected by biases in the net radiation and ground heat flux measurements, including a lack of representativeness over nonuniform surfaces.

57.3.4 Soil Water Balance

All of the methods for estimating ET only provide estimates of the average actual ET from a field, watershed, or region under consideration. As might be expected, for point measurements, the larger and more diverse the area, the more uncertain the estimate. This issue becomes particularly problematic when the area under consideration encompasses a wide variety of vegetation species, vegetation heights, aerodynamic roughnesses, leaf development stages, rooting depths, soil types, and differing responses to soil water levels and weather conditions (e.g., watersheds or regions).

For watersheds, all components of the soil water balance are usually estimated, including water runoff, and the ET is estimated from the resulting equation. For small watersheds where interbasin groundwater flow is highly restricted and runoff can be measured, the ET can be determined from the hydrologic balance if the watershed precipitation is accurately measured or estimated.

The basic soil-water balance equation for a study volume (i.e., a defined area with a depth z_s) during a specific time period Δt can be written as

$$\Delta\theta z_s = P - Q_r + I - ET_a - DP + GW, \quad (57.8)$$

where $\Delta\theta$ is the change in the mean water content of the soil profile over the depth z_s of the soil profile monitored. The depth of the surface runoff Q_r that is leaving the study area is measured or estimated, and the gross irrigation depth I is the depth of water that infiltrates from irrigation over the study area. The most challenging measurements and estimates in (57.8) are the depth of percolation below z_s DP and the depth of the groundwater (GW) that moves upward or horizontally into the profile. Equation (57.8) is solved for ET_a as the actual evapotranspiration depth over the area. Generally, the soil profile depth of interest is the plant root zone, which is by definition the upper portion of the soil where water is extracted by plant roots. In this case, GW and DP are, respectively, the total flux densities into and out of the bottom or side of the root zone during the time period of interest.

Generally, when solving the soil-water balance equation for ET, θ should be sampled to depths well below the root zone. Even if there is no change in the soil water content at lower depths between sampling dates, we cannot assume that there is no drainage, because drainage can occur under a unit hydraulic gradient with no apparent change in the soil water content. Periods with little or no precipitation are generally selected for evaluation. Occasionally, sharp changes in soil texture such as a sand or gravel layer below the root zone or the presence of bedrock can reduce the rate of deep percolation and improve measurement accuracy.

Situations where there are saturated conditions (i.e., a water table) near the root zone should be avoided. In the absence of a shallow water table (GW = 0), and with an adequate sampling depth, a record of the soil water fluctuations over a period of 7–10 days or more can yield reliable measurements of ET at the measurement site [57.41].

57.3.5 Bulk Approaches

The simplest method of determining the evaporation is to use the bulk approach. In this approach, a uniform (linear) gradient is assumed for the given layer, and only values at the upper and lower boundaries are used [57.42]. If the lower boundary of this layer has properties that are identical to those of the surface, then, strictly speaking, the method is only applicable over water bodies because the gradient between surface values and the measurement data at a certain upper measurement height (generally 10 m) can only be ex-

PLICITLY determined over a water body. Therefore, the method can be used to determine the potential evaporation. That is not to say that there are no problems when applying the bulk method above water bodies, because it is often not the surface temperature that is measured but the temperature decimeters below the water surface, and this temperature may be about 0.5 K higher than the cold film temperature due to evaporative cooling at the surface. Also, the absorption of shortwave-infrared and infrared radiation at the surface can lead to a warmer film temperature at the surface than immediately below it. Remote-sensing methods such as infrared thermometers or satellite sensors can be used to determine the surface temperature with absolute accuracy, similar to that of the subsurface measurements [57.43].

Instead of turbulent diffusion coefficients, bulk coefficients are used in bulk approaches. The latent heat flux can be determined via the Dalton number C_E using

$$\frac{Q_E}{\rho\lambda} = C_E(z)u(z)[e(z) - e(0)]. \quad (57.9)$$

The bulk coefficients depend on the stability and wind speed. Over the ocean, with mostly neutral stratification, the first of these influences is generally not a problem. On average, the Dalton number $C_E \approx 10^{-3}$. The values over lakes are slightly higher [57.44]. Several approaches that utilize the bulk concept are available. A theoretical formulation for C_E under neutral conditions is

$$C_E = \frac{0.622}{\rho_w P} \frac{\kappa^2}{\ln\left(\frac{z}{z_o}\right) \ln\left(\frac{z}{z_{oq}}\right)}, \quad (57.10)$$

with appropriate units. The roughness height for water vapor z_{oq} is generally considered to be similar to or smaller than z_o for momentum, or it may even exceed z_{om} when applied to water [57.45], κ is the von Kármán constant (values of 0.40 and 0.41 are used by different authors). In saline water bodies, the salinity of the water will reduce the surface saturation vapor pressure.

Dalton Approach

The simplest way to determine the potential evaporation over open water is the Dalton approach. Instead of the Dalton number alone, simple correction functions are used to account for the wind-speed dependency, i.e.,

$$\frac{Q_E}{\rho\lambda} = f(u)[E(T_0) - e(z)] \quad \text{with } f(u) = a + bu^c, \quad (57.11)$$

where $a = 0.16 \text{ m s}^{-1}$, $b = 0.2 (\text{m s}^{-1})^{0.5}$, $c = 0.5$ for lakes in Northern Germany [57.46], and E the water-vapor pressure of saturation at a certain temperature. Possible areas of application for this method are given in Sect. 57.5.

57.3.6 Priestley–Taylor Method

The Bowen ratio is the starting point for the derivation of several methods that are used to determine sensible and latent heat fluxes. The Priestley–Taylor approach starts from (57.2), which can be written with the potential temperature and the dry adiabatic temperature gradient $\Gamma_d = 0.0098 \text{ K m}^{-1}$ as

$$\text{Bo} = \gamma \frac{\partial \bar{\theta} / \partial z}{\partial \bar{q} / \partial z} = \frac{\gamma [(\partial \bar{T} / \partial z) + \Gamma_d]}{\partial \bar{q} / \partial z}. \quad (57.12)$$

Using the temperature dependence of the saturation water vapor pressure given by the Clausius–Clapeyron equation (Chap. 5)

$$\frac{dq_s}{dT} = s_c(\bar{T}), \quad (57.13)$$

it follows that

$$\text{Bo} = \frac{\gamma [(\partial \bar{T} / \partial z) + \Gamma_d]}{s_c(\partial \bar{T} / \partial z)} = \frac{\gamma}{s_c} + \frac{\gamma \Gamma_d}{s_c(\partial \bar{T} / \partial z)} \quad (57.14)$$

if the dry adiabatic temperature gradient is significantly smaller than the temperature gradient in the surface layer; γ is the psychrometric constant in K^{-1} (Chap. 8).

For the further derivation, the second term on the right-hand side of (57.12) will be ignored. However, this is valid only if the gradient in the surface layer is significantly greater than the dry adiabatic gradient, which is not the case for neutral stability. Introducing the Priestley–Taylor coefficient $\alpha_{\text{PT}} \approx 1.26$ for region-scaled surfaces with an adequate water supply and applying energy balance equation (57.3) yields the Priestley–Taylor approach [57.47]

$$Q_H = \frac{[(1 - \alpha_{\text{PT}}) s_c + \gamma] (-Q_s^* - Q_G)}{s_c + \gamma}, \quad (57.15)$$

$$Q_E = \alpha_{\text{PT}} s_c \frac{-Q_s^* - Q_G}{s_c + \gamma}. \quad (57.16)$$

Typical values of the ratios $c_p/\lambda = \gamma$ and $de_s/dT = s_c$ in K^{-1} are given in Table 57.3. These can be calculated approximately with the relation [57.31, 48] (t : temperature in $^\circ\text{C}$)

$$\frac{s_c}{\gamma} = -0.40 + 1.042e^{0.0443t}. \quad (57.17)$$

This method can be used for vegetated surfaces at the regional scale if the Priestley–Taylor coefficient is adjusted for its dependence on the regional water availability (i.e., the soil water content) and therefore the stomatal resistance [57.49]. Possible areas of application for this method are given in Sect. 57.5.

Table 57.3 Values of the temperature-dependent parameters γ and s_c [57.48]

Temperature (K)	γ (K^{-1})	s_c (K^{-1})
270	0.00040	0.00022
280	0.00040	0.00042
290	0.00040	0.00078
300	0.00041	0.00132

57.3.7 Penman Method

A commonly used method for determining the potential evaporation or reference ET is the combination method that was proposed by Penman [57.14] to eliminate the need to measure the surface temperature. This method was developed for southern England and tends to underestimate the evaporation in arid regions when using the original wind function. The derivation involves combining the Dalton approach with the energy balance via the Bowen ratio. The evaporation in mm d^{-1} is

$$Q_E = \frac{s_c (-Q_s^* - Q_G) + \gamma E_a}{s_c + \gamma}, \quad (57.18)$$

where the available energy must be expressed in mm d^{-1} . The conversion factor from mm d^{-1} to W m^{-2} is 0.0353 at 20°C . The second term in the numerator of (57.18), E_a (also in mm d^{-1}), is called the ventilation term, and represents the influence of turbulence according to the Dalton approach. In humid regions, E_a is significantly smaller than the first term and is often ignored in the simplified Penman approach [57.50] to derive the Priestley–Taylor equation [57.51] when $\alpha_{\text{PT}} = 1.26$.

The ventilation term is a function of the wind speed and the saturation deficit,

$$E_a = (E - e) (f_1 + f_2 u) \quad [\text{mm d}^{-1}]. \quad (57.19)$$

While one can use daily averages in (57.18), the use of 10–60 min averages is considerably more meaningful, although the units must be converted in this case. Typical values for the wind factors f_1 and f_2 are given in Table 57.4. These values are valid for water surfaces, but they can also be used for well-saturated grass surfaces, where ET is to a large degree the potential evaporation for a grassed surface, largely equivalent to the grass reference ET. To include the effects of increased roughness, the ventilation term can be applied according to the approach devised by van Bavel [57.52],

$$E_a = \frac{314 \text{ K}}{T} \frac{u}{[\ln(z/z_0)]^2} (E - e) \quad [\text{hPa m s}^{-1}]. \quad (57.20)$$

Table 57.4 Values of the wind factors in the ventilation term of (57.19) [57.31]

Surface and reference	f_1 (mm d ⁻¹ hPa ⁻¹)	f_2 (mm d ⁻¹ hPa ⁻¹ m ⁻¹ s)
Original approach for water bodies [57.54]	0.131	0.141
Small water bodies [57.51]	0.136	0.105
Water bodies [57.55]	0.0	0.182
Grass surfaces [57.24, 56]	0.27	0.233

Possible values for different areas of application of this method are given in Table 57.4. With no surface resistance term, the Penman equation is not particularly accurate for many vegetated surfaces, especially those with insufficient soil water to supply the potential ET rate. When it is applied to open water, a shortcoming is the need to measure or estimate Q_G , which can be substantial for deep cold-water systems and thus cannot be ignored [57.53]. Possible areas of application of this method are given in Sect. 57.5.

Another, very simple, approach to calculating the evaporation from the available radiation energy is that employed by Turc,

$$Q_{E-TURC} = k(K\downarrow + 209) \frac{0.0933t}{t + 15}, \quad (57.21)$$

where the only input parameters are the air temperature t (in °C) and global radiation (in W m⁻²) [57.57], and k is an empirical factor. The Turc method is empirical and was developed to approximate the potential ET in the Mediterranean region. To make it applicable in Germany, (57.12) requires a correction factor of about $k = 1.1$ [57.51]. The Turc method tends to yield an underestimate in dry convective conditions where evaporation can substantially exceed the available energy due to regional and local advection. Possible areas of application of this method are given in Sect. 57.5.

57.3.8 Penman–Monteith Method

The transition from the Penman to the Penman–Monteith approach [57.14, 48, 58, 59] includes considering unsaturated surfaces and cooling due to evaporation, which reduces the energy of the sensible heat flux. Including both of these aspects leads to the Penman–Monteith method for determining the actual evaporation (evapotranspiration),

$$Q_H = \frac{\gamma(-Q_s^* - Q_G) - F_w}{R_{Gs_c} + \gamma}, \quad (57.22)$$

Fig. 57.3 Schematic representation of the modeling of the atmospheric surface layer, including plants and soil (after [57.66])

$$Q_E = \frac{R_{Gs_c}(-Q_s^* - Q_G) + F_w}{R_{Gs_c} + \gamma}, \quad (57.23)$$

where the ventilation term

$$F_w = C_E \bar{u} (R_G - R_s) q_{sat}. \quad (57.24)$$

Here, R_G is the relative humidity of the surface, R_s is the relative humidity close to the surface, and q_{sat} is the specific humidity for saturation.

Equation (57.23) can also be formulated according to the resistance approach, where the near-surface domain is not separated into different layers. Instead, it is assumed that plants act like a big leaf over the soil (the *big leaf model*), and only the saturation vapor pressure and actual vapor pressure at a height of z are utilized, following Penman's original formulation. These models are mainly based on surface layer physics and are illustrated schematically in Fig. 57.3 [57.60–65].

The resistance concept is based on the assumption that the turbulent resistance counteracts the turbulent flux in the turbulent layer, a molecular turbulent resistance counteracts the flux in the viscous and molecular layer, and all resistances in the plant and soil can be combined into a resistance known as the canopy resistance. The canopy resistance is exerted along various transfer pathways, especially the stomata–mesophyll pathway, the cuticula pathway, and direct transfer to the soil, as schematically illustrated in Fig. 57.2 (right-hand side). The simplest generalization is the comparison with Ohm's law,

$$I = \frac{U}{R}. \quad (57.25)$$

Here, the flux is analogous to the current I , and the vertical difference in wind speed or temperature is analogous to the voltage U . The resistance R can be de-

scribed as a network of individual resistances with the simple form

$$r_g = r_a + r_{mt} + r_c + r_b. \quad (57.26)$$

This concept neglects the molecular turbulent resistance, and the soil resistance is included in the canopy resistance. The ventilation term

$$F_w = \frac{q_{sat} - q_a}{r_a + r_c}. \quad (57.27)$$

In the simplest case, the canopy resistance r_c is replaced by the bulk stomatal resistance r_s , and it is assumed that the stomatal cavities are at saturation and the surface temperature. The bulk stomatal resistance can be calculated from the stomatal resistance of a single leaf r_{si} and the active leaf-area index (LAI, the leaf surface of the upper side per elemental area of the underlying surface) via

$$r_s = \frac{r_{si}}{\text{LAI}_{\text{active}}}, \quad (57.28)$$

where $\text{LAI}_{\text{active}}$ is the leaf-area index of the active sunlit leaves. Generally, this is only the upper part of a dense canopy, so $\text{LAI}_{\text{active}} = 0.5\text{LAI}$ [57.2]. In the simplest case, the turbulent resistance is given by [57.48]

$$r_a = \frac{1}{C_E \bar{u}}. \quad (57.29)$$

Usually, however, r_a is calculated from the profile equation for the surface layer (Chap. 1),

$$r_a = \frac{\ln\left(\frac{z-d}{z_0}\right) \ln\left(\frac{z-d}{z_{0q}}\right)}{\kappa^2 u(z)}. \quad (57.30)$$

In the non-neutral case, universal functions can be used in (57.30), leading to

$$r_a = \frac{\left[\ln\left(\frac{z-d}{z_0}\right) - \Psi_m\right] \left[\ln\left(\frac{z-d}{z_{0q}}\right) - \Psi_{q,h}\right]}{\kappa^2 u(z)}, \quad (57.31)$$

and the resistance-style formulation of the Penman–Monteith equation is

$$Q_E = \frac{s_c (-Q_s^* - Q_G) + \frac{\rho c_p (E - e)}{r_a}}{s_c + \gamma \left(\frac{r_s + r_a}{r_a}\right)}. \quad (57.32)$$

Equation (57.32) is generally simpler to apply than (57.23) and (57.24) because it does not require the R of the surface, R_G , which is difficult or nearly impossible to measure. Typical values of the parameters are given in Table 57.5. Possible areas of application of this method are given in Sect. 57.5.

Table 57.5 Typical values of the LAI [57.67] and the stomatal resistance of single leaves [57.53, 68]

Surface	Height (m)	LAI ($\text{m}^2 \text{m}^{-2}$)	r_{si}^a (s m^{-1})
Seedlings (beginning to grow)	0.05	0.5	
Clipped grass	0.05–0.15	2–3	70–150
Grassland	0.3–1	2–3	100–500
Sagebrush	1	0.5	1000
Cereal	1	3.0	50–320
Maize	2–3	3–6	80–100
Lucerne	0.3–0.7	3–5	80–100
Forest	12–20	1–6	120–2700

^a The lower values in the range represent high-moisture conditions; the higher values in the range represent moderately dry moisture conditions

Implications of Boundary Layer Feedback in the Penman–Monteith Method

When it is applied in hydrology, a disadvantage of the Penman–Monteith (PM) equation is that it is challenging to quantify the bulk surface resistance for complex canopies, especially when the soil water is limiting [57.69]. In addition, significant errors may be introduced when weather data used in the PM equation are measured above surfaces that are significantly different from a complex canopy. For example, applications that use weather measurements taken over a clipped grass surface to estimate the ET from forest vegetation do not represent surface boundary layer profiles that exist in nature because the air temperature, vapor content, and wind speed conditions are different over a forest than over grass.

Other challenges when using the PM and other combination equations include the difficulty involved in characterizing the relationships between the leaf stomatal resistance and environmental variables for sparse or multilayered vegetation, such as forests in semiarid regions and immature crops [57.70, 71]. In these situations, the mean heights and locations of sinks for momentum and radiation are different from the mean heights and locations of sources for Q_E and Q_H . These variations can create differences in eddy diffusivities and aerodynamic resistances within and directly above canopies. In such situations, multisource and/or multilayer models may be more suitable.

In its simplest form (in which the outgoing radiation and ground heat flux are used, only the air temperature is employed to calculate s_c , and neutral stability is assumed), the PM works best only under well-watered conditions and for near-full vegetation cover, for example when it is used as a reference ET method [57.2, 72]. Under these conditions, the surface temperature is

closest to the air temperature and the surface resistance is relatively constant, so these simplifying assumptions are valid.

Necessary Allowances for Nonpotential Conditions

The single-layer PM model blends microclimate variations within the vegetation and soil surface and assumes that each surface contributes to energy exchange at similar temperatures and with the same saturation deficit at its surface. In the PM method, all surface resistance values for leaf and soil subareas must contribute to the value of the bulk r_s .

It is often assumed during the application of the combination equation that the surface temperature is sufficiently similar to the air temperature that s_c , as well as the longwave radiation emitted from the surface and the ground heat flux, can be calculated using the air temperature only, and the stability correction can be ignored. However, dry nonpotential surfaces tend to have substantially higher temperatures than the air temperature, and under these conditions s_c , the net radiation, the soil heat flux, and the boundary layer stability correction should be calculated using both the surface and air temperatures, where the surface temperature is derived iteratively based on Q_E , Q_H , Q_G , and Q_s^* and the energy balance. As illustrated by AFIB (aerodynamic fluxes using iterative energy balance) method described later in this section, the PM formulation is only completely accurate when T_s is a measured quantity or determined iteratively.

The Penman–Monteith Method as a Reference ET Method

The Food and Agriculture Organization of the United Nations (FAO) and the American Society of Civil Engineers (ASCE) have put much effort into developing a uniform standardized method of determining the reference evapotranspiration, and they recommend the use of a convenient equation with a limited input dataset [57.2, 53, 72–74]. To facilitate comparisons of evapotranspiration rates from around the world and to ensure that the input parameters are available every-

where, the FAO has formulated a (grass) reference ET equation [57.2] that is based on (57.16) but includes the estimated input parameters given in Table 57.10. A further standardization was made by the ASCE, which unified the calculation steps and applied the equation to both grass and alfalfa (lucerne) reference surfaces [57.75].

When applied to estimate the reference ET, three important simplifications to the PM method facilitated by the assumption of near-neutral conditions are generally practiced, as proposed by Penman [57.14]. These three simplifying assumptions are that s_c can be estimated using the air temperature only, that stability correction of r_a is not required, and that longwave radiation emitted from the surface can be estimated using T_a only.

When expressed using terms adopted for this Handbook, the standardized PM equation for reference ET becomes

$$Q_E = \frac{s_{cc} (-Q_s^* - Q_G) + \rho c_p \frac{E - e}{r_a}}{s_{cc} + \gamma_c \left(1 + \frac{r_s}{r_a}\right)}, \quad (57.33)$$

where r_s and r_a are given by (57.28) and (57.30), respectively (Table 57.6). The factors $s_{cc} = s_c p / 0.622$ and $\gamma_c = \gamma p / 0.622$ are both in units of hPa K⁻¹, just as in the original reference.

The Penman–Monteith-based reference ET approach is widely used in diverse applications, such as in hydrologic studies and irrigation water management. During the daytime, the accuracy of data computed hourly is satisfactory, and daily sums of the evaporation and sensible heat fluxes are generally acceptable. The available energy is the main forcing, but the atmospheric turbulence and humidity and the control by the plants – defined for the reference surfaces – influences the ventilation term.

When the supporting parameter equations for r_a , ρ_a , and λ are simplified and incorporated into (57.32), the PM equation simplifies to a standardized reference form presented by the FAO [57.2] and ASCE [57.74] and commonly found in the literature,

Table 57.6 Input parameters for the FAO (grass) reference evaporation [57.2]

Parameter	Value	Remark
r_a	$d = 2/3z_B$; $z_0 = 0.123z_B$; $z_{0q} = 0.1z_0$, with $z_B = 0.12$ m for the short grass reference (ET ₀) and $z_B = 0.50$ m for the tall alfalfa reference (ET _T), and $z = 2$ m produces $r_a = 208/u$ (2 m) for the short grass reference	$\kappa = 0.41$ is applied
r_s	For $LAI_{active} = 0.5LAI$; $LAI = 24z_B$ for the short grass reference with $r_{si} = 100$ s m ⁻¹ for 24 h timesteps, and for $z_B = 0.12$ m follows $r_s = 70$ s m ⁻¹ for 24 h timesteps, and $r_s = 50$ s m ⁻¹ for daytime hourly timesteps for the grass reference	
$-Q_s^* - Q_G$	Other simplifications are a recommended albedo of 0.23 and an assumption that $T_s \cong T_a$	[57.2]; see Chap. 11 for $-Q_s^*$ and Chap. 61 for Q_G

Table 57.7 Values of C_n and C_d in (57.25) and the ratio Q_G/Q_s^* that is used to estimate the soil heat flux density [57.74]

Calculation timestep	Short reference, ET _o			Tall reference, ET _r			Units for ET _o , ET _r	Units for Q _s [*] and Q _G
	C _n	C _d	Q _G /Q _s [*]	C _n	C _d	Q _G /Q _s [*]		
Daily	900	0.34	0.00	1600	0.38	0.00	mm d ⁻¹	MJ m ⁻² d ⁻¹
Hourly during daytime	37	0.24	0.10	66	0.25	0.04	mm h ⁻¹	MJ m ⁻² h ⁻¹
Hourly during nighttime	37	0.96	0.50	66	1.7	0.20	mm h ⁻¹	MJ m ⁻² h ⁻¹

$$ET_{\text{ref}} = \frac{0.408s_{\text{cc}}(-Q_s^* - Q_G) + \gamma \frac{C_n}{(t+273)} u_2 (e_s - e_a)}{\Delta + \gamma_c (1 + C_d u_2)}, \quad (57.34)$$

where ET_{ref} has units of mm d^{-1} for 24 h timesteps and mm h^{-1} for hourly timesteps, and applies to both clipped grass and alfalfa reference surfaces. Q_s^* and Q_G are in units of $\text{MJ m}^{-2} \text{d}^{-1}$ or $\text{MJ m}^{-2} \text{h}^{-1}$; t is the mean daily or hourly air temperature ($^{\circ}\text{C}$); u_2 (m s^{-1}) is the mean daily or hourly wind speed at a height of 2 m; e_s and e_a are the saturation and actual vapor pressures for the air in kPa; s_{cc} and γ are in units of $\text{kPa } ^{\circ}\text{C}^{-1}$; and C_n and C_d are coefficients that vary with the calculation timestep, reference type (grass ET_o or alfalfa ET_r), and, in some cases, with the time of day, as shown in Table 57.7. The values of the hourly C_d for ET_o are based on the use of $r_s = 50 \text{ s m}^{-1}$ during the daytime and $r_s = 200 \text{ s m}^{-1}$ during nighttime, and the 24 h timestep value for C_d is based on $r_s = 70 \text{ s m}^{-1}$. Additional background on r_s for ET_o is provided in [57.72, 74]. For ET_r, the values of the hourly C_d are based on the use of $r_s = 30 \text{ s m}^{-1}$ during the daytime and $r_s = 200 \text{ s m}^{-1}$ during nighttime, and the 24 h timestep value for C_d is based on $r_s = 45 \text{ s m}^{-1}$. The standardized definitions imply vegetation heights for the ET_o and ET_r surfaces of 0.12 and 0.5 m, respectively. Generally, ET_r is 20–30% stronger than ET_o (depending on the wind and aridity) due to the stronger aerodynamic features of the alfalfa reference and its lower stomatal resistance and larger leaf area. ET_r is often used as an upper limit on the ET for an extensive, well-watered surface.

The AFIB Alternative (Aerodynamic Fluxes Using Iterative Energy Balance)

For dry nonreference surfaces, with increasing T_s , the net radiation can decrease by as much as 100 W m^{-2} compared with the reference condition due to the increased thermal radiative emission from the warmer surface. In addition, buoyancy-driven mixing of the boundary layer with the increased T_s (as compared with T_a) caused by increasing Q_H can mean that stability correction is required to reduce r_{ah} (resistance for sensible heat). It is also necessary to provide an accurate estimation of Q_G . Therefore, when the vegetation cover is low or the water supply limits ET (i.e., there are nonreference crop conditions), T_s should be iteratively

determined using, for example, the AFIB procedure. Ironically, when T_s is iteratively solved for or measured, the reason for the existence of the PM and other combination equations essentially evaporates because the substitution of a T_s - and T_a -based computation of s_{cc} into the equation causes it to decompose back to the original component equations for Q_H and Q_E , making the formulation of the PM unnecessary.

The required suite of equations and the inversion of the sensible heat equation to replace the PM equation is termed the AFIB (aerodynamic fluxes via iterative solution of the energy balance) approach [57.53], and can be summarized as

$$Q_s^* = (1 - \alpha)R_s + R_{L\text{-in}}(1 - \varepsilon) - \varepsilon\sigma T_s^4, \quad (57.35)$$

$$Q_G = [0.05 + K_G \exp(-0.5\text{LAI})] (Q_s^* + Q_H), \quad (57.36)$$

$$Q_E = \frac{\rho_a c_p [e^0(T_s) - e^0(T_a)]}{\gamma_c \frac{r_a + r_s}{r_a + r_s}}, \quad (57.37)$$

$$T_s = \frac{(-Q_s^* - Q_G - Q_E) r_{\text{ah}}}{\rho_a c_p} + T_a, \quad (57.38)$$

$$Q_H = \rho_a c_p \frac{T_s - T_a}{r_{\text{ah}}} \quad (57.39)$$

$$r_{\text{ah}} = r_{\text{aq}} = \frac{\left\{ \ln\left(\frac{z_u - d}{z_o}\right) - \Psi_m\left[\frac{z_u}{L(Q_H)}\right] \right\} \left\{ \ln\left(\frac{z_T - d}{z_{0h}}\right) - \Psi_h\left[\frac{z_T}{L(Q_H)}\right] \right\}}{\kappa^2 u_z}, \quad (57.40)$$

where r_{ah} is the resistance of sensible heat, z_u is the height above the ground surface for the wind speed measurement, d is the zero plane displacement of the logarithmic wind profile, z_o is a roughness length governing the transfer of momentum from the surface, ψ_m is the correction factor for momentum transfer to account for the instability or stability of the boundary layer, z_T is the height of the air temperature measurement above the ground surface, z_{0h} is an assumed roughness length governing the transfer of sensible heat from the surface, ψ_h is a correction factor for sensible heat transfer to account for the instability or stability of the boundary layer, and u_z is the wind speed measured at a height of z_u . Equations for estimating ψ_m and ψ_h are given in [57.53, 76, 77]; see also Chap. 1. Equation (57.36) represents the likelihood that Q_G is influenced by Q_H due to their codependence on temper-

ature gradients that share a common T_s . K_G is a fitting coefficient that is affected by the relative thermal conductivity of the soil; $K_G = 0.2$ is recommended for tilled soils and $K_G = 0.10\text{--}0.15$ is recommended for soils in a natural state with less bulk particle-to-particle contact. When Q_H is low and most of the Q_s^* is converted into Q_E , Q_G becomes a function of Q_s^* , which is a traditional estimation method [57.78]. The $L(Q_H)$ in (57.40) indicates that the Obukhov length L is a function of Q_H and thus T_s . Equations (57.35)–(57.40) are iteratively solved until the estimate for T_s is obtained. At that point, Q_E can be evaluated via (57.37).

Once T_s is known from (57.38), Q_E can be calculated from the PM equation, if desired, using

$$s_{cc} = \frac{e^0(T_s) - e^0(T_a)}{(T_s - T_a)} \quad (57.41)$$

and Q_s^* , Q_G , and r_{ah} from (57.35)–(57.40). Estimates will be within a few percent of, or even identical to, the value of Q_E obtained using (57.37), provided that similar estimates are made for Q_s^* , Q_G , and r_{ah} , including the stability correction. Application areas for the AFIB method are listed in Sect. 57.5.

Solving (57.35)–(57.40) does not represent a computational challenge for modern computing systems, and, once coded, these equations tend to provide consistent estimates. The iteration can progress through the equations in any order, and can be initiated with the assumption that $Q_H = 0$. Numerical stability can be ensured for the solution by dampening the calculations, which is achieved by averaging the new values of T_s and—if needed—the correction parameters ψ_m and ψ_h with their values from the previous iteration step.

Upon observing the performance of the AFIB method, it becomes apparent that the PM equation—or any combination equation—is only really useful for *reference* conditions, based only on T_a , neglecting T_s (to adjust the estimates of s_c , Q_G , Q_s^*), and r_a , and where the reference conditions represent the near-maximum ET. Under all conditions other than the reference conditions, the AFIB method of (57.35)–(57.40) is recommended. It is best applied using data obtained hourly or even more frequently. This limitation is caused by the potentially strong nonlinearity in the buoyancy or stability corrections, which can vary hourly.

57.3.9 Cover, Crop, and Landscape Coefficients: Applications and Limitations

The Penman–Monteith equation is now widely used to estimate the ET in hydrology, meteorology, and agriculture, where the equation serves as the reference ET (ET_{ref}) (57.34) in a two-step crop (or cover) coefficient

$K_c ET_{ref}$ approach. The $K_c ET_{ref}$ procedure is not a measurement technique but rather a method of inferring the ET by considering the influence of boundary-layer and radiation effects on ET demand and including a scaling factor to account for specific vegetation effects. It is described here because it is a robust and consistent method of estimating ET that has physically imposed constraints. The first step in the two-step approach is to estimate the ET_{ref} that accounts for near-potential weather or climate effects on the ET process. The second step is to apply a crop or vegetation (cover) coefficient to estimate the actual ET (ET_c) according to growth stage, plant type, cover, and the wetness of the soil surface and soil profile. This section focuses on the use of the two-step approach to estimate the ET for farm crops, landscapes, and some natural vegetation. Applications of this approach to forests are described in the *ASCE Handbook of Hydrology* [57.79].

The crop (or cover) coefficient K_c was proposed as a modifier of ET_{ref} in [57.80], and its usage was popularized internationally by the FAO [57.24]. The two-step procedure for estimating the ET for well-watered agricultural crops can be applied to various types of natural vegetation, to crops under rainfed conditions, and to hydrologic studies in general. For these reasons, K_c is perhaps more appropriately referred to as a *vegetation cover coefficient* rather than a *crop coefficient*. The K_c approach is an empirical approach, but it has limits that are physically based, and the method tends to have good reproducibility and transferability. K_c is readily visualized and therefore relatively straightforward to parameterize.

Some K_c curves have been refined for dry surface soil or visually dry soil (i.e., visual inspection suggests that the soil is dry); the corresponding coefficients are called *basal crop coefficients* (K_{cb}) [57.81]. More accurate ET estimates can be obtained by adjusting K_{cb} for the wetness of the surface soil for several days following rain or irrigation using the dual K_c approach [57.2, 81].

Numerous publications over the past decades have focused on the measurement of ET and the calculation of associated crop coefficients. The primary factor that influences the crop coefficient is a change in plant cover or the evolution of leaf area per unit area (LAI) as a plant develops, which results in a decrease in bulk surface resistance. Most publications on crop coefficient curves have presented K_c as a function of some form of absolute or scaled time. Some studies provide the rate of increase in LAI and therefore K_c as a function of the daily weather, such as cumulative degree days, as discussed in the section on lengths of growth states.

When applying the standardized reference ET equation (57.34) under humid conditions (where most of the

Fig. 57.4 Generalized K_c cover coefficient curves showing the effects of growth stage, wet surface soil, and limited available soil water (after [57.53] republished with the permission of the American Society of Civil Engineers)

energy for the ET process comes from the net radiation) for large expanses of similar vegetation, K_c does not exceed about 1.0 relative to the alfalfa reference and about 1.2 relative to the grass reference. In dry climates, where additional advection of warm, dry air can increase the ET from wet surfaces, K_c still does not exceed about 1.0–1.1 relative to the alfalfa reference, but it can reach about 1.3–1.4 relative to the grass reference. The reason for the near-constant crop coefficients of 1.0–1.1 for the alfalfa reference is that this reference crop has about the same albedo, LAI, stomatal resistance, and roughness as most agricultural crops at full cover. An expanse of a reference crop (especially alfalfa) will approach the maximum conversion of available energy into Q_E , so the ratio of Q_E for any other tall, leafy crop to the Q_E for alfalfa will be around 1.0. Higher values for K_c are likely to indicate problems with field measurements. Such measurement problems include:

- 1) Improper computation of the vegetated area in lysimeter studies [57.82, 83]
- 2) Violation of the fetch requirements in boundary-layer (energy-balance) measurements
- 3) Weather data collection difficulties and errors [57.83].

Two families of K_c curves for agricultural crops have been developed, based on the two commonly used reference crops (tall and short). These are the grass-based curves produced by William Pruitt [57.2, 21, 24] and the alfalfa-based K_c curves of James Wright [57.81, 84] and others [57.85–87]. It is clearly important to avoid mixing a grass-reference-based K_c with an alfalfa reference and vice versa.

Generalized crop coefficient curves for estimating the ET_c are shown in Fig. 57.4. The K_{cb} curve presents the *basal* crop coefficient for conditions where the soil surface is visually dry, so that evaporation from the soil is minimal, but where the availability of soil water does not limit plant growth or transpiration. This curve represents a minimum potential ET_c situation for adequate soil water. The spikes in Fig. 57.3 indicate precipitation or irrigation events that wet the soil surface and temporarily increase the total ET_c for 1–5 days. These spikes decay to the K_{cb} curve as the soil surface dries. The spikes generally approach a maximum value of 0.8–1.0 for an alfalfa ET_r base [57.81] and 1.0–1.2 for a grass ET_o base [57.2]. The K_{cm} curve in Fig. 57.3 presents the so-called *mean* crop coefficient, which includes the averaged effects of wet soil (spikes) under specific rainfall or irrigation frequencies. K_{cm} is sometimes referred to as the *single* K_c . The final *limited soil water* curve in the figure represents the decrease in ET_c when plant water uptake is limited by the available soil water.

The actual ET, denoted $ET_{c,act}$ or ET_a here, is the ET rate that occurs under actual field conditions. The value of $ET_{c,act}$ may be less than the value of the potential ET_c , sometimes denoted $ET_{c,pot}$, when water stress occurs in the vegetation. $ET_{c,act}$ or ET_c is calculated as

$$ET_{c,act} = ET_c = K_c ET_{ref} \quad (57.42)$$

Both $ET_{c,act}$ and ET_c (and $ET_{c,pot}$) can include varying degrees of direct evaporation from the soil, as represented by the evaporation coefficient K_e .

Basal Crop Coefficients

Basal crop coefficients mainly represent the transpiration component of ET, although they also incorporate

a small evaporation component from soil that is visually dry at the surface. It is necessary to adjust for wet soil effects after rain or irrigation when using these coefficients, as this leads to better daily estimates of ET_c for use in soil water modeling than achieved using mean coefficients, where the effects of local rainfall or irrigation frequencies are averaged. The total crop coefficient K_c is computed from K_{cb} as

$$K_c = K_s K_{cb} + K_e, \quad (57.43)$$

where K_s is a dimensionless coefficient that is dependent on the available soil water and K_e is a coefficient to account for the increased evaporation from wet soil immediately after rain or irrigation. The value of K_s is 1 unless the available soil water limits transpiration, in which case it is less than 1. The values of K_e represent the spikes shown in Fig. 57.3. The estimation of K_e for bare soil conditions is described later in this chapter; see (57.45)–(57.47).

Evaporation from Soil

Evaporation from bare soil is often divided temporally into two or three stages characterized by different limitations on the evaporation process and rate. Ritchie and others [57.88] defined stage 1 evaporation as the rate of evaporation following wetting, when the evaporation rate is limited by energy availability. During stage 1, the soil is sufficiently wet that water is transported to the surface at a rate that is at least equal to the evaporation potential. The duration of stage 1 and the amount of water evaporated are related to the hydraulic conductivity and water-holding capacity of the soil and the evaporative conditions. In stage 2, the surface soil water content has decreased to a level at which the hydraulic capacity of the soil is unable to supply the potential-energy-limited rate. The evaporation rate progressively decreases during stage 2, often in proportion to the square root of time [57.89, 90]. Occasionally, with deep-cracking soils, there is a third evaporation stage in which there is a low rate of evaporation of water exposed by deep cracks over a long period [57.75, 91–93].

The duration of stage 1 can range from one to several days after rainfall or irrigation, depending on the amount of water applied and the soil and evaporative conditions present. The total depth of cumulative evaporation during stage 1, referred to as the readily evaporable water (REW) in the FAO 56 procedure [57.2], varies with soil type. The REW can be estimated from Table 57.8 based on recommendations in [57.94], or using methods presented in [57.53, 88], where cumulative amounts of stage 1 evaporation for four soils are reported, ranging from 6 mm for sand to 12 mm for a clay loam. Stage 2 evaporation is often said to begin when

Table 57.8 Typical values of the evaporation parameter REW for different soil types (for more on the US soil texture classification, see Chap. 5) [57.2]

Soil type	REW (mm)
Sand	2–7
Loamy sand	4–8
Sandy loam	6–10
Loam	8–10
Silt loam	8–11
Silt	8–11
Silty clay loam	8–11
Silty clay	8–12
Clay	8–12

the soil surface becomes visibly dry for most of the day. Local observations of the REW are recommended.

E for stage 1 drying can be estimated using

$$E_1 = K_{e\max} ET_{\text{ref}}, \quad (57.44)$$

where the reference ET represents the potential evaporation energy. E_1 can change daily, depending on the value of ET_{ref} . $K_{e\max}$ generally ranges from 1.05 to 1.2 when used with ET_o and from 0.8 to 1.0 when used with ET_r , depending on the ambient temperature of the soil prior to wetting, as heat stored in hot, dry soil prior to wetting may contribute to the evaporation rate. When the total E_1 during stage 1 exceeds the REW, stage 1 ends and stage 2 begins.

The FAO 56 [57.2] evaporation procedure calculates the water balance for the effective evaporation layer of the soil (Z_e), which tends to be approximately 0.1–0.15 m in depth. This method represents a compromise between complexity and general application, as it assumes that the upward flux of water or vapor into this layer from below is small, or that its effects are incorporated into the effective depth of Z_e , which dries to a threshold dryness point. The threshold point is taken as the mean soil water content halfway between the air-dry and wilting points. This is an arbitrary dry point, but it is straightforward to utilize this point in the field, and it is reproducible. The maximum depletion depth for the layer provides a consistent stopping point for the evaporation cycle to ensure conservation of mass, and can be customized for each application to fit observations. Z_e is typically the upper 0.1–0.15 m during the first three or four weeks of a drying event, but potentially increases to depths of 0.2–0.25 m for longer time periods between wetting events.

The general FAO model for K_e in stage 2 is

$$K_e = K_r (K_{c\max} - K_s K_{cb}), \quad (57.45a)$$

such that

$$K_e \leq f_{ew} K_{c\max}, \quad (57.45b)$$

where $K_{c\max}$ is the maximum value of K_c for wet vegetated conditions following rain or irrigation and K_r is a dimensionless evaporation reduction coefficient (0–1). K_r is expressed as a function of the cumulative depth of water depleted by evaporation from the soil. f_{ew} is the fraction of the soil surface from which most of the evaporation occurs, which is generally taken to be the fraction of the soil surface that is both wetted during the wetting event and exposed to drying. The use of the cumulative depth of evaporation to estimate K_r stretches out drying periods when ET_{ref} is low and shortens them when ET_{ref} is high. The daily water balance of the effective surface evaporation layer is required. In (57.40), energy consumption through transpiration is preferred to energy consumption through evaporation from the soil. $K_s K_{cb}$ is set to 0 when (57.40) is applied to completely bare soil.

$K_{c\max}$ is the maximum value of K_c following rain or irrigation for both bare soil and soil with some degree of vegetation cover. The value of $K_{c\max}$ is governed by the amount of energy available to evaporate water, which is largely encapsulated by the reference ET_{ref} . Because K_c is the ratio of ET to ET_{ref} , the value of $K_{c\max}$ is not expected to exceed 1.0–1.3 for the grass reference or approximately 1.05 for the alfalfa reference. For the grass reference, the value varies with the general climate [57.2, 95]. When it is applied with ET_o , $K_{c\max}$ is adjusted for the effects of air dryness and wind speed via

$$K_{c\max o} = \max \left\{ 1.2 + [0.04(u_2 - 2) - 0.004(R_{\min} - 45)] \left(\frac{h}{3} \right)^{0.3}, (K_{cb o} + 0.05) \right\}, \quad (57.46)$$

where u_2 is the average wind speed at 2 m, R_{\min} is the average daily minimum relative humidity (%), and h is the mean plant height (m) during the growth stage or period (initial, development, midseason, or late season). $K_{c\max o}$ denotes the use of $K_{c\max}$ with ET_o , and K_{cbo} denotes the use of K_{cb} with ET_o .

$K_{c\max}$ for the tall reference ET_r , denoted $K_{c\max r}$, does not need to be adjusted for the climate due to the increased roughness of the alfalfa reference basis. Thus,

$$K_{c\max r} = \max[1.0, (K_{cb r} + 0.05)], \quad (57.47)$$

where K_{cbr} denotes a basal K_{cb} that is used with ET_r . Equations (57.46) and (57.47) require that $K_{c\max}$ is greater than or equal to the sum $K_{cb} + 0.05$, suggesting that K_c exceeds K_{cb} by at least 0.05 following complete wetting of the soil surface, even during periods of full ground cover.

Assuming that the soil is at field capacity (θ_{fc}) shortly after rainfall or irrigation, and that it can dry to halfway between 0 and the wilting point (θ_{wp}), the total amount of water that can be evaporated from the effective evaporation layer during a drying cycle can be estimated as

$$TEW = 1000(\theta_{fc} - 0.5\theta_{wp})z_e, \quad (57.48)$$

where TEW is the total evaporable water in mm, θ_{fc} and θ_{wp} are in $m^3 m^{-3}$, and z_e is the effective depth (in m) of the surface layer dried by evaporation. The value of θ_{fc} in (57.48) may be set a few percentage points above the normal values listed in Table 57.9 to compensate for the extra soil water retained in the evaporation layer above θ_{fc} for a few days after wetting.

The cumulative depth of evaporation D_e at the end of stage 1 is the readily evaporable water (REW), which normally ranges from 5 to 12 mm depending on the soil texture [57.88]. During the falling rate stage, where $D_e > REW$, the evaporation rate is estimated as a proportion of the amount of water remaining in the surface soil layer, and K_r in (57.45) from [57.53] is calculated via

$$K_r = F_{stage 1} + (1 - F_{stage 1}) \times \max \left[\min \left(\frac{TEW - D_{e(i-1)}}{TEW - REW}, 1.0 \right), 0.0 \right], \quad (57.49)$$

where $D_{e(i-1)}$ is the cumulative depth of evaporation at the end of timestep $i-1$ (the previous timestep), and $F_{stage 1}$ is the fraction of the timestep (day or hour) during which there is stage 1 evaporation (i.e., stage 2 evaporation occurs during $1 - F_{stage 1}$ of the timestep). The max and min functions limit the value of K_r to $0 \leq K_r \leq 1.0$.

According to [57.96], $F_{stage 1}$ can be approximated as

$$F_{stage 1} = \frac{REW - D_{REW, i-1}}{K_{e\max} ET_{ref}}, \quad 0 \leq F_{stage 1} \leq 1.0, \quad (57.50)$$

where the timestep can be a day, a tenth of a day, or one hour in length. $D_{REW, i-1}$ is the depletion (in mm) of the upper soil surface layer (the *skin* layer) that directly contributes to stage 1 drying at the end of timestep $i-1$, and $K_{e\max}$ is the expected value of K_e during stage 1 drying. $K_{e\max}$ can typically be set equal to $K_{c\max}$, as defined earlier. $F_{stage 1}$ is limited to the range $0 \leq F_{stage 1} \leq 1.0$. The water balance equation for determining D_{REW} is given later in this chapter; see (57.54). Figure 57.5 illustrates three distinct soil profile layers in the presence of plants: the skin layer, the total evaporation layer z_e ,

and the root zone depth z_r . Each layer is a subset of the next layer down in the FAO 56 model, which is different from most layered soil water models.

In the FAO 56 dual K_c model described in (57.2), f_w (the fraction of the surface wetted by irrigation and/or precipitation) is used to limit the potential spatial extent of evaporation. When the soil surface is completely wetted by precipitation or a sprinkler, the fraction of exposed wetted soil f_{ew} is set equal to $(1 - f_c)$, where f_c is the fraction of the soil surface that is effectively covered by vegetation. For irrigation systems where only a fraction of the ground surface is wetted (f_w), f_{ew} is limited to f_w and

$$f_{ew} = \min(1 - f_c, f_w). \quad (57.51)$$

For numerical stability, both $(1 - f_c)$ and f_w are limited to the range 0.01–1. f_c (and thus f_{ew}) can be estimated using a general relationship between f_c and K_{cb} given in FAO 56,

$$f_c = \left(\frac{K_{cb} - K_{c \min}}{K_{c \max} - K_{c \min}} \right)^{1+0.5h}, \quad (57.52)$$

where $K_{c \min}$ is the minimum (basal) K_c for dry bare soil with no ground cover and h is the height of the vegetation in m. The differences $K_{cb} - K_{c \min}$ and $K_{c \max} - K_{c \min}$ are limited to ≥ 0.01 for numerical stability. The value of f_c can change daily as K_{cb} fluctuates. $K_{c \min}$ ordinarily has the same value as K_{cb} during the initial growth period of vegetation, which has a dormant period and a leaf-off period when the soil is almost bare (i.e., $K_{c \min} \approx 0.10-0.15$). $K_{c \min}$ is set to zero or nearly zero in scenarios where there are long time periods between wetting events (e.g., in applications involving natural vegetation in deserts). The value of f_c decreases during the late season in proportion to K_{cb} to account for the local transport of sensible heat from senescing leaves to the soil surface. The FAO 56 dual K_c model can be applied using both references (ET_0 and ET_r) provided the K_{cb} values used in the procedure are associated with the specific reference.

The estimation of K_e requires daily (or even more frequent) water balance data for the fraction f_{ew} of the surface soil layer, i.e.,

$$D_{e,i} = D_{e,i-1} - \left[(1 - f_b) \left(P_i - RO_i + \frac{I_i}{f_w} \right) + f_b \left(P_{i+1} - RO_{i+1} + \frac{I_{i+1}}{f_w} \right) \right] + \frac{E_i}{f_{ew}} + T_{ei,i}, \quad (57.53)$$

where $D_{e,i-1}$ and $D_{e,i}$ are the cumulative depletion depths (in mm) at the end of day $i-1$ and the end of day i , respectively; P_i and RO_i are the precipitation and the precipitation runoff from the soil surface on day i

(both in mm); I_i is any irrigation depth on day i that infiltrates the soil (in mm); E_i is the evaporation on day i (i.e., $E_i = K_e ET_{ref}$) (in mm); $T_{ei,i}$ is the depth of transpiration from the exposed and wetted fraction of the soil surface layer on day i (in mm); and f_b is the fraction of the precipitation and irrigation that occurs during a calculation timestep (hour or day) which is assumed to contribute immediately to evaporation during the same timestep ($1 - f_b$ of the precipitation and irrigation does not contribute to the evaporation until the following timestep, on average). The value of f_b is limited to the range 0–1.0; if its value is not known, it can be set to 0.5. f_b effectively controls the immediacy of evaporation from a wetting event, which may occur at an unknown time within the calculation timestep (e.g., nighttime precipitation events during a daily timestep). Variables with subscripts of $i+1$ correspond to values for the timestep following the current timestep i . Assuming that the surface layer is at field capacity following heavy rain or irrigation, the minimum value for $D_{e,i}$ is zero. The values of $D_{e,i}$ and $D_{e,i-1}$ are constrained to $0 \leq D_{e,i} \leq TEW$. Any P or I additions in excess of $D_{e,i}$ and $D_{REW,i}$ in (57.54) are assumed to infiltrate to depths below z_e (or below the skin in the case of $D_{REW,i}$).

Dividing the irrigation depth I_i by f_w gives the approximate depth of infiltration into the wetted portion f_w of the soil surface. Similarly, E_i is divided by f_{ew} because all E_i other than the residual evaporation implicit to K_{cb} is assumed to be taken from the exposed fraction f_{ew} of the surface layer.

The parameter $D_{REW,i-1}$ in (57.50) is the depletion of water from the REW layer, also referred to as the skin layer, at the end of the previous timestep ($i-1$). Equation (57.50) estimates F_{stage1} in order to simulate any stage 1 evaporation that may occur from light or heavy wetting events. The calculation of $D_{REW,i}$ is designed to be forward-looking with regard to the wetting event, so that the soil surface wetting and corresponding evaporation from a wetting event occurring during the current timestep i are considered. Therefore,

$$D_{REW,i} = D_{REW,i-1} - \left[(1 - f_b) \left(P_i - RO_i + \frac{I_i}{f_w} \right) + f_b \left(P_{i+1} - RO_{i+1} + \frac{I_{i+1}}{f_w} \right) \right] + \frac{E_i}{f_{ew}}, \quad (57.54)$$

where $D_{REW,i-1}$ and $D_{REW,i}$ are the cumulative depletion depths (in mm) at the end of day $i-1$ and the end of day i , respectively; all other terms have the same definitions as in (57.53). The values of $D_{REW,i}$ and $D_{REW,i-1}$ are constrained to the range $0 \leq D_{REW,i} \leq REW$.

For shallow-rooted annual crops with rooting depths of less than about 0.5 m and in the absence of

deep cultivation, T_e , fed by lateral extraction by plant roots, may significantly affect the water balance of the surface layer and therefore the estimation of the evaporation component during the development period. An extension to FAO 56 proposed in [57.95] estimates T_e from the exposed fraction f_{ew} of the evaporation layer as a proportion of the water content of that layer. In this extension,

$$T_e = K_t K_s K_{cb} ET_{ref}, \quad (57.55)$$

where K_t (range: 0–1) is the proportion of the basal ET ($= K_{cb} ET_{ref}$) extracted as transpiration from the exposed fraction f_{ew} of the surface soil layer. K_s is the soil water stress factor computed for the root zone (range: 0–1). K_t is determined in proportion to the relative water availability in the layers z_e and z_r (the root zone; recall that z_e is a subset of z_r) along with the presumed rooting distribution. For f_{ew} ,

$$K_t = \frac{1 - D_e/TEW}{1 - D_r/TAW} \left(\frac{z_e}{z_r} \right)^{0.6}, \quad (57.56)$$

where TAW is the total depth of available water in the root zone that can be extracted by roots before any stress occurs. The numerator and denominator of the first expression are limited to values ≥ 0.001 , and the value of K_t is limited to ≤ 1.0 . z_e and z_r have the same units. D_r is the depletion of the total effective root zone, estimated as $D_r = (\theta_{fc} - \theta)z_r$, where θ is the mean volumetric soil water in the root zone (in $\text{m}^3 \text{m}^{-3}$). In the simple water balance procedure described in FAO 56, the soil water content of the surface layer is assumed to

be limited to $\leq \theta_{fc}$ on the day of a wetting event that is larger in depth than REW. This is a reasonable assumption considering the shallowness of the surface layer.

Adjustment for Water Stress

Several linear and curvilinear functions have been proposed to account for the influence of the available water on the ET or for the K_s used in (57.37) and (57.39). A commonly used simple linear model for estimating K_s is [57.97]

$$K_s = \frac{\theta - \theta_{wp}}{\theta_t - \theta_{wp}} \quad \text{for } \theta < \theta_t, \quad (57.57)$$

where θ is the mean volumetric soil water in the root zone (in $\text{m}^3 \text{m}^{-3}$) and θ_t is the threshold θ below which transpiration decreases linearly due to water stress. $K_s = 1.0$ for $\theta \geq \theta_t$. The wilting point θ_{wp} is the soil water at the lower limit of soil water extraction by plant roots (in $\text{m}^3 \text{m}^{-3}$). Typical values of θ_{wp} and θ_{fc} for various soil texture classes are listed in Table 57.9. The threshold soil water θ_t can be estimated from the relationship

$$\theta_t = (1 - p)(\theta_{fc} - \theta_{wp}) + \theta_{wp}, \quad (57.58)$$

where p is the average fraction of available soil water that can be depleted before water stress arises and ET decreases. All θ parameter values are averages over the effective root zone.

Parameter p normally ranges from 0.30 (i.e., 30% depletion of the available soil water, $\theta_{fc} - \theta_{wp}$) for shallow-rooted plants at high rates of ET_c ($> 8 \text{ mm d}^{-1}$)

Table 57.9 General soil water classes for agricultural soils (the water contents are given on a volume basis) [57.53]

Texture class	Field capacity		Permanent wilting point		Available water	
	Average range		Average range		Average range	
	(%)	(%)	(%)	(%)	(%)	(%)
Coarse						
Sand	12	7–17	4	2–7	8	5–11
Loamy sand	14	11–19	6	3–10	8	6–12
Moderately coarse						
Sandy loam	23	18–28	10	6–16	13	11–15
Medium						
Loam	26	20–30	12	7–16	15	11–18
Silt loam	30	22–36	15	9–21	15	11–19
Silt	32	29–35	15	12–18	17	12–20
Moderately fine						
Silty clay loam	34	30–37	19	17–24	15	12–18
Fine						
Silty clay	36	29–42	21	14–29	15	11–19
Clay	36	32–39	21	19–24	15	10–20

to 0.70 (i.e., 70% depletion of the available soil water) for deep-rooted plants at low rates of ET_c ($< 3 \text{ mm d}^{-1}$) [57.2, 53, 98]. A value of 0.50 is commonly used for many agricultural crops.

The mean soil water balance for the root zone can be computed on a daily basis in terms of θ using

$$\begin{aligned} \int_0^{z_r} \theta_{2z} dz &= \int_0^{z_r} \theta_{1z} dz + \Delta \theta_{z_r} \\ &= \int_0^{z_r} \theta_{1z} dz + P - Q_t - ET_a - DP + GW, \end{aligned} \quad (57.59)$$

where $\theta_{1(z)}$ is the volumetric water content to depth z ($\text{m}^3 \text{ m}^{-3}$) at time $t = 1$, $\theta_{2(z)}$ is the volumetric water content to depth z ($\text{m}^3 \text{ m}^{-3}$) at time $t = 2$, and z_s is the effective depth of the root zone (mm). Generally, the deep percolation flux density is estimated using the field capacity of the soil. θ_{fc} represents the water content that the soil will attain after draining under a unit hydraulic gradient (gravity) for 2–3 days after wetting, which represents the upper limit of the soil's ability to retain water after initial rapid drainage. The available water is calculated as $AW = \theta_{fc} - \theta_{wp}$. Where possible, specific values for θ_{fc} and θ_{wp} should be determined from field studies [57.99].

When the calculation timestep for (57.59) is 1 day, DP is often assumed to occur if the total θ of the root zone is greater than θ_{fc} on any particular day. In this case,

$$\begin{aligned} \text{if } & \int_0^{z_s} \theta_{2(z)} dz > \theta_{fc} z_s, \\ \text{then } & DP = \int_0^{z_s} \theta_{2(z)} dz - \theta_{fc} z_s \\ & \text{and } \theta_{2(z)} = \theta_{fc} \text{ from } 0 \text{ to } z_s; \\ \text{otherwise } & DP = 0. \end{aligned} \quad (57.60)$$

One may wish to delay applying (57.60) until two days after a major precipitation or irrigation event to account for the ET of water above θ_{fc} during the first two days while the soil profile is draining to field capacity. When it is applied to layered soils with different water-holding characteristics, the term $\theta_{fc} z_s$ can be replaced with an integral of θ_{fc} from 0 to z_s to account for the variation of θ_{fc} with z . Computations are performed for the complete root depth z_r , including the evaporation layer.

Capillary rise (CR). The amount of water transported upward by capillary rise (or GW) from the water

table to the root zone or soil surface depends on the soil type, the depth of the water table, and the wetness of the root zone. CR can normally be assumed to be zero when the water table is more than a few meters below the bottom of the root zone. Medium-textured soils tend to have higher upward fluxes than fine- and coarse-textured soils due to a favorable combination of capillarity and hydraulic conductivity. The equations that are used to estimate the CR for a range of soil textures are presented in [57.53].

Values for Basal Crop Coefficients

Extensive tables of K_{cb} for agricultural crops and for some forms of natural vegetation are available on the Internet; for example, those provided by FAO [57.2]. The FAO approach is to construct a simple linear curve of K_{cb} piecewise, as demonstrated in Fig. 57.5.

The procedure for constructing crop (cover) coefficients is presented in [57.2, 24]. In the FAO procedure, a K_{cb} curve such as that shown in Fig. 57.4 is constructed by:

- Dividing the growing season into four parts corresponding to distinct crop phenology or growth stages:
 - Initial period (1)
 - Crop development period (2)
 - Midseason period (3)
 - Late-season period (4)
- Selecting three K_{cb} values that represent:
 - The average K_{cb} during the initial period ($K_{cb\text{ini}}$)
 - The average K_{cb} during the midseason period ($K_{cb\text{mid}}$)
 - The average K_{cb} at the end of the late season (i.e., around harvest or leaf-fall) ($K_{cb\text{end}}$)
- Drawing a straight line through the points in each period (the lines through the initial and midseason periods are horizontal).

Only three tabularized values of K_{cb} are required to describe and construct an FAO-style K_{cb} curve. $K_{cb\text{mid}}$ represents the average value of K_{cb} expected during the midseason period, rather than the absolute peak daily K_{cb} presented by the crop or other vegetation.

The four vegetation growth stages generally correlate with benchmark growth stages. The initial period is from the planting or greening of vegetation to the attainment of 10% ground cover. The crop development period corresponds to the increase in ground cover from 10% to effective cover (i.e., 80% or more shading of the ground or the initiation of flowering for many vegetation types). The midseason period stretches from the attainment of effective cover to the start of senescence (browning of leaves), while the late-

Fig. 57.5 FAO crop coefficient curve and stage definitions (after [57.75] republished with the permission of the American Society of Civil Engineers)

season period is from the start of maturity to harvest or complete leaf death. The length of the initial period is strongly dependent on the type of vegetation present and the time of year. Trees have a relatively short initial–development period of only a few days to a week, whereas broadleaved annuals may have an initial–development period of more than a month. The start of the late period is often indicated by the onset of leaf aging, yellowing, or senescence, or fruit browning.

This approach to identifying generalized values for K_{cb} is most successful for agricultural crops due to the height uniformity and consistent stand density of this vegetation, as well as the reproducibility of the canopy characteristics from region to region. Natural vegetation systems present more of a challenge when attempting to specify universal values for K_{cb} . Such K_{cb} values are more likely to be useful when canopy characteristics such as the fraction of ground cover and the height as well as the relative stomatal resistance are used to estimate an expected value [57.100], or when (57.52) is inverted and solved for K_{cb} .

Estimated K_c Curves for Natural and Agricultural Vegetation

The two-step $K_c ET_{ref}$ approach provides a simple and convenient way to estimate ET_c from natural vegetation, where, if necessary, K_c can be estimated from the fraction of the ground that is covered by vegetation. The resulting cover (crop) coefficient curves represent the ratio of ET_c to ET_{ref} during various growth stages. The previous section described the estimation of growth stage durations. Often, when the K_c curve is not available, the K_c during the peak growth period ($K_{c\ mid}$) can be estimated from the amount of ground shaded by veg-

etation, the plant density and height, and the amount of stomatal regulation under moist soil conditions. When soil water availability is low, the value of K_c is generally determined using (57.57) coupled with (57.43).

The K_c development process should adhere to the upper limit for K_c of 1.1 with an alfalfa reference and about 1.25 with a grass reference for stands of vegetation larger than 500–2000 m² in order to adhere to energy-exchange principles within established equilibrium boundary layers. When there are *clothesline effects* (i.e., the vegetation is higher than its surroundings) or *oasis effects* (the vegetation has higher soil water availability than its surroundings), the peak K_c may exceed these limits.

The value of $K_{c\ mid}$ for natural vegetation decreases when the plant density or leaf area is less than that required for full ground cover, which is often taken to be when $LAI < 3$. $K_{c\ mid}$ can be expressed as a function of the density coefficient K_d , [57.100], where

$$K_{cb\ mid} = K_{c\ min} + K_d (K_{cb\ full} - K_{c\ min}) . \quad (57.61)$$

Here, $K_{cb\ mid}$ is the approximation for K_{cb} during the midseason period, $K_{cb\ full}$ is the estimated basal K_c during peak plant growth when there is almost full ground cover (or $LAI > 3$), and $K_{c\ min}$ is the minimum basal K_c for bare soil ($K_{c\ min} \approx 0.15$ under typical agricultural conditions and ≈ 0.0 – 0.15 for native vegetation, depending on the rainfall frequency). The density coefficient K_d can be estimated as a function of the measured or estimated leaf-area index LAI or as a function of the fraction of the ground that is covered by vegetation. For trees or forest with grass or some other ground cover beneath the primary tree canopy, (57.61)

can take the form [57.53, 100]

$$K_{cb\,mid} = K_{cb\,cover} + K_d \left[\max \left(K_{cb\,full} - K_{cb\,cover}, \frac{K_{cb\,full} - K_{cb\,cover}}{2} \right) \right], \quad (57.62)$$

where $K_{cb\,cover}$ is the K_{cb} of the ground cover in the absence of tree foliage. The second term of the max function reduces the estimate for $K_{cb\,mid}$ by half of the difference between $K_{cb\,full}$ and $K_{cb\,cover}$ when this difference is negative. This accounts for the impact of surface shading by vegetation with a lower K_{cb} than that of the ground cover due to differences in stomatal conductance. Equation (57.61) can be applied to estimate K_{cb} during other periods besides the midseason by estimating K_d using (57.65) and (57.66) along with the LAI or $f_{c\,eff}$ for that period.

For large vegetation stands ($\approx 500\text{ m}^2$) where the crops are not listed in the literature, the $K_{c\,full}$ used with ET_o can be approximated as a function of the mean plant height and adjusted for climate similar to the $K_{c\,mid}$ parameter [57.2], as shown below.

For ET_o ,

$$K_{cb\,full} = \min(1.0 + 0.1h, 1.20) + [0.04(u_2 - 2) - 0.004(R_{min} - 45)] \left(\frac{h}{3} \right)^{0.3}, \quad (57.63)$$

and for ET_r ,

$$K_{cb\,full} = \min(0.8 + 0.1h, 1.0), \quad (57.64)$$

where the parameters are defined as in (57.46). The climatic correction is not required for $K_{cb\,full}$ when it is used to derive the K_{cb} for ET_r because of the aerodynamic and canopy characteristics of the alfalfa reference crop.

$K_{c\,full}$ represents a general upper limit on $K_{cb\,mid}$ for tall vegetation with full ground cover and $LAI > 3$ under a full water supply. Equations (57.65) and (57.66) yield general approximations for the increase in $K_{cb\,full}$ with plant height and climate.

When LAI can be measured or approximated, K_d can be approximated under normal conditions [57.2] as

$$K_d = 1 - e^{(-0.7LAI)}. \quad (57.65)$$

The LAI is defined as the area of leaves per area of ground surface averaged over a large area, in units of $\text{m}^2\text{ m}^{-2}$. Only one side of healthy green leaves that are active in vapor transfer is considered. The relationship in (57.65) is similar to that used in [57.101].

When estimates of the fraction of the ground surface covered by vegetation are available, K_d can be estimated as [57.100]

$$K_d = \min \left[1, M_L f_{c\,eff}, f_{c\,eff}^{\left(\frac{1}{1+h}\right)} \right], \quad (57.66)$$

where M_L is a multiplier (range: 1.5–2.0) of $f_{c\,eff}$ that encompasses the effects of canopy density and conductance on the maximum relative ET per fraction of the ground shaded, $f_{c\,eff}$ is the effective fraction of the ground that is covered or shaded by vegetation near solar noon (range: 0.01–1), and h is the mean height of the vegetation in m. For canopies such as trees or randomly planted (i.e., not in rows) vegetation, $f_{c\,eff}$ can be estimated according to [57.2] via

$$f_{c\,eff} = \frac{f_c}{\sin(\beta)} \leq 1, \quad (57.67)$$

where β is the mean angle of the sun above the horizon during the period of maximum ET (generally between 11.00 and 15.00). $f_{c\,eff}$ can generally be assigned to solar noon (12.00), so β can be calculated as

$$\beta = \arcsin [\sin(\phi) \sin(\delta) + \cos(\phi) \cos(\delta)], \quad (57.68)$$

where ϕ and δ are the latitude and solar declination, respectively (Chap. 5).

M_L , the multiplier of $f_{c\,eff}$ in (57.66), imposes an upper limit on the relative magnitude of transpiration per unit of ground area as represented by $f_{c\,eff}$ [57.2], and is expected to range from 1.5 to 2.0, depending on the canopy density, thickness, and maximum conductance. M_L is an attempt to simulate the physical limits imposed on the water flux through the plant root, stem, and leaf systems [57.100]. The value of M_L can be modified to fit the specific vegetation. K_d values for a range of $f_{c\,eff}$ and h values and for $M_L = 1.5$ and $M_L = 2$ when $h = 5\text{ m}$ are shown in [57.100].

When the mean stomatal control exerted by the vegetation is greater than that for agricultural vegetation, then FAO 56 [57.2] suggests that the estimate obtained using (57.65) and (57.66) should be reduced by about 10 or 20% for each doubling of r_1 above 100 s m^{-1} . The value of $K_{cb\,mid}$ estimated from (57.62) is applied as a basal coefficient using the dual $K_{cb} + K_c$ method, where the actual K_c may increase to 1.0 for ET_r or 1.2 for ET_o following precipitation (even if the estimated $K_{cb\,mid}$ is small) due to surface evaporation from sparse vegetation. In addition, K_c should be reduced using K_s from (57.57) when the soil water is low.

Equation (57.66) suggests that as h increases, the total leaf area and resulting net radiation capture will increase, thereby increasing K_c . In addition, as h increases, there is more opportunity for the microadvection of heat from the soil to the canopy, and turbulent exchange within the canopy increases for the same amount of ground coverage. Both of these conditions increase the relative magnitude of $K_{cb, mid}$. Values of $K_{cb, end}$ can be scaled from $K_{cb, mid}$ in proportion to the health and leaf condition of the vegetation at termination as well as the length of the late-season period (i.e., whether leaves senesce slowly or are killed by frost). f_c and h are probably the simplest indices to estimate in the field. In [57.102], it was suggested that C3 photosynthetic behavior should be distinguished from C4 photosynthetic behavior when performing LAI- and f_c -based estimation, because C4 vegetation can have limited stomatal control. Equations (57.54)–(57.57) and (57.59) were applied in [57.103] to savannah vegetation in Ethiopia, and good agreement between the estimated ET and the ET measured gravimetrically was observed. Vegetation types ranged from sparse grazed grasses to the full forest canopy.

The techniques of this section can also be applied to landscaped systems such as those found in urban and residential environments, including lawns, gardens, and shade trees. Specific equations for the application of these techniques are given in [57.53, 76, 83], as are examples and tables.

Lengths of Growth Stages

FAO 24 [57.24] and FAO 56 [57.2] provide guidance regarding the durations of the growth (development) stages for various types of climates and locations. The rate of vegetative development and attainment of effective full cover is affected by the weather conditions, especially the mean daily air temperature [57.104]. Therefore, the length of time between planting or plant emergence and effective full cover for various crops or other vegetation will vary with climate, latitude, elevation, and planting date (if cultivated), as well as with species and cultivar (variety). Generally, once effective full cover has been reached for a plant canopy, the rate of phenological development (flowering, seed development, ripening, and the senescence or death of leaf tissue) often proceeds at a rate that depends on plant genotype rather than weather [57.81]. In some situations, the emergence of vegetation, greenup, and the attainment of effective full cover can be estimated using cumulative degree-based regression equations or plant growth models [57.38, 104–112]. The use of cumulative growing degree days allows the K_c curves generated for years or growing seasons that run cooler or warmer than average to be quantitatively stretched or compressed. K_c

curves are provided in [57.53]; those curves are based on the cumulative number of growing degree days.

Local observations of plant stage development should be utilized where possible, with tabular values used as a guide and for comparison. Local information can be obtained from farmers, ranchers, agricultural extension agents, local researchers, or remote sensing. When determining stage dates from local observations, the following guidelines may be helpful.

Effective full cover for annual vegetation is generally considered to occur when the leaves of plants in adjacent rows intermingle such that near-complete soil shading occurs near solar noon, or when the plants reach nearly full size if there is no intermingling and the plant cover is $> 75\%$ [57.81]. Incomplete ground cover may occur due to reductions in plant growth caused by disease, grazing, pests, soil water stress, or cultural practices that call for vegetation-free strips between crop rows.

Because it is difficult to visually determine when dense vegetation such as grasses and cereals have reached effective full cover, the more easily detectable stage of heading has been used [57.81]. For dense grasses, effective full cover will occur at a height of about 0.10–0.15 m. For thin stands of grass (dry rangeland), the grass height may approach 0.3–0.5 m before effective full cover is reached. Densely planted forages reach effective full cover at a height of about 0.3–0.4 m. For many agricultural plants, effective full cover is considered to occur when the leaf area index (LAI) approaches 3.0 [57.81, 88, 104, 113, 114].

57.3.10 Remote Sensing for Estimating Evapotranspiration

Techniques for determining E and ET from both local and large areas using the energy balance and ground-based, aerial, and satellite imaging have been available since about 1990 [57.76, 115–125]. Remote-sensing techniques are inference techniques, rather than direct measurements of ET. The emerging field of energy balance determination using satellite imaging is showing substantial promise, and has already been used to quantify and demonstrate the variance in ET for the same vegetation type, and even to refine crop (or cover) coefficient curves [57.76, 125–127]. Remotely sensed energy-balance techniques are useful for identifying areas that are experiencing water stress and the corresponding reductions in ET. The use of thermal imaging by satellite systems to estimate [57.120, 123] the stress-limited ET and the ability of satellites to view the signatures of evaporation from wet soil are reviewed in [57.128, 129]. Those reviews discuss the constraints caused by the resolution of satellite images and derived

ET images. The Landsat system currently provides the highest-resolution images (pixel size: 30 m), repeat coverage, and thermal images. 16 day return coverage is needed to follow the evolution of vegetation development and increases or decreases in water stress. The Landsat thermal archive covers a period of more than 35 years, beginning in 1982.

Many satellite-based energy-balance models for determining ET solve (57.7) for Q_E or solve (57.39) for Q_H [57.76, 116, 119, 126, 129, 130]. For example, the remote-sensing-based models SEBAL (Surface Energy Balance Algorithms for Land) [57.116, 131] and METRIC (Mapping Evapotranspiration at High Resolution Using Internalized Calibration) [57.124, 125] apply (57.39), estimating the difference $T_s - T_a$ or $\theta_{T2} - \theta_{T1}$ by indexing to the surface temperature: $\theta_{T2} - \theta_{T1} = a + bT_s$, where a and b are empirical coefficients that depend on the satellite image date and T_s is the surface temperature for each pixel in the satellite image. The relationship between $\theta_{T2} - \theta_{T1}$ and T_s is established in SEBAL and METRIC by inverse calibration under extreme (wet and dry) conditions to reduce the impact of biases in the estimates for net radiation, soil heat flux, and other parameters [57.124, 132, 133].

Other remote-sensing models apply the PM equation (57.32), estimating resistance parameters from vegetation indices and obtaining the vapor pressure deficit terms from weather measurements and iteration [57.134–136]. The advantage of the PM equation and other models is that they can be applied using routine hourly or daily weather data. This has several notable benefits: it incorporates the effects of precipitation and changing weather conditions on the total aggregated ET, and such data can be coupled with soil water balances to provide feedback on the water available for the ET process. On the other hand, a disadvantage of soil- and weather-based process models is the need to parameterize these models for large areas with wide variations in vegetation and surface conductance, water availability, and boundary-layer characteristics (air temperature, humidity, and wind speed). Biases in estimates are commonplace. Generally, the remotely sensed information is provided by satellites, given their vast surface coverage.

Consistent satellite coverage at moderate resolution (< 50 m pixel sizes) is generally only available from polar-orbiting satellites such as Landsat, Sentinel 2 SPOT (Satellite Pour l'Observation de la Terre), and QuickBird, so each location is imaged rather infrequently. Generally, the greater the spatial resolution (i.e., the smaller the pixel size), the longer the revisit time. On its own, such infrequent coverage may be insufficient to estimate the time-integrated ET [57.124]. However, even infrequent satellite imaging can greatly

improve estimates of surface albedo, surface temperature, surface roughness, and the partitioning of surface energy between latent and sensible heat fluxes. Coupling such data with an hourly or daily ET process model that may be based on the reference ET can markedly enhance the accuracy of the estimates provided by the model. The use of airborne thermal data for surface energy balance computations is becoming more prevalent [57.137, 138].

Remotely sensed measurements of surface reflectance and temperature were used in [57.139] to improve estimates of percent vegetation cover and canopy resistance before applying the PM equation to partially vegetated fields. The PM equation was combined with the energy balance equation to estimate the T_s values of surfaces characterized by full-cover vegetation and bare soil under potential and zero-evaporation conditions. T_s values from satellite data were linearly interpolated between full-cover and bare-soil conditions to provide information for intermediate states. Maps of surface air temperature and wind speed were combined with maps of surface temperature and spectral vegetation index to produce regional estimates of evaporation rates for a grassland biome.

The development of the two-source patch model TSEB (Two Source Energy Balance), which utilizes radiometric surface temperature inputs from satellites, surface reflectance, and vegetation indices to estimate ET from sparse canopies, is described in [57.119–123, 140].

The Mapping Evapotranspiration at High Resolution Using Internalized Calibration (METRIC) model [57.124] and its counterpart based on the Google Earth Engine, EEFlux (Earth Engine Flux), apply a full-surface energy balance to image products from thermally equipped satellites such as Landsat, MODIS (Moderate Resolution Imaging Spectroradiometer), and VIIRS (Visible Infrared Imaging Radiometer Suite, Chap. 42) to develop images of the fraction of alfalfa-reference ET, which are interpolated between satellite image dates using a spline function and then multiplied by the daily ET_r to produce time series of daily and monthly ET. Satellite-based mapping of ET provides valuable spatial information on within-field and field-to-field variations in ET [57.126, 133, 137, 138, 140], which will be increasingly utilized in water rights management, water transfers, and streamflow depletion studies, as well as to inform other ET models.

Equations (57.7) and (57.39) are commonly used in ground-based research studies to estimate ET. The technique works best for surfaces with uniform vegetation, where measurements of Q_s^* and Q_G are representative of the source areas of Q_H and Q_E . Additional challenges are associated with the measurement of T_s , as there are directional effects due to the position of the sun and

shading that complicate bulk surface temperature determination.

Simpler, easy-to-apply approaches have been used to estimate the basal K_{cb} or a mean value for K_c based on vegetation indices such as the normalized difference vegetation index (NDVI). The resulting K_{cb} or K_c is then multiplied by a ground-based calculation of ET_{ref} . Examples include [57.141–144]. One challenge when using direct vegetation indices to estimate ET is to detect the effects of soil water shortages, as these tend to reduce ET but may not affect the NDVI.

57.4 Devices and Methods

This section describes devices and methods associated with the determination of evaporation and evapotranspiration. More detailed discussions of these devices and methods are provided in other chapters. For eddy-covariance system measurements, see Chap. 55; for lysimeter measurements, see Chap. 58; for chamber measurements, see Chaps. 59 and 60; and for aerodynamic and modified Bowen ratio systems, see Chap. 54.

57.4.1 Measurement Devices

Specifications for measuring air temperature and near-surface humidity are covered in Chaps. 7 and 8. For the localized determination of evapotranspiration (ET), temperature and humidity measurements must be performed in the near-surface layer, where gradients are in equilibrium with the fluxes from the surface (Chap. 1). In other words, fluxes in the near-surface equilibrium layer should be constant in the vertical and horizontal directions, which requires sufficient fetch of a relatively uniform surface. This also applies to temperature, humidity, and wind velocity (Chap. 9) measurements used in the Penman and PM equations, where the measurements should reflect the flux characteristics of the surface, as described earlier. Some of the station types described in Chap. 43—mainly agrometeorological stations—can be employed for ET calculations. Compact sensors can also be used if the requirements for the measurement height are fulfilled.

Specifications for measurements of net radiation and ground heat flux are discussed in Chaps. 11 and 61. For these measurements, there must be a sufficient number of sensors to develop weighted averages of measurements that can highlight any heterogeneities in the vegetation and surface. Heterogeneities are caused by variations in vegetation densities and types in natural

57.3.11 Standardization

The American Society of Civil Engineers (ASCE) has standardized the calculation of the reference ET via the ASCE Penman–Monteith equation [57.74], utilizing most of the parameterizations from the international standardizations outlined by the Food and Agriculture Organization in FAO 56 [57.2]. Similar standards have been adopted in Germany by the Association of German Engineers [57.145] and the German Water Association [57.146].

systems and canopy variations in agricultural systems such as row architectures. For forested systems, net radiometers should be elevated well above the canopies, and the use of multiple sensors is recommended to obtain averages and to facilitate intercomparisons for error checking (see Chaps. 2 and 3). Ground heat flux sensors should be used in even greater numbers in heterogeneous systems since they provide point measurements. Sensor measurements should be weighted according to vegetation type and cover and the level of shading. Any systematic biases in net radiation and ground heat flux measurements will translate into direct systematic errors in latent heat fluxes determined by the Bowen ratio method, the eddy-covariance method (with forced closure), the Penman and Penman–Monteith equations, and residual methods such as (57.7).

Generally, it is best to carry out the measurements performed using the methods described in this section on an hourly basis (or even more frequently), so that the hourly variations in radiation, air temperature and humidity, wind speed, and ground conduction remain synchronized. For example, the air temperature and vapor pressure deficit often increase in the afternoon, when wind speeds are also larger. These parameters are often multiplicative in the methods described here. That said, although many of the methods are nonlinear, the use of daily or daytime averages for weather data can often provide sufficiently accurate estimates for evapotranspiration [57.74].

57.4.2 Class A Pan

The US Class A pan [57.17] is a round pan with a water surface area of 1.14 m² (diameter 120.65 cm, height 25.4 cm) (Sect. 57.3.1). The water should be 15.2–17.8 m deep; if it is not, the water level must be corrected. The water depth is measured in a cylinder connected to the water body, so that the measurements

Fig. 57.6 Class A pan with a cylinder to measure the water level; temperature and wind sensors are also present (photo provided courtesy of the Hong Kong Observatory of HKSAR)

are not affected by an uneven water surface. The height of the water level in the connected cylinder is measured using a needle connected to a micrometer screw gauge. Electrical systems are also available. The US Class A pan is shown in Fig. 57.6. Instruments for performing the required accompanying wind and temperature measurements are also visible in the figure. Measurements from an accurate rain gauge are necessary to correct the gross pan measurements. Additional maintenance precautions and physical effects are described in Sect. 57.6.1.

57.4.3 Bowen Ratio System

The Bowen ratio system consists of ventilated temperature (Chap. 7) and humidity (Chap. 8) sensors at two levels. Additional wind measurements at both levels are also recommended as a means to monitor

57.5 Specifications

The characteristics of the three primary measurement methods other than eddy covariance (Chap. 55) are summarized in Tables 57.10–57.12. The errors associated with the Bowen ratio and residual methods are evaluated assuming that the net radiometer measure-

57.6 Quality Control

Generally, all of the quality control procedures for sensors that are used to determine evapotranspiration are applicable to the methods of this chapter.

Fig. 57.7 Bowen ratio measurement system (photo © Campbell Scientific, Inc.)

the atmospheric turbulence [57.31]. A net radiometer (Chap. 11), soil temperature sensors, soil moisture sensors, and heat flux plates (Chap. 61) are also required. A commercially available instrument is shown in Fig. 57.7. The distance between the two levels should be as large as possible, but the lowest level should be at least 20 cm above the plant surface and the upper level should be below any possible internal boundary layers (Chap. 1 and Sect. 57.6.2).

ments are accurate (Chap. 11). Furthermore, the heat storage in the soil should be calculated very accurately (Chap. 61) to reduce the influence of the residual of the energy balance closure (Chap. 55).

Intercomparisons between instruments in terms of equation inputs and Q_E and Q_H are strongly encouraged. Intercomparisons can detect differences caused

Table 57.10 Characteristics of the three primary measurement methods other than eddy covariance according to Sects. 57.3.2–57.3.4

Criterion	Class A pan	Bowen ratio method [57.31]	Residual of the energy balance
Area of application	Applied research, short-time and continuously running programs		
Personnel required	Technical support	Partly continuous scientific and technical support	
User education required	Knowledge of measurement techniques	Knowledge of micrometeorology and measurement techniques	Knowledge of measurement techniques and radiation and convection physics
Error		10–30% (depending on the micrometeorological conditions, and assuming a closed energy balance)	
Sampling	Daily to weekly	1–10 s	
Time resolution of evapotranspiration	Daily to weekly	10–30 min	
Requirements for application	Grass in the surroundings	Sufficient footprint area, turbulent conditions	Surroundings with a homogeneous surface

Table 57.11 Potential areas of application of the simpler estimation approaches [57.31] according to Sects. 57.3.5–57.3.7

Criterion	Dalton approach	Turc approach	Penman approach	Priestley–Taylor approach
Defining quantity	Potential evaporation from free-water bodies	Potential evaporation from free-water bodies, possibly for well-watered meadows	Potential evaporation from free-water bodies and a reference ET representing well-watered conditions	Potential evaporation from free-water bodies or regional well-watered vegetation in the absence of advection
Area of application	According to the validity of the area-specific constants [57.51]	Mediterranean Sea, Germany (lowlands) with correction factor $k = 1.1$	Universally	Universally
Resolution of input parameters (min)	10–60 averages	10–60 averages	10–60 averages	10–60 averages
Representativeness of the results	(Daily), decadal, and monthly averages	Decadal and monthly averages	(Hourly, daily), decadal, and monthly averages	(Daily), decadal, and monthly averages
Error (%)	20–40	20–40	10–20	10–40

Criterion	Penman–Monteith approach [57.31]	AFIB approach	Remote-sensing approach
Defining quantity	Actual, potential, or reference evapotranspiration	Actual, potential, or reference evapotranspiration	Actual or potential evapotranspiration
Area of application	Universally	Universally	Universally
Resolution of input parameters (min)	3–60 averages and extremes	10–60 averages	10–60 averages combined with 24 h weather data
Representativeness of the results	Hourly and daily averages	Hourly and daily averages	Hourly and daily averages
Error (%)	10–30	10–25	10–30

by variations in manufacturer design, fabrication, and calibration, as well as differences between sensors of the same type caused by age, malfunction, or manufacturing variations. Care should be taken to stabilize the uniformity of the surfaces over which the intercomparisons are conducted. Error statistics for intercomparisons are provided in Chaps. 2 and 3.

In addition to intercomparisons, comparisons of measurements with independently derived estimates are encouraged. These include calculations of net radiation from individual shortwave and longwave components, comparisons of measured solar radiation with theoretical clear-sky solar radiation, and estimations of ground heat flux from a ground temperature balance. Remotely

sensed surface temperatures and reflectances can be useful for developing independent comparisons.

57.6.1 Class A Pan

Proper guidelines for the siting and maintenance of evaporation pans are not always followed closely. Care should be taken to locate pans in settings that are not obstructed by buildings, trees, fences, and tall vegetation. The pan should be surrounded by substantial evaporating surfaces such as well-watered grass out to a distance of ≥ 50 m. Some pans have screens placed on them to keep birds and animals from drinking the water. If used, the impact of such a screen on the evaporation rate should be quantified. The side and bottom surfaces of the pan must be kept clean so that they maintain their original reflection characteristics, and the water should be clear, with no turbidity due to dust or algae. Heating devices have been used to keep ice from forming on the pan in the spring and fall, thus facilitating observations during those seasons. When used, the energy input from the heating device should be quantified and used to adjust the calculated evaporation rate accordingly. Pans are sometimes moved to new locations that do not meet the criteria for a representative pan evaporation site. Differences in pan behavior should be monitored by performing the double mass balance or a similar technique [57.147].

57.6.2 Bowen Ratio System

Error analyses for the Bowen ratio method are widely available (see [57.31, 148–150] and references therein). However, many of these investigations have yielded unreasonable or faulty conclusions because they are based on either single measurements or false assumptions. Often, the electrical error of the sensor (about 0.01–0.001 K) is considered but the error associated with the adaptation of the sensor to the surrounding medium and atmosphere (which influence sensor readings through radiation, ventilation, and other effects) is ignored. It is possible to achieve differences of less than 0.05–0.1 K or hPa between sensors that are mounted close together and experience the same meteorological conditions, but this requires considerable effort and attention to measurement techniques and instrument placement. Therefore, errors in atmospheric temperature and humidity measurements are significantly higher than the electrical error alone [57.151].

The error plots given in Fig. 57.7, which are taken from [57.150], are based on an accepted measurement error of ± 0.05 K or hPa. From Fig. 57.7, we can see that an error of 20 or 40% in the Bowen ratio corresponds to an error of about 10 or 20% in the sensible and la-

Fig. 57.8 Dependence of the error in the Bowen ratio (20 or 40%) on the measured temperature and water vapor differences (after [57.150] with permission from the Austrian Meteorological Society)

tent heat flux, respectively. Examination of the three Bowen ratio values in Fig. 57.8 shows that the error is smallest when $Bo = 0.667$. To keep the error in the Bowen ratio down to $< 20\%$ ($< 40\%$), temperature and humidity differences must be > 0.6 (> 0.4) K or hPa. This underlines the need for a large distance between the measurement heights. Limitations result from internal boundary layers and possible roughness sublayers, which should be avoided within the measurement range (Chap. 1). Note that in this error analysis, the potential error due to energy imbalances caused by measurement and the estimation error in Q_s^* and Q_G are not taken into account. Utilizing systems that periodically interchange their temperature and humidity sensors can help to remove sensor bias.

57.6.3 Collection of Data for Calculation Methods

As previously discussed, quality control of the measurements used in ET calculation methods must consider the accuracy of the measurement itself and how representative the measurement is of the surface for which ET is calculated. Measurement accuracy is affected by sensor design and functioning as well as by the local environment of the sensor, including the effects of radiation shielding on air temperature measurements and local obstacles that may affect anemometer measurements.

It is important to remember that most ET and energy balance methods assume that the near-surface layer and surface are in equilibrium, so T , q , u , and Q_s^* must be measured over the target surface and with appropriate fetch. In nearly all cases, except for the reference

ET, weather data should be collected under ambient conditions in the equilibrated boundary layer. In dry climates, surface and boundary-layer measurements may exhibit the effects of reduced ET from the surface due to a shortage of soil water. Consequently, the air temperature is elevated and humidity is reduced compared to that above a well-watered surface.

However, the weather measurements performed to calculate the reference ET are somewhat different from those performed to estimate the ET under ambient conditions. For both the grass and alfalfa reference estimates yielded by the standardized PM method, the weather measurements are *expected* to be performed over well-watered clipped grass surfaces. Thus, the calculated ET_{ref} represents the ET rate that is expected to occur from an extensive and well-watered vegetated surface with the near-surface boundary layer in equilibrium, such that the Penman–Monteith combination equation is applicable.

However, meteorological datasets collected from true *reference* settings in agricultural locations are generally difficult to come by. Often, weather stations are located over or adjacent to annual row crops that may undergo a distinct annual growth and cover cycle, or stations may be placed over pasture land that is subject to seasonal deficits in soil moisture or is within the vicinity of small buildings, roadways, or dry airports. Many urban weather stations fail to comply with both the underlying surface requirement and the recommended separation distance from obstacles for reference ET estimation. The failure of a weather station site to meet the defined reference conditions does not preclude the use of the data to estimate ET_{ref} . However, data from such a station should be examined carefully before use, and may in some cases require adjustment to make it more representative of reference

conditions. New weather stations installed for the express purpose of estimating ET_{ref} should be located in sites that closely approximate the reference conditions expected by the PM reference equation. In addition, operators of agricultural weather stations should not be lulled into assuming that T and q measurements collected over small patches of grass, rather than over an extensive fetch, will fulfill the requirements of a reference weather station and produce weather data that accurately reflect the characteristics of the reference surface. These requirements recognize that the ET_{ref} method has been calibrated to utilize reference weather data. Further discussion of weather data quality and the location requirements when calculating ET_{ref} are given in [57.53, 74].

Accurate estimation of the evapotranspiration (ET) requires accurate and representative weather data. Combination equations such as the Penman–Monteith equation are relatively sensitive to the error in the weather data. This sensitivity varies depending on the time of year and the climate. During summer, solar radiation can dominate the ET estimate. Therefore, especially in humid and subhumid climates where the vapor pressure deficit/wind term of the PM is relatively small compared to the radiation term, the error in solar radiation measurements can have the greatest impact on the accuracy of the ET estimate. During wintertime, when there is less solar radiation, the wind speed and vapor pressure deficit can be strong drivers of the accuracy of the ET calculation. Errors in the wind speed and vapor pressure deficit can also dominate in arid and semiarid climates.

Quality assessment and quality control (QA/QC) are discussed for various input measurements in Chaps. 7–9 and 11. In addition, simple and rapid visual assessments of weather data are described in [57.2, 23, 53, 75]. The utilization of these methods is encouraged.

57.7 Maintenance

This section addresses the maintenance of the various sensors that are used to measure and calculate evapotranspiration. Further information on this topic is available in the relevant chapters: Chap. 7 (temperature), Chap. 8 (humidity), Chap. 9 (wind speed and direction), Chap. 11 (radiation), and Chap. 12 (precipitation). For more on combinations of sensors, see Chap. 43. The Class A pan and Bowen ratio measurement systems require system-specific maintenance, as described in Table 57.13.

Table 57.13 Maintenance requirements for the Class A pan and Bowen ratio methods, including the requirements for specific sensors ►

Maximum interval	Class A pan	Bowen ratio system
Daily	Check the water level	
Weekly	Control/cut the vegetation in the surroundings	Check the distance between the vegetation and the lowest measurement level Clean the radiation sensors
Monthly	Clean the pan	
Annually		Calibrate or replace the sensors

57.8 Application

The methods described in this chapter are widely used, and examples of their application can be found in several publications, along with operating and maintenance instructions. The following provides a few examples, primarily of comparisons between methods.

57.8.1 Comparison of the Bowen Ratio Method with the Eddy-Covariance Method and the Penman–Monteith Approach

The Bowen ratio method is based on the energy balance equation (57.3), and it implicitly assumes that the energy balance is closed at the Earth's surface and that the net radiation and soil heat flux measurements are accurate representations. This may not be true in heterogeneous landscapes [57.36]. Furthermore, the Bowen ratio method fails if $Bo = -1$ and (57.4) and (57.5) cannot be solved. Often, such data are replaced with a zero flux or an estimate from a calibrated combination equation, because these cases only occur during transition times in the morning and evening. The variation in the latent heat flux over a grassland over the course of a day obtained with the Bowen ratio method is shown in Fig. 57.9, as are the corresponding latent heat flux measurements provided by the eddy-covariance method. It is obvious that the energy balance is not closed for the site, given that the flux values from the eddy-covariance method are lower than those from the Bowen ratio method.

Fig. 57.9 Curves showing the variation in the latent heat flux over a grassland, obtained using the Bowen ratio (BR) and eddy-covariance (EC) methods (after [57.152] with permission from Schweizerbart'sche Verlagsbuchhandlung, Stuttgart, Germany)

Fig. 57.10 Daily evapotranspiration measured with the Bowen ratio method and calculated with the Penman–Monteith method over a grassland in Bayreuth, Germany (measurements were taken during April to May 2013)

In another example shown in Fig. 57.10, values of the daily evapotranspiration over a grassland over the course of a month are plotted. The values were obtained using either the Bowen ratio method or the Penman–Monteith approach. Because both methods base their estimates on the available energy (the net radiation reduced by the ground heat flux), the fluxes provided by the two methods are clearly similar, and are not independent. Differences between the two methods are mainly caused by the influence of the wind speed on the temperature and the moisture field.

57.8.2 Comparison of the Penman–Monteith Approach with Lysimeter Data

Figure 57.11 shows the variation in the latent heat flux for alfalfa (lucerne) grown in Kimberly (ID, USA) over a number of months, as measured with a weighing lysimeter (Chap. 58) and estimated using the standardized Penman–Monteith method (57.34). Only periods in which the vegetation height was greater than 0.3 m are shown. The PM method was applied using a calculation timestep of 24 h. The correlation between the two datasets is relatively good; both show similar fluctuations over time as the weather varied.

Fig. 57.11 Variation in the latent heat flux for alfalfa (lucerne) grown in Kimberly (ID, USA) over many months, as measured by a weighing lysimeter and estimated using the standardized Penman–Monteith method (57.34). Only periods in which the vegetation was taller than 0.3 m are shown. The PM method was applied using a calculation timestep of 24 h. Data from Dr. J.L. Wright, USDA-ARS ◀

57.9 Future Developments

The remote sensing of evapotranspiration using satellite, aerial (Chap. 42), and UAS (Unmanned Aircraft Systems, Chap. 49) imaging is advancing rapidly and will play a major role in future estimation programs. Satellite-based remote sensing provides high spatial coverage of the globe, and satellites such as Landsat—with its thermal imaging—allow ET to be estimated at the 30 m scale, which is generally sufficient to capture the impacts of human activity on vegetation and water consumption. It is, however, challenging to obtain accurate ET values using remote sensing on its own. Its main strength is its ability to provide the spatial distribution of ET. Ground-based ET and surface energy balance measurements will remain essential for calibrating and verifying remote-sensing procedures, and weather measurements or forecasting will be needed to interpolate ET values between satellite overpasses.

ET determinations using the eddy-covariance method have long been plagued by a lack of energy balance closure (Chap. 55) [57.36]. However, recent improvements in the correction of the transducer-shadow effect of sonic anemometers [57.153, 154] and correction methods [57.37] suggest that substantially improved closure is possible. It is anticipated that further advances will be made.

Evapotranspiration measurement techniques continue to evolve, and the costs of the corresponding systems continue to decrease. With the evolution of low-cost wireless communication systems and the reduced measurement system cost, the deployment of localized networks of ET measurement systems is expected to expand rapidly in the future (see Chap. 45).

Richard Allen

Soil and Water Systems
University of Idaho
Kimberly, USA
rallen@uidaho.edu

Richard Allen has degrees in agricultural engineering and civil engineering. An expert in engineering estimates of evapotranspiration, he developed the METRIC process for crop water consumption over large areas, and helped develop Google EEFlux for free global access to water consumption information. Allen was a member of the NASA/USGS Landsat Science Team from 2007 to 2017, and is a member of the NASA ECOSTRESS Science Team.

Thomas Foken

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

Ayse Kilic

School of Natural Resources and Dept.
Civil Engineering
University of Nebraska–Lincoln
Lincoln, USA
akilic@unl.edu

Dr. Ayse Kilic is a Professor at the University of Nebraska–Lincoln and has degrees from the University of Florida in agricultural and biological engineering. She develops procedures for applying satellite imagery to determine evapotranspiration from agricultural and natural vegetation. Her Google Earth Engine EEFlux software supports satellite-based remote sensing of water consumption around the globe. Dr. Kilic was a member of the national Landsat Science Team from 2012 to 2017.

Ricardo Trezza

California Irrigation Management
Information System (CIMIS)
California Department of Water Resources
Sacramento, USA
ricardo.trezza@water.ca.gov

Ricardo Trezza is a Senior Environmental Scientist at the California Department of Water Resources and a former Associate Research Professor at the University of Idaho. He is the manager of the California Irrigation Management Information System (CIMIS), which handles a network of more than 150 agricultural weather stations in California. His research focuses on the application of remote sensing and micrometeorological weather data to estimate evapotranspiration using surface energy balance.

Samuel Ortega-Farías

Research and Extension Center for
Irrigation and Agroclimatology (CITRA)
Universidad de Talca
Talca, Chile
sortega@utalca.cl

Dr. Samuel Ortega-Farías obtained a bachelor's degree in agronomic science at the Catholic University in Chile. He obtained both a master's degree and a PhD in bioresource engineering from Oregon State University. His research has focused on regulated deficit irrigation, sustainable water management, and mapping evapotranspiration and plant water status using remote-sensing images obtained from unmanned aircraft systems (UASs) and remote-sensing satellites.

Lysimeter

58. Lysimeter

Sascha Reth , Oscar Perez–Priego , Heinz Coners , Reinhard Nolz 

It is challenging to study the mechanisms underlying the dynamics of water in the soil–plant–atmosphere continuum. Although micrometeorological techniques are widely used in hydrology, their applicability is typically restricted to certain environmental conditions (i.e., homogeneous and flat surfaces, sufficiently turbulent conditions). Weighing lysimeters allow the water fluxes in vegetated soil columns to be measured gravimetrically with high accuracy. They are complementary and provide valuable information on transport processes within and across the upper and lower boundaries of undisturbed monolith samples. Measurements include evapotranspiration and precipitation, seepage into groundwater, and additional supporting information—soil hydraulic properties such as soil water retention and hydraulic conductivity, which are key parameters for model parameterization. In addition to water fluxes, the transportation of matter into, within, and from soil can be probed.

A lysimeter is an instrument for investigating the water budget of a volume of bare or vegetated soil. There are a variety of distinctive lysimeter designs and sizes that are suitable for specific purposes and site characteristics. Depending on the object studied, lysimeters can range in size from just a few centimeters in diameter (which are used to study grass swards or herbaceous vegetation) to several meters in diam-

eter (which are used to study large trees). There are also various possible lysimeter configurations, including weighing lysimeters, controlled-temperature systems, and controlled-tension systems. In this chapter, we provide an overview of lysimetry, including the general concepts involved, the procedure used to calculate the flux, and quality control. We also present practical recommendations for the appropriate use of lysimeters.

58.1 Principles and Parameters

In general, a lysimeter consists of a soil-filled container that is inserted into the ground such that its top is level with the surrounding surface. The soil inside the container can be an excavated soil monolith, soil with near-natural horizons, or an artificial substrate, depending on the goal of the investigation. A weighing lysimeter is a well-established tool that monitors changes in the weight of the soil mass over time. These changes are then used to estimate the water budget of the confined soil. The main advantage of lysimetry is that it enables precise determination of evapotranspiration (ET).

Lysimeters are also utilized to investigate water and solute fluxes through soil and the chemical properties of percolating water. For instance, the rates at which plant nutrients are leached from soils are of broad interest in many ecological studies. In this regard, containers equipped with suction plates or suction cups for sampling soil water are sometimes referred to as lysimeters. Note that we do not cover hydrochemical aspects here, as this Handbook is focused on atmospheric measurements.

58.1.1 Principle and Relevance of Lysimeter Measurements

Lysimeter experiments are suitable methods for determining water-balance components at different scales (ranging from individual plants to ecosystems) or the crop water used by rainfed crops. When used in combination with precipitation measurements, a weighing lysimeter experiment can be carried out to directly calculate the ET rate from the recorded soil mass changes. A lysimeter equipped with a leachate collection system

allows seepage water to be investigated both quantitatively and qualitatively (in the laboratory).

Lysimeters can also be equipped with additional sensors such as tensiometers, soil moisture probes, thermometers, and suction probes, permitting the investigation of ecosystem functions and mechanisms. As they can be employed to perform long-term field investigations, lysimeter experiments can be used to explore differences in water balance between climate scenarios. A common research goal is a comparison of the results from several identical lysimeters located in areas with different weather conditions, or a comparison of different soil types or vegetation under the same weather conditions over a long period. Such investigations provide the foundations for many of the models that are used to estimate the effects of climate change, the spread of contamination in the soil, and the success of remediation measures.

58.1.2 Measured Variables

The main parameters measured by weighing lysimeters are the evapotranspiration ET (mm h^{-1}) and the drainage F (mm h^{-1}), which are the quantities of water exiting the soil mass per unit time through its upper and lower boundaries (i.e., the surface and bottom of the mass), respectively (Table 58.1). Changes in soil water content θ ($\text{m}^3 \text{m}^{-3}$ or % vol) can also be calculated from the water balance if the soil bulk density ρ (kg m^{-3}) is known (Table 58.2).

Other parameters that are relevant when calculating the water balance include the soil water storage over time ΔS (kg h^{-1}) and the water input in the form of precipitation P or irrigation I (mm). Finally, the soil

Table 58.1 Parameters measured using lysimeters

Parameter	Description	Unit	Symbol
Evapotranspiration	Sum of evaporation from all surfaces and plant transpiration	mm h^{-1}	ET
Drainage	Water leaving the soil mass at the bottom	mm h^{-1}	F
Soil water content	Total volume of water inside the lysimeter	$\text{m}^3 \text{m}^{-3}$ or % vol.	θ
Ground heat flux	Heat flux through the soil surface	W m^{-2}	G

Table 58.2 Other relevant parameters for lysimeter measurements

Parameter	Description	Unit	Symbol
Soil water storage	Change in soil water storage over time	kg h^{-1}	ΔS
Precipitation	Water entering the system by precipitation	mm	P
Irrigation	Water entering the system by irrigation	mm	I
Soil matric potential	Potential energy (expressed as a negative pressure) of soil water due to the capillary forces between water and the soil matrix	hPa	H
Soil bulk density	Dry mass density (depends on particle composition and compaction)	kg m^{-3}	ρ

matric potential H (hPa)—the potential energy of the soil water due to both the water content and the soil texture—is relevant for vegetated soil masses in lysime-

ters. For more detailed information on soil-related parameters, see Chap. 61 on soil chamber measurements.

58.2 History

The word *lysimeter* is derived from the Greek words *lysis* (dissolution or movement) and *metron* (to measure) [58.1]. Lysimeters have been used for over 300 years to investigate percolation processes and the utilization of water by vegetation [58.2]. *F.B. Salisbury and C.W. Ross* [58.3] were among the first to review the development of lysimeter technology chronologically. Detailed information on lysimeter installations from 1688 to 1939 and the chronology of lysimeter development is also provided by *H. Kohnke, F. R. Dreibelbis, and J. M. Davidson* (see Table 58.2 and Table 58.3 [58.4]). Lysimeters have mainly been used in two fields of research: plant physiology and hydrological expertise [58.5]. The techniques used in lysimetry have gradually been improved, and lysimetry has been applied to ever more complex research topics.

We now highlight the main achievements in lysimeter studies in chronological order (see also the reviews [58.5, 6]). Johan Baptista van Helmont (1580–1644) is credited with performing the first quantitative soil water budget investigation [58.5]. He grew a willow tree for 5 years in a pot filled with disturbed soil and then sealed the pot with a perforated lead lid to show that the willow removed water from the soil.

It is believed that the first actual lysimeter investigation was started in Paris in 1688 by Philippe de La Hire (1640–1718), who was interested in determining the origin of springs [58.4]. The first lysimeter designs were simple, consisting of vessels that isolated a volume of soil from the surface to a certain depth. However, such lysimeters can only be used for empirical experiments, not to explore processes occurring in the soil. It was not until 1724 that Stephen Hales (1677–1761) provided

the first evidence of processes that cause soil weight loss, thus demonstrating the roles of evaporation and transpiration. Following this study, John Dalton (1766–1844) and Maurice reported the first hydrological study that included water budgets [58.5]. In 1850, Way reported first results of soil chemistry using a laboratory lysimeter experiment.

A great advance in lysimeter design occurred in 1870, when John Bennet Lawes (1814–1900) and his colleagues built the first undisturbed *monolith* lysimeters, which preserved the natural structure and profile of the soil. Another advanced configuration utilized a perforated iron bottom that was placed under the soil and surrounding masonry walls. This system was used to investigate the quantity and chemical quality of the deep drainage component of the water balance. Further improvements to weighing lysimeters by Conrad von Seelhorst (1853–1930) in 1937 included the first self-recording weighing systems.

Due to technological advances in the field of recording systems, weighing lysimeters became widely established as reference measuring instruments for ET. Although they were initially used in hydrological studies, highly instrumented lysimeters have also found increasing application in ecology. One example of the use of lysimetry in hydrological studies is the large-scale field lysimeter installation established at a site in Oxfordshire, UK, in 1978 (for more details, see [58.6]). In Europe, more than 2500 lysimeters are operated by research institutes and industry [58.7] to study, for example, soil hydrology, biodiversity, ecosystem approaches, remediation, and the fate of pollutants.

Table 58.3 Principles and applications of lysimeter measurements

Type of lysimeter	Lower interface material	Pressure at lower soil interface	Application	
			Stationary	Mobile
Free drainage	Sand, gravel	Atmospheric	×	×
Wick drainage	Fleece, wicks	−100 hPa m ^{−1} wick length/soil pit depth → usually −10 to −100 hPa		×
Suction plate	Ceramics	0 to −1000 hPa, fixed or controlled by tensiometers	×	×
Groundwater	Impermeable, e.g., plastics, concrete	Sealed, no interface at bottom	×	
Non-rain water input NRWI microlysimeters	Impermeable, e.g., metal, plastics	Sealed, no interface at bottom	×	×

58.3 Theory

In this section, after describing the basic principles of lysimeter measurements, we discuss some of the considerations associated with lysimeter measurements and provide some examples of the applications of lysimeters.

58.3.1 Water Balance Components

The main purpose of a weighing lysimeter is to determine ET (mm h^{-1}) from changes in soil water storage over time (ΔS), excluding the water entering and leaving the system due to precipitation (P), irrigation (I), and infiltration (F) (58.1). Precipitation can enter the system in the form of rain or snow or as non-rain water input (NRWI) such as dew hoarfrost or water absorbed by soil particles. Note that, by convention, ET is expressed as a positive integer, and is calculated as

$$\text{ET} = \Delta S + P + I + F. \quad (58.1)$$

Drainage is usually assessed by collecting the amount of water that leaves the soil monolith at the bottom.

Lysimeter-based ET measurements provide independent estimates that are used when developing and validating ET models [58.8–10].

58.3.2 Weighing System

Some traditional weighing facilities still utilize a lever-arm system with a balancing mass to reduce a mass of several tons to a fractional amount. Such systems incorporate a single load cell.

Modern lysimeters typically employ three precision weighing cells of accuracy class C3/C6 (Table 58.5). A structure made of tubular stainless steel mounted on a concrete base provides a safe support for the weighing technology. The so-called load triangle guarantees stable and precise installation of the weighing cells, ensuring that measurements performed with the cells are sufficiently accurate. The weighing cells are installed with shock mounts that are torque-free and shear force-free. These shock mounts provide some mechanical flexibility when force is directed onto the scales. This prevents tension between the weighing cells due to temperature fluctuations, flexion, and vibrations, which could lead to considerable measurement errors.

58.3.3 Soil Water

While ET can be determined by simply measuring changes in soil water storage, studies may wish to ex-

plore other parameters too, such as the soil water status or the vertical water fluxes within the soil. Such investigations require measurements of soil water tension and soil water content at different depths in the soil profile. The relationship between soil water tension and soil water content measured in-situ, which is typically visualized as a retention function (or pF curve), is an important aspect of the hydraulic properties of a studied soil mass. These hydraulic properties depend on soil parameters such as particle size distribution and bulk density. The soil water tension encompasses all of the influences of the soil matrix on the water, and is also called the soil matric potential (or simply the pressure head H , in kPa). This tension is defined as a negative pressure, and is therefore positive if the applied pressure is negative. A pressure of -50 kPa in the pore water accords a tension of 50 kPa. The tension is closely linked to the water content of the soil. At the groundwater surface, H is zero, and a drier soil has a higher H value. H can be understood as the force that a plant must apply at its roots to extract water from the soil pores. The difference in tension between two points in the soil is the driving force for soil water transport. This process is expressed by the well-known Richards equation [58.11] (Chap. 61). Several numerical and analytical models are based on this equation that describes the transport of water and solutes through the soil [58.12–14].

The soil water tension is typically measured using a tensiometer. Determining a gradient with tensiometers enables the movement of water in the soil to be investigated (i.e., the flow direction and velocity). Most of the instruments used in this context are water-filled tensiometers, which typically cover the narrow range 0–90 kPa [58.15]. Using the latest tensiometer techniques and designs, including high-capacity tensiometers (filled with a polymer) and those based on electrical resistance, H values of up to 1.5 MPa (pF4.2) can be measured [58.16].

The soil water content θ ($\text{m}^3 \text{m}^{-3}$ or % vol.) relates the volume of water to the volume of soil. Changes in water content in a monitored volume are due to fluxes into and from this volume. There are well-established principles for measuring the soil water content in-situ that are based on correlations of the frequency-dependent electric and dielectric properties of the soil with its water content. Established sensor techniques include time-domain reflectometry and frequency-domain resonance (capacitance).

58.3.4 Tension Control at the Lower Boundary

Water movement in the soil is mainly driven by the matric potential present. However, in a typical lysimeter, the matric potential within the vessel can be very different from the actual matric potential in the field. Hence, without tension control, the processes observed in a lysimeter often do not accurately reflect the actual processes that occur in the field. To address this issue, porous ceramic bars can be installed at the bottom of the lysimeter to link the capillary system of the soil to a water reservoir with regulated pressure. The pressure in the reservoir can be adjusted to either the tension in the surrounding soil (as measured by a tensiometer) or an arbitrary value. This allows the tension in the surrounding soil to be transferred to the bottom of the lysimeter or the tension at the lysimeter bottom to be adjusted regardless of the natural conditions present.

Without any drainage system, the soil matric potential at the bottom of a lysimeter will equal the air pressure (i.e., the potential will be zero). This differs markedly from the conditions in the intact soil surrounding the lysimeter, and can lead to artificially high soil moisture levels in the lower compartment. In vegetated lysimeters, this may attract root growth, modifying allocation patterns.

58.3.5 Soil Temperature Control

Temperature control is needed to ensure a congruent temperature regime inside the lysimeter vessel and the surrounding soil, making it an important tool for ecosystem studies. When cutting the monolith from the surrounding soil, the soil temperature changes significantly, so it must be regulated. This is important because, for instance, microorganisms are affected by changes in soil temperature. An example of the N_2O efflux from soil as a function of the temperature is provided in [58.17]. The amount of N_2O emissions is to be mapped with an optimum curve with regard to the soil moisture content. Similar effects were found in several investigations of the CO_2 efflux (e.g., [58.18]). To control the soil temperature within the lysimeter vessel, the vessel is first insulated to prevent heat exchange between the surrounding air and the soil in the lysimeter. Furthermore, heat exchange between the surrounding soil and the lysimeter soil is facilitated by a closed water cycle system between the outside soil and the lysimeter soil installed at the same depth [58.19]. Temperature differences between the lysimeter and the surrounding

soil can be minimized to 0.5 K, in contrast to the differences of up to 1.6 K that occur without temperature control [58.20].

58.3.6 Comparison of Evapotranspiration Measurements to Eddy-Covariance Measurements

Lysimeters provide direct, independent measurements of the ET, and are thus recommended by the World Meteorological Organization for the evaluation and calibration of eddy-covariance measurements [58.21] (Chap. 55). It is, however, difficult to directly link these two methods, given their different temporal and spatial scales. For example, eddy-covariance measurements are typically performed every half-hour. However, the widely observed lack of energy balance closure introduces uncertainty into eddy-covariance ET measurements, which could lead to a less accurate description of the diurnal ET course as compared to that derived through lysimeter measurements [58.22]. The data obtained from a lysimeter are most reliable when measurements are taken at intervals of hours to days, depending on the size and resolution of the installed weighing technique. The spatial dimensions of the two methods also differ markedly. The footprint area of an eddy-covariance system has a radius of several dozen to several thousand meters, depending on the relief, installation height, and wind speed. This size cannot be addressed using a single lysimeter. Thus, the size, number, and distribution of the lysimeters that are used to investigate an eddy-covariance system must be considered carefully. Furthermore, surface properties may vary in the eddy footprint area; for example, there may be plant communities with various heights and densities or areas of bare soil [58.23]. Attempts to represent this variation in surface properties may necessitate even more lysimeters.

58.3.7 Acoustic Tomography

With the aid of runtime measurements involving the correlation analysis of acoustic sound paths, the air temperature, wind speed, and wind direction at different levels above the measuring surface of a lysimeter can be determined in a contactless manner. Based on these data, the energy and material flows, especially evapotranspiration, can be elucidated from the gas concentration changes along the flow lines determined with different gas analyzers and temperature sensors. This technique is described in more detail in Chap. 35.

58.4 Devices and Systems

Lysimeters can be categorized according to (i) size, (ii) the drainage control system employed, and (iii) the soil texture (defined by the filling technique used). In a given research facility, these three components can be varied according to the actual goal and physical and financial circumstances. A general classification of lysimeter types is still under discussion [58.24].

58.4.1 Lysimeter Sizes

Lysimeters can be classified according to size (or weight) into microlysimeters (< 1 kg), medium-sized lysimeters, and large lysimeters (> 1000 kg). Their dimensions can also be tailored to particular applications and scientific goals.

Small Lysimeters

Small lysimeters (those with internal diameters of between 70 and 200 mm) have been used for both seepage water collection and to measure ET and dewfall [58.25, 26]. Early studies with lysimeters indicated that the accuracy of ET estimates is strongly affected by the dimensions (width and depth) of the lysimeter [58.27]. Lysimeters with small surface areas and short lengths can suffer from an increased influence of boundary effects, inhomogeneities, and disturbances from installed sensors on measurements than encountered with large lysimeters. Therefore, small lysimeters should be installed in larger numbers to compensate for individual errors through repetition. Furthermore, obtaining and inserting several natural soil monoliths can be beneficial when investigating small-scale variations in soil properties.

Large Lysimeters

There are a range of materials that can be used to house large lysimeters. Firstly, it is possible to build the lysimeter basement from solid concrete, which is usually selected for large installations. Europe's largest lysimeter station, which has 72 lysimeters, is well described in [58.28, 29]; Asia's largest (which has 92 lysimeters) is discussed in [58.30]. Concrete shafts can also be constructed for individual lysimeters. These shafts are created from separate concrete rings. A good alternative is a hermetically sealed polyethylen high density (PE-HD) container station, which has many advantages compared to a concrete structure; for instance, it is waterproof and gas-tight. PE-HD is also considerably lighter and more stable than concrete, greatly simplifying transportation and installation.

Unlike concrete, a plastic station can also be used in contaminated and aggressive media. Finally, in contrast

to a lysimeter shaft constructed from concrete rings, the basement integrated into a PE-HD station permits simple access to the lysimeter, in turn allowing simple and comprehensive maintenance.

Drainage Control Systems

One major component of the lysimeter water balance (58.1) is the infiltration F . As the bottom of the monitored soil mass is disconnected from the natural soil water tension gradient, it is important to consider the drainage control system of the lysimeter.

Free Drainage

The simplest solution is a free-drainage system where the bottom of the lysimeter soil consists of a layer of gravel and coarse sand with a low water-holding capacity. Water percolating downwards through the lysimeter can run off freely and is captured by a drop collector. This low-cost solution requires almost no maintenance and needs no extra instrumentation.

The disadvantage of a free-drainage system is the risk of a relatively high soil water content, particularly in the lower horizons (due to missing water tension). This is especially important when there is a large fine particle fraction (i.e., a high water storage capacity) in the soil under investigation. A high subsoil water content can attract artificial root growth, which will influence the transpiration rate, leading to an underestimated percolation rate. Furthermore, if soil water propagates upwards, it can influence the measured ET rates through a small-scale oasis effect.

Regulated-Tension Lysimeters

In this design, porous ceramic cups are installed in the bottom of the lysimeter. These cups connect the capillary system of the soil to an adjustable-pressure water tank.

The pressure in the tank can be adjusted according to the tension in the surrounding soil as measured by a tensiometer, or to any preferred value. In this way, it is possible to transfer the soil water tension present outside to the lower boundary of the lysimeter or to check the soil water tension in the lysimeter soil regardless of the natural conditions. Tension control can occur in both directions. Separate feed and discharge lines enable the cups to be easily vented and rinsed.

Wick Drainage

When an active draining system (e.g., one that uses regulated-pressure ceramic plates) is unaffordable, a constant negative water potential can be achieved by applying a wick drainage system [58.31]. In this case,

a bundle of small wick fibers are spread across the bottom of the soil such that they merge and pass through the bottom plate via a small tube [58.23]. Inside this tube, a hanging water column in the wick pore space generates a negative pressure proportional to the length of the system, which is usually limited by the space available under the lysimeter.

Groundwater Lysimeters

A groundwater control system enables the groundwater level beneath the soil surface to be adjusted [58.33]. Disconnecting this control system leads to free drainage. The core part of a groundwater control system is a vertically aligned acrylic tube mounted to the ceiling next to each lysimeter. When the system is run in automatic mode, the equalizing tank and the lysimeter are connected. Therefore, the water level inside the lysimeter adjusts until it is the same as in the equalizing tank due to gravimetric equalization (Fig. 58.1). The water level in the equalizing tank is controlled by a pressure transducer at the bottom of the tank. If the water level is lower than the value set in the data logger, the pump is automatically switched on and

water is transferred from the reservoir into the equalizing tank until the designated water level is reached. The data logger saves the water level in the equalizing tank before refilling it. This means that the height difference at every control interval is known and can be used to work out the amount of water drawn into the lysimeter. When it rains, the water level inside the lysimeter will rise, and so will the water level in the equalizing tank. If the water level in the equalizing tank gets higher than the designated water level, water is discharged back into the reservoir.

Closed-Bottom Lysimeters

In some cases (e.g., in microlysimeters that measure dewfall in the desert), percolation is irrelevant and unlikely to occur. Thus, simple cup lysimeters with closed bottoms can be applied [58.34, 35].

Comparison of Drainage Systems

Each of the three main drainage categories—free drainage, wick drainage, and controlled tension—has its advantages and limitations (Table 58.4). Free drainage, the most affordable and simple technique,

Fig. 58.1 Scheme of a lysimeter with a groundwater control system and a concrete basement (after [58.32] © UGT GmbH, reprinted with permission)

Table 58.4 Advantages and disadvantages of the different drainage methods

Device	Advantages	Disadvantages
Free drainage	Inexpensive, easy to set up	Incomplete drainage, artificially high water content inside lysimeter
Wick drainage	Inexpensive, prevents waterlogging at low horizons	Just one small, fixed tension is available, which depends on the available depth/length of the water column; drainage is still poorer than that of surrounding dry soil
Controlled tension		Expensive, laborious to set up and maintain, drainage is still limited compared to that of very dry soil ($H < 1000$ hPa)

can lead to an artificially high water content inside the lysimeter due to incomplete drainage. Depending on the soil and experimental conditions, waterlogging may even occur. This can be prevented using wick drainage, which is still comparatively inexpensive and easy to install. On the other hand, a wick drainage system can only apply one fixed tension, which depends on the space available below the lysimeter vessel. Finally, although they are laborious and expensive, controlled-tension drainage systems can highly accurately simulate the soil water conditions in surrounding moist to moderately dry soils ($H < 1000$ hPa).

58.4.2 Lysimeter Filling Techniques

Lysimeters can be filled with soil in different ways depending on, for example, the goals and funding of the research project, the type of soil and vegetation to be studied, and the planned period of lysimeter operation. The properties of the investigated soil substrate strongly influence the operation of the lysimeter. Sandy soils exhibit relatively constant density under dry and moist conditions, whereas loamy substrates tend to swell and shrink according to the soil moisture present. Gleyic horizons can hinder vertical water flow through the lysimeter and introduce errors into the calculated water balance. The quality of the water balance can also be impaired by the presence of artificially introduced preferential flow pathways. For instance, water can condense on and flow along the walls of the vessel. Stones sliding along the wall during monolith retrieval can form vertical water channels. Inhomogeneities caused by artificial vessel filling or soil cracks induced by movement during near-natural soil monolith retrieval can also influence water flow paths inside the lysimeter.

Soil monoliths can be classified as disturbed or undisturbed.

Disturbed Filling

The lysimeter vessel can be filled with a more or less homogeneous substrate, or an attempt can be made to

construct a more natural sequence of horizons with different soil materials. Compared to natural soil, the latter filling technique usually results in lower soil densities, and settling processes may occur over time. Disturbed soil monoliths can be filled with loose soil, or they can be excavated without accounting for the influence of excavation on the soil.

Monolith Excavation

A soil monolith with its natural horizons and soil density can be excavated and transferred into the lysimeter vessel. This can be done manually or using a machine. During the transfer process, the soil structure will likely be disturbed. Also, there may be irregular contact of the soil with the vessel wall, and the resulting gaps may lead to artificial preferential flow pathways.

Better soil–wall contact is achieved when the lysimeter vessel is forced into the soil using a hydraulic cylinder or an excavator. In order to stop the cylinder from tilting on stones or other obstacles, the area around the cylinder is excavated so that the lower rim can be monitored and stones can be removed as the vessel is forced into the soil. This means that quite a large area of soil is disturbed during monolith extraction.

More sophisticated techniques allow the excavation of undisturbed monoliths using cutting techniques. In general, the cutting tool gradually excavates the soil monolith, and the lysimeter vessel is then lowered onto it gravitationally or with the aid of a little external force (Fig. 58.2). A lot of experience is needed to use a cutting technique effectively, and it is offered as a commercial service. Different techniques have been developed and patented for the extraction of distinct soil horizons or soils with particular properties (e.g., mineral soil or organic and fen soil) [58.36–38].

A simple method for extracting small ready-to-measure monoliths with minimal destruction is shown in Figs. 58.3 and 58.4. Soil monoliths that include natural vegetation and are intended for small lysimeters ($d < 20$ cm) can be retrieved onsite and subsequently reinserted directly into the hole they were extracted from. This saves coring space and allows a sufficient

Fig. 58.2 Schematic of equipment employed for the vertical collection of large undisturbed soil monoliths (after [58.32] © UGT GmbH, reprinted with permission)

Fig. 58.4 Manual extraction of a near-natural monolith and conversion into a small in-situ lysimeter (schematic adapted from [58.23] with permission from Elsevier) ◀

number of replicate measurements to be performed relatively quickly. A Plexiglas tube segment fitted with a steel cutting ring at the bottom and an aluminum plate at the top is driven into the ground with a soil-filled ram pole. After it has been extracted, the monolith is inspected through the transparent wall for texture disturbance or artificial preferential drainage. Following this optical inspection, the monolith remains in the Plexiglas segment, and this system is converted into a lysimeter with a drainage plate glued to the bottom. The hole in the ground produced by monolith extraction is extended and then fitted with a supporting tube that is slightly larger in diameter than the monolith and about 20 cm deeper, which leaves enough room for the drainage system. When the lysimeter is finally reinserted into the hole the height is adjusted so that lysimeter surface and surrounding soil surface are at one level.

58.5 Specifications

The weighing module is the main measuring device of a weighing lysimeter. A variety of high-precision load cells such as compression load cells, tension load cells, and beam weighing cells with a wide range of maximum capacities are commercially available. Optimal selection of the load capacity is essential to maximize the signal. In practice, this will depend on the application; load capacities range from a few grams (suitable for a microlysimeter that measures tiny mass changes) up to several tons (when large lysimeters are used). Another specification to consider is their temperature dependency. Typically, high-precision load cells with high load capacities (> 3 tons) are operated in the temperature range between -20 and $+65^{\circ}\text{C}$ (effect of temperature on the sensitivity: $< 0.001\%$ of the rated load/ $^{\circ}\text{C}$), and can detect mass changes in the lysimeter of up to 10 gm^{-2} . It is worth noting that fluxes

Table 58.5 Comparison of weighing systems used in lysimetry

Type of lysimeter	Weighing system	Measurement range (kg)	Accuracy (g)
Lab lysimeter	Platform weighing	60	1
Small lysimeter	C3 weighing cells	3×2500	10
Large lysimeter	C6 weighing cells	3×4500	10

below the accuracy of the load cell, such as dewfall, can be measured with large lysimeters by optimizing the rate of change in mass. Other error sources can also influence the performance of the lysimeter. The main characteristics of various weighing systems for lysimeters are summarized in Table 58.5. The next section sheds some light on lysimeter data processing and quality control procedures.

58.6 Quality Control

The first step in the processing of lysimeter data is to convert the analog output signal from the load cell to digital data and store that data for further processing. Typical storage intervals are 1–10 min; each stored value represents the mean of several read-

ings. Using a calibration function, the measurements are converted into physical mass changes. The latter correspond to water fluxes into and from the lysimeter. The load cell resolution and the quality of the calibration function determine the data preci-

sion and accuracy. State-of-the-art systems enable mass changes of ± 0.1 kg to be measured. Frequent evaluation of the weighing system and the calibration function is recommended to assure high-quality lysimeter data.

Like any measurement system, a lysimeter weighing device is prone to measurement errors and inaccuracies. An important possible error source is wind-induced forces, which can cause the weighing system to oscillate, leading to unintended fluctuations in the weighing signal [58.39]. The key challenge is to separate such noise from real mass changes due to ET and rainfall. In this regard, filtering and smoothing routines can help to improve data quality by reducing noise and errors and excluding outliers [58.40]. Traditional approaches include well-adjusted averaging procedures such as moving average and Savitzky–Golay filters. In [58.41–43], a polynomial spline function was ap-

plied to a noisy lysimeter weighing dataset to improve data quality. In general, a critical measurement period is needed to achieve efficient routines, and the length of the filtering window crucially influences the result [58.43]. Recently developed routines utilize adaptive filter parameters that depend on the signal strength and noise [58.40].

The advantage of high-quality datasets (high quality in terms of accuracy, temporal resolution, integrity, and sophisticated data processing) is that they allow both the ET and P as well as sources such as dewfall to be determined directly from the weighing data [58.44]. This involves the use of a simple water balance equation for which changes in soil water and fluxes across the lower boundary of the lysimeter are known from measurements. Consequently, negative mass changes within a short measurement interval are assigned to ET and increases in mass are assigned to P .

58.7 Maintenance

Though a lysimeter is a self-measuring system, the quality of the results it provides depends on how well the installation is maintained (see Table 58.6). A visual

inspection of the installation, including the sensors, and a data plausibility check should normally be performed at least once a week.

Table 58.6 Maintenance of lysimeter systems

Maximum interval	Balance	Tensiometer	Full-range tensiometer	Soil moisture sensor	Suction system	Tension control
1 week		Refill water if needed			Change the collection bottles	Refill tank water if needed
	Visual check of the complete system, data plausibility check					
6 months	Check mechanical function and accuracy Check cable and connectors		Zero-point calibration			
1 year	Calibrate instruments If the check reveals a possible malfunction, the instrument should be replaced					

58.8 Applications

Lysimeter experiments can be conducted in the laboratory or the field. Typical areas in which lysimeters are used include agricultural sites, forest sites, landfill sites, postmining landscapes, and contaminated sites that require rehabilitation. In order to be able to draw statistically verifiable conclusions, it is recommended that several lysimeters should be used in combination.

58.8.1 Measurements Under Controlled Conditions

A laboratory lysimeter is a miniature lysimeter that is especially designed for use in labs (indoors). The design and functionality of a laboratory lysimeter are always defined by the aim of the experiment (Fig. 58.5).

Fig. 58.5 Example of a laboratory lysimeter (photo © S. Reth)

Studying soil processes under laboratory conditions has several advantages: the controlled environment allows more precise experiments; the scale is suited to several processes and permits shorter test times than in field studies; and different materials can be integrated quickly.

Column experiments with laboratory lysimeters are used to examine physical soil parameters in multistep outflow or multistep flux experiments. They can also be used to measure conservative or reactive transport.

58.8.2 Application of Small Lysimeters In-Situ

Small lysimeters can be applied in large numbers to monitor ET and F in large field-research projects. In [58.45], 20 cm diameter lysimeters with intact soil monoliths and constant-tension ceramic bottom plates were used in a multidisciplinary onsite experiment with a randomized block design. Also, soil degradation on the Tibetan plateau was investigated at different scales using a combination of eddy-covariance and lysimeter measurements [58.46].

58.8.3 Green Roof Lysimeters

Among the most popular areas of research relating to ecological roofs and urban tracks are new technological vegetation systems to bind particulate matter (fine dust) and the development of new substrates, vegetation mats, and fertilizer products. Plants such as succulents and xerophytes are used in large green roofs and train tracks because they are slow-growing and require less

maintenance. Scientific measurement tasks and advantages of green roofs can be measured with the help of lysimeters [58.47, 48]. Parallel measurements of the climate at the lysimeter site (Fig. 58.6) can aid data interpretation:

- Reduced precipitation runoff from the roof, and relief of canalization and clarification plants
- Decreased rainwater (by 50–90%) and successive release of moisture into the atmosphere through evapotranspiration, thereby increasing air humidity and cooling the surrounding air
- Decreased heat irradiation of buildings during the summer period
- Decreased air pollution due to the deposition of particulate matter on the rough vegetation surface, where it can be adsorbed, bound, or taken up
- Reduced sound reflection

58.8.4 Large Lysimeter Facilities

When a high number of parameters must be examined, a large number of replicates are required. The largest lysimeter station in Europe was built by Agroscope Reckenholz Zürich in 2009. It contains 72 lysimeters each with a surface area of 1 m^2 and a depth of 1.5 m [58.29]. The three main soils of Switzerland are united in this large-scale lysimeter system. The work done at this lysimeter station relates to the need to minimize the ingress of fertilizers—particularly nitrate—into groundwater, as specified by agricultural policy guidelines. The effects of different farming approaches

Fig. 58.6 Green roof lysimeter and climate station at the Hochschule Weihenstephan campus (photo © S. Reth)

Fig. 58.7 Large lysimeter station of the RDA South Korea (photo © S. Reth)

and crop rotation on groundwater contamination with fertilizers are examined under the same climatic conditions.

Asia's largest lysimeter station was constructed at Jeonju by the National Institute of Agricultural Science (RDA) South Korea in 2012 (Fig. 58.7). The research

performed at this station has a similar focus to the Swiss station. Again, the three most typical soils of Korea are united in a total of three lysimeter systems on campus. Fifty-four lysimeters each with a surface area of 1 m² and a depth of 1.7 m as well as 38 small lysimeters each with a diameter of 0.3 m and a depth of 1 m are utilized in research into a healthy environment for agricultural production. The research also addresses the protection and preservation of the Korean environment through technological development, such as renewable bioenergy production.

A different approach is followed in a large lysimeter network known as TERENO (TERrestrial ENvironmental Observatories), which includes 132 lysimeters, each with a surface area of 1 m² and a depth of 1.5 m. These lysimeters obtain data on the hydrosphere, biosphere, pedosphere, lower atmosphere, and anthroposphere along multiple spatial and temporal gradients in climate-sensitive regions across Germany [58.49]. The long-term ecological, social, and economic impacts of global climate change are being explored by this lysimeter network.

58.9 Future Developments

Lysimeters will increasingly be used in complex controlled conditions to identify drivers of ecosystem changes. These *ecotrons* (lysimeter applications; not necessarily investigations of soil processes) are per-

formed to investigate processes occurring in the soil–plant–atmosphere system as well as interactions between the compartments. Good examples of *ecotrons* are given in [58.50–52].

Reinhard Nolz is Senior Scientist at the Institute for Soil Physics and Rural Water Management (SoPhy) at the University of Natural Resources and Life Sciences, Vienna (BOKU). He received a PhD in 2013, and a postdoctoral lecture qualification (*venia docendi*) in 2017. His research interests include agricultural water management, lysimetry, soil water monitoring, and environmental soil physics.

59. Plant Chamber Measurements

Oscar Perez-Priego 

Enclosure-based techniques are widely used in physiological studies and largely constitute the foundation of our current understanding of the processes controlling the plant–soil–atmosphere gas exchange, such as photosynthesis, respiration, and evaporation. Back in the 1970s, chamber systems became highly developed to overcome the difficulties in integrating gas-exchange measurements from single leaves to obtain whole canopy estimates (whole plant or plant parts). The main principle of chamber-based measurements involves enclosures of a relatively large volume of air, so that the changes in the gas properties by diffusive processes can be continuously monitored over time. Typically, the basic components of a chamber system consist of an infrared gas analyzer, an air sampling circuit, the transparent enclosure, and a software-logging module to store and process data. Although a variety of types of enclosures and operating systems can be found, chamber fluxes can be subject to considerable uncertainties, making it fundamental to adapt appropriate error treatment protocols and flux calculation methods to improve the flux estimates. Accuracy and precision of the fluxes are largely determined by the degree of chamber disturbance. In addition to the more stable compounds, such as CO₂, CH₄ and water vapor, canopy chambers have been adapted to measure reactive trace gases (e.g., NO₂, NO, O₃, VOCs, HONO, HNO₃, CH₂O, etc.) with short lifetimes. In this chapter, we will provide a practical guide to the use of plant chambers and an elaborated discussion on basic considerations, including error treatment protocols and flux calculation procedures.

Canopy chambers are currently the only tool for measuring integrated fluxes directly, such as photosynthesis and transpiration rates on an intermediate scale between leaf-scale cuvette measurements and ecosystem-scale eddy-covariance measurements. This includes branch, stem (or even root) scales to the whole-plant

scale [59.1]. Such enclosure measurements are also able to observe the primary emissions of compounds that are not detected by atmospheric studies over forests due to their high reactivity. In the following section, we will describe the principles and relevance of chamber measurements.

59.1 Measurement Principles and Parameters

The operating principle of chambers is somewhat simple and offers flexibility at a comparatively low cost. Although canopy chambers are usually portable, and a suitable number of replicates can be performed (measurements can be made in < 3 min), their design can be adapted, and automatic measurements can be obtained over the course of a day and or a season [59.2]. This is particularly interesting for manipulation experiments that do not require extensive experimental areas, e.g., studies focusing on treatment effects such as irrigation and nutrient amendments [59.3–5], or those evaluating different soil management techniques [59.6, 7].

The configuration and design can be customized, so that environmental conditions of the chamber can be artificially controlled. This provides a unique tool to elucidate component fluxes under certain conditions. For instance, transparent and opaque enclosures can be combined quasi simultaneously to measure directly net CO_2 exchange rates and respiration during daytime conditions [59.4]. Isolated enclosures can be used to separate below and aboveground processes, so that

plant and soil components can be independently characterized [59.3, 8]. In addition, chambers have been proven to be a valid tool for separating the isotopic composition of the transpired water vapor [59.9]. Both provide the means to partition evapotranspiration into its constitutive components (plant transpiration and soil evaporation), which is necessary to link plant-water use strategies to environmental variability.

Canopy chambers allow measurements over a wide range of environmental conditions, which is particularly relevant for situations where other techniques are less appropriate. For instance, chamber data provides independent and complementarity information to eddy-covariance measurements in situations with stable conditions (i.e., calm nights) or in terrains with pronounced slopes [59.10]. Other benefits are, for instance, when the research objective is to cover spatial features within eddy-covariance footprints due to moisture gradients or coverage by different functional plant forms [59.11–13]. With air-controlled settings, such as free-air CO_2 enrichment experiments, open-top cham-

Table 59.1 Parameters measured parameters in a chamber system

Parameter	Description	Unit	Symbol
Trace gas	Molar fraction of the trace gases M_i	mol mol^{-1}	$[M_i]$
Air temperature	Air temperature inside the chamber	K	T_a
Atmospheric pressure	Atmospheric pressure inside the chamber	hPa	P_a
Partial pressure of water vapor	Derived from the molar water vapor fraction (C_w) as $e_a = P_a C_w$	kPa	E_w
Absolute humidity	Mass of water vapor in a given volume or mass of air	kg m^{-3}	AH
Light intensity	Photosynthetic active radiation	$\mu\text{mol m}^{-2} \text{s}^{-1}$	PAR

Table 59.2 Other relevant physiological parameters for chamber measurements

Parameter	Description	Unit	Symbol
Evaporation	Total or plant evaporation	$\text{mmol m}^{-2} \text{s}^{-1}$	ET
Photosynthesis	Gross photosynthetic flux	$\mu\text{mol m}^{-2} \text{s}^{-1}$	P_h
Respiration	Ecosystem or plant respiration	$\mu\text{mol m}^{-2} \text{s}^{-1}$	R_{eco}
Net ecosystem exchange	Net ecosystem CO_2 exchange	$\mu\text{mol m}^{-2} \text{s}^{-1}$	NEE
Water use efficiency	Ratio between P_h and transpiration	$\mu\text{mol mol}^{-1}$	WUE
Leaf area index	Surface of leaf per unit of ground surface area	$\text{m}^2 \text{m}^{-2}$	LAI
Radiometric temperature	Vegetation surface temperature	K	T_{sur}
Plant-to-air water vapor pressure deficit	Calculated as the difference between saturated E_w (considering plant/leaf surface temperature) and ambient (E_w)	hPa	VPD_{veg}
Absolute humidity	Mass of water vapor in a given volume or mass of air	g m^{-3}	AH
Volume	Effective chamber headspace volume	m^3	V_e
Air flow rate	Air flow velocity	m s^{-1}	F

Leakage diffusion coefficient	Diffusion-based coefficient determining the leakage error	$\text{m}^2 \text{s}^{-1}$	θ
Starting time	Time after chamber enclosure that defines the initial slope of the nonlinear fit	s	δ

bers are typically used to evaluate how elevated CO₂ impacts vegetation processes [59.14–16] as well as air pollution [59.17, 18].

Other studies use chamber data as a valuable reference for comparing other techniques, such as sap flow [59.3, 19], micrometeorological methods [59.2,

12, 20–23], gravimetric methods [59.24], or even to facilitate interpretation of remotely sensed observations [59.4]. Chamber measurements have also provided a valuable tool for modeling proposes [59.25].

Tables 59.1 and 59.2 include the most relevant parameters measured in chamber systems.

59.2 History of Chamber Measurements

First canopy chamber measurements were conducted under field conditions over more than a century ago. In 1905, a pioneering study by W.A. Cannon [59.26] described the principles of a *transpiration apparatus* (Fig. 59.1) and developed an analytical method and the equations to calculate plant transpiration. The methodology was simple and effective: single plants were placed in a tight bell glass, and transpiration rates were computed as a function of the changes in the absolute humidity (AH) of the confined atmosphere. This measurement technique was formerly termed the polymeter method. The polymeter system consists of a hygrometer and a thermometer and was originally designed to be placed on the inside a translucent bell to observe changes in air moisture. This system preceded the fast-response psychrometer that allowed ET measures for shorter periods [59.27, 28].

The use of translucent chambers also became very popular in photosynthesis research, and pioneering studies with canopy CO₂ exchange measurements can be found elsewhere [59.28–32]. For instance, an early study by A.J. Heinicke and N.F. Childers [59.32] described the first prototype of an open system that maintained steady-state conditions by continuously drawing air into the chamber headspace of the chamber. Former chamber prototypes measured CO₂ in the samples with colorimetric detection methods, which relied on the electrical conductivity properties of a dry absorbent material (typically, alkali solution) to provide accurate CO₂ estimates [59.28]. The rapid interest in the use of canopy chambers occurred with the first developments of infrared gas analyzers, which made chamber mea-

surements more feasible, portable, and accurate [59.33]. With the advancement of gas analyzers, hybrid designs provided simultaneous measurements of both CO₂ and water vapor exchange, which was the start of a new era in ecophysiological measurements [59.18, 27, 28, 33–38]. Currently, canopy chambers are also used to measure reactive trace gaseous fluxes (e.g., NO₂, NO, O₃, VOCs, HONO, HNO₃, CH₂O, etc.), as well as their isotopic compositions. For these measurements, a twin-cuvette system with an empty reference enclosure can be of great advantage [59.39–42]. The empty reference enclosure will act as a *zero calibration* for all effects of the chamber and piping materials on the composition of the flushing air (Fig. 59.1).

Fig. 59.1 Twin-cuvette system that can be used for measuring reactive trace gaseous fluxes under field and laboratory conditions (photo © Jürgen Kesselmeier)

59.3 Theory

The basic principle of the canopy chamber technique is to confine a given volume of air around a plant so that the transient-state changes of the air properties (i.e., humidity, CO₂, temperature) can be monitored over time. Given that disturbances in the internal mi-

croclimate (e.g., humidification and overheating) are typically introduced by sporadic enclosures, new chamber configurations and techniques were developed to minimize measurement bias. Therefore, chambers can be designed to operate under two different condi-

tions: open (steady-state) and closed (transient-state) systems [59.38]. Regardless the differences associated with the operating conditions, a common aspect of the chambers is that they modify the microenvironment of the canopy to varying degrees. Here, we will discuss basic aspects with respect to each operating configuration, with particular focus on canopy enclosures; general descriptions of the chamber techniques can be found in Chap. 60 along with classical literature [59.33, 43].

59.3.1 Steady-State Flowthrough (Open-Top Chambers)

Canopy chambers operating under steady-state flowthrough conditions are typically referred to as open-top chambers [59.44]. As an open system, a constant air flow is maintained through the chamber head space and is controlled via an air control unit that regulates the atmosphere inside in a way that does not depart from the actual conditions outside (open-top chambers, Fig. 59.2a) or any other targeted conditions (i.e., climate-controlled chambers or glasshouses). When the volume of air enclosed by the chamber is proportionate to the capacity of a pump, unvarying environments can be held without the needing to be controlled (passive open-top chambers). In both cases, once the flow rate is known, and after a steady-state condition has been

reached inside the chamber, fluxes are computed from the differences in concentration of the air entering and exiting the chamber. Based on this equilibrium status, open-top chambers are suitable for prolonged measurements.

For large climate chambers they require heavy machinery and a strong power supply, which make them less portable and, hence, less suitable for field research. However, passive open-top chamber systems can be transported in the field, and their use has been extended to measure whole-plant gas exchange under natural conditions [59.45–49]. Among different designs, enclosure materials with a mylar balloon provide a practical solution for mid-size plants [59.48].

59.3.2 Non-Steady-State Flowthrough (Transient Chambers)

Closed dynamic chambers are typically designed to be light and more portable than open-top chambers. Transient chambers (also known as closed dynamic chambers) are usually restricted to mid-size plants (e.g., crops). A closed sampling circuit is used to derive a subsample of air from the chamber to the IRGA (Fig. 59.2b). Fluxes are calculated from the rate of change in the gas concentration during the enclosure period. Although measurements require an operator,

Fig. 59.2a–c Whole-plant gas-exchange systems of the (a) flow-through steady-state system, (b) flow-through non-steady-state system, and (c) non-flow-through non-steady state system. The basic components of a chamber system consist of an infrared gas analyzer (IRGA), an air sampling circuit connected to a pump, the transparent enclosure, the air control unit, and software and logging modules to store and process data

they can be automatized [59.2]. Given the difficulties of moving large chambers, Perez-Priego et al. [59.3] built a framed-type transient chamber of $\approx 40 \text{ m}^{-3}$ around a tree with a novel design that can be compatible with orchard use. Transitory closures were made with a revolving top and windows, which could be left open just after the measurements were taken. This minimizes disturbances to the tree environment and provides an alternative to open-top chambers.

59.3.3 Non-Steady-State Non-Flowthrough (Closed Static)

Measurements with a closed static system (also known as the cover-box method) require a series of manual samplings of the targeted gas at an appropriate frequency over short enclosure periods [59.50]. This is a fundamental aspect to better interpret the evolution of the gas concentration inside the chamber and its associated diffusive flux over time. Typically, a number of air samples are taken during the enclosure time with a gas syringe and through a sample port (Fig. 59.2c).

59.3.4 Flux Calculation and Error Analysis

Field measurements with chambers are subject to a number of pitfalls and disturbances. Regular calibration of the system and adapting adequate error treatment protocols in data processing and flux calculation methods are essential. Prior to field measurements it is crucial to understand the performance of the chamber system through a rigorous protocol, including a number of calibration methods together with the final flux calculation and error analysis.

Chamber Calibration

Depending on the enclosure/configuration type, a series of adjustments and tests are recommended. Typically, this consists of (i) calibration of the gas analyzer using reference gas samples and the chemical properties of the cover material (Sect. 59.7), and (ii) characterization of the main systematic source of errors, including leaks, determination of the effective chamber volume (V_e , particularly relevant for closed chamber), the effects of condensation of water vapor and alteration of the radiation by the chamber wall, and turbulence regimes by the ventilation system:

- **Leaks:** While leakages induce minor errors in open-top chambers [59.51], this artefact causes flux underestimation in closed systems and should be accounted for [59.3]. With a diffusion-based model, Perez-Priego et al. [59.3] predicted that the degree of these errors depends largely on the magnitude

of the fluxes, the time of enclosure (Δt), and the geometry of the chamber, which is defined by a dimensional factor (i.e., collar contact length (l_c) – the enclosure surface, typically the bottom of the chamber for closed systems – to V_e ratio)

$$\varepsilon_1 = \frac{\theta l_c}{2V_e} \Delta t, \quad (59.1)$$

where θ is the leakage diffusion coefficient that can be determined experimentally by inducing an artificial gradient in CO_2 between the confined atmosphere in the chamber and the outside one as

$$\theta = \frac{-V_e}{\Delta t l_c} \ln \left(\frac{[\text{CO}_2]_{t2} - [\text{CO}_2]_{\text{atm}}}{[\text{CO}_2]_{t1} - [\text{CO}_2]_{\text{atm}}} \right), \quad (59.2)$$

where $[\text{CO}_2]_{t1}$ and $[\text{CO}_2]_{t2}$ are the chamber CO_2 concentration at times 1 ($t1$) and 2 ($t2$), with Δt the period considered between $t1$ and $t2$; $[\text{CO}_2]_{\text{atm}}$ refers to the ambient CO_2 concentration outside the chamber. As an example, for typical θ values between 6.5×10^{-5} and $1 \times 10^{-4} \text{ m}^2 \text{ s}^{-1}$, 3 min of Δt , and a l_c (4 m) and V_e (1 m^3), ε_1 would result in 2% of the flux. However, it is worth remarking here that ε_1 would cause much larger errors, with V_e lower than 0.2 m^3 . Although tight enclosures can be obtained with foam gaskets, it should be kept in mind that nondiffusive leakage issues due to pressure differences from wind gusts can occur in the field. In particular, this might cause leakage in nonrigid enclosures, such as the mylar balloon. Avoiding pressure artefacts caused by chamber deployments is crucial for closed static chambers [59.52]. In addition, it has been demonstrated that a small differential pressure of 0.1 kPa between inside and outside the chamber might change the concurrent flux rate by a factor of 10 [59.53]. This suggests the benefits of small leaks when they might act as an air-vent system ensuring pressure equilibration.

- **Determination of V_e .** Flux biases can also be caused by inaccurate determination of V_e [59.54]. The V_e is usually considered as the nominal volume of the chamber but is dispersed by the volume occupied by the plant or when the chamber is placed on a soil collar with undetermined porosity. Similar to the leakage test, Drewitt et al. [59.55] proposed an injection technique to derive V_e values under field conditions.
- **Effects of the condensation of water vapor.** The injection technique can be also used to determine the water absorption properties of the wall chamber and the sampling circuit [59.3]. To this end, hydroponic systems or lysimeters have been used to calibrate transpiration [59.27, 36]. Dew formation inside the

chamber and saturation problems remain an important limitation of the use of chamber, particularly under wet conditions. Particular attention of the influence of water condensation should be paid for measuring soluble trace gases species (e.g., NH_3 , SO_2 , and NO_x among others), for which an empty chamber might be required as a reference to account for such effects [59.40].

- *Effects of light attenuation.* As it has already been discussed, the transmission properties of the wall chamber can disturb the light environment within the chamber, decreasing the intensity of incident radiation and changing light quality (i.e., the direct to diffuse radiation ratio). To account for such effects, a characterization of the optical properties of the translucent material is usually recommended. According to the typical photosynthetic light response curve, Perez-Priego et al., pointed out in 2010 that this effect is minor under light-saturation conditions ($< 10\%$ of the flux when $\text{PAR} > 50 \text{ mol m}^{-2} \text{ s}^{-1}$). However, caution should be taken under light-limitation conditions when small light disturbances would cause stronger impacts on photosynthesis. It is also important to consider edge effects, when self-shading of the chamber frames may affect radiation inside the chamber, particularly in small-size chambers [59.56].
- *Effects of ventilation.* Similar to leaf-cuvette measurements, a critical aspect of chambers lies in the fact that enclosures always modify the aerodynamic characteristics of the confined atmosphere. This is a common problem for closed and open chambers; while a good mixing is required in closed systems to ensure a representative sampling, the effect can be large in open systems when they require recirculating a large air stream through the chamber head space. In closed systems, a sampling circuit consisting of a number of hanging tubes with intake points spaced over the head space of the chamber provides an effective multisampling strategy without the need for a high-power pump or ventilation system [59.3].
- *Effects of flushing air composition.* The quality of the air flushing of the enclosures may be of great relevance in particular for reactive trace gases. Primary emissions of highly reactive compounds can only be detected when oxidizing processes are excluded. For example, it may be necessary to filter ozone before entering the enclosure under field conditions. Otherwise, sensitive compounds will not be observed. However, cleaning the flushing air may also lead to fundamental errors. Purified air may cause a release of compounds that are typically taken up under normal conditions.

- *Effects of wall materials.* All enclosures may affect trace gas compositions by physical and chemical interactions between trace gases and wall materials. These effects must be carefully checked before making final conclusions on exchange processes. A twin-cuvette system may help to overcome such problems.

This needs particular consideration in high-ventilated systems such as large open-top chambers, the strong airstream of which is needed to hold the steady-state conditions inside the chamber [59.57]. However, some authors have concluded that ventilated chambers have a very little impact on transpiration rates under certain environmental conditions, such as equilibrium evaporation [59.37] and those measurement conditions when the aerodynamic resistance (a measure of turbulence and defined by the wind speed inside the chamber) to stomatal resistance ratio is very low [59.3]. The latter can be suitable to sclerophyll plants with roughness surfaces, which are very well coupled to the environment, and transpiration rates are mostly controlled by stomata regulation. Under such conditions, disturbances that are potentially caused by the extent on which stomata respond to overheating and/or changes in humidity during chamber deployments. In closed or transient chambers, those impacts can be minimized by short enclosure times and the use of nonlinear models that allow regressing instantaneous fluxes at the initial time of measurements.

Flux Calculation

Given that the use of closed chambers is more widespread than that of open-top chambers [59.53], in this section, we will focus on the chamber configuration of the transient-state type. The general assumption of this technique is that short enclosure times have a minor impact on the calculated fluxes. However, measurements should last long enough to increase confidence in flux estimates. Therefore, optimizing, the time window of chamber enclosure is crucial to reduce uncertainties [59.11]. The determination of an optimal enclosure time involves the following:

- *The starting time (δ),* which is defined as the time required for stabilizing the atmospheric conditions inside the chamber (*stabilization time*) and for transporting a gas sample of it to the gas analyzer (*lag time*). While the stabilization time depends on the ventilation system and the dimensions of the chamber, the lag is determined by the pump power (typically 1 L min^{-1}) and the distance of the sampling circuit.
- *Number and frequency of gas samples.*

Fig. 59.3 (a) Dynamics of changes in CO₂ and water vapor molar fractions during a measurement on April 2014 in a grassland, and (b) calculated net CO₂ fluxes from different window lengths. According to the time from the chamber closure a rapid measurement is classified as those deployments < 1 min. It is shown that while short measurement periods cause large uncertainties, longest measurements (3 min) improve confidence in flux estimates. Net CO₂ fluxes were calculated using the RespChamber-Proc package (after [59.58])

As an example, Fig. 59.3a illustrates the progression of changes in the CO₂ and water vapor concentration inside a transient chamber. Although ongoing processes, such as photosynthesis and evapotranspiration drive changes in CO₂ and water vapor just after chamber closure, a different stabilization time is observed between trace gases. While a rapid decrease in CO₂ was detected after chamber closure, a longer δ for water vapor was identified with a change-point detection algorithm. These varying responses across scalars cause important uncertainties in the respective flux estimates, particularly in the absence of any criteria to optimize the duration of the chamber enclosure. This is a particular issue for rapid measurements (< 1 min), which flux uncertainties are largely subject to IRGA noise and a fixed calculation window [59.11]. On the other hand, the environmental and physiological conditions are modified, uncertainties are largely reduced with prolonged closure times (3 min), as long as undisturbed fluxes can be inferred with nonlinear models (Fig. 59.3b). Even though the shape of the curvature of the gas progression

might change upon physiological and meteorological conditions, the principles to select the appropriate fitting function remains a subject of debate. A number of alternative nonlinear regression models have been proposed [59.59–62]. To overcome fitting problems, a practical algorithm implemented in the RespChamberProc package and developed in R software [59.58] incorporates novel methods for accuracy and precision analysis of systematic and random errors. Based on statistical tests of residuals, different nonlinear and linear regressions are evaluated, and fluxes are then inferred from the best parameter fit of the regression (instead of fitting a specific regression model to a fixed calculation window). Parameters from the different regressions are sensitive and may fluctuate largely depending on enclosure time *duration* and *noise* inherent to the gas analyzer. While δ is determined using the change-point detection method, duration and noise are addressed using a bootstrapping resampling-based flux calculation method, which enable a better assessment of random errors and improve flux precision.

59.4 Devices and Systems

The elementary components of a canopy chamber consist of a cover material with a sample port or an air sampling circuit attached to an instrument for gas analysis. Other components include a software-logging module to store and process data. Here, we will focus on the most common principles of gas analysis and the enclosure material.

59.4.1 Gas Analysis

Flux calculations from observations of any trace gases inside the chamber involves density effects, which can bias flux estimates [59.63]. In practice, the addition of water molecules through transpiration depresses the mole fraction of any component of a gas mixture (e.g.,

Table 59.3 Advantages and disadvantages of the different chamber configurations

Operating conditions	Advantages	Limitations
Closed dynamic	Simple, portable and suitable for field conditions, adaptable (transparent and opaque for photosynthesis and respiration) Instantaneous during an optimal period of enclosure at low ventilation rates can be achieved	An operator is required but unattended systems is possible Disturbances and artefacts during the enclosure periods (e.g., physiology, non-steady-state conditions with increasing humidification and saturation problems, dew formation, leakages)
Open dynamic	Continuous and repeated measurements Allows flux measurements under controlled conditions Capacity to hold unvarying environmental conditions during the enclosure period	Requires heavy equipment Ventilation regimes can be highly altered Complex operation (particularly under intermittent environmental conditions)

CO₂). Another disturbance is, typically, overheating, and therefore, any trace gas quantity taken from inside a *control-volume* chamber is better expressed in terms of the mixing ratio (i.e., dry mole fraction; [59.64]). That being said, chamber measurements do not require fast-response or high-precision instrumentation to detect small fluxes – a standard gas analyzer can detect fluxes 100 times smaller in chambers than what it can detect in micrometeorological applications [59.53]. According to such requirements, we will proceed to describe the principles of the most relevant infrared gas analyzers and spectroscopy devices for chamber use. To simplify the discussion, here we will focus on CO₂ gas analyzers, while a wide range of devices for other trace gases species can be found elsewhere, e.g., [59.5, 39, 40, 42, 53, 65–70]

Trace gases are measured by determining the absorption of a released infrared light source through a particular sample gas. Two main instrumentations are available: open-path and closed-path IRGAs. Since most of the off-the-shelf IRGAs incorporate a water vapor channel with a temperature and pressure-controlled cell, the trace gas molar fraction is provided (e.g., Licor 7000, 7200, 6400). Although Li-840/840A measures water vapor pressure and cell temperature and pressure, it does not give dry mole fractions, and thus water dilution correction is required. By contrast, when using IRGAs with no water vapor channel (e.g., Li-820) the change in density due to fluctuations in relative humidity and temperature must be quantified with independent sensors.

Although IRGAs are the most common technique in use for chamber measurements, a range of spectrometric techniques are available for measuring trace gases. A detailed technical description of the methods is provided in Chaps. 16 and 28.

59.4.2 Transparent Enclosures

A common issue in the chamber technique regards the impact of the translucent material on the radiative properties. A wide range of materials are typically used to build canopy chambers including acrylic glass [59.71], transparent polycarbonate [59.2], transparent low-density polyethylene [59.45], fluorinated ethylene propylene [59.42] or biaxially oriented polypropylene [59.72], as well as polyester-like films [59.3]. Those studies reported that the attenuation might range between 3 and 20% of the incident light according to the optical properties of the enclosures.

Another property to consider is the gas permeability and adsorption characteristics, as well as the chemical properties of the cover material. This is particularly relevant to certain volatile sulfur compounds, such as carbonyl sulfide (COS), which require inert material (e.g., glass bells with a sample line of Teflon and a pump head covered by polytetrafluoroethylene; [59.73]).

As a conclusion, Table 59.3 summarizes the main advantages and limitations of the two main chamber configurations. Comparative studies evaluating the performance of the two enclosure types can be found elsewhere [59.35, 74, 75].

59.5 Specifications

Here, we will focus on the gas analyzer, the main measuring device in the chamber system. A wide range of gas analyzers with different specifications and characteristics are available commercially. As previously discussed in Sect. 59.4.1, chamber measurements do not require fast-response or high-precision instrumentation to detect small fluxes with high accuracy. Although most commonly used gas analyzers typically provide measurements of CO₂ and water vapor within a wide range (i.e., 0–20 000 ppm and 0–60 ppt, respectively), the output signal can be optimized to more appropriate measurement ranges upon instrument configu-

ration options; e.g., an analog voltage range 0–2.5 V and 1 Hz signal filtering are recommended for the LI-840A, which gives an accuracy of < 1.5% of reading (< 1 ppm close to ambient CO₂). Generally, gas analyzers with low power requirements (12–30 V DC) are light (1 kg), which allows portability and flexibility of operation within an acceptable temperature range (–20 to +45 °C). Finally, when measuring fluxes in evaporative surfaces, factors including spectral cross sensitivity and inherent instrument cross sensitivity, as well as the dilution effects of the gas samples by the addition of water vapor molecules should be accounted for.

59.6 Quality Control

As part of the quality control procedure, removing bad data by instrument malfunction or measurement artefacts is highly advisable to guarantee high-quality chamber data. In addition to adapting appropriate flux calculation and error analysis protocols (Sect. 59.3.4), flagging or rejecting data that are out of the established range of tolerance is suggested (Table 59.4). Another

common practice to identify problems and validate the plausibility of the data is simply the verification of the chamber measurements according to theoretical expectations (e.g., light-response curve) or the comparison with other measurement approaches (i.e., eddy covariance). A short overview of this application is given in the following sections.

Table 59.4 Typical test criteria for chamber measurements

Method	Error	Reason
IRGA	Initial CO ₂ out of the expected range (e.g., 380–450 ppm) Dewpoint temperature (e.g., > 40 °C)	New calibration necessary
Flux	Flux out of the accepted range according to the experimental conditions	Poor fitting caused by potential disturbances, which will depend on chamber configuration (e.g., air flushing system malfunctioning for open-top chambers or leakages by pressure gradients for closed systems). Visual inspection on the progression of the respective gas concentration over chamber deployment. Check IRGA values as new calibration might be required
Statistical analysis (e.g., median absolute deviation) of a group of observations	Residual analysis from the expected response (e.g., photosynthetic light response curve) or based on the distribution of a set of observations	Potential outlier
Ancillary data	Values of T_a , P_a , VPD, PAR within the expected ranges	Replacement of the sensor or new calibration necessary

Note: particular consideration should be paid to reactive gases species (Sect. 59.8.3)

Table 59.5 Basic maintenance tasks of chamber systems

Maximum interval	IRGA	Filters and sampling tubes	Chamber cover
Regular maintenance	Cleaning of the optical bench and/or calibration		Cleaning of the chamber material
> 1 year	Check the manufacture for estimated duration of life of the infrared source (e.g., LI-840 is rated for about 18 000 h of life)	Replacement (but depending on hours of chamber use and conditions it might require a regular maintenance)	

59.7 Maintenance

One practical aspect of the maintenance procedure regards the regular calibration of the gas analyzer and chamber checking. That said, careful attention should be paid to the choice of the chamber material and an appropriate setup according to the conditions. For instance, sorption/desorption of water vapor by chamber materials might compromise the suitability of the chamber method. This does not only apply to the transparent cover but any other material, such as the sampling tubes. For this reason, short gas lines that minimize this effect are recommended, mostly in humid environments where heating sampling tubes up to 30 °C have been proven to

prevent water vapor condensation [59.66]. When the enclosure components, air lines and/or filters get dirty, dust acts as water condenser particles, so frequent cleaning and exchange when appropriate is compulsory.

Other artefacts are associated with the chemical properties of the chamber components. For example, foam gaskets typically used to tighten up the enclosure might emit COS to a varying degree. In such a case, performing a reference or *zero-flux* measurement with the empty chamber is required [59.76]. Table 59.5 summarizes some basic maintenance tasks of chamber systems.

59.8 Application

Studies concerning leaf gaseous exchange have proven to be elusive when most of the observations have typically been reported under light-saturated conditions, which might fail in representing the whole plant behavior [59.77]. This can explain the observed mismatch between leaf gas exchange and landscape-scale eddy-covariance measurements [59.78]. The main appeal for measuring canopy-scale processes is to then integrate the whole canopy trait plasticity and microclimate of a plant into a single measurement.

A number of chamber applications have already been described in the introductory part of this chapter. Below is a brief summary with particular examples of canopy chamber measurements and applications.

59.8.1 Effect of Water Supply on Water Use Efficiency of Single Trees

The following example shows the novel design of a canopy chamber for measuring CO₂ and water vapor fluxes of individual trees of up to 30 m³ under different water supply conditions (Fig. 59.4). Note that one of the novelties is that the chamber excluded soil fluxes, and only aboveground fluxes were measured (i.e., net canopy photosynthesis (P_n) and transpiration, Fig. 59.4a).

The example in Fig. 59.4 shows the diurnal time courses of canopy P_n (Fig. 59.4b) and transpiration

rates (Fig. 59.4c) for two olive trees under varying water status. No differences in plant leaf area were found ($\approx 23 \text{ m}^2$), both P_n and transpiration rates were clearly reduced by the water stress effect compared to the well-irrigated tree. Overall, canopy P_n peaked early in the morning and decreased over the afternoon. On the contrary, transpiration rates were high in the afternoon (note that a less accentuated pattern was observed in the deficit-irrigated tree). As a result, high water-use efficiency (WUE, the amount of CO₂ assimilated by unit of water transpired, Fig. 59.5a) was found in the morning and low in the afternoon. Nevertheless, higher P_n rates per a given stomatal conductance during the morning led to divergent enhanced WUE for the deficit-irrigated tree compared to full irrigation (Fig. 59.5b). This reveals the importance of considering not only spatial but also temporal scales when optimal shifts in the transpiration pattern (e.g., maximum in the morning or in the growing period when P_n is higher) may cause a higher increased WUE at the daily and seasonal scales.

59.8.2 Evaluating Functional Properties Across Scales

The next example in Fig. 59.6 illustrates the varying responses of canopy P_n to variable light conditions, phenology, and degree of water stress. Following mi-

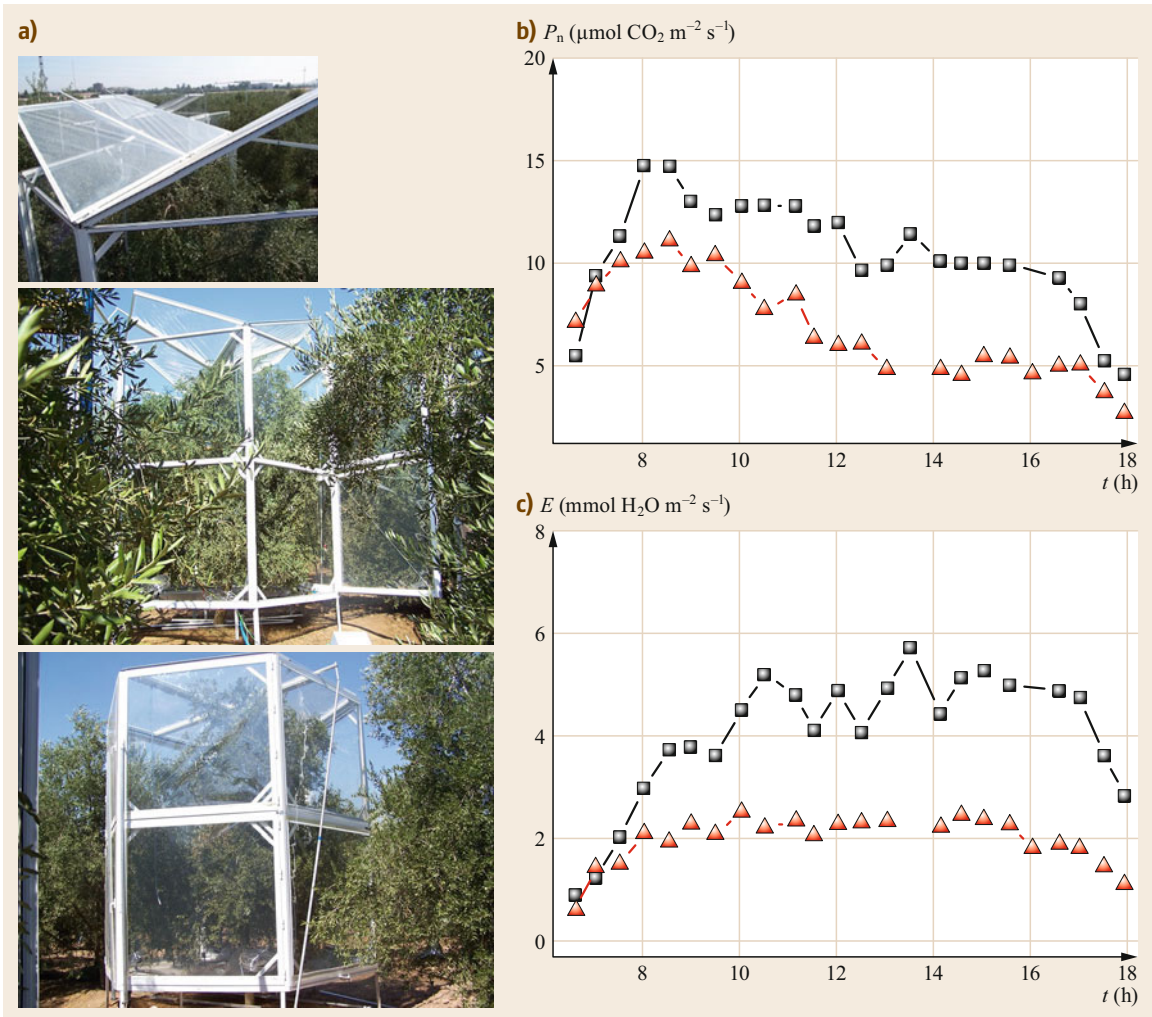

Fig. 59.4 (a) The photos show the performance of the chamber during a field campaign in an olive orchard measuring CO_2 and water vapor fluxes from single trees. (b,c) Example of a diurnal pattern of canopy photosynthesis (P_n) and transpiration rates from single trees under different water irrigation management. Squares represent the well-irrigated tree (absence of water stress), while red triangles represent the tree under moderate water stress by deficit irrigation treatment. The reduction in P_n and transpiration by water stress is observed (photos © Oscar Perez-Priego)

cometeorological convention, P_n rates are expressed as negative (net CO_2 uptake) and positive values (net CO_2 release). Measurements were conducted in two coexisting Mediterranean species from a shrubland for two different phenological periods (black squares indicating the growing period during spring, and red triangles the beginning of the dry period in summer). A divergent pattern in the response was found for the two contrasting periods, which reflects diverse functionalities. Although both species showed similar responses in spring (with similar leaf water potentials), the grasses (*Festuca* sp.) reduced P_n rates during the dry period when the shrubs (*Genista* sp.) showed moderate drought

effects. This opposing physiological behavior among coexisting species revealed a higher capacity of shrub canopies for carbon sequestration under water-limited conditions.

Aboveground fluxes along with soil respiration measurements with chambers were used to scale the net CO_2 flux up to the ecosystem level (NEE) and compared measurements of a nearby eddy-covariance tower (Fig. 59.7). Consistently, the comparison of eddy-covariance NEE and chambers showed that shrubs dominated NEE during the summer period. Chamber measurements shed lights onto our understanding of adaptive strategies for sclerophyll shrublands to im-

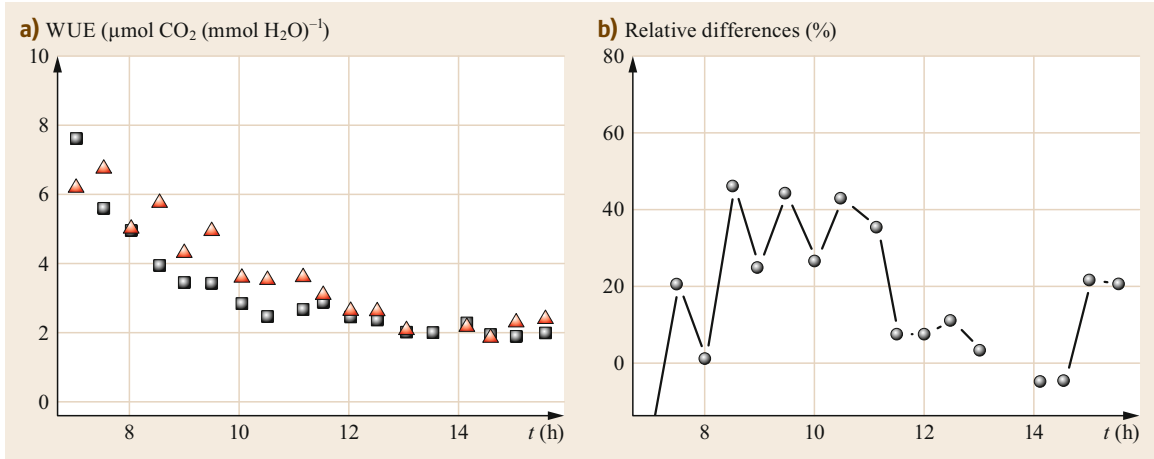

Fig. 59.5 (a) Diurnal time course of water use efficiency (WUE) for two trees under varying water supply (*squares* represent the well-irrigated tree (absence of water stress), while *red triangles* represent the tree under moderate water stress by deficit-irrigation treatment), and (b) relative differences of WUE calculated as $(\text{WUE}_{\text{deficit}} - \text{WUE}_{\text{irrigated}}) / \text{WUE}_{\text{irrigated}}$

prove carbon productivity and stress resistance in arid environments.

59.8.3 Other Relevant Processes

Exchange processes of other important trace gases, including COS, CO, CH₄, N₂O, as well as a variety of reactive trace gases (e.g., VOC, NO_x, O₃) by vegetation have been extensively studied with chamber enclosures [59.5, 39, 40, 42, 53, 65–70]. Gas-exchange rates of reactive trace gases are typically determined by using a carrier gas system either using a reference gas or atmospheric gas samples. To this end, ambient-air enclosures are widely used for measuring biogenic sulfur gases such as isoprene, monoterpenes, and sesquiter-

penes, among others, which are rapidly oxidized in the atmosphere [59.69, 70]. Advance setups not only allow measurements in the gaseous phase but also in the aerosol phases [59.79]. The load of atmospheric aerosol and its radiative properties represents an important research line due to their associated role in pollution and climate-related processes [59.69, 73]. In addition to enclosure systems, dedicated infrastructures to monitor atmospheric aerosol by combining multiwavelength lidar and ceilometer-radiometer instruments are in common use by global networks (e.g., AERONET). It is also worth remarking here that the use of chambers have been extended beyond terrestrial plants; for instance, in estimating CH₄ emissions from aquatic plants [59.80], or even from animals [59.81].

59.9 Future Developments

A common criticism of chamber-based measurements is that they may not reflect the real gas-exchange process due to the disturbances of enclosures. Although this remains the main pitfall of the technique, a number of methods have been described to quantify and reduce the impact of such disturbances. On making the best of it, understanding to what extent enclosures impact the process under study always helps us to better interpret how plants respond to varying environmental conditions (independently of the nature of those impacts, and whether they are artificially or naturally imposed). Therefore, chamber designs capable of regulating and mimicking atmospheric conditions are highly desirable.

In such a way, open-top chambers operate under the premise that a steady-state situation is achieved af-

ter establishing certain conditions. The time scale at which it is realistic to achieve steady-state conditions remains elusive, particularly when plants respond faster than in 1 min. It is also clear that the imposed steady air flow is often higher than the natural wind speed and does not reflect certain atmospheric conditions, i.e., low turbulence. In practice, internal ventilation is also used by transient-state configurations to facilitate air sampling. It has been proven that multisampling methods that assure a well-distributed air sampling over the whole head space of the chamber provide a solution for achieving optimal air mixing. This may provide certain advantages against open-top chambers when considering aerodynamic effects. Although a suitable ventilation rate is difficult to get, controlled transient-state enclo-

tures capable of automatizing the actual aerodynamic conditions within a canopy are required. This would definitely improve our current understanding of leaf gaseous exchange processes across layers and canopy structures. Finally, improvements in the technique and methods aiding the reduction of uncertainty errors are always encouraging, particularly those relevant to the associated water vapor condensation effects.

Dr Oscar Perez-Priego is postdoctoral research fellow at Macquarie University, Australia. He received a PhD in Bioscience (2011), a postdoc at University of Granada (2011–2013, Spain) and the Max Planck Institute for Biogeochemistry (2014–2018, Germany). He studies soil–plant–atmosphere interactions by combining field experiments and models. He is interested in gas and energy exchange from single leaves to the whole plant and ecosystem scales, ecosystem modeling, and theory.

Soil Chamber

60. Soil Chamber Measurements

Jens-Arne Subke , Lars Kutzbach , David Risk 

Chamber measurements form a fundamental approach in quantifying the exchange of trace gases between soils and the atmosphere. A range of chamber approaches has been used, reflecting the progress in our understanding of soil gas flux dynamics and technical capabilities. Minimizing measuring artefacts that are associated with soil chamber measurements have mainly driven these advances, along with a need to obtain soil flux data of appropriate spatial replication and temporal resolution. We here present an overview of the main *classic* CO₂ flux chamber approaches, noting that general principles apply also to chamber measurements of other trace gases. The chapter introduces measuring principles, data evaluation, and key parameters, and covers recent advances in autonomous measurements in the field. We explicitly address the respective strengths and weaknesses of some automated measuring approaches, as these are likely to be critical for long-term assessments of gas flux across many biomes and linked to other atmospheric gas exchange approaches.

Soil CO₂ efflux constitutes the most significant route for carbon assimilated by an ecosystem back into the atmosphere. It integrates a range of different sources of CO₂, such as heterotrophic decomposition of organic matter, metabolic processes by roots and associated mycorrhizas, respiration by soil-dwelling animals, and mineral CO₂ sources [60.1, 2]. Accurate measurement of this flux is fundamental for establishing C

exchange dynamics within ecosystems, and chamber methods are the most commonly employed methodology to do so. Knowledge of soil CO₂ efflux dynamics over diurnal, synoptic, seasonal, or annual scales provides important insights into the processes underlying it and allows a more detailed analysis of ecosystem-scale fluxes (such as total ecosystem CO₂ exchange) into aboveground and belowground fluxes. As well as

providing direct estimates of soil metabolic activity and its biotic and abiotic drivers, flux measurements are often coupled with experimental manipulations or complementary measurements that enable a more detailed investigation of flux sources (e.g., autotrophic versus heterotrophic C sources) and biological interactions (e.g., root and mycorrhizal dynamics, or soil faunal and plant phenological dynamics).

The exchange of other trace gases between soil and atmosphere is no less important and has similarly received considerable attention in the scientific literature. For example, the emission of methane (CH_4) in wetlands is an important component of the greenhouse-gas balance of these systems [60.3]. Uptake of methane through microbial oxidation in upland soils, on the other hand, also affects regional budgets, whilst emissions of nitrous oxide (N_2O) is of relevance in agricultural studies, particularly under high fertilizer use [60.4, 5].

The aim of this chapter is to give an updated appraisal of the main chamber designs in the scientific literature and to highlight current systems and recent advances. A number of overviews of chamber methods for soil trace gas exchange exist, and we acknowledge the range of information provided in these [60.6, 7]. We summarize information also given in earlier reviews, with our own critical appraisal of designs and data processing, and include recent approaches and instrumentation to measure soil–atmosphere gas exchange using chambers. Much of the overview focuses on soil CO_2 flux chambers, as the majority of published methods and applications are on CO_2 exchanges, but general principles apply to the measurement of other trace gas exchanges between soil and atmosphere, and we include some details on recent instrumentation and considerations for applications of chambers.

60.1 Measurement Approaches, Principles, and Parameters

The purpose of any chamber is to create an enclosed air volume in which changes in concentration of gases exchanged between soil and atmosphere can be monitored. As such, the placement of a chamber on the soil surface causes an alteration of the natural conditions in terms of abiotic parameters (e.g., temperature and humidity), as well as gas concen-

trations and exchange processes due to alterations of diffusive and turbulent transport across boundary layers [60.8, 9] or variations in static pressure [60.10–12]. The degree to which any artefacts resulting from chamber placement affect flux estimates depends on the type of chamber and measuring principle involved.

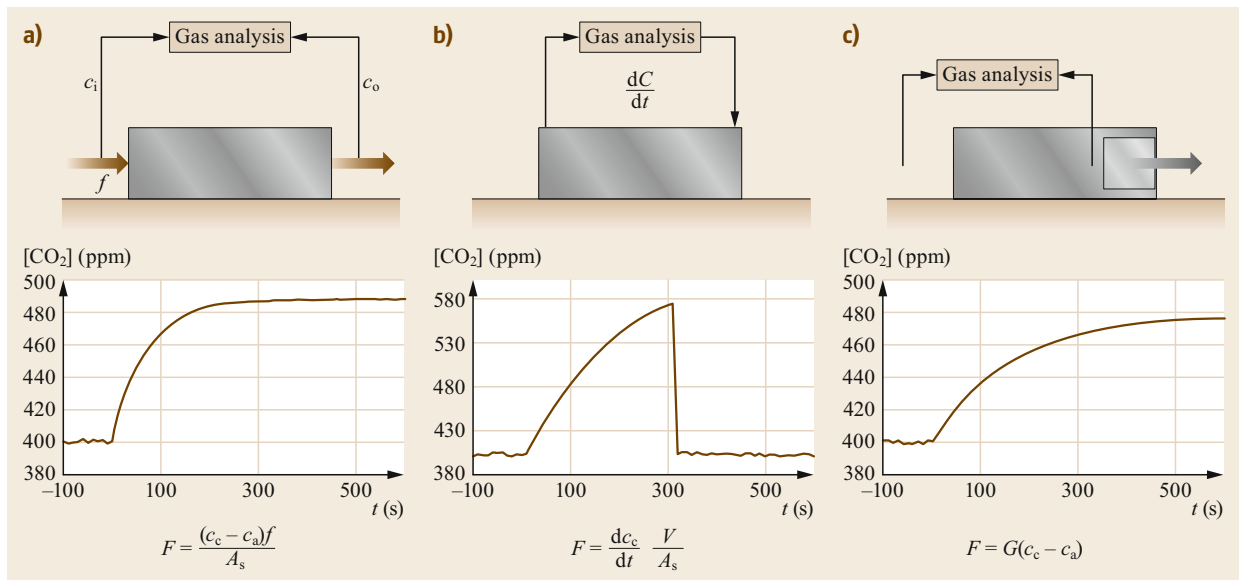

Fig. 60.1a–c Overview (principle, internal CO_2 concentration, flux calculation) of main chamber designs used to measure trace gas exchange between soil and atmosphere: (a) steady-state chamber, (b) non-steady-state chamber, and (c) forced diffusion chamber. See Table 60.1 for the meaning of measurement parameters of flux calculations

Soil chambers have been used to measure CO₂ flux for the past 100 years [60.13, 14], and different shapes, designs, and principles have evolved throughout this period. Chamber types have been categorized into *closed/open*, *dynamic/static*, *flowthrough/non-flowthrough*, or *steady-state/non-steady-state* designs [60.15]. Many of these descriptors are, in fact, synonymous, e.g., an *open* chamber is also necessarily *flowthrough* and *steady state*, and a *closed* chamber can be *flowthrough* or *non-flowthrough*, and measurements are derived from *non-steady-state* conditions. For simplicity, we here adhere to the classification of chambers based on whether fluxes are measured at *steady state* or *non-steady state* [60.16], but note the potentially confusing use of other categorizations used in the literature.

Non-steady-state chambers work on the principle that chambers are closed for a specific length of time, and fluxes are calculated from changes in chamber con-

centration during this period. *Steady-state* chambers monitor gas exchange based on the concentration differential between ambient air and chamber headspace volumes. The steady-state conditions are created by continuous exchange of CO₂ with the ambient atmosphere. *Open* chambers have a continuous flow of air through the headspace, maintaining a connection to the ambient atmosphere. Flux calculations are based on the concentration differential between air entering and leaving the chamber. A novel *steady-state* approach measures the rate of CO₂ diffusion across a permeable membrane to establish soil CO₂ efflux based on the CO₂ concentration within an otherwise closed chamber headspace (*forced diffusion*). Figure 60.1 gives an overview of the key features of these broad chamber categories, whilst a detailed description of theory of operation and implications for specific measurement tasks are given in Sect. 60.3.

Table 60.1 Measured parameters of soil chamber measurements

Parameter	Description	Unit	Symbol
All chamber approaches			
Gas concentration in chamber	Amount (mass) of gas species in chamber headspace	kg m ⁻³	c_c
Ambient gas concentration	Amount (mass) of gas species in ambient air	kg m ⁻³	c_a
Molar fraction	Fraction of a gas species in air	mol mol ⁻¹ or ppmv	χ
Pressure	Air pressure in chamber headspace	Pa	p
Temperature	Air temperature in chamber headspace	K	T
Water vapor concentration	Fraction of water vapor in air	mol mol ⁻¹ or ppmv	χ_{H_2O}
Chamber area	Area of soil covered by chamber	m ²	A_s
Chamber volume	Total volume of chamber (including external volume of tubing, analysis cell and pump)	m ³	V
Steady-state chamber			
Air flow rate	Volume flow of external air passing through chamber headspace	m ³ s ⁻¹	f
Non-steady-state chamber			
Duration of closure	Exact time of sampling from headspace since start of chamber closure	s	t
Forced diffusion chamber			
Diffusivity	Area-specific effective membrane diffusivity	m ² s ⁻¹	D
Path length	Effective diffusive path length	m	L
Scalar	Single term for conversion of chamber-specific membrane area, diffusivity and path length	m s ⁻¹	G

Table 60.2 Other measurements commonly performed alongside chamber flux measurements

Parameter	Description	Unit	Symbol
Soil temperature	Current temperature of soil, ideally covering a number of depth increments	°C	T_s
Soil moisture	Volumetric or gravimetric water content of soil; normally applied to surface soil layers, but ideally obtained across several depths	m ³ m ⁻³ or kg kg ⁻¹	SWC
Air temperature	Temperature of ambient air	°C	T_{ambient}
Water table depth	Depth of water table below soil surface	m	h

60.2 History of Soil Chamber Measurements

Soil CO₂ flux chambers have been used for about 100 years [60.13], and their design has changed with the variety of research and monitoring requirements, analytical capabilities, and the advancement of the understanding of the disturbance that may be created by chambers themselves. The main measurement principles of chambers used today have not changed over many decades, and the basic theory outlined in Sect. 60.3 and models presented in Sect. 60.4 represent refinements on what has been only a small number of successful measurement designs.

However, whilst the principal physical design of soil chambers has not changed fundamentally, methods of determining the flux rates measured with these chambers have, in fact, evolved. In this section, we outline a number of key methods to determine CO₂ concentrations that have been widely used in the past but are now only rarely used.

60.2.1 Offline Sampling and Chemical Absorption

Initial chamber designs follow the current *closed chamber* principle, where a headspace of known volume is created over a specific soil area to trap CO₂ emitted from the soil (Sect. 60.3.1). This *respiration bell* (Fig. 60.2) [60.13] was left in place over a defined period of time (e.g., 10–20 min [60.13] or 1 h [60.17]), and CO₂ concentrations were determined either by extracting a small volume of gas (e.g., 20 mL) from the headspace for determination of CO₂ concentration at the end of this period, or by allowing CO₂ to be absorbed onto a chemical trap throughout the period of chamber closure. The calculation of soil CO₂ flux rates was then simply based on the total amount of CO₂ observed in the headspace, following analogous calculations to those presented in Sect. 60.3.1.

These early measurements provided useful insights into the general dynamics of CO₂ flux and allowed comparative studies of flux rates from different soils and over different measurement periods. However, the static nature of these measurements creates a number of

problems associated with the buildup of the CO₂ concentration following chamber closure.

The offline sampling method assumes that the buildup of concentration in the headspace is linear or, in other words, that the rate of CO₂ flux from soil to chamber is constant throughout the period. However, the soil surface flux rate is highly sensitive to changes in the concentration differential between the chamber headspace and air in superficial soil pores. As the headspace volume progressively enriches in CO₂, this differential progressively decreases, leading to a lower rate of net flux of CO₂ from soil to chamber. Over time, also the soil profile beneath the chamber is enriched in CO₂ relative to the natural soil CO₂ profile, leading to lateral diffusion of CO₂ and, hence, an underestimation of CO₂ efflux. Figure 60.3a illustrates the reduction in the concentration gradient from the headspace into the soil profile. Note that the graph is not based on direct measurements but was produced using a 1-D diffusion model. It clearly shows the reduction in concentration difference between headspace and superficial soil pores, as well as within the soil profile (here illustrated for 3 and 5 cm soil depth), resulting in a diminishing diffusion gradient and hence decreasing measured CO₂ flux (Fig. 60.3c). The 1-D model does not account for lateral diffusion in soil pore spaces adjacent to the chamber footprint, which is likely to occur once a lateral gradient has been established. This would further reduce the CO₂ gradients beneath the chamber, as the observed increase in soil pore concentration would be less pronounced owing to the *loss* of CO₂ from soil pores beneath the chamber. Scenarios shown in Fig. 60.3 simulate an initial surface CO₂ flux of 1.5 μmol m⁻² s⁻¹. For a static chamber with continuous CO₂ enrichment, the flux reduces soon after chamber closure (0 min) and continues to drop up until the chamber is opened after 60 min. The spike in soil CO₂ efflux seen after 60 min is a result of the artificially increased CO₂ concentrations in the soil profile. Early measurements of soil CO₂ flux based on prolonged period of concentration enrichment are, therefore, likely to represent underestimates of soil CO₂ efflux.

Closed chamber methods using continuous chemical absorption of CO₂ have the opposite effect on the atmosphere–soil concentration gradient, as the efficient absorption of CO₂ in the headspace would artificially increase the CO₂ concentration differential to soil pore spaces. The impact on the soil CO₂ gradient is much lower compared to chambers with CO₂ enrichment, so that the overall bias from this effect alone is of smaller magnitude (Fig. 60.3b,d). However, there are

Fig. 60.2 Early model of a closed respiration chamber termed *respiration bell* by Lundegårdh in 1926 (after [60.13])

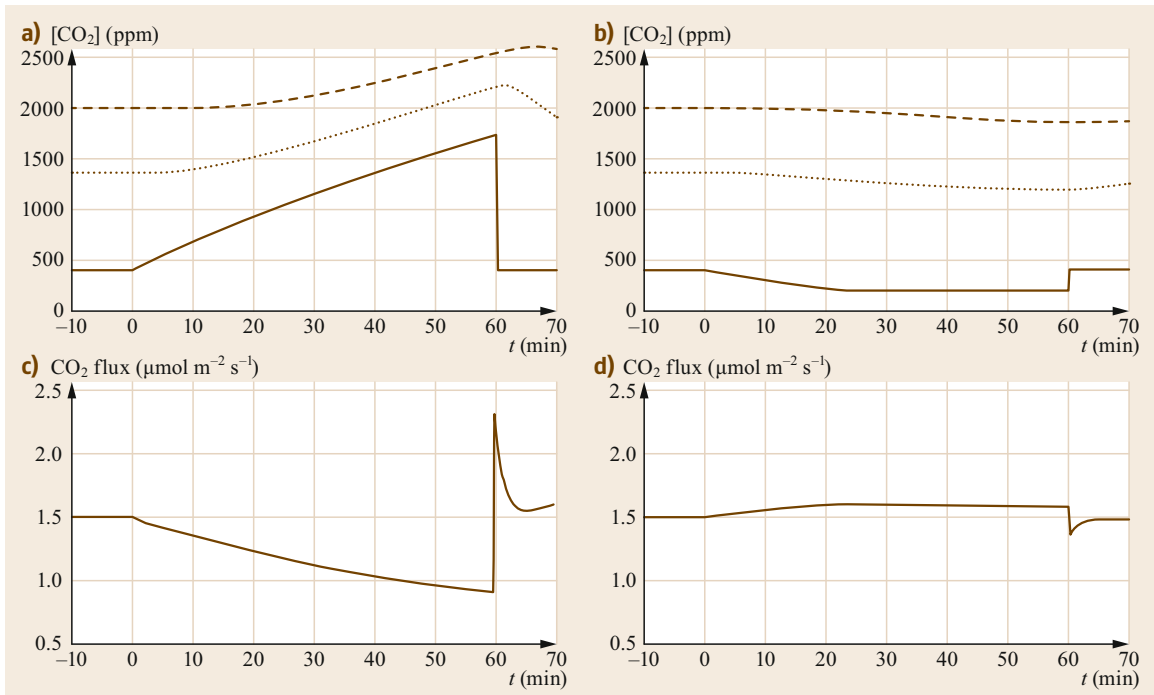

Fig. 60.3a–d Simulated CO₂ concentrations in the chamber headspace (*solid black line*) and soil pores beneath the chamber at 3 cm (*dotted line*) and 5 cm (*dashed line*) soil depth for a closure time of 1 h. **(a)** CO₂ enrichment scenario, **(b)** CO₂ absorption scenario, and **(c,d)** calculated surface CO₂ flux for both scenarios

further uncertainties associated with the efficiency of CO₂ absorption over the period of chamber closure, and additional efforts associated with handling of chemical reagents in the field combined with a more labor intensive analysis of CO₂ concentration determination mean that this method is used very rarely for flux measurements of CO₂ in the field.

60.2.2 Steady-State Flowthrough Chamber Designs (*Open Chambers*)

An early design for continuous soil respiration measurement from a single chamber was proposed in 1953 by drawing ambient air through the headspace of a soil cover to estimate soil CO₂ efflux from the enrichment in CO₂ [60.18]. These early chambers consisted of a frame firmly anchored in the soil, on which a lid was placed to create a chamber headspace. Single chambers of this design were then connected to an infrared gas analyzer (IRGA), with air flowing at a known rate through the chamber, and the difference between ambient air and chamber air recorded (Sect. 60.3). Further development of that technique with multiple chambers sampled sequentially were reported in the late 1960s [60.19–21] to improve spatial coverage and pro-

duce a first complete time series of soil CO₂ efflux in forest ecosystems. To avoid prolonged disturbance of the soil environment caused by the presence of chambers, early versions of these steady-state chambers already included *moving chamber* designs, where robotic drives opened and closed chambers between measurement cycles [60.22].

60.2.3 Field-Portable Chambers

Field-deployable IRGAs enabled direct monitoring of CO₂ increase in chamber headspace concentrations. Commercial availability of small IRGA units from the early 1990s facilitated shorter deployment periods and a more robust analysis of CO₂ concentration evolution in headspaces [60.23, 24]. In this chamber design, air is continuously exchanged between the chamber headspace and a portable infrared gas analyzer via tubing or by directly mounting the analyzer on the chamber (Fig. 60.4). This (quasi) continuous monitoring of concentration increments over the deployment period yields data with which assumptions regarding the linearity of the concentration increase can be tested, and potential errors resulting from a diminishing CO₂ diffusion gradient corrected (Sect. 60.3.1). The more

portable design of chamber and analyzer and significantly shorter deployment period when compared to the chemical absorption methodology meant that researchers could measure from a larger number of loca-

tions with significantly reduced effort. Several off-the-shelf measuring systems have since become available, incorporating much of the advancement provided by the early experimental setups (Sect. 60.4).

60.3 Theory

Gas exchange between soil and atmosphere is mainly driven by the gradient in concentration within the soil profile, where there may be a range of sources of sinks of trace gases. Random movements of molecules lead to a net flux across the soil surface due to concentration differentials between soil layers and across the soil–atmosphere interface. In the absence of turbulent exchange or mass movement of air due to pressure fluctuation caused by wind, the trace gas flux could theoretically be calculated using Fick's law if concentration profiles, effective soil porosity, and diffusion constants in air are known [60.25]. However, the typical heterogeneity in physical structure, as well as organic matter and moisture contents of especially the superficial soil horizons, renders it difficult to predict

the actual diffusivity across the soil–atmosphere interface. Furthermore, atmospheric turbulence induced by advection (wind) near the soil surface or pressure fluctuations due to wind gusts results in a *flushing* of superficial soil pores. Such mass movements of air produce a much faster transport of trace gases than diffusion processes and also impact the soils' internal concentration gradients.

Besides the fluxes into the chamber headspace, the design of flux chambers must account for the processes driving exchanges of CO₂ *within* chambers. Some chamber models use small fans to minimize the development of boundary layers that would cause the buildup of concentration gradients within chambers as an artefact of chamber placement. Especially in the case of the non-steady-state chambers, where fluxes are calculated based on the changes in concentration over time, an effective mixing of chamber headspace is important. Turbulence caused by fans partly compensates for the absence of the *natural* turbulence caused by wind but has the risk of increasing soil–surface exchanges by artificially *eroding* the soil surface boundary layer and enhancing the flushing of soil pore spaces, resulting in artificially large soil CO₂ efflux estimates [60.9]. Moderation of fan speeds and careful placement of fans to avoid directing airflow directly towards the soil surface can mitigate this risk. Many chamber designs, however, do not include forced air movement by fans and use airflow induced by the circulation of air between analyzers and chamber to create an effective mixing of the chamber headspace (Fig. 60.4).

Fig. 60.4 Portable non-steady-state soil CO₂ flux chamber (after [60.23] © John Wiley and Sons)

60.3.1 Mass Flow and Pressure Issues

Pressure changes within the chamber headspace result in mass flow of air in and out of soils [60.26]. Where the chamber itself induces pressure changes, this represents a potentially significant artefact for flux rate measurements [60.27, 28]. Placement of a chamber on the soil, or closure of chamber covers onto a chamber base or collar, are potential situations where a positive pressure within the chamber may push atmospheric air into the soil profile. In situations where the presence of the chamber operator near the chamber causes compression of soil, displacement of air volumes under the measure-

ment area of a chamber would also influence observed chamber fluxes owing to artificial flushing of soil pores. This is likely to be a significant consideration in peatlands or other high-organic soils, where compaction of soil leads to lateral movement of either air or water, hence propagating mass movement and artificial soil–atmosphere gas exchange.

The act of pushing air volumes from the chamber headspace into the superficial soil layers alters the gas concentration profile and is likely to lead to an initially lower exchange of the trace gas, as an artificially low concentration gradient between the uppermost part of the soil column and atmosphere is created. Compaction of soil around chambers is likely to result in the opposite effect, where air is forced from pore spaces beneath the chamber, creating an apparently greater flux than what would occur naturally.

Prolonged chamber deployment (commonly used for the measurement of rarer gases than CO₂) may also lead to a heating of the chamber volume, resulting in an expansion of the air volume and resulting in pressurization of the headspace. Alongside the physical expansion of air following an increase in temperature (following the relationship between temperature and pressure described by the ideal gas law), evaporation of water from soil and plant surfaces can contribute to a slight increase in chamber pressure, whilst also diluting the concentration of trace gases (Sect. 60.3.2).

In contrast to such artificial pressures effects in soil chambers, naturally occurring atmospheric pressure fluctuations can be considered to form part of the inherent gas exchange between soil and atmosphere. However, closing off these fluctuations by the use of a chamber could underestimate flux values.

Most chamber models include small pressure vents that minimize air pressure differentials between ambient and chamber headspace atmospheres (Fig. 60.4). These vents mitigate both pressure artefacts from placement/closure of chambers and continuous wind-induced fluctuations. The design of the vents with small diameters aims to minimize ingress and egress of CO₂, whilst allowing equilibration of pressure differentials by a small volume flow of air.

60.3.2 Concentration Corrections and Flux Calculations

All chamber approaches have to account for changes in partial pressure of other gases that occur during the period of measurement. Evaporation from the soil surface, as well as transpiration by plants present within the chamber, can cause increases in water vapor in the chamber headspace. This addition of water molecules to the mixture of gases making up the chamber air means

that the rate of trace gas fluxes can be underestimated (in the case of a net efflux from soil) or overestimated (in the case of a net soil uptake).

It is, therefore, advised to include measurement of water vapor pressure ($\chi_{\text{H}_2\text{O}}$; Table 60.1) content in both air streams and correct measured CO₂ concentrations accordingly. Many commercial chamber systems can perform such a correction as a factory default, providing e.g., *dry* CO₂ readings.

60.3.3 Non-Steady-State Chambers

Non-steady-state chambers are the most commonly used in the scientific literature. The measuring principle relies on a chamber being placed on the ground to create an effective isolation of a defined airspace (*headspace*) in which gas exchange with the underlying soil surface leads to changes in headspace gas concentrations. These gas concentration changes are then monitored continuously by either having a sensor placed directly in the chamber or by pumping a small volume in a closed loop between chamber headspace and the measurement cell of an analyzer (e.g., nondispersive infrared gas analyzer, cavity ringdown spectrometer). The CO₂ mass flux rate at a given time point during the chamber closure ($F(t)$; in kg m⁻² s⁻¹) is calculated from the mass concentration change with time ($dc/dt(t)$; in kg m⁻³ s⁻¹), chamber volume (V ; in m³), and chamber area (A ; in m²)

$$F(t) = \frac{dc}{dt}(t) \frac{V}{A}. \quad (60.1)$$

The mass concentration of the gas of interest $c(t)$ is calculated from the measured fraction of CO₂ in air ($\chi(t)$; in mol mol⁻¹), pressure ($p(t)$; in Pa) and temperature ($T(t)$, in K) of the headspace air, molar mass of the gas of interest (M ; in kg mol⁻¹) and the universal gas constant ($R \approx 8.314 \text{ m}^3 \text{ Pa K}^{-1} \text{ mol}^{-1}$) [60.29]

$$c(t) = \chi(t) \frac{p(t)}{T(t)} \frac{M}{R}. \quad (60.2)$$

Commonly, water vapor evaporates from the soil surface or vegetation (if present) into the chamber headspace during chamber closure. This addition of molecules leads to expansion of the headspace air and dilution of the gas of interest [60.16, 30, 31]. The effect of this dilution on the molecular fraction of the gas of interest can be approximately corrected for if the amount fraction of water vapor $\chi_{\text{H}_2\text{O}}(t)$ is monitored in the chamber headspace

$$\chi_{\text{corr}}(t) = \chi_{\text{uncorr}}(t) \frac{1 - \chi_{\text{H}_2\text{O}}(t_0)}{1 - \chi_{\text{H}_2\text{O}}(t)}, \quad (60.3)$$

where $\chi_{\text{H}_2\text{O}}(t_0)$ is water vapor amount fraction at the start of chamber closure.

Unfortunately, there is no general agreement about the best time interval for determining dc/dt following chamber closure. Traditionally, a linear regression function was fitted to the complete concentration time series recorded during chamber closure, and the slope of that linear function was set equal to dc/dt . However, various studies demonstrated that the concentration time series often does not develop in a linear way, even over short closure periods [60.32–34]. Whilst linear regressions applied over short periods provide robust estimates, it should be noted that they can underestimate real fluxes by up to 40%, depending on the absolute flux rates [60.33, 35]. There is no consensus about how long exactly a measurement (chamber closure) should last, or which nonlinear regression method is the most appropriate. Software solutions are now available [60.36] that provide diagnostic statistics and initial recommendations for whether nonlinear or linear regression is the most appropriate. They allow users to define custom criteria for a given experimental setting.

Non-steady-state chambers need to open after completing measurement to allow the reequilibration of CO_2 concentrations between soil and atmosphere and to minimize the modification of abiotic conditions through e.g., rainfall exclusion or temperature increases. In order to obtain continuous time series of soil flux measurements, robotic systems that close and open chambers at predetermined intervals have been widely used. As, generally, multiple chambers are measured using a single gas analyzer, switching between different chamber locations is required to enable quasi continuous measurement of flux within a given area. The size of this area is determined mainly by the length of tubing (radius of 10 m, with additional pumps included, up to 20 m) between chambers and CO_2 analyzer, where an efficient exchange of air between headspace and analyzer has to be guaranteed in order to obtain meaningful estimates of concentration change over time. Power draw of robotic drives as well as pumps to circulate air over considerable distances are a major consideration for these systems, and there are usually higher maintenance costs due to the necessity of having moving parts within the chamber design compared to manually operated systems or passive methods (Sect. 60.3.3).

60.3.4 Steady-State Chambers

Steady-state chambers operate by having a continuous flow of air through the headspace. As air passes through the chamber, the CO_2 concentration within the headspace is enriched by soil CO_2 efflux, and air leaving the chamber will over time equilibrate at a con-

stant concentration (assuming constant soil CO_2 efflux) that is determined by the rate at which the headspace atmosphere is turned over by the air stream. Calculation of the soil CO_2 efflux rate, hence, relies on direct measurements of the CO_2 concentration drawn from the chamber headspace (out-flowing concentration, c_o ; ppm, or $\mu\text{mol mol}^{-1}$), the ambient air CO_2 concentration (incoming concentration, c_i ; ppm, or $\mu\text{mol mol}^{-1}$), the flow rate of air through the headspace (f ; mol s^{-1}), and the surface area of soil enclosed by the chamber (A_s ; m^2)

$$F = f \frac{c_o - c_i}{A_s} . \quad (60.4)$$

The flow of air through the chamber headspace is commonly achieved by continuously drawing air from within the headspace and allowing air to enter the headspace passively from the ambient atmosphere. Alternative modes of either pumping air into the chamber, with chamber air exiting the headspace passively [60.25, 37], or creating airflow by simultaneous drawing and pushing of air out of and into the chamber [60.26] have also been trialled but are less common.

As for all chamber methods, a complete seal between chamber headspace and ambient atmosphere is critical. An intentional opening integral to the chamber design to either allow ingress or egress of air (depending on whether air is actively drawn or pushed from/into the chamber), therefore, has to be designed carefully to achieve an effective air seal. This means that the rate at which air flows through the inlet/outlet has to exceed the diffusion speed of CO_2 in air for the range of temperatures under which the chamber operates. The cross-sectional area of the inlet/outlet must, therefore, be dimensioned in accordance with the volumetric air-flow rate (f). The critical speed of air flow (a_c) across the cross-sectional area of an inlet has been determined experimentally to be around 50 cm s^{-1} [60.10], and the appropriate inlet area (A_i ; cm^2) for a given volumetric flow rate of air through the headspace (f_V ; $\text{cm}^3 \text{ s}^{-1}$) can, hence, be calculated according to

$$A_i = \frac{f_V}{a_c} . \quad (60.5)$$

To ensure that no CO_2 is lost through the inlet, this critical speed should be maintained over some distance by the use of an inlet tube of the appropriate diameter. However, it should be noted that any airflow generated by drawing air from the chamber headspace necessarily results in a lower pressure inside the headspace compared to the ambient atmosphere (as this is the principle on which air is drawn into the chamber). The magnitude of this pressure differential is a function of the length

and diameter of the inlet tube, as well as the airflow velocity. An excessive length of the inlet tube should be avoided, as a longer inlet tube increases air friction and, hence, the pressure differential between atmosphere and chamber headspace.

In contrast to closed chambers, open chamber designs have the potential to measure continuously, without the need to open and reclose chambers, as steady-state conditions are created within the headspace. A change in F over time is detected through the continuous monitoring of $(c_o - c_i)$, meaning that a different soil CO₂ efflux rate will result in a new steady-state chamber concentration and, hence, a new concentration differential between soil surface and headspace.

60.3.5 Forced Diffusion Chambers

Forced diffusion (FD) chambers are a specific type of steady-state chamber, which were first described by Risk et al. [60.38]. Like for other steady-state chambers, the soil CO₂ efflux rate is calculated based on the difference between the outside atmospheric concentration and the concentration inside the chamber. The main difference is that the FD chamber uses a membrane instead of a pump. The membrane is responsible for maintaining proportionality between chamber air and outside air through molecular diffusion instead of active pumping. In the currently available commercial forced diffusion chambers, a single IRGA measures both atmosphere and chamber concentrations through a switching arrangement. Forced diffusion chambers, therefore, have reduced power demand and better long-term durability compared to robotic chambers.

The factors that control the exhaust rate of a FD chamber and the proportionality between flux and inside air concentration include the area-specific effective membrane diffusivity (D), the effective diffusive path length (L), and surface areas exposed to the soil and air (A_a , A_s). Changing any of these factors alters the proportionality between chamber and atmospheric air, or the concentration retained in the chamber per unit flux. These factors are represented by a single scalar (G), which is established for each FD chamber by calibration on a flux generator [60.39]

$$F = \frac{A_a}{A_s} \left(D \frac{c_c - c_a}{L} \right) = G (c_c - c_a). \quad (60.6)$$

The empirical calibration simplifies the design requirements and mathematical approach for flux calculations. It also validates that the FD chamber measures fluxes accurately. Most other chamber systems are calibrated only for concentration, which means that pump issues, air leaks, or other operational issues are more likely to go unnoticed in those systems.

Modern FD chambers incorporate two membrane-covered cavities within the same structure. The main cavity consists of a chamber that is exposed to the soil at the bottom and in contact with the atmosphere through a membrane. This membrane imposes the diffusional limitation or *forces* it to a specific rate. The secondary cavity is to measure the free atmospheric concentration of the gas, at the same height above ground as the primary chamber membrane. Both cavities should have identical membranes and the same volume-to-surface-area characteristics, so that they respond with identical time constants to changes in atmospheric concentration. Membranes are normally made of a synthetic material that is hydrophobic, impermeable, highly diffusive, and resistant to ultraviolet (UV) degradation.

Ideally, the FD chamber should be designed to retain a minimum level of soil gas (small $c_c - c_a$ per unit flux) in order to minimize lateral diffusion [60.40]. However, higher diffusivity is not necessarily better if the FD chamber analyzer or sensor cannot adequately resolve small concentration differences between the cavities. If concentration differences cannot be resolved at flux rates of interest, $c_c - c_a$ per unit, the concentration buildup must be increased by decreasing the membrane surface area or by using less diffusive membrane material.

Forced diffusion chambers use less power than other chamber variants, mainly because active pumping is not required. FD autochambers and their sensors can theoretically remain unpowered most of the time and only need to be activated to *grab* concentration values at preprogrammed intervals. FD chambers are also tolerant to long-term analyzer baseline drift, because a single analyzer is used to measure the difference in concentrations between the two cavities. Because FD chambers lack moving parts, maintenance intervals are reduced. However, annual recalibration of chambers is advised, but more frequent calibration may be necessary, for example in environments where biofouling is important. Because they lack moving parts, FD chambers can be used in snow, as long as the snowpack is fresh and highly diffusive, or where special-purpose manufacturer add-on accessories are used. Winter deployments often require a reduction in measurement frequency, to minimize heating and snowmelt, and to conserve battery power when solar charging is at a minimum. Owing to their low power consumption and good reliability, FD chamber systems have been used year-round even under harsh Arctic and Antarctic conditions [60.41, 42]. FD chambers can also be used without modification on floating platforms in studies that aim to contrast terrestrial and aquatic fluxes or on vertical surfaces including trees to quantify bole flux.

60.3.6 Comparison of Measuring Principles

All chamber measurements create some degree of disturbance to the physical environment, affecting the natural flux of gases between soil and atmosphere. The contrasting measuring principles of steady-state and non-steady-state chambers influence different aspects of the headspace environment, relating to e.g., duration of chamber closure or effects of pressure and airflow. Several studies have compared different chambers directly, indicating general biases between the different principles [60.15, 43–45]. For earlier non-steady-state chamber systems, consistent underestimates of known

flux rates have been reported. Subsequent changes to chamber designs, for example introducing controlled air vents and improving air flow within chamber headspaces, seem to have eliminated this bias. The most recent comparison study showed that both steady-state and non-steady-state chambers provided estimates close to known flux rates [60.15]. Forced diffusion chambers, however, have not been included in any comprehensive comparison study. Nonetheless, since individual FD chambers are calibrated against known flux rates before deployment, any biases resulting from instruments, chamber geometry, or materials are accounted for in the measured fluxes.

60.4 Devices and Systems

A variety of chamber systems have been built by researchers over the past decades, driving the development of the methodologies outlined above. The considerable volume of existing publications reflects this diversity of devices and measuring setups, in turn reflecting the variety of contexts and research questions being addressed. Here, we outline some of the most commonly used systems with examples of commercially available models. Further development of chamber systems is ongoing and is largely driven by modifications of existing setups or custom-built designs.

The objective of most soil gas flux studies is to better understand the sources and sinks of gases and drivers of flux dynamics across the soil–atmosphere interface. Analyses of the relation of flux rates from chamber measurements with abiotic conditions, such as air or soil temperature, precipitation volumes and frequencies, soil moisture content, or static pressure, are performed regularly, guided mainly by the specific objectives of a given investigation. Many commercially available chamber systems provide at least some of these ancillary measurements as part of the setup. However, as these ancillary measurements are not an integral part of the chamber approach, we do not cover them in any detail here.

60.4.1 Manual Chambers

Portability is an important requirement for soil chambers to enable surveys across wider areas, during which instruments often have to be carried between measurement locations. Infrared gas analyzers (IRGAs) have been used for soil CO₂ flux measurements for many decades now and continue to be widely used. The decrease in size of IRGA units over the years has

promoted the development of portable systems, with a number of models now commercially available.

Battery power is a further crucial factor for the use of portable systems in field surveys. Energy consumption, and hence the need to carry sufficient battery power into the field, is driven by the need to pump air between chamber and analyzer as well as auxiliary functions, such as internal fans or chamber closing mechanisms and the thermostatic requirements of the optical bench within the analyzer.

Operation of manual survey chambers is nowadays greatly facilitated by simple routines carried out by analytical units that facilitate flushing of chamber headspaces prior to chamber closure, automatic logging of chamber concentration changes over time, and direct computation of flux rates based on chamber geometry.

The small and relatively lightweight chambers by PP Systems (Amesbury, Massachusetts, USA) are placed directly on the soil surface or on previously installed soil collars to initiate a flux measurement. A choice exists between a smaller opaque chamber for respiration measurements and a larger chamber of transparent materials (enabling net CO₂ exchange) (Fig. 60.5, top). The console containing the infrared gas analyzer provides a numerical and graphical display of CO₂ concentration, and raw data as well as computed fluxes can be stored on an external USB (Universal Serial Bus) flash drive. The relatively simple operation with low power consumption means that battery power of the control unit is sufficient for more than 6 h of continuous flux measurements (assuming about 20 measurements per hour). The unit alone weighs only 1.5 kg (including batteries), with the two types of chambers weighing an additional 1 kg.

Li-Cor Biosciences (Lincoln, Nebraska USA) commercializes a very robust survey chamber setup, with

**Fig. 60.5a–c**

Portable soil respiration chambers used with infrared gas analyzers.

(a) PP Systems soil chamber (diameter: 10 cm, $V = 1180 \text{ cm}^3$).

(b) PP Systems canopy chamber (diameter: 14.6 cm, $V = 2430 \text{ cm}^3$).

(c) Li-Cor survey chamber (diameter: 20 cm, $V = 4840 \text{ cm}^3$).

Note that other sizes of chambers are available from these and other manufacturers (images **(a)** and **(b)** reprinted with permission from PP Systems; image reprint with permission of LI-COR Biosciences)

the infrared gas analyzer contained in a rugged hard case and without a physical user interface to protect electronics and gas handling parts (Fig. 60.5, bottom). Survey chambers with a diameter of 10 or 20 cm can be placed either directly on the soil surface or onto matching soil collars prior to flux measurements. An individual measurement is initiated by the system's on-board control, with which the user can either interact directly via wireless devices or an Ethernet/serial cable, or by preprogramming a sequence of measurements at user-specified intervals. To minimize disturbance from chamber placement, the Li-Cor survey chambers have

a bellows that operates the closing mechanism to initiate a measurement; CO_2 concentrations are then logged by the analyzer unit and stored along with any auxiliary measurements, and flux rates are computed at the end of measurements. Data are stored in a large internal memory and can be downloaded after field operation. The Li-Cor analyzer unit (Li8100A) in combination with the bellows-based closure mechanism in chambers has relatively high power demands. With a battery providing power for about 2 h of measurements (assuming about 20 measurements per hour), the analyzer unit weighs about 6.7 kg, with the 10 and

Fig. 60.6a–c Portable gas analyzers suitable for combined chamber-based measurements of CH_4 , H_2O and CO_2 . **(a)** GasScouter™ by Picarro, with attached soil chamber (diameter: 28 cm, $V = 9340 \text{ cm}^3$), which has the analytical unit contained in a backpack. 20 cm chambers weighing a further 1.6 and 2.9 kg, respectively.

Recent advances in laser spectroscopy, and particularly the cavity-ringdown technique, have led to new, portable analyzers capable of measuring CH_4 and H_2O alongside CO_2 . The Picarro GasScouter (Picarro, Santa Clara, CA, USA) weighs just over 10 kg and is housed in a backpack case (Fig. 60.6). A soil chamber is available for this analyzer, and battery life enables measurement of up to 8.5 h (according to manufacturer specifications). Using a related technology (cavity-enhanced absorption), two further portable trace gas analyzers have recently become available. The Microportable Greenhouse Gas Analyzer (M-GGA) by Los Gatos Research (San Jose, CA, USA) weighs only around 5.4 kg, which includes a small internal battery that allows operation of up to 2 h. The Li-7810 by Li-Cor (Lincoln, NE, USA) weighs 11.4 kg and like the M-GGA comes in a hard case. All three trace gas analyzers provide on-board data storage and easy interfacing for external data storage or remote downloads. Combining these trace gas analyzers with existing custom-built chambers or commercially available CO_2 flux systems is relatively unproblematic.

60.4.2 Automated Chambers

Continuous soil flux measurements can be carried out using chamber systems from a number of manufacturers. As in the case of portable chambers, the automated chambers can be interfaced with either CO_2 analyzers or other trace gas analyzers. As these systems are typically employed in more permanent setups, portability and energy supply are of less relevance, and larger analyzers with potentially better analytical resolution and greater signal stability can be used. They do, however, require a weather-proof shelter.

Most automated chambers are equipped with moving components to ensure that soil conditions of the chamber footprint (usually contained within a soil collar) are disturbed as little as possible by the presence of the chamber. However, it should be noted that the chambers are likely to have indirect impacts, even when in their *open* position. The physical presence of chamber, support structures, and motor drives can affect the thermal regime through shading or reflectance of solar radiation. The same is true for the rainfall and soil wetting regime, through interception and displacement of nonvertical rain, which can result in artefacts from ad-

Fig. 60.7a,b Automated long-term chamber models. **(a)** PP Systems (diameter: 20 cm, $V = 2500 \text{ cm}^3$) (image reprinted with permission from PP Systems). **(b)** Li-Cor (diameter: 20 cm, $V = 4080 \text{ cm}^3$) (image reprint with permission of LI-COR Biosciences)

ditional or reduced rain splash and infiltration into the collar area.

Robotic non-steady-state chamber models are available from a number of suppliers; Fig. 60.7 shows two examples. The CFLux-1 model (PP Systems) opens and closes by lifting a dome-shaped chamber vertically and locking it in an open position adjacent to the chamber collar. The gas analyzer is located next to the chamber, so that gas analysis occurs locally with only electricity having to be provided externally. The eosAC model (Eosense, Dartmouth, NS, Canada) has a similar mechanical layout as the CFLux-1 but requires air from the chamber headspace to be pumped to and from a centrally located analyzer via a multiplexed switching unit. This is also the case for the Li-8100A system (Li-Cor). Its chambers open and close in a combined vertical and swing motion, so that the chamber covers in the open position rest at a greater distance from the soil collars than is the case for other systems.

Fig. 60.8 Forced diffusion chamber eosFD by Eosense (diameter: 10.2 cm, 20 cm high) (reprinted with permission from Eosense Inc.)

The maximum length of tubes and power/data cables limits the spatial reach of continuous chambers. Tube length is limited by the associated increase in flow resistance and, hence, by pressure considerations for pumping air between chambers and analyzers or multiplexers. Excessive tube length also increases the time required to flush tube volumes prior to measurements and leads to attenuation of concentrations that may affect the calculation of CO_2 evolution rates. The PP Systems approach of individual gas analyzers for each long-term chamber overcomes these constraints on spatial reach, but the costs per automated chamber are comparatively high because of these individual analyzers.

All automated chambers have moving parts, so their maintenance is an important consideration. Long-term measurements in environments with extreme conditions (high or low temperatures, precipitation, dust) have to be carefully considered because of the increased likelihood of mechanical failures. Appropriate housing particularly for analyzers and power supply are clearly critical for such systems.

Forced diffusion systems provide a recent alternative to the above-mentioned systems (Fig. 60.8).

Using steady-state chambers, FD systems operate well in continuous mode, and their relatively low power consumption means that long-term measurements are easily achieved. Chambers run on extremely low power (average below 1 W for longer deployment) and have onboard data storage. Having no moving parts, FD systems furthermore have a reduced risk of mechanical failure. However, continuous operation of FD chambers at the same location is likely to have substantial impacts on the abiotic environment inside the chamber, as the headspace is likely to heat to temperatures above those of the surroundings and as it excludes rainfall. This limitation can be (partially) overcome by relocating the chambers at regular intervals, so that roving FD chamber systems should have an elevated potential for continuous monitoring in locations with no continuous electricity supply [60.42].

60.4.3 Overview

This section aims to provide an overview of some of the most commonly used chamber-based measuring systems to give a representative sample for users. Table 60.3 summarizes the main advantages and disadvantages of the three main types of measuring systems and reflects a general summary of most common features of the systems available at the time of writing. The most appropriate measuring setup will depend strongly on the specific research question(s). Given a certain research budget, there will often be a clear tradeoff between the spatial and temporal resolution that can be achieved, using portable versus automated systems. In many cases, however, a combination of both systems will be ideal for a comprehensive assessment.

Table 60.3 Advantages and disadvantages of the three main types of systems

Devices	Advantages	Disadvantages
Manual chambers	Few spatial constraints due to low weight & small size Versatile for comparative analyses across ecosystems and treatments	Manual operation Limited by battery power Limited temporal replication
Automated chambers	Low demand on person time High temporal resolution Can be operated in response to specific environmental triggers/events	Significant maintenance demand for continuous operation Risk of mechanical failure Limited in spatial reach Requires secure power supply
Forced diffusion chambers	No spatial limitation Continuous data collection Very low power demand Reduced maintenance requirements due the absence of moving parts	Potential impacts on abiotic and biotic conditions in the case of prolonged placement at the same location

60.5 Specifications

Soil flux chambers are available over a range of sizes (Sect. 60.4), and there is a range of analytical equipment that can be interfaced with these. We here provide an overview of analyzers that are commonly used in soil flux studies and are included in the overview given in Sect. 60.4. Note that the specific information is provided by manufacturers, and variations from stated values may occur depending on, e.g., integration intervals of laser spectrometers or across concentration

and temperature ranges. Specification should, therefore, be regarded as indicative only. In this overview, we focus on portable chamber systems, which are of most immediate interest to many researchers. Permanently installed, continuous chamber systems may use these same analyzers, but a wide range of other analyzers is available, as permanent setups typically involve few restrictions on the size and weight of analyzers.

60.6 Quality Control

Estimates of soil–atmosphere gas fluxes based on soil chamber measurements are characterized by the following four major sources of uncertainty:

- Imperfections of the instrumental analysis of the gas concentration (e.g., due to noise, drift, and cross sensitivities).

Table 60.4 Error and temperature ranges for a selection of key instruments used in currently chamber systems to measure soil gas flux. (All specifications from manufacturers' information)

Instrument	Error (precision)	Temperature range (°C)	Manufacturer
Infrared gas Analyzers			
Li-8100	1.5% of reading	−20 to 45	Li-Cor, Lincoln, NE, USA
EGM-5	1% over calibrated range	0 to 50	PP Systems, Amesbury, MA, USA
Laser spectrometers			
GasScouter™	CO ₂ : 0.4 ppm CH ₄ : 3 ppb H ₂ O: 100 ppm	10 to 45	Picarro, Santa Clara, CA, USA

- Artefacts induced by the chamber method, such as pressure shocks during chamber setting; pressure differences between chamber headspace and ambient air; decreased or increased turbulence strength in the headspace compared to ambient conditions; reduced insolation levels due to the chamber walls; changed air, plant and soil temperatures; changes in the gas concentration gradients between soil and headspace air during chamber closure; leakages through the soil and chamber structure.
- Imperfect sampling of spatial variability in gas fluxes at the relevant scales (centimeters to kilometers).
- Imperfect sampling of temporal variability in gas fluxes at the relevant scales (seconds to years).

These different sources of uncertainty need to be estimated and specified when presenting and interpreting results. The uncertainty thresholds should be defined when planning a study, and the experimental setup should be designed considering the different sources of uncertainty.

60.6.1 Uncertainties in Instrumental Gas Concentration Analysis

The accuracy and precision of the measurements of the molar fraction of the gas of interest, as well as of the headspace air temperature and pressure, and of the gas transport rate in flow-through systems has to be regularly evaluated to assess and minimize uncertainty due to instrumental gas analysis. Systematic errors must be kept small through regular calibration of the instruments involved, and it is important to evaluate drift of gas analyzers in response to temperature and pres-

sure changes. The same is true for cross sensitivities of analyzers between different gases. The effects of water vapor on gas measurements based on absorption spectroscopy are particularly important, because water vapor has many absorption bands, and its concentration typically increases during chamber closure. This is especially true for non-steady-state chambers. The precision of the instruments should be checked regularly across the entire measurement range. A deterioration of precision indicates staining of sensors and/or electronic problems and implies the need for instrument maintenance or repair.

60.6.2 Uncertainties Due to Artefacts by the Non-Steady-State (Closed) Chamber Method

It is very important to minimize the various potential artefacts associated with the closed chamber method through careful chamber design and experiment planning. The functioning of non-steady-state chambers should be tested under controlled conditions at regular intervals. It is necessary that:

- Chambers walls are composed of gas-tight and non-reactive materials.
- The air-tightness of the seals between chamber bases and tops is tested for leakages.
- Chamber bases are sealed well against the soil surface, potentially inserted deep enough into the soil to prevent any mass flow of air between the chamber headspace and the ambient air (where experimental objectives allow).
- The chamber is equipped with a properly dimensioned vent that is open during chamber deployment

and allows propagation of ambient air pressure fluctuations into the chamber [60.32].

- The chamber is equipped with additional closable large-diameter vents that are opened during chamber placement to avoid short-time pressurization of the chamber headspace.
- Turbulent mixing of the headspace air is ensured by installation of appropriately dimensioned fans or, in the case of flowthrough systems, by a properly designed sample intake manifold.
- The change of temperature during chamber closure is recorded and – if necessary – controlled by a cooling system.

Some artefacts due to suboptimal chamber application can be identified by careful evaluation of the time series of gas concentrations during chamber closure. The measurement principle of the closed chamber method assumes that the gas concentration time series during a successful chamber closure experiment can be well described by either a strictly monotonically increasing (net gas release) or a strictly monotonically decreasing (net gas uptake) function. Based on diffusion theory, the monotonically increasing or decreasing functions are expectedly nonlinear and degressive. The relative quality of different regression functions can be compared with the Akaike information criterion [60.46] or tested using an F-test of the residual variances of two potential regression functions [60.47]. A best-fitting function that shows a nonlinear progressive form cannot be explained by diffusion theory, indicating a disturbed chamber experiment that should be flagged for quality control [60.48]. The most important quality control criterion is the standard deviation of the residuals of the best-fitting function, as it provides an estimate of the unexplained variance in the gas concentration time series during chamber closure. A standard deviation of the residuals for the best-fitting function higher than a critical threshold level indicates technical errors or other problematic artefacts, which should be flagged for quality control. By contrast, the coefficient of determination, R^2 , cannot be recommended as a quality control criterion, as it inherently discriminates against lower fluxes [60.33].

60.6.3 Uncertainties Due to Spatial Variability

Soils are characterized by a pronounced spatial heterogeneity on the scales of centimeters up to many kilometers [60.49]. The higher the spatial variability of soils within the investigated area of interest, the greater the uncertainty of the estimated mean of the fluxes due to sampling variability $u_{\text{mean,space}}$. Under the assumption

that the sampled population is normally distributed, $u_{\text{mean,space}}$ can be estimated as

$$u_{\text{mean,space}} = t_{\alpha/2, n-1} \frac{s}{\sqrt{n}}, \quad (60.7)$$

where s is the sample standard deviation, n is the sample size, and $t_{\alpha/2, n-1}$ is the upper $(1-\alpha/2)$ quantile of the Student's t -distribution, and α is the significance level. A pilot study should be performed for estimating s and assessing the distance between sample plots that is enough for spatial interdependence (e.g., by a semivariogram, e.g., [60.50]), which is needed for an unbiased estimation of the population variance by s .

The necessary sample size n_{min} to estimate a mean flux within a specified margin of uncertainty d at a confidence level α can be estimated by finding the lowest value of n for which the following inequality is true

$$\frac{\sqrt{n}}{t_{\alpha/2, n-1}} \geq \frac{s}{d}. \quad (60.8)$$

Since the number of spatial replicates in typical soil chamber measurement campaigns is severely limited by resources and logistical constraints, these are prone to considerable margins of error due to suboptimal sampling in space (e.g., [60.51, 52]). With large uncertainties due to small sample sizes, effect sizes (i.e., means or differences between means from different areas) must be large to be detected at usually accepted significance levels (e.g., $\alpha \leq 0.05$) [60.53].

60.6.4 Uncertainties Due to Temporal Variability

Soil gas fluxes are highly variable through time. Temporal variability occurs on scales of seconds to years. Chamber flux measurements are discrete samples in time with a specified temporal resolution. Chamber closure times can vary from 15 s [60.54] to about an hour [60.55]. Chamber closure intervals at a specific measurement spot can vary from hours for automatic chamber systems [60.55] to weeks for manual chamber campaigns [60.56]. Depending on the research question of the study, the sampling design must account for diurnal cycles, meteorological changes on the synoptic scale, seasonal cycles, and inter-annual variability. For unbiased gas balances, sampling must not be restricted to certain environmental conditions, e.g., only summer, only daytime, or only times without precipitation [60.57]. A low sampling frequency can lead to high uncertainty of seasonal or annual gas-exchange balances [60.58, 59].

Since chamber measurements cannot provide continuous time series of flux measurements, smaller and

larger gaps need to be filled by models. The uncertainty of seasonal or annual cumulative fluxes due to temporal variability is typically dominated by the ability of the models to simulate the true fluxes [60.60, 61]. Model performance is characterized by residuals between sim-

ulated and measured data. These should be evaluated in both the time and frequency domain [60.62]. Monte Carlo simulations are useful to assess the uncertainty of cumulative fluxes due to the uncertainty in the model predictions used for gap filling [60.63].

60.7 Maintenance

In order to obtain reliable flux estimates, chambers and associated analytical equipment require maintenance. Exact intervals for maintenance are strongly dependent

on the application, but Table 60.5 provides a general overview of typical maintenance schedules.

Table 60.5 Servicing schedule for contrasting chamber systems

	Manual chambers	Automated chambers	Forced diffusion
Weekly	<p> Tubes are free of dust, condensation or obstructions, all electrical and gas connections sound</p> <p> Fans (where present) working</p>	<p> Check physical condition, no obstruction in closing mechanisms</p>	N/A
Monthly	<p> Check zero and span of analyzers</p> <p> If used consistently in dusty environments, check filters</p>	<p> Check physical condition and if deployed over long periods, either relocate or check seal with soil is intact</p>	
Annually	<p> Send analyzer for service and calibration</p> <p> Pump replacement (potentially)</p>	<p> Full service of all moving parts</p>	<p> Send entire chamber setup to manufacturer for recalibration</p>

60.8 Application

Soil gas flux chambers have been used in a wide variety of settings, where they may measure a number of different trace gases and serve a range of purposes. Whilst it is beyond the scope of this chapter to cover the full range of chamber applications over the past decades, we use a small number of examples here to illustrate the applicability of soil flux chambers. The examples were selected to cover the key chamber types outlined in Sect. 60.3 and address aspects of continuous monitoring, experimental manipulation, and challenges of remote operation.

60.8.1 Ecosystem Flux Components

Chambers have been widely used in order to quantify constituent fluxes from different parts of ecosystems. Methods such as the eddy-covariance technique (Chap. 55) provide net fluxes between ecosystems and the atmosphere integrated over time (usually 30 min) and space. However, researchers generally require a more detailed understanding of the flux contributions from different areas within the *flux footprint* of

the eddy-covariance setup (Chap. 55). Knowledge of the relative contributions of, e.g., vegetation versus soil versus open water, contrasting vegetation types/covers, distinct (micro)topographic units are critical in order to understand the drivers of the fluxes from these contrasting areas and provide a way to independently validate net ecosystem fluxes. It also allows a more detailed understanding of contributing fluxes, such as the separation of CO₂ assimilation and respiration by canopy and understorey vegetation and respiration from soil, which is not possible by eddy covariance alone.

Analyses of fluxes from within the footprint area of eddy-covariance towers are typically conducted using manual chambers in distinct measurement campaigns [60.33, 64–66]. This enables the measurement of fluxes across the entire flux footprint area, which is typically larger than what an automated flux system with permanently installed chambers can accomplish. Such campaigns should aim to capture a wide range of flux situations, i.e., resolve diurnal as well as seasonal patterns. The exact number of measurement points required depends on the nature of the footprint area, i.e.,

the multitude of different surface covers, and spatial variability within these units. Ideally, all relevant surface cover types are sampled to allow an upscaling of contributing flux estimates at any given period using the weighted areal representation of the respective covers.

Whilst manual chamber measurements have the benefit of a wider spatial reach, they require the presence of an experimenter within the footprint of the eddy-covariance measurement, possibly affecting the flux estimate within that particular time interval. Depending on the magnitude of ecosystem fluxes and the size of the footprint, this disturbance may be significant for the net ecosystem flux estimates, and a direct comparison of fluxes obtained by the two techniques may not be possible. Most studies attempt an area-weighted average of fluxes within footprint areas that is then compared to representative flux averages that are not necessarily obtained simultaneously but based on comparable conditions (in terms of abiotic drivers of fluxes). Continuous measurements using automated chambers have also been used to develop a more detailed understanding of the contribution from soils or even subcomponents within the soil to ecosystem carbon exchange (Sect. 60.8.2) [60.67, 68].

60.8.2 Long-Term Monitoring of Soil Gas Flux

Continuous measurements of soil–atmosphere gas exchange enable powerful investigations into the drivers of gas fluxes as well as their temporal dynamics over short (intraday) to long intervals (interannual). Automated systems with multiple chambers (both steady-state and non-steady-state), can give up to (half-)hourly soil CO₂ efflux readings and have been powerful in disentangling influences of temperature and soil moisture, as well as diurnal and seasonal flux dynamics. The wealth of data generated by continuous measurements (subject to appropriate quality checks) allows detailed analysis of, e.g., temperature responses under contrasting moisture regimes or during different parts of the growing season [60.69].

In manipulative field experiments, continuous soil flux measurements can reveal further details, for example, on the interaction of biotic and abiotic drivers of gas fluxes. Studies in a boreal black spruce forest [60.68] and a temperate oak forest [60.67] illustrate compellingly how the allocation of carbon by plants to the soil via root and mycorrhizal networks differs between seasons. As both studies were carried out within the footprint of an above-canopy eddy-covariance tower, the continuous data further enabled a detailed analysis

of the relationship between soil flux and total ecosystem dynamics, revealing a link between C assimilation by the canopy and magnitude of soil fluxes.

Long-term chamber systems can be interfaced with a range of gas analyzers to provide continuous soil–atmosphere gas exchange for trace gases other than CO₂. For example, by integrating a methane analyzer into a measuring setup for soil CO₂ efflux, it was possible to resolve short-term dynamics of methane uptake by forest soil [60.70]. Apart from a known relationship with soil moisture, these measurements revealed novel insights into the diurnal fluctuation of methane oxidation flux in response to small changes in background methane concentration above the forest floor.

60.8.3 Gas Exchange in Remote Locations

Accessibility to field sites and availability of grid power have been key factors in the selection of long-term observation sites. This has created a strong bias towards areas easily accessed by road and well-equipped research sites. For Arctic areas, this bias is extreme, given the much sparser population and, hence, lower density of road and power infrastructure. As an illustration, about 31% of all Arctic studies focused on climate change (including many flux studies) originate from measurements within 50 km of just two Arctic research sites (Toolik Lake, Alaska, and Abisko, Sweden) [60.71]. There is, therefore, a real need to obtain more data from more remote and less accessible areas. The portability of analyzers and chamber systems has enabled researchers to obtain soil flux measurements from a wide range of locations, but this is limited to distinct, infrequent measuring campaigns.

Whilst this has so far been mostly limited to CO₂ flux systems, advances in analyzer design have led to more frequent measurements also of other trace gases (Sect. 60.4). For continuous measurements in remote locations, moving chamber designs associated with air pumps between chambers and analyzers are limited by power availability. Forced diffusion chambers offer a new opportunity to continuously monitor CO₂ flux in remote locations. This is illustrated by a 1-year record obtained by permanently installed FD chambers in the dry valleys of Antarctica [60.42]. Whilst the steady-state measurement in nonmoving chambers creates some problems in relation to precipitation and organic matter entering the soil environment, this study was able to identify specific abiotic conditions during which microbial activity led to soil CO₂ efflux. The dry and cold nature of the study system facilitated the use of FD chambers, which may be prone to greater artefacts when deployed continuously in other ecosystems.

60.9 Future Developments

Chamber measurements of all trace gases form an important part of gas exchange studies. They can resolve small spatial scales and are adaptable to specific settings with regards to, e.g., microtopography, vegetation cover, or landscape features that larger scale flux approaches, such as eddy covariance, cannot address. Therefore, chamber measurements will continue to play an important role in future investigations.

The scientific literature is rich in contrasting designs of flux chambers, and there are many applications besides soil respiration measurements that have driven their original development. Recent advances in the detection of important atmospheric trace gases have led to ever-smaller analyzers capable of resolving small concentration changes with good accuracy and precision. Gas flux measurements that were historically

severely limited by the requirement of using offline sample collection and a-posteriori analyses of samples in the laboratory can now be carried out using in-situ analyzers, enabling fast and more mobile measuring setups. We anticipate this trend to continue, and more gases, as well as isotopic ratios of trace gases, to become detectable by flux chambers operated on portable or automated devices. The development of chambers has led to a great level of sophistication, so that current models can operate at minimal disturbance of the soil environment. Further advances, e.g., in materials used or in chamber geometry for specific tasks, are likely to occur in the future, but the general measuring principles described in this chapter will most likely continue to be the basis of any chamber flux measurement.

David Risk is an Associate Professor of Earth Sciences at St. Francis Xavier University. His interests lie in gas measurement, isotope tracers, developing new sensor techniques, and in risk studies of soil gas emissions in natural ecosystems, and the energy industry.

Soil Measurement

61. Soil Measurements

Bernd Huwe , Christina Bogner , Thomas Foken 

Atmosphere and soil are intensively coupled and interlinked in manifold aspects. The most relevant interfaces are the very soil surface, where water is stored and water fluxes are split into evaporation, runoff and infiltration, and the soil–root system, which controls transpiration. Hence, important topics are surface properties like roughness, wettability, sealing and crusting, water storage, water availability for plant roots, water retention, and conductivity characteristics of the subsurface soil. In this chapter, we give an overview of soil hydraulic measurements and analyses with relevance for the soil–plant–atmosphere system that have been used in the past and are still of high relevance in the context of ecosystem research. More specifically, we focus on devices and procedures that are fundamental for soil systems and highlight recent developments. We close this chapter with an outline of promising future developments.

Soil and atmosphere are two compartments of ecosystems that are closely interlinked by direct fluxes of heat, water, gas, and matter, as well as by mutual coupling of system parameters. These coupling processes occur, on the one hand, at the interface between soil and atmosphere, the soil surface, and, on the other hand, through the activity of vegetation cover, mainly the plant–root system. The atmosphere constitutes the upper boundary for the soil system (e.g., infiltration, evaporation and heat fluxes) and the soil the lower boundary for the atmosphere (e.g., surface temperature, albedo, evaporation, and surface roughness). On the macroscopic scale (m^2), plant roots represent a sink or a source in the soil system by taking up water and nutrients or secreting root exudates, for example.

Another aspect in soils that is of uppermost importance for the atmospheric system is storage, storage change (water, energy, and solutes), and availability of water and solutes for plants. To understand these processes, we need to consider the distributions of particle and pore sizes, porosity (aggregate and interaggregate porosity), transport and storage characteristics for all species involved (water, gases, heat, and solutes), and their mutual interactions (process coupling). The result is a nonlinear system of interacting (transport) processes, described by a system of (fully-coupled) partial differential equations (PDEs). Their handling is still demanding and time as well as labor consuming. Crucial in this respect is the extreme spatial heterogeneity of almost all soil parameters, which challenges the

manageability and predictability and, thus, limits the practical use of PDEs to a high degree. However, parameters characterizing the hydrological and thermal behavior of the soil system, especially near the soil–atmosphere interface, can support the understanding of atmospheric systems and may even be used to improve the quality of atmospheric models.

The protection of soils from erosion by wind and water is another important ecological aspect that links soils and the atmosphere. Here, relevant soil parame-

ters are cohesion of soil particles at the soil surface, surface roughness, surface water storage potential, soil aggregate size, and aggregate stability. In this chapter, we focus on soil hydrological processes and parameters and on heat transport. We mainly give an overview of state variables and transport characteristics and present selected measurements and case studies exemplarily. For both water and heat flow, we present estimation functions for transport parameters that are increasingly used on the landscape scale.

61.1 Measurement Principles and Parameters

Multiple interactions between soil and the atmosphere exist, as described in the introduction to this chapter. On the very soil surface, snow cover, snow melt, runoff, infiltration, and water storage are important and need to be measured in an adequate way. In the soil profile, water availability, storage of available water, and hydraulic conductivities are directly linked to water uptake by plant roots. The upper (atmospheric) boundary has a pronounced impact on the coupled transport of water, vapor, and heat in soil. Soil temperature affects water properties relevant for heat storage, heat transport, water binding, and water transport. This influence is moderate for most parameters over a range of 0–55 °C, except for dynamic viscosity (which has a direct impact on soil water conductivity).

61.1.1 Measured and/or Estimated Parameters

Table 61.1 provides an overview of basic soil physical parameters that are regularly measured to characterize compaction, porosity, and aggregation. Particle density is almost exclusively used to calculate porosity. Note that for the calculation of the porosities n_A and n_I , the determination of the volume of individual aggregates n_i is required.

Loam soils have the highest compaction potential, while clay soils possess the highest porosity due to the *card-house* structure of the primary platy clay minerals. However, in clays, most of the water is strongly bound in very fine pores and is unavailable to plant roots.

Table 61.1 Basic soil physical parameters with m_t : mass of dry soil, v_{soil} : volume of bulk soil, v_{slid} : volume of solids, v_{por} : volume of pore space, v_A : volume of pores in soil aggregates, v_I : volume of pores between soil aggregates, v_{agg} : volume of aggregates. Index i indicates individual aggregates

Parameter	Definition	Unit	Significance	Comment
Bulk density	$\rho_b = \frac{m_t}{v_{\text{soil}}}$	kg m ⁻³	Soil compaction, calculation of porosity	Used in pedotransfer functions ^a
Particle density	$\rho_s = \frac{m_t}{v_{\text{slid}}}$	kg m ⁻³	Mean density of individual grains	Calculation of porosity
Bulk porosity	$n = \frac{v_{\text{por}}}{v_{\text{soil}}}$	m ³ m ⁻³	Maximum available pore space	$n = \frac{1 - \rho_b}{\rho_s}$
Individual aggregate ^b porosity	$n_i = \frac{v_A}{v_{\text{agg}}}$	m ³ m ⁻³	Aggregate pore content within soil aggregates	$n_i = \frac{1 - \rho_i}{\rho_s}$
Bulk aggregate porosity	$n_A = \frac{v_A}{v_{\text{soil}}}$	m ³ m ⁻³	Aggregate pore content of bulk soil	$n_A = n_i \frac{1 - n}{1 - n_i}$
Bulk interaggregate porosity	$n_I = \frac{v_I}{v_{\text{soil}}}$	m ³ m ⁻³	Interaggregate pore content of bulk soil	$n_I = n - n_A$
Void ratio	$e = \frac{v_{\text{por}}}{v_{\text{slid}}}$	m ³ m ⁻³	Soil compaction studies	$e = \frac{n}{1 - n}$

^aSee Sect. 61.4.4 for more details.

^bIndividual spatial units of organization of solids in soils as a result of swelling/shrinking and biological activity (e.g., earthworms, microorganisms) [61.1].

Table 61.2 Soil material functions for water and heat transport with ψ : matric potential, θ : volumetric water content (for quantities see Chap. 5)

	Definition	Unit	Significance	Comment
Particle size distribution	Equivalent particle diameters (spheres), Stoke's law	m	Used in pedotransfer functions ^a	Synonym for soil texture
Water retention curve (WRC)	$\theta = f(\psi, \text{soil structure})$	$\text{m}^3 \text{m}^{-3}$	Ecological functions of soil water transport modeling	Nonlinear function of matric potential
Pore size distribution	Equivalent pore diameters (tubes), equation for capillary rise	m	Same as WRC used in pedotransfer functions ^a	Classification of pore systems
Hydraulic conductivity function	Parameter in Darcy's law $k = f(\theta, \text{soil structure})$	m s^{-1}	Water transport in soil, water transport modeling	Nonlinear function of water content
Volumetric heat capacity function	$c_V = f(\theta, \text{soil composition})^a$	$\text{J m}^{-3} \text{K}^{-1}$	Heat storage in soil heat transport modeling	Linear function of water content
Thermal conductivity function	Parameter in Fourier's law $\lambda = f(\theta, \text{soil composition})$	$\text{J m}^{-1} \text{s}^{-1} \text{K}^{-1}$	Heat transport modeling	Nonlinear function of water content

^aSee Sect. 61.4.4 for more details.

^bHere, soil composition means volumetric contents of quartz, other minerals, organic matter, water, and air [61.2, 3].

Fig. 61.1 Particle size distribution of typical soil textures. Please note that clay and sand have two meanings, namely particle size class (x -axis) and texture class (i.e., a particular distribution curve)

Soil is physically characterized by scalar parameters (porosity, bulk/particle density, mineral composition, wilting point, etc.), as well as by material functions like particle and pore size distribution, and parameter functions like conductivity characteristics (water, heat), water retention curve, and volumetric heat capacity (Table 61.2).

In principle, all these functions can be measured in the laboratory, some of them also under field conditions. However, measurements are time and labor consuming and are often not applicable at the catchment or landscape scale. Thus, for most of these characteristics, numerous estimation functions have been developed in the past. Some frequently used approaches will be presented in Sect. 61.4.4.

Particle size distribution is a fundamental material function for the characterization of soils. It is

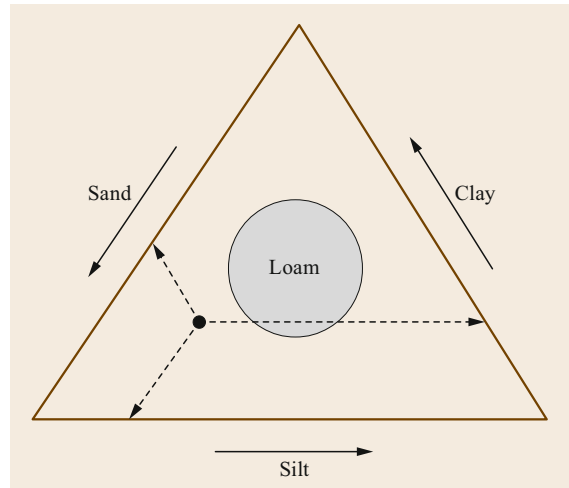

Fig. 61.2 Texture triangle with three main particle size classes: sand, silt, and clay; the soil texture class *loam* is a balanced mixture of sand, silt, and clay

required in soil genesis, as well as in soil fertility assessment. In soil hydraulic studies, it is often used for the estimation of soil hydraulic parameters and parameter functions. Basically, it is a cumulative distribution function of particle sizes (Fig. 61.1). For practical purposes, it is usually aggregated to soil texture classes and represented in triangle diagrams as a function of clay, silt, and sand contents (Fig. 61.2). Unfortunately, most nations have their own particle size classifications and triangle diagrams. Figure 5.1a–d (Chap. 5) exemplarily show the soil texture classes according to FAO/HYPRES (Hydraulic Properties of European Soils/Food and Agriculture Organization of the United Nations), USDA (United States Department of Agriculture), GEPPA (Groupe d'Étude pour les Problèmes de

Fig. 61.3 Ecologically relevant points and ranges of a water retention curve, also called pF-curve (AC: air capacity; FC: field capacity; aFC: available field capacity; WP: wilting point; WWC: wilting point water capacity)

Pédologie Appliquée, France), and SSSG (Soil Science Society of Germany). Following the SSSG, particle size classes are defined as clay (T): < 2 μm, silt (U): 2–63 μm, sand (S): 63–2000 μm. This differs slightly

from the USDA system with clay (T): < 2 μm, silt (U): 2–50 μm, sand (S): 50–2000 μm [61.2, 4].

A second basic material function is the (equivalent) pore size distribution. It is typically derived from the water retention curve assuming cylindrical pores with a contact angle of 0°. A symbolic diagram is given in Fig. 61.3. As the pF-value (see the definition in Table 61.3) is a logarithm, soil saturation occurs at $pF \rightarrow -\infty$. Figure 61.3 also contains the ecological subdivision of the pore space. An important characteristic of almost all material functions is a pronounced *hysteresis*. For example, the water retention curve, the hydraulic conductivity–soil-water, and the thermal conductivity–soil-water relationships change shape depending on whether soil drying or wetting occurs. Thus, a whole family of (scanning) curves can be derived, restrained by upper and lower envelopes (Fig. 61.4). Hysteresis is hard to predict and introduces a considerable uncertainty in estimates of the target variables and the prediction of future changes, even when initial and boundary conditions are perfectly known.

Parameters and material functions characterize the relevant physical properties of soil regarding water and heat status and dynamics, and contribute to the understanding of complex hydraulic and thermal behavior

Table 61.3 Variables of soil moisture and water availability with v_w : water volume, v_s : soil volume, m_w : water mass, m_t : dry soil mass, n : porosity

Variable	Symbol	Definition	Units	Comments
Water content (volumetric)	θ_v	$\frac{v_w}{v_s}$	$m^3 m^{-3}$	Soil volume based water content $\max(\theta_v) = n^a$
Water content (gravimetric)	θ_g	$\frac{m_w}{m_s} = \theta_v \frac{\rho_w}{\rho_b}$	$kg kg^{-1}$	Soil dry mass based water content $\theta_g \gg 1$ is possible (organic soils)
Degree of saturation	s	$\frac{\theta_v}{n} \times 100\%$	–	$s_{\max} = 100\%$
Matric potential	h, ψ	Specific binding energy of pore water	m; Pa	Corresponds to soil water tension $t_{sw} = -\psi$
pF-Value	pF	$\log_{10}(-\psi)$	–	ψ in cm, defined only for unsaturated conditions
Air entry point	ψ_{aep}	$\max(\psi)$ with $\theta_v < n$	m; Pa	Defines capillary fringe in soil profiles Note that $\psi < 0$ in unsaturated soil Ecological indicator for soil aeration
Field capacity potential ^b	ψ_{fc}	$\psi_{fc} = -10^{1.8} \times 10^{-2}$	m	Matric potential at hydraulic equilibrium, i.e., water flux close to zero throughout the soil profile;
Wilting point potential	ψ_{wp}	$\psi_{wp} = -10^{4.2} \times 10^{-2}$	m	Matric potential at which typical crops start wilting
Field capacity ^b	θ_{fc}	$\theta(\psi_{fc})$	$m^3 m^{-3}$	Ecological indicator for water retention against gravity
Air capacity	θ_{ac}	$n - \theta_{fc}$	$m^3 m^{-3}$	Ecological indicator for soil aeration
Wilting point water capacity	θ_{wwc}	$\theta(\psi_{wp})$	$m^3 m^{-3}$	Ecological indicator for water stress
Plant available field capacity	θ_{pwc}	$\theta_{fc} - \theta_{wwc}$	$m^3 m^{-3}$	Ecological indicator for plant available water

^a For definition of n see Table 61.1

^b There are two approaches for the definition of field capacity: (a) the amount of water that is kept by the soil against the gravitational force at hydrological equilibrium (not a material characteristic); (b) the field capacity as a point of the water retention curve (θ_v at $pF = 1.8$); here we use approach (b), which is a property of the soil pore system.

Fig. 61.4 Hysteretic behavior of the water retention curve. The shaded area is the area of scanning curves, i.e., curves of incomplete drainage and/or imbibition. The imbibition/drainage history of a soil is usually unknown and so is the position within the shaded area

of ecosystems. However, direct measurements of processes, dynamics, and fluxes are quite often likewise of great interest.

Most important for the hydrological and ecological behavior of soils and landscapes is the division of fluxes at the soil surface. For water, the relevant processes are given in the water balance equation

$$P + I = ET + D + \Delta W + R + \Delta S, \quad (61.1)$$

where P represents precipitation, I irrigation, ET evapotranspiration, D deep seepage, ΔW storage change in the soil profile (including surface storage), R surface runoff, and ΔS storage change in snow cover, respectively.

Parameters and fluxes related to surface processes comprise infiltration and infiltration capacity, surface runoff, surface storage, and surface roughness. The division of incoming water into infiltration and runoff is quite often controlled by the uppermost few mm of a sealing layer at the soil surface [61.5, 6].

Relevant variables to determine soil heat flux are soil temperature, thermal conductivity, volumetric heat capacity, ground heat flux at the soil surface, and heat fluxes in the soil profile. Undisturbed measurement of soil water and soil heat fluxes is occasionally attempted by direct use of Darcy’s and Fourier’s transport equations (gradient method). In soil hydrology, this approach is in most cases misleading due to the extreme spatial variability and other uncertainties. However, the variability is usually lower and accuracy of measurements is higher for heat flux measurements or rather estimates. Lysimeters and soil heat plates are alternative devices for water and heat flux measurements. However, these methods may disturb the soil to an unknown degree and, thus, change the fluxes. Table 61.4 gives an (incomplete) overview of water and heat fluxes in the soil.

61.1.2 Principles of Measurements

In general, measurements are to be justified by specific project goals (e.g., assessment of soil fertility, soil mapping, process-based modeling, hypothesis testing), and the validity of underlying model concepts. For example, measuring the hydraulic conductivity when Darcy’s law is invalid will yield meaningless results. Measurements are in many cases linked to models. However, intuitive measurement approaches justified by empirical concepts like soil fertility, soil health, or sustainability also exist. From a hydrological point of view, soil is a *hierarchical porous medium* with a pronounced spatial heterogeneity, nonlinear material functions, and associated hydrological processes like runoff, infiltration, and redistribution, especially under field conditions.

Spatial heterogeneity of soil needs to be reflected by adapted *sampling strategies*. One concept is the *representative elementary volume REV*, a sampling volume that covers all relevant structural elements of the site and reduces the fluctuations of a variable to its minimum. However, each variable has its own REV, and it

Table 61.4 Water and heat flux measurements near the soil surface

Flux	Unit	Measurement, determination	Comments
Throughfall	$\text{m}^3 \text{m}^{-2} \text{s}^{-1}$	Rain gauges	High spatial variability, direct interface soil–atmosphere
Stemflow	$\text{m}^3 \text{m}^{-2} \text{s}^{-1}$	Stemflow collectors	Point infiltration, generation of heterogeneity and preferential flow
Runoff	$\text{m}^3 \text{m}^{-2} \text{s}^{-1}$	Runoff plots, flow divider systems	Complementary to infiltration
Infiltration	$\text{m}^3 \text{m}^{-2} \text{s}^{-1}$	Infiltration rings, runoff plots, flow divider systems	Critical processes: sealing, crusting, surface storage
Evaporation	$\text{m}^3 \text{m}^{-2} \text{s}^{-1}$	Estimated from ET_p (potential evaporation) and LAI (Leaf Area Index)	Direct interface soil–atmosphere
Ground heat flux	W m^{-2}	Application of Fourier’s law, heat flux plates	Upper boundary for soil heat flux
Soil temperature profiles	K, °C	Soil temperature sensors, several principles	Installation along soil profile

Fig. 61.5 Determination of the water retention curve in a sampling cylinder (principle)

may even not exist for specific site conditions. Mapping requires the set up of *sampling grids* and demands consideration of spatial autocorrelations in the field and in landscapes. Here again, each soil variable has its own spatial structure expressed in terms of autocorrelation length and variance. *Bulk samples*, usually taken with a soil auger (Sect. 61.4.1) are used for soil texture and for soil chemical analyses. Many soil hydrological parameters shown in Tables 61.1–61.3 require *volume samples* (Sect. 61.4.1). Bulk samples and volume samples are both destructive, i.e., it is not possible to repeat measurements at the same sampling location. Therefore, in order to measure temporal changes in form of *time series*, great effort has been devoted in the past to develop sensors for relevant state variables in the soil like water content, matric potential, or soil temperature. A major obstacle is quite often the limited number of sensors due to financial restrictions.

Because soil hydrological processes are nonlinear, their *averaging* requires special care. A physically meaningful averaging should always be preferred to standard statistical averaging. Averaging is a vast field and cannot be covered comprehensively in this chapter. In practical applications, effective parameters may often be obtained by calibrations at the study scale

61.2 History

A comprehensive history of measurements in soil physics and soil hydrology is outside of the scope of this chapter. However, the following overview gives a short impression of the milestones. Soil physics and soil physical measurements are as old as agricultural land use. Irrigation, drainage, and storage of soil water for plant use were the processes early farmers were particularly interested in, and this remains relevant today [61.2, 9]. Progress in measurements and in theory

based on distributed point measurements. Some measurements are *intuitive* in the sense that basic and intuitive understanding of soil processes and properties allows the development of measurement designs, e.g., for bulk/particle density, water content, infiltration tests, surface runoff, surface storage, or surface roughness. Intuitive does not imply simple (e.g., Fig. 61.5). Measurement design is often derived from basic physical properties and/or transport laws (Darcy's law, Fick's law, Fourier's law, Richards equation, etc.). Advanced measurements use field data or soil column experiments in the laboratory together with *inverse modeling* to identify soil hydrological parameters like conductivity, for example [61.7].

Measuring soil physical and hydrological parameters in the lab as well as in-situ faces many challenges that cannot be fully covered in this contribution. We emphasize the most important ones only like shrinking, swelling, heterogeneity of soil parameters, system disturbance by measurements, hysteresis of material functions, or violation of assumptions for field measurements (homogeneity, isotropy). Further, technical restrictions and problems like impermeable core walls in soil column experiments, smearing effects, or boundary fluxes along measurement devices (field sensors) can hamper measurements. For some sensors like thermocouples, tensiometers, and gypsum blocks, equilibrium between the soil and the sensors is a precondition that is not always met in dynamic situations (e.g., rapid infiltration of water).

Forces acting on the soil water cannot be measured directly. However, we can measure potentials and calculate the forces as their negative gradients. Water flux can be measured in lysimeters of different sizes and locations in the soil profile. The main limitation of lysimeters is the disturbance of the flow field in the soil. This can lead to completely wrong measurements. Devices to overcome this problem are expensive and need intensive maintenance. Soil heat fluxes are often measured using heat-flux plates assuming that disturbances by the plates can be neglected [61.8].

were interlinked. However, quite often improvements of measurements resulted from a general technological progress in mechanics, electronics, and computer technology and not from advances in theory.

Henry Darcy (1803–1858) was the first to study the movement of water experimentally and developed a simple empirical linear formula for the description of water fluxes in saturated soils with the saturated hydraulic conductivity k_s as a proportionality con-

stant [61.10]. Darcy's law was often criticized for its simplicity, and its validity is doubted to date. However, it is still used in even advanced theoretical approaches and models. *Edgar Buckingham* (1867–1940) [61.11] extended the applicability of Darcy's law to unsaturated soil conditions by replacing k_s by the nonlinear conductivity function $k(\theta)$ and the matric potential (61.8), which can be measured with tensiometers. This marked the birth of the potential theory in soil hydrology. *Lorenzo A. Richards* (1904–1993) [61.12] built upon this approach and combined it with the equation of continuity (61.9). The resulting Richards equation (61.10) is a nonlinear, second-order parabolic differential equation that cannot be solved with elementary methods. Thus, empirical formulas like the approach by *Green* and *Ampt* [61.13] for infiltration or the Ernst equation [61.9, 14] for the determination of k_s have survived to date. Simultaneously, mathematicians, physicists, and soil hydrologists developed the potential theory and quasi-analytical solutions of Richards equation at advanced levels [61.15–18] with useful applications in drainage and irrigation science [61.19–22]. As they claim to be mathematically exact, the solutions of these days are still useful at least for the testing of numerical models.

This theoretical progress was accompanied by a technological progress that brought about substantial improvements of sensors, data recording and transmission technologies, automating methods, tomographic methods for microscale structure analyses [61.23–26], and computer power. The latter considerably accelerated the application of numerical methods and the

development of numerical, process-based simulation models [61.27, 28]. Numerical and statistical models were increasingly used for the analysis of measurements, parameter and process identification by inverse modeling [61.7, 29], time series, risk, and error analyses [61.30–32]. The improvement of the sensors allowed the development of sophisticated measurement designs in soil profiles and in the laboratory [61.7, 29, 33].

Recent and still ongoing research focuses on non-Darcian flow in macropore systems (kinematic wave theory) [61.34–36], the analysis of preferential flow paths, e.g., with dye tracers [61.31, 32, 37, 38], tomographic methods for detailed structural analyses and modeling at the microscale [61.23, 25], time series methods for hydrological time series [61.30], spectral methods, and remote sensing [61.39, 40].

Measurements of surface temperatures have been part of the measurement program since the beginning of regular meteorological measurements in the second half of the nineteenth century. The soil temperature as a part of the heat balance of the Earth's surface was already discussed in textbooks of this time. With the beginning of comprehensive surface energy studies in the 1950s to 1970s (Chap. 55) and more accurate radiation measurements, the interest to measure the ground heat flux increased [61.41]. One of the first comprehensive studies was published in 1973 [61.42]. The available energy as the sum of net radiation and ground heat flux was necessary for the determination of evapotranspiration with the Bowen-ratio method or the Penman–Monteith method (Chap. 57). *Sauer* and co-workers [61.43] offer a review of different thermal sensors.

61.3 Theory

Soil water storage and dynamics are governed by forces and local balances (equation of continuity). Forces cannot be measured directly in soils. However, assuming that they are conservative, forces can be derived from potential fields. Therefore, potential theory together with transport laws and local balances constitute the theoretical backbone of water dynamics in porous media.

61.3.1 Potentials and Forces

Water in soil is moved by forces in force fields that are considered as conservative (force field without curls: $\nabla \times \mathbf{F} = 0$). Such forces can be formulated as negative gradients of associated potentials [61.44] (e.g., gravitational force can be derived from gravitational potential)

$$\mathbf{F} = -\text{grad } V = -\nabla V. \quad (61.2)$$

The symbol ∇ is called the nabla operator and is defined in Cartesian coordinates as

$$\nabla \equiv \begin{pmatrix} \frac{\partial}{\partial x} \\ \frac{\partial}{\partial y} \\ \frac{\partial}{\partial z} \end{pmatrix}. \quad (61.3)$$

In soil hydrology, ∇ is used as formal operator to express gradients of potential fields (∇V), divergence of flow fields ($\nabla \cdot \mathbf{v}$), and curl densities of force fields ($\nabla \times \mathbf{F}$).

The potential of soil water is defined as work to transfer a given amount of water (mass, weight, volume) from a chosen point (\mathbf{r}_1) in the soil to an (arbi-

trarily) defined reference point (level, r_0)

$$V(x, y, z) = - \int_{r_0}^{r_1} \mathbf{F} ds. \quad (61.4)$$

This integral is independent of the selected integration path, and the potential difference between two points (r_1, r_2) is given by the difference of their potentials.

$$\begin{aligned} W &= \int_{r_1}^{r_2} \mathbf{F}(\mathbf{r}) ds = - \int_{r_1}^{r_2} \nabla V ds \\ &= - \int_{r_1}^{r_2} dV = -(V(r_2) - V(r_1)). \end{aligned} \quad (61.5)$$

This is equivalent to

$$\oint \mathbf{F} ds = 0. \quad (61.6)$$

In each point in the soil, several forces are superimposed. Accordingly, the total hydraulic potential H is the sum of subpotentials h_i along any selected path

$$\begin{aligned} H &= \int_r^{r_0} \mathbf{F} ds = \int_r^{r_0} \left(\sum_i \mathbf{F}_i \right) ds \\ &= \sum_i \int_r^{r_0} \mathbf{F}_i ds = \sum_i h_i. \end{aligned} \quad (61.7)$$

Dimensions and units of potentials depend on the type of reference quantity, namely mass, volume, and weight of water. In soil hydrology, all three references are used and have their distinct advantages and disadvantages (Table 61.5). The hydrologically relevant subpotentials are given in Table 61.6.

61.3.2 Gradients, Fluxes, and Transport Equations

Transport of soil water is widely described by Darcy's law [61.10], which was extended by *Buckingham* [61.11] for unsaturated conditions. It states that flux densities are proportional to the driving force

$$\mathbf{q} = -\bar{\mathbf{k}} \cdot \nabla \psi_t, \quad (61.8)$$

where ψ_t is the total hydraulic potential and $\bar{\mathbf{k}}$ the hydraulic conductivity tensor, respectively. Under isotropic conditions $\bar{\mathbf{k}}$ simplifies to the scalar parame-

ter k . Please note that $\bar{\mathbf{k}}$ is a nonlinear function of the soil water content θ .

Storage change in soil is described by the equation of continuity

$$\frac{\partial \theta}{\partial t} = -\nabla \cdot \mathbf{q}, \quad (61.9)$$

in which \mathbf{q} denotes the vector of water flux density. Equation (61.9) describes the temporal change of water content by the spatial change of local flux densities and is also called a local balance of soil water.

Combining (61.8) and (61.9) and adding a source/sink term yields the transport equation for saturated/unsaturated transient conditions, the so-called extended Richards equation [61.12]

$$\frac{\partial \theta(\psi_m)}{\partial t} = \nabla \cdot [\bar{\mathbf{k}}(\theta(\psi_m)) \cdot \nabla \psi_t] + U. \quad (61.10)$$

Usually, transpiration is considered in the sink term U , whereas evaporation from the soil surface is taken into account by an appropriate formulation of the upper boundary condition of the flow region. Similarly, using Fourier's law of heat conduction $\mathbf{Q} = -\bar{\lambda} \cdot \nabla T$, a corresponding continuity equation and adding a convection term yields the equation for heat transport in soil

$$\frac{\partial (c_v(\theta)T)}{\partial t} = \nabla \cdot [\bar{\lambda}(\theta(\psi_m)) \nabla T] - c_w \nabla \cdot (T \cdot \mathbf{q}) + V. \quad (61.11)$$

For isotropic conditions, the thermal conductivity tensor $\bar{\lambda}$ simplifies to the scalar parameter λ . Parameter functions $\theta(\psi_m)$, $\bar{\mathbf{k}}(\theta(\psi_m))$, and $\bar{\lambda}(\theta(\psi_m))$ are nonlinear functions, whereas $c_v(\theta)$ is a linear function of water content.

If we further assume that water flow is negligible, water content is constant in a homogeneous soil, and no heat sources or sinks are present, (61.11) simplifies to

$$c_v \frac{\partial T}{\partial t} = \lambda \nabla^2 T, \quad (61.12)$$

and

$$\frac{\partial T}{\partial t} = \frac{\lambda}{c_v} \nabla^2 T = D_T \nabla^2 T, \quad (61.13)$$

which is the thermal diffusion equation with $D_T :=$ heat diffusivity. In one dimension this is

$$\frac{\partial T}{\partial t} = D_T \frac{\partial^2 T}{\partial z^2}. \quad (61.14)$$

This simplified version is quite often successfully used in micrometeorology to determine D_T with field data by a finite difference approximation of (61.14), for example.

Table 61.5 Dimensions and units of potentials in soil

Reference quantity	Dimensions	Unit	Comments
Mass	$L^2 T^{-2}$	$m^2 s^{-2}$	Reference quantity unchanged at pressure changes
Volume	$MT^{-2} L^{-1}$	Pa	Corresponds to measurement devices like tensiometers and piezometers
Weight	L	m	Intuitive for gravitational potential and experimental setups in laboratories (column experiments, pressure plates)

Table 61.6 Relevant sub-potentials of soil water; all sub-potentials add up to the total potential and contribute to the driving force of water movement in soil

Potential	Symbol	Corresponding forces	Comments
Matric potential	h_m, ψ_m	Capillary forces	Caused by surface tension at the water air interface in unsaturated soil pores
Piezometric potential	h_p, ψ_p	Water pressure forces in saturated soil	Corresponds to hydrostatic pressure only at hydraulic equilibrium (zero flux for all depths)
Gravitational potential	h_g, ψ_g	Gravitational force	Depends on the position of the reference level (which cancels out in transport equations)
Osmotic potential	h_o, ψ_o	Force to move water against a concentration gradient	In moist soils negligible (in dry soils are the extremely low conductivities the limiting factor), particularly important in the vicinity of semipermeable membranes
Gas potential	h_a, ψ_a	Pressure forces of soil air in unsaturated soil	Pressure changes caused by soil temperature variation, air pressure variation at the soil surface, nonequimolar chemical reactions in soil (CH ₄ and N ₂ O production, O ₂ consumption)
External load potential	h_l, ψ_l	Forces associated to mechanical stresses by grain–grain contacts	Not well defined in the sense of (61.4)

61.3.3 Ground Heat Flux

The ground heat flux is an important parameter in atmospheric science because it is part of the energy balance equation at the Earth's surface together with the net radiation and the sensible and latent heat fluxes. In contrast to the scales in the atmosphere, the scale of measurements in the soil is very small, and the heterogeneity of soil properties is ignored [61.45] (Chap. 1, Sect. 61.4.3). The ground heat flux, Q_G , is mainly based on molecular heat transfer and is proportional to the temperature gradient and the thermal molecular conductivity λ in the soil (Sect. 61.1.1).

$$Q_G = -\lambda \frac{\partial T}{\partial z}, \quad (61.15)$$

where T is the temperature and z the depth, respectively.

The heat flux directly at the surface is particularly interesting. Several methods are used [61.46–48], and two principles are common, namely the calculation according to (61.15), where the temperature gradient is extrapolated to the surface, or the determination of the heat flux at a certain depth and the calculation of the change of the heat storage in the layer above.

$$Q_G(0) = Q_G(-z) + \int_{-z}^0 \frac{\partial}{\partial t} c_v(z) T(z) dz, \quad (61.16)$$

with the time t and the volumetric heat capacity c_v . Based on (61.16) and a sensitivity analysis [61.8] two optimal designs for ground heat flux measurements are possible: (i) a soil heat-flux plate should be buried rather deeply (0.1–0.2 m) with several temperature measurements made above it to calculate the heat storage; (ii) a similar accuracy can be achieved if only one temperature profile is measured to calculate both the soil heat flux according to (61.15) over the depth of 0.1–0.2 m and the heat storage term above this layer and the surface.

The volumetric heat capacity $c_v = a_G/\nu_T$ (ν_T is the molecular thermal diffusivity; see Chap. 5) can be assumed constant with depth in the case of a uniform soil moisture and can be determined as [61.3]

$$c_v = c_{v,m}x_m + c_{v,o}x_o + c_{v,w}\theta, \quad (61.17)$$

with the heat capacity of the mineral and organic compounds

$$c_{v,m} = 1.9 \times 10^6 \text{ J m}^{-3} \text{ K}^{-1},$$

$$c_{v,o} = 2.479 \times 10^6 \text{ J m}^{-3} \text{ K}^{-1},$$

and for water

$$c_{v,w} = 4.12 \times 10^6 \text{ J m}^{-3} \text{ K}^{-1}.$$

The contribution of mineral components (assumed particle density of minerals: 2650 kg m^{-3}), x_m , in $\text{m}^3 \text{ m}^{-3}$

can be determined by measurements of bulk density and volumetric content of organic matter of the soil. For depths up to 20 cm, the volumetric content of organic matter x_o can often be neglected. The volumetric moisture content of the soil is θ and is given in $\text{m}^3 \text{m}^{-3}$. For the calculation of soil heat flux from the temperature gradient according to (61.15), the coefficient of heat conductance, λ , is necessary

$$\lambda = c_v D_T, \quad (61.18)$$

where D_T is the thermal diffusion coefficient that can be determined using a simple method [61.49], in which the temperature sensors are installed at three depths (0.10, 0.15, and 0.20 m), and the temperature difference between two time steps ($\Delta t = 1 \text{ min}$, $\Delta z = 0.1 \text{ m}$) is determined

$$\frac{T_{15 \text{ cm}}^{n+1} - T_{15 \text{ cm}}^n}{D_T \Delta t} = \frac{T_{20 \text{ cm}}^n - 2T_{15 \text{ cm}}^n + T_{10 \text{ cm}}^n}{(\Delta z)^2}. \quad (61.19)$$

The simplest method is the measurement with an integrating temperature sensor of the mean temperature of the soil layer between the surface and the heat-flux plate. For the ground heat flux near the surface, it then follows that

$$Q_G(0) = Q_G(-z) + \frac{c_v |\Delta z| \left[\overline{T(t_2)} - \overline{T(t_1)} \right]}{t_2 - t_1}. \quad (61.20)$$

For the modeling of the ground heat flux, multiple layers are used. The most appropriate and accurate model is the two-layer model (force-restore method) developed by *Blackadar* [61.50]. The ground heat flux can be calculated from two components, i.e., from the change of the temperature of the thin surface layer due to radiation and from the slow wave of the temperature difference between the surface layer and a deeper layer [61.51].

61.3.4 Soil Heat Flux Plates

Soil heat flux can be measured at a certain depth with soil heat flux plates. They consist of two metal-

lic plates separated by a layer of resin, with a heat conductance matching that of the soil. The temperature difference between the plates is measured with thermocouples; their output signal is proportional to the soil heat flux (61.15). The most important sources of measurement errors are the differences of the heat conductivities between the plates and the soil and at the edges of the plates (deflection error), which are insufficiently included in the temperature measurement [61.52]. The widely used correction factor f suggested by *Philip* [61.53] relates the measured soil heat flux, Q_G and the soil heat flux through the surrounding soil, Q_G

$$f = \frac{Q_G}{Q_G} = \frac{\epsilon}{1 + (\epsilon - 1)H}, \quad (61.21)$$

where ϵ is the ratio of the heat conductivities $\lambda_{\text{plate}}/\lambda_{\text{soil}}$. The factor H depends on the geometry of the heat flux plate and is given for square plates as

$$H = 1 - \frac{1.7d_{\text{plate}}}{L} \quad (61.22)$$

and for round plates as

$$H = 1 - \frac{1.92d_{\text{plate}}}{D}, \quad (61.23)$$

where d_{plate} is the thickness of the plate, L is the length of the square plate, and D is the diameter of the round plate. A similar correction is the one by *Morgensen* [61.54]

$$f = \frac{Q_G}{Q_G} = \frac{\epsilon}{\epsilon - 1.7(d_{\text{plate}}/\sqrt{A_{\text{plate}}})(\epsilon - 1)}. \quad (61.24)$$

Such a correction is recommended by some authors [61.55], however, it is doubted by others [61.51]. The problem is the knowledge of λ in the soil that is highly variable [61.56] (Sect. 61.1.1).

61.4 Devices, Systems, and Analyses

In this section, we describe selected hydrological and thermal measurements and associated evaluations. We start with surface processes, including surface runoff, infiltration, and surface storage. Then, we continue with soil moisture, hydraulic parameters, and hydraulic functions, and finally, we present thermal methods to characterize and quantify the heat transport in soil. For

more complete information, the reader is referred to Sect. 61.10.

61.4.1 Infiltration and Runoff

At the soil surface the incoming precipitation or irrigation water is divided into runoff and infiltration. Quite

Fig. 61.6 Double-ring infiltrometer for quantifying actual infiltration capacity and/or field saturated conductivity. The water levels in the inner and outer rings are the same (and as low as possible) and are kept constant using two Mariotte bottles. The reading is performed only in the inner ring where parallel flow is assumed

often, e.g., in erosion studies, one is interested in the infiltration capacity, i.e., the maximum influx rate of water under the given boundary conditions. No runoff will be generated as long as infiltration capacity and surface storage capacity remain below their respective thresholds. In this section, we present standard methods to measure the saturated and unsaturated infiltration and a more demanding method for surface roughness and surface storage capacity.

Double-Ring Infiltrometer

Double-ring infiltrometers are simple devices for measuring actual infiltration capacities (Fig. 61.6). However, considering infiltration theory in a homogeneous soil they further allow us to interpret the infiltration rate as field saturated conductivity (or as effective saturated conductivity in the case of not perfectly homogeneous soils), as $\lim_{t \rightarrow \infty} d\psi/dz = 0$ and – according to Darcy’s law – we get $\lim_{t \rightarrow \infty} q = k_s$. In principle, this is a constant head infiltration experiment and different empirical, semiempirical, analytical, and numerical methods can be used to evaluate the measured data.

The *Green and Ampt* equation [61.13] is derived using a physically motivated approach with unrealistic assumptions. It is still used nowadays, even in comprehensive simulation packages like the Soil and Water Assessment Tool (SWAT) [61.57].

$$i = i_f + \frac{b}{I}, \quad (61.25)$$

where i is the infiltration rate, I the cumulative infiltration, and i_f and b are characteristic constants, respec-

tively. Please note that initially $I = 0$ and $\lim_{I \rightarrow 0} i = \infty$. On the other hand, $\lim_{I \rightarrow \infty} i = i_f$ and, thus, i_f may be interpreted as the saturated conductivity k_s .

The equation by *Kostiakov* [61.58] is simple and completely empirical

$$i = at^b. \quad (61.26)$$

The parameters a and b are completely empirical. For $b < 0$ the infiltration rate, i asymptotically approaches zero. Therefore, it is impossible to estimate k_s from this equation.

Horton [61.59] introduced an initial infiltration rate i_0 and a final infiltration rate i_f in an exponentially decreasing function, which intuitively makes sense

$$i = i_f + (i_0 - i_f)e^{-kt}. \quad (61.27)$$

For $t = 0$, this equation gives $i = i_0$, for $t \rightarrow \infty$ we find $i = i_f$, which again may be interpreted as the (effective) saturated conductivity.

The equation by *Philip* [61.15] is a simplification of a rigorous mathematical treatment (power series) of Richard’s equation (61.10).

$$i = \frac{1}{2}st^{-1/2} + i_f, \quad (61.28)$$

where the sorptivity s is given by $s = I/t^{1/2} = s(\theta_0, \theta_i)$. Again, for $t \rightarrow 0$ the infiltration rate is ∞ .

Surface Runoff

The second important water flux at the very soil surface is surface runoff. The splitting of the incoming rainfall or irrigation into infiltration and runoff is often controlled by a thin sealing layer with a thickness of only few millimetres [61.5, 60]. It makes no sense to take undisturbed soil cores for laboratory measurements. However, in a constant rate irrigation experiment microtensiometer arrays can be used to determine integrated hydraulic parameters for characterization of the sealing layer, the hydraulic impedance, defined by

$$I_h = \int_{z_s}^{z_0} \frac{1}{k} dz,$$

and the hydraulic conductance, which is just the reciprocal of I_h . Parameters z_s and z_0 are the sealing depth and the soil surface, and k is the hydraulic conductivity [61.61]).

Other important factors are slope and microtopography. The latter plays an important role for surface storage of soil water and can delay runoff and reduce

Fig. 61.7 Using stereo photography for quantifying surface storage of water

associated erosion losses considerably. An effective method for the assessment of the topographical surface structure is stereo photography with adequate analysis tools [61.62] (Fig. 61.7).

Runoff in the landscape can be measured using runoff collectors (Fig. 61.8) [61.63–67]. Under field conditions routing of soil water and soil suspension needs to be considered. Nowadays, this can be performed using geographic information systems (GIS). Runoff collectors need to be equipped with flux partitioning devices to measure short and intensive runoff events. A simple but effective flow diver system is shown in Fig. 61.9. A rather complex experimental design to study the interaction of precipitation, surface properties, runoff, and infiltration was used in [61.68] and is presented in Fig. 61.10. Results from a similar study at an agricultural study site in Avignon (France) are presented in Sect. 61.8.1 [61.62].

61.4.2 Water in the Soil Profile

Soil water is an essential and temporally variable constituent of soils that is fundamental for ecological func-

Fig. 61.8 Collector for surface runoff and sediment delivery measurements in the landscape (image courtesy of *Arnhold* [61.63]); runoff water and sediment is measured with flow divider systems (Fig. 61.9)

Fig. 61.9 Flow divider system for surface runoff and sediment delivery measurements in the landscape (image courtesy of *Arnhold* [61.63]); runoff water and sediment is collected with a runoff collector (Fig. 61.8)

tioning. The water content is a basic parameter that is highly variable in space and time. For the same soil matric potential the water content varies with the textural composition of sand, silt, and clay. Other sources of this pronounced spatiotemporal variability are the dynamics and spatial heterogeneity of precipitation and/or irrigation water caused by the canopy structure, and the heterogeneity of the subsurface root system.

However, the water content alone is often not very meaningful. It is crucial to distinguish between mass-based and volume-based water content. Further, the

Fig. 61.10 Experiment design for assessment of surface storage, runoff, infiltration, and seepage (image courtesy of Arnhold [61.63])

availability of water to plants (see *Soil Water Potentials* in this subsection) and the mobility regarding seepage or evaporation (see *Conductivities* in this subsection) are important characteristics of water in soil porous media.

Gravimetric Measurement of Water Content

Gravimetric measurement of θ_g and θ_v is basic and straightforward (Figs. 61.11 and 61.12) [61.69]. Often, disturbed soil is used to determine mass-based gravimetric water content θ_g . However, to determine water storage in soil, volumetric water contents θ_v are required, which can be calculated by $\theta_g \rho_b / \rho_w$ (Table 61.3). Gravimetric measurements have the disadvantages to be labor-consuming and destructive. However, they are still the reference for calibrations of other methods, even though these methods face some problems themselves, like swelling and shrinking of the

samples. Indeed, it remains unclear how to define a reference volume in shrinking soil.

Indirect Methods for Water Content Measurements

The drawbacks of gravimetric water content measurements (time and labor-consuming, destructive) brought about the urgent need for nondestructive and fast methods to measure repeatedly at the same location with sufficient accuracy. Early attempts to use matric potential measurements and the water retention curve for water content estimations proved unsuccessful due to the limited measurement range of tensiometers (< -800 hPa) and the often pronounced hysteresis of the water retention curve (Fig 61.4). Successful indirect devices are based on radioactive radiation (neutron scattering, gamma-ray attenuation). Overviews can be found in [61.69, 70].

Fig. 61.11 Bulk sampling of soil. The sampling is destructive, and the internal pore structure is destroyed by sampling

Fig. 61.12 Volume-based sampling of soil. The sampling is still destructive. The internal pore structure is ideally not destroyed by sampling

Neutron probes based on neutron thermalization were the first widely accepted indirect and reliable instruments for water content measurements [61.2, 71] and are probably still used today. The idea is to capture thermalized neutrons as a measure for protons in the soil. The probe consists of a source of fast neutrons (Ra-Be mixture) and a detector for thermalized neutrons. It is (manually) inserted via a cable through the protection shield into an access tube (consisting of Al, for example) to the desired depth. Thermalized neutrons are counted by battery powered external rate meter. As the ratio of protons to soil water varies with organic matter and clay content, the method needs site-specific calibration [61.72]. Thus, it is most suitable for long-lasting monitoring programs. The method faces difficulties in shallow (neutron emissions partly go into the atmosphere) and in stony soils, in which an accurate installation of the access tube may be impossible. The major drawback, however, is the radiation exposure hazard, the required protection measures, and safety rules (dosimeters, secured storage space, trained radiation protection officials).

The *γ-ray absorption method* is another radioactive approach for the measurement of soil water [61.2, 73, 74]. It typically needs two access tubes, one containing the radioactive source emitting gamma radiation (^{137}Cs) and the other for a detector, typically a scintillation counter. The method was first developed for laboratory studies. *Vomocil* [61.75] customized the design for field conditions. The method has a better depth resolution compared to neutron scattering that allows the identification of wetting fronts, measurements around sharp material layers, and measurements closer to the soil surface. However, the installation of two exact parallel tubes might pose serious problems, especially in stony soils. It also needs thorough calibration, which can be difficult for a higher resolution in the range of, e.g., 1 cm [61.76]. The *radioactivity* drawbacks are the same as for the neutron probe.

Customization of the *time-domain reflectometry* (TDR) method – which was initially and is still a technique to detect cable leakages – to soil conditions brought a great progress for water content measurements in the field [61.2, 70, 77, 78]. The method is nonradioactive and allows recording of high-resolution time series. It relies on the considerable difference of the relative dielectric constant of water ($\epsilon_r \approx 81$) and dry soil ($\epsilon_r \approx 4-8$). The principle of measurement is the analysis of the propagation velocity v of a high-frequency electromagnetic wave in soil and the calculation of ϵ_r from $v = c/\epsilon_r^{0.5}$, where c is the velocity of light in vacuum. The measurement design comprises a high-frequency generating and recording unit and, typically, two parallel antenna rods inserted

Fig. 61.13 Nondestructive measurement of volumetric water content using the TDR technique. The sensors can be installed in any depth, and the signal can easily be recorded by data loggers

into the soil (Fig 61.13). The electromagnetic wave is reflected on each discontinuity, and the reflected signal is recorded and analyzed in the TDR unit. With L being the length of the rods, ϵ_r can be calculated as $\epsilon_r = (ct/2L)^2$. An empirical functional relation between θ_v and ϵ_r was provided by [61.79]

$$\theta_v = -5.3 \times 10^{-2} + 2.9 \times 10^{-2} \epsilon_r - 5.5 \times 10^{-4} \epsilon_r^2 + 4.3 \times 10^{-6} \epsilon_r^3. \quad (61.29)$$

This equation was successfully used in an irrigation scheduling study in [61.77]. Other calibration curves were provided, e.g., by [61.80–82]. The measurements need a precise insertion of the waveguides into the soil to avoid air gaps around the rods. TDR measurements are sensitive to salinity, which can be measured simultaneously but may also disturb the water content measurements. For organic soils, a recalibration is recommended, as (61.29) only holds for mineral soils.

TDR measurements are known to have accuracy limitations in clayey soils and heavy soils with high salinity [61.83–85]. *Frequency domain reflectometry* (FDR) tries to overcome or mitigate these problems by analyzing the frequency domain instead of the time domain. Early attempts to transform time-domain waveforms into the frequency domain were later replaced by techniques that capture the signals directly in the frequency domain with significant improvements, like lower sensitivity to salinity. A sensor that has a bandwidth that allows us to measure salinity as well as water content with improved accuracy was developed in [61.83].

In recent years, capacity probes and impedance probes have been developed that are all based on the difference of ϵ_r between water and soil. Princi-

ples of measurements are the determination of capacitance or impedance (fixed frequency, shifting frequency, often using amplitude changes along a standing wave [61.86]), sometimes called *amplitude domain reflectometry* (ADR). The signal is often converted to a voltage to simplify the measurement and facilitate data recording [61.86, 87]. Twelve dielectric sensors of different types under saline conditions were compared in [61.88]. Results were reported by the authors to be comparable and acceptable.

Other Methods for Water Content Estimation

Other methods for water content estimation exist and are based on physical principals and stochastic correlations, like thermogravimetry, electrical conductivity, soil thermal properties, heat pulse sensors, ground penetrating radars, electromagnetic induction, direct current resistivity, passive and active remote sensing, acoustic wave propagation, or optical methods. Several of these methods have the potential of soil moisture mapping on different scales. These methods were described and discussed comprehensively in [61.70].

Soil Water Potentials

Soil water potentials were defined in Sect. 61.3. Relevance and measurements are described, e.g., in [61.2, 69]. For water movement in the soil matrix, the matric potential (unsaturated soil), piezometer potential (saturated soil), and gravitational potential are generally the most relevant potentials. The availability of soil water to plant roots is controlled by matric potentials (specific binding energy). However, unsaturated conductivities are another essential soil property when we look at water uptake by plant roots and transpiration rates.

The measurement of potentials is comparatively simple (Sect. 61.10). The *gravimetric potential* is the length difference between a point of measurement and the reference level in the gravity field (soil surface, groundwater, or elsewhere), provided that the reference quantity is weight (Table 61.5). The *piezometer potential* corresponds to the matric potential in the saturated zone. It can be measured as pressure at the bottom of piezometers (groundwater access tubes that are open at the bottom). In the case of hydraulic equilibrium (zero flux at all points), the measurements reflect the hydrostatic pressure. This is not the case under nonequilibrium conditions like drainage in agriculture or in confined aquifers.

Matric potentials are measured using tensiometers. A simple design is shown in Fig. 61.14. The range of measurements depends on the pore size distribution of the porous cell and is typically > -800 hPa. Tensiometers can also be operated under saturated conditions and may, thus, replace piezometers. The size of the

Fig. 61.14 A simple tensiometer for manual matric potential measurement in soils. The pressure caused by the water column must be subtracted from the pressure reading

porous cell must be chosen according to the research question (sample size, spatial resolution). Under field conditions, the pressure sensors are typically connected to data loggers. Measurement of matric potentials requires equilibrium between the soil and porous cell. This condition is violated under highly dynamic field conditions. The retardation of equilibrium depends on the amount of air in the system and the soil type. Most critical are sandy soils, because hydraulic conductivities are close to zero at high potentials of, e.g., -100 hPa already (which is a moist soil).

In the drier range down to $-15\,000$ hPa (wilting point), *electrical resistance blocks* (gypsum blocks, fiber) can be used [61.2, 89]. However, the precision is quite low [61.69]. These sensors need careful calibration in the laboratory and are prone to hysteresis (Fig 61.4) [61.90]. This also holds for newer approaches based on water content measurement in ceramic blocks. The so-called *pF-meter* [61.91], for example, is based on the volumetric heat capacity. However, c_v is a function of the volumetric water content and not of the matric potential. Hence, calibration and hysteresis are again issues to be addressed. Another sensor for dry conditions is the *thermocouple psychrometer* that determines the relative humidity in air-filled porous cells that are in hydraulic equilibrium with the soil [61.92].

Fig. 61.15 Measurement of points of the water retention curve in the low-pressure range (wet to moist soil) with a ceramic plate equipment

The required moist and dry temperatures are obtained by utilizing the so-called Peltier effect. The measuring range is rather narrow, with a maximum pF value of 4.8 and a minimum one of 3.3 [61.93].

Matric potential measurements provide information about the momentary availability of soil water but tells us nothing about the available amounts. To get this information we need the *water-retention curve* (WRC), which was already defined in Fig. 61.3 and Table 61.3. WRC can be estimated from field data of θ_v and ψ_m using a suitable parametrization of WRC and nonlinear regression. However, the result is quite often unsatisfactory due to the small range of measurements and the tremendous spatial heterogeneity of data. Water retention curves are, therefore, in most cases measured in the laboratory. Typical devices are ceramic suction (Fig. 61.15, $-\infty < \text{pF} \leq 2.5$) and pressure plates (Fig. 61.16, $2.5 < \text{pF} < 4.2$). Values for the drier range can be obtained with high-concentration salt solutions equilibrated with soil samples [61.92]. WRC is mostly determined as the drainage curve starting from saturated samples. Hysteresis is usually not considered. Anyway, even if we had hysteresis information we would still face considerable unavoidable uncertainties under field conditions, as the *history* of measured water contents and associated matric potentials remains unknown [61.2].

Conductivities

Hydraulic conductivity is – in addition to the potential gradients – the crucial parameter function that controls water flow to groundwater (groundwater recharge) and/or soil surface (evaporation) and plant roots (transpiration). The function is strongly nonlinear and hysteretical. Nonlinearity is extreme for sandy soil which hydrologically behaves like a switch. Down to a matric potential of -10^4 Pa (pF = 1), the conductivity is close

Fig. 61.16 Measurement of points of the water retention curve in the high-pressure range (dry soil) with ceramic plate equipment; the height of the samples is drastically reduced due to the extremely low hydraulic conductivity in the moist to dry range

Fig. 61.17 Hydraulic conductivity in soils at saturation (k_s). The minimum values are determined by soil texture, the maxima by soil structure. The maximum values are independent of texture and more or less the same for all texture classes

to saturation and falls within a 1 pF step (pF = 2) to practically zero [61.2]. Typical for conductivities is the pronounced spatial heterogeneity. Figure 61.17 gives an impression of possible ranges of values. Measurements are done under controlled laboratory conditions, as well as in the field. For several practical and theoretical reasons, laboratory data cannot be easily used under field conditions (e.g., isolation of the sample from the continuous pore system of the soil). In this section, we focus on selected field methods for hydraulic conductivity in saturated and unsaturated soils. For other methods and more details, the reader is referred to [61.77, 94, 95].

Fig. 61.18 Borehole method

In Sect. 61.4.1, we already discussed the use of double-ring infiltrometers *double-ring infiltrometer* for the measurement of k_s . The method assumes homogeneity over the extent of the infiltration front in which $d\psi_m/dz = 0$ and, thus, k_s is equal to the infiltration rate i . The double-ring infiltrometer is typically used in initially unsaturated soil. The required amount of water is comparably high.

The *borehole method* (Fig. 61.18) was developed to measure hydraulic conductivity in saturated soils in landscapes with high groundwater levels. It is a rising-head borehole measurement. The water level is lower to the desired depth. The initial velocity of the rising water level is measured and used for the calculation of the conductivity. Water flow is described by the Laplace differential equation. Boundary conditions are clearly defined by the experiment. However, there are two solutions to this boundary value problem, namely the equations of *Ernst* [61.14] and the solution of *Boast and Kirkham* [61.96]. Both solutions are based on the potential theory. Ernst proposed a set of two equations

$$k_s = \frac{4000r}{(d + 20r)(2 - y/d)} \frac{r \Delta y}{y \Delta t} \quad (61.30)$$

for $3 \text{ cm} < r < 7 \text{ cm}$, $20 \text{ cm} < d < 200 \text{ cm}$, $0.2 < y/d < 1$, and $s > d$, or

$$k_s = \frac{3600r}{(d + 10r)(2 - y/d)} \frac{r \Delta y}{y \Delta t} \quad \text{for } s = 0. \quad (61.31)$$

The restrictions of (61.30) and (61.31) were later lowered in [61.9, 97] for unknown reasons. In [61.96], an

Fig. 61.19 Principal design of a Guelph permeameter

analytical solution to the boundary value problem was derived

$$k_s = c_{\text{bk}} \frac{\Delta y}{\Delta t}, \quad (61.32)$$

$$c_{\text{bk}} = \frac{864\pi r}{[Q/k_s y r] y}, \quad (61.33)$$

$$\frac{Q}{k_s y r} = 2\pi \left[\frac{r}{2s} - \sum_{m=1,2,\dots}^{\infty} A_m \frac{I_1(m\pi r/s)}{I_0(m\pi r/s)} + \sum_{n=1,2,\dots}^{\infty} B_n b_n \frac{1 - \cos(n\pi)}{n\pi} \right], \quad (61.34)$$

where Q is the amount of water per time that flows into the borehole. Constants A_m , B_n , and b_n are described in detail in [61.96]. Functions $I_0(x)$ and $I_1(x)$ are modified Bessel functions. A table with c_{bk} -values (Table 61.8) was prepared in [61.96]. A comparison of (61.30) and (61.31) with (61.34) was made in [61.98], where differences of up to 30% were found. These results were confirmed using a numerical approach in [61.99].

The *Guelph permeameter* [61.100] is a constant head borehole permeameter for measuring field-saturated hydraulic conductivity k_{fs} under unsaturated soil conditions. The possibility to measure in unsaturated field soils, the low water consumption per measurement, and the possibility to perform measurements in different depths are clear advantages of this method. A similar instrument following the same principles was developed by [61.101]. The so-called *Amoozometer* uses a more rigid operating scheme compared to the Guelph permeameter [61.101]. Assumptions of the method are homogeneity and isotropy of the soil under study. The principal geometry is given in Fig. 61.19. Technical details can be found, e.g., in [61.102]. Data

Fig. 61.20 Tension infiltrometer for quantifying unsaturated infiltration at prescribed negative matric potentials at the soil surface. The negative boundary matric potential is achieved by using two connected Mariotte bottles

evaluation is based on equations in [61.100]

$$Q = \left(\frac{2\pi H^2}{C} + r^2 \pi \right) k_s + \left(\frac{2\pi H}{C} \right) \Phi_m$$

$$= Ak_s + B\Phi_m, \quad (61.35)$$

where Q is the water uptake per time of the soil, k_s is the saturated conductivity, H the height of the water table in the borehole, r the radius of the borehole, $C = f(H/r)$ a dimensionless form factor [61.102], and Φ_m the matric flux potential (61.37), respectively. For a simplified model for $k(\psi)$, the parameter Φ_m is usually determined from $\alpha^* = K_s/\phi_m$, which depends on soil structure and texture. Values for α^* are provided in [61.100]: for coarse sand and strongly aggregated soils $\alpha^* = 0.36 \text{ cm}^{-1}$, for medium and fine sand or normal structured soils $\alpha^* = 0.12 \text{ cm}^{-1}$, for unstructured, fine textured soils $\alpha^* = 0.04 \text{ cm}^{-1}$, and for compact clay $\alpha^* = 0.01 \text{ cm}^{-1}$. These values are rough estimates, and an error analysis is strongly recommended.

Tension infiltrometers (Fig. 61.20) are used to determine infiltration rates in unsaturated soils with a known (prescribed) negative matric potentials at the soil surface. Like double-ring infiltration, it is also a constant head boundary experiment with a negative matric potential at the upper boundary, and we can derive unsaturated conductivities for the prescribed soil suction ψ_i for homogeneous and isotropic soils. In contrast to double-ring infiltration, only a single ring is used here. Thus, the analysis is less straightforward. The evaluation follows the approach of *Elrick* and *Reynolds* [61.100] to describe the (steady) end infiltration rate Q_{TI}

$$Q_{TI} = \pi r^2 K(\psi_t) + 4.2r\Phi_m. \quad (61.36)$$

Fig. 61.21 Instantaneous profile method

Rearranging (61.36) and introducing $\alpha_{TI}^* = K(\psi_t)/\Phi_m$ we get

$$K(\psi_t) = \frac{Q_{TI}}{\pi r^2 + 4.2r/\alpha_{TI}^*}. \quad (61.37)$$

The parameter Φ_m is the matric flux potential, defined by

$$\Phi_m = \int_{\psi_i}^{\psi_t} k(\psi) d\psi.$$

ψ_i is the initial matric potential, and ψ_t the matric potential at the infiltration front (i.e., potential at the upper boundary). Values for α_{TI}^* are provided by [61.100] and can be found in Table 61.7.

The *instantaneous profile method* or *internal drainage method* is another concept for measuring unsaturated conductivities in the laboratory and directly in the field [61.2, 33, 103]. Measurements are based on a time–space grid of matric potential and water content measurements (Fig. 61.21). Initial conditions are known from the first measurement. The upper boundary is typically a zero flux condition, and the evaluation is done by a finite difference approximation of the continuity equation and Darcy–Buckingham’s law for unsaturated conditions (i.e., in fact, Richard’s equation). Starting from the top of the profile with a known upper boundary, the flux in the next compartment can be calculated and solved for the conductivity using Darcy–Buckingham’s law. To smooth out uncertainties in measurements the difference of integrated water contents to depth z and $z + \Delta z$ are used instead of local water content measurements alone. This step is repeated

Fig. 61.22 Measurement plot for soil temperatures according to World Meteorological Organization (WMO) regulations (after [61.104] photo © T. Foken)

sequentially for all compartments by using the just calculated flux from the upper compartment as the upper boundary condition.

61.4.3 Soil Heat

Soil temperature measurements in several depths near the soil surface are basic for the analysis of soil heat dynamics and provides valuable information about amplitudes and damping depths (the depth where $A_0/A_z = 1/e$). Soil heat fluxes may be calculated using the gradient method by applying (61.19) for determination of the thermal diffusivity D_T . Using heat flux plates is an alternative that is usually preferred due to its simplicity and robustness.

Temperature Sensors

Soil temperature measurements are part of a standard meteorological station ([61.104], Chap. 43). Within the station area, a bare patch of ground of about $2\text{ m} \times 2\text{ m}$ is used for observations of the state of the ground (Chap. 22) and of soil temperature measurements (Fig. 61.22). Typical depths for liquid-in-glass thermometers (Chap. 7) are -0.05 , -0.10 , and -0.20 m (seldom -0.02 m). Soil temperatures at depths greater than 20 cm can be installed outside this bare patch of

ground, and the liquid-in-glass thermometers for -0.5 and -1.0 m are mounted on wooden, glass, or plastic tubes. Recently, these thermometers have been replaced by tubes with platinum wire (Pt 100) temperature sensors (Chap. 7) in the relevant levels. Soil temperature measurements for the determination of the ground heat flux must be installed below natural surfaces. Usually, some more levels are necessary or temperature sensors integrating over a certain soil column, if (61.17) is to be applied. For the determination of the soil heat capacity, parallel measurements of the soil moisture are necessary.

Soil Heat Flux Plates

The principle construction of a heat flux plate is shown in Fig. 61.23. A number of thermocouples (Chap. 7) is connected with the upper and lower surfaces of the plate. The sensor body has an averaged heat conductivity of soil. Therefore, the heat flux can be calculated from the temperature difference between the upper and lower sides with (61.15). Self-calibrated plates have a heater at the upper surface. The heater generates a well-known heat flux for a short time period. From this flux, the deflection error can be calculated, and the data can be corrected. This type of plate has the advantage of a higher accuracy but a significant disadvantage in that the data cannot be used during the heating and immediately after the heating [61.105]. An important disadvantage of heat flux plates is the installation of the plates in the soil, because both sides should have an excellent contact with the soil, which should be free of stones. Rain or a water flow along the cables may also be a reason for contact problems. Therefore, the installation at a depth of about 0.2 m (Sect. 61.3.3) may reduce these effects, and the flux is lower, and possible errors have a less significant influence on the ground heat flux at the surface. The installation of three or more plates would help to identify possible misreadings.

Fig. 61.23 (a) Principal schema of a heat flux plate with a number of thermocouples of two different alloys, where the connections of the alloys are connected to the upper and lower sides of the plate. In the case of a self-calibrating plate, a heater is connected with the upper surface of the plate, (b) heat flux plate (image used with permission from Hukseflux, Delft, The Netherlands)

61.4.4 Specific Analyses

Measured time series of state variables (temperatures, potentials, etc.) may contain information that is not intuitively detectable. Adequate analysis methods are, therefore, needed to elucidate their hidden complexity. Permutation entropy, a promising method in this context, is briefly introduced in this section. Measurement of hydraulic and thermal transport parameters is often time, labor, and cost-consuming. For many practical applications (e.g., studies on the landscape level), it is preferable to replace these measurements by estimation functions or algorithms that use parameters that are readily available from soil maps or can be measured easily. Some of these so-called pedotransfer functions, like capillary bundle models and neural networks for hydraulic parameter functions [61.106–108], or mixing models for thermal parameters [61.3, 109, 110], are presented below.

Complexity of Time Series

Time series capture the temporal dynamics or patterns in soils. Typical examples of time series are water content or water potential measurements. Time-series analysis is a vast field in statistics, and many different methods and models exist. Here, we want to highlight the *permutation entropy*, an ordinal method that allows us to describe the complexity of time series. The method is called ordinal because it operates on ranks values instead of actual values in a time series. It has the advantage of being simple, fast, robust, and of having only a few assumptions about the data [61.111]. Permutation entropy was proposed by *Bandt* and *Pompe* in 2002 [61.112] as a *natural measure of complexity* for real time series. Generally speaking, a complexity measure characterizes the dynamics in a time series. Low complexity means a regular time series (e.g., a sine wave), and a high complexity is typical for noise. The complexity in a time series of the water potential, for example, is a result of underlying processes, like infiltration and evapotranspiration, and is influenced by soil hydraulic properties and measurement noise.

Here, we show briefly how to calculate the permutation entropy. For more details the reader is referred to the original publication [61.112]. We take as an example the time series $x = (3.2, 4.2, 6.8, -3.5, 4.0, 12.3, 0.1)$ and compare the direct neighbors by counting pairs for which $x_t < x_{t+1}$ (we call this permutation 01) and pairs for which $x_t > x_{t+1}$ (we call this permutation 10), t being the time index. In this time series, we find four

pairs of permutation 01 and two pairs of permutation 10. This information is plugged into the famous formula for entropy introduced by *Shannon* [61.113]

$$H(n) = - \sum p(\pi) \log(p(\pi)), \quad (61.38)$$

where $p(\pi)$ are the probabilities of the permutations, and summation runs over all permutations of order n . Thus, in our case, using the relative frequencies of permutations 01 and 10 determined above, we get

$$\begin{aligned} H(2) &= - \left(\frac{4}{6}\right) \log\left(\frac{4}{6}\right) - \left(\frac{2}{6}\right) \log\left(\frac{2}{6}\right) \\ &\approx 0.92. \end{aligned} \quad (61.39)$$

There are $n!$ permutations of order n , and the permutation entropy will vary between 0 and $\log(n!)$. By dividing it by $\log(n!)$ we obtain a normalized measure in the range $[0, 1]$. Obviously, the number of samples (consecutive values) that we can use to determine the permutations decreases for increasing n . *Bandt* and *Pompe* [61.112] suggested that the length of the time series should be larger than $n!$ and recommend *for practical purposes* [...] $n = 3, \dots, 7$. The time series of the water content of the matric potential often show abrupt changes (e.g., when water infiltrates rapidly into the soil). To take this behavior into account, an extension of the permutation entropy, the so-called *weighted permutation entropy* (WPE) can be used [61.114]. It modifies the original permutation entropy (PE) by weighting the frequencies of permutations by the variance of the measured values.

Estimation of Soil Hydraulic Material Functions

Direct measurements of hydraulic and thermal parameters and functions in the laboratory and in-situ are cost, labor, and time intensive. For landscape studies, they can only be conducted at selected sites. For areal studies, geostatistical methods may be used if the measuring grid is sufficiently dense. In most cases, utilization of pedotransfer functions is required. The accuracy and reliability of these functions depend on underlying models and most often on site conditions. In principle, pedotransfer functions use easily measurable soil parameters like bulk density, porosity, soil texture, organic matter content, and – for thermal conductivities – quartz content. Direct estimations of soil physical material functions from geophysical methods and remote-sensing data are still a matter of ongoing research.

While water retention (desorption) curves and saturated hydraulic conductivity can be measured by standard procedures in the laboratory, the measurement of the hydraulic conductivity characteristics for unsaturated conditions is still time consuming and demanding. In an early approach [61.106], a capillary bundle approach was developed that calculates the relative conductivities k_r from the saturated conductivity k_s and M points of the water retention curve (θ_i, h_i) , assuming a pore size distribution of continuous cylindrical pores derived from the water retention curve using the Young–Laplace equation, a contact angle between pores and water of zero, and a uniform tortuosity for all pore size classes.

$$k(\theta_s - i\Delta\theta) = k_s k_r (\theta_s - i\Delta\theta) \\ = k_s \frac{\sum_{j=i+1}^M \frac{1}{h_j^2}}{\sum_{j=1}^M \frac{1}{h_j^2}} \quad (61.40)$$

This approach was improved by [61.108] by considering the tortuosity of the pore system

$$k(\theta_i) = k_s \left(\frac{\theta_i}{\theta_s} \right)^{4/3} \frac{\sum_{j=i+1}^M [2(j-i) + 1] \frac{1}{h_j^2}}{\sum_{j=1}^M [2j-1] \frac{1}{h_j^2}}. \quad (61.41)$$

Water content θ_i is again $\theta_s - \theta_i$. Please note that $\theta_0 = \theta_s$. In (61.40) and (61.41), the summation index is given by j . Index i denotes the i -th point of the discretized water retention curve. *Mualem* [61.107] came up with an integral approach to allow for continuous calculation of relative conductivities

$$k_r = \Theta^{1/2} \left[\frac{\int_{s=0}^{s=\Theta} \frac{1}{h(s)} ds}{\int_{s=0}^{s=1} \frac{1}{h(s)} ds} \right]^2, \quad (61.42)$$

where the reduced degree of saturation Θ is given by $\Theta = (\theta - \theta_r)/(\theta_s - \theta_r)$ with the porosity θ_s , and the residual water content θ_r (at which the continuity of the liquid phase is interrupted).

Later, *van Genuchten* [61.115] introduced a parameterization of the water retention curve, which can be analytically integrated in (61.42) under the assumption

$$m = 1 - 1/n$$

$$\theta(h) = \theta_r + \frac{\theta_s - \theta_r}{[1 + (\alpha h)^n]^m}, \quad (61.43)$$

$$k(h) = k_s \frac{\left\{ 1 - (\alpha h)^{n-1} [1 + (\alpha h)^n]^{(1-n)/n} \right\}^2}{[1 + (\alpha h)^n]^{(n-1)/(2n)}}. \quad (61.44)$$

This approach was extended by [61.116] to be able to consider multimodal pore size distributions. Methods for estimation of the *van Genuchten–Mualem* parameters can be found in [61.117–119].

Estimation of Soil Thermal Material Functions

De Vries [61.3] developed and tested functions for estimating volumetric heat capacity $c_v(\theta)$ and thermal conductivity $\lambda(\theta)$. The parameter c_v is a strictly linear equation of volumetric water content (X_0), quartz content (X_1), other minerals (X_2), organic matter (X_3), and soil air (X_4)

$$c_v = \sum_{i=0}^4 X_i c_{v,i}. \quad (61.45)$$

Values for $c_{v,i}$ can be found in Table 61.9. Values for quartz and other minerals are obviously identical (61.17).

Values for the thermal conductivity characteristics of a soil material $\lambda(\theta)$ can be estimated as weighted mean of the thermal conductivities λ_i of its components X_i (water, quartz, other minerals, organic matter, and soil air)

$$\lambda = \frac{\sum_{i=0}^4 k_i X_i \lambda_i}{\sum_{i=0}^4 k_i X_i}. \quad (61.46)$$

The weighting factors are calculated as

$$k_i = \frac{1}{3} \sum_{j=1}^3 \frac{1}{1 + ((\lambda_i/\lambda_0) - 1) g_j}. \quad (61.47)$$

Here, λ_0 is the embedding component (air or water) depending on water and air contents. Parameters g_i are shape factors, and $g_1 + g_2 + g_3 = 1$. Under the assumption of ellipsoids of rotation, a value of $g_1 = 0.125$ is often assumed [61.109] (values of $g_1 = g_2 = g_3 = 1/3$ hold for spherical particles). For k_4 (air) approximation formulas are provided in [61.3, 110].

61.5 Specifications

Below we give some specific information about coefficients in some formulas and specific data for some selected sensor types.

Values for α_{TI}^* in (61.37) are provided in Table 61.7, for c_{bk} in (61.32) in Table 61.8, and for thermal properties for (61.45) and (61.46) in Table 61.9.

Soil temperature measurements have a range from -50 to 50 °C, a resolution of 0.1 K, an uncertainty 0.2 K, a time constant 20 s, and an averaging time of 1 min [61.104]. Heat flux plates can be operated from -30 to $+70$ °C. They have a range of ± 2000 W m⁻² and an uncertainty $\pm 3\%$.

Table 61.9 Densities (ρ_s), volumetric heat capacities (c_v), and thermal conductivities (λ) of soil constituents (10 °C) and of ice (0 °C) (after [61.2], modified)

Material	ρ_s (kg m ⁻³)	c_v (J m ⁻³ K ⁻¹)	λ (W m ⁻¹ K ⁻¹)
Quartz	2.66×10^3	2.0×10^6	8.8
Other minerals	2.55×10^3	2.0×10^6	2.9
Organic matter	1.3×10^3	2.5×10^6	0.25
Water	1.0×10^3	4.2×10^6	0.57
Ice	0.92×10^3	1.9×10^6	2.2
Air	1.25	1.25×10^3	0.025

Conventional tensiometers typically have a range from -800 hPa under unsaturated to values > 0 hPa under saturated conditions, and an accuracy of about 1 hPa. The maximum value under saturated conditions depends on the height of the water table above the sensor and the flow situation (e.g., around drain tubes). According to the data sheet of the manufacturer [61.91] pF-meters have a range from $pF = 0$ to $pF = 7$ and resolution of $pF = \pm 0.01$.

61.6 Quality Control

Experimental studies need to keep scientific standards in measurement design and data evaluation, like site selection, instrumentation schemes, and sampling designs in relation to project goals and hypothesis, statistical analyses, and data-based modeling studies. Furthermore, operational and technical aspects have to be considered to perform successful measurement campaigns. Some of these quality control measures are listed below. Disturbed and undisturbed soil sampling should consider spatial heterogeneity of soils either by taking enough replicates or by taking (weighted) pooled samples.

Soil cores should be big enough to cover most organizational soil structures (REVs). Further, they should be inserted perfectly in axial direction. Smearing at the upper and lower boundary planes should be strictly avoided. Samples should be checked for voids along the cylinder walls. Both would be detrimental for conductivity measurements and column experiments. Smearing is also a problem in borehole measurements in saturated (borehole method) and unsaturated soils (Guelph permeameter). For double-ring infiltrometers, voids between soil and steel cylinders must be avoided.

For tensiometers and tension infiltrometers, close contact between measuring surfaces and soil is of uppermost importance. For both instruments, air entrapments need to be controlled. This holds equally

for laboratory measurements of water retention curves with ceramic plate systems. Voids around the steel rods of TDR and FDR sensors are an important source of measurement errors. The installation of TDR and FDR probes should be carried out with care. Accompanying sampling for improving indirect measurements of soil water content is recommended to improve calibration and accuracy.

Volume-based water content has a range from 0% to 100%. Standard gravimetric methods with oven drying are reported to have an accuracy (given in % of volumetric water content) of $< 1\%$. Neutron probes were found to have a standard error of 2%. For TDR and FDR probes, similar values for root-mean-square error (RMSE) of 2% were determined. However, in the case of poor probe construction, dielectric dispersion (permittivity change with frequency), and/or salinity, the errors may increase up to 40% [61.70].

Outlier control should be carried out very cautiously. Extreme values are typical for soil parameters and are an intrinsic ecologically relevant property of the soil system. Therefore, extreme values are not automatically measurement errors.

For temperature sensors, all quality control actions according to Chap. 7 should be applied. Because of the problem of good contact of the sensor and the soil, gradients should additionally be controlled. This can be done by a nonlinear approximation of the temperature profile. If one sensor shows differences of > 0.2 K for longer times, this sensor should be replaced or newly installed.

The best quality control for heat flux plates is the installation of at least three identical plates. As long as all show nearly the same result, an averaged value should be the best measure. If one sensor fails, the installation of the sensor should be controlled.

61.7 Maintenance

Maintenance of measuring equipment should meet at least the following requirements:

- i) Regular (weekly, daily) check of devices (permeameters, tensiometers, suction plates) for air inclusions, obstruction of tubes, and soil–sensor contact. If necessary, sensors are to be replaced.
- ii) Regular technical control of data recording units. Regular read-out and check for data losses and malfunctioning.
- iii) Check for mechanical damages of equipment. If required add mechanical protection (against animals, humans, rain, heat, radiation) and/or replace the devices.
- iv) Weakly or after rainfall control of the temperature gradients and the heat flux plates.

61.8 Applications

To give an impression of hydrological and thermal measurements in the context of ecosystems, in this section, we briefly present selected results from different agricultural and forest sites. The first example describes a study on surface water storage and addresses the very interface between soil and atmosphere on a partly compacted agricultural field soil. In the second study, we highlight the moisture dynamics in a soil profile of a forest stand, and the third example illustrates daily temperature propagation in the soil of an open grassland.

61.8.1 Water Storage on the Soil Surface

The microtopography of the soil surface influences the partitioning of incoming precipitation into surface storage, surface runoff, and infiltration. Agricultural soils often have a dynamic microtopography because of tillage and compaction by agricultural machinery. A combination of an irrigation experiment and stereo photography allows us to study the dynamics of water storage and surface runoff. Here, we describe some results of such an irrigation experiment. For a complete report, the reader is referred to the original publication [61.62].

The irrigation experiment was done at the Institut National de Recherche pour l'Agriculture, l'Alimentation et l'Environnement (INRAE) research station in Avignon (France) on an agricultural soil previously tilled with a plough share followed by a circular spike harrow combined with a cultipacker. Subsequently, the middle part of the plot was compacted by repeated passage of a tractor wheel. A stereo system equipped with two Nikon D100 cameras installed at ≈ 3 m height (Fig. 61.7) was used to take pictures of the soil surface before and during the irrigation (64 mm h^{-1} for 1 h) to calculate a digital surface model (DSM), delineate puddles, and derive the stored volume of water. The stereo system produced paired images of the soil surface from different angles that were matched point-by-point to derive the DSM. This procedure is called photogrammetry, e.g., [61.120]. Figure 61.24 shows the microtopography before the start of irrigation, i.e., after tillage and compaction. The central depression created by compaction stored most of the water during the irrigation. Despite the compaction of the soil, puddles infiltrated quickly after the stop of irrigation (Fig. 61.25).

61.8.2 Time Series of Soil Matrix Potentials and Corresponding Weighted Permutation Entropies

Figure 61.26 shows the time series of precipitation and matric potentials in three depths measured in a forest

stand at the study site Coulissenhieb II in the Lehstenbach Catchment (Fichtelgebirge Mountains, Germany), together with calculated weighted permutation entropies (WPE). The WPE values are complexity measures that quantify the dynamics of the measured time series. The

Fig. 61.24 Digital surface model of a bare soil with compaction by a tractor tire, obtained by stereo photography (Fig. 61.7) for assessment of surface storage, runoff, infiltration, and seepage (after [61.62] © John Wiley & Sons, Ltd). The image was generated in R (after [61.121])

Fig. 61.25 Surface storage of water and puddle area ($> 20 \text{ cm}^2$) in an irrigation experiment with a dye tracer on the plot in Fig. 61.24. The irrigation was stopped after 60 min (after [61.62] © John Wiley & Sons, Ltd.)

Fig. 61.26 (a) Rainfall, matric potentials (Ψ_m , gray curves) in (b) 20 cm, (c) 40 cm and (d) 90 cm depth and associated weighted permutation entropies (WPE, blue curves) in a forest stand (after [61.30])

interested reader can find more information on this long-term research and monitoring site in [61.122]. In general, the drying of the soil and its subsequent rewetting (for example, during summer 2008) are characterized by a minimum of the matric potential and a drop of the WPE. Indeed, decreasing/increasing matric potentials contain mainly monotonically descending/ascending patterns and, therefore, have a low complexity. The overall level and variation of the WPE are comparable in different depths, indicating similar dynamics. Note that the measured matric potentials are different. This is, of course, the very definition of a rank-based statistical measure,

Fig. 61.27 Daily cycle of soil temperatures at different depths on 05.06.1998 at the field site of the Richard-Aßmann Observatory Lindenberg, Germany (high clouds for 11:00–15:00 UTC high clouds (after [61.45]) ►

i.e., it is sensitive to the relative order of the measured values not to their absolute value.

61.8.3 Daily Cycle of Soil Temperature

The soil temperature is an important parameter in agricultural meteorology. Furthermore, it is important for the energy balance at the Earth's surface and, therefore, for all fluxes between the atmosphere and the underlying surface. The upper levels up to a depth of -0.1 to -0.2 m are highly influenced by solar radiation, while the lower levels are phase shifted and give only information as to the temperature of the previous days (Fig. 61.27). The upper few centimeters are even affected by variations of the irradiation. At -10 m depth, the phase shift is about half a year.

61.9 Further Developments

Both new instruments and new algorithms are expected to contribute to further advances in soil physical measurements. A new development in recent years for indirect in-situ soil water content measurements along larger transects (up to a scale of kilometers) is based on carbon-fiber heated cable technology (CFHC). Volumetric water content is derived from temperature–time curves. A detailed description of technical details, procedures, and algorithms of this SM-DTS (soil moisture distributed temperature sensing) can be found in [61.123]. The method assumes that the surrounding soil is uniform and isotropic, and the thermal diffusivity is constant. The method requires calibration of soil water content against thermal response in the laboratory. The authors found absolute errors (in terms of volumetric water content) in the range of 0.01% to 6.6%. The use of the actively heated fiber optic method for mapping of water content in three depths along transects of 250 m length was impressively demonstrated in [61.124].

Another promising new method for water content measurements in topsoil is the application of cosmic-ray neutron sensors (CRNS) [61.125]. The sensors count neutrons from cosmic rays reflected from topsoil molecules with relatively heavy atoms (compared to hydrogen, which thermalizes neutrons due to the same atomic mass). A comparison with the incoming radiation gives a measure for water content. In contrast to neutron probes, which are inserted into the soil using access tubes, CRNS measures above ground and is nondestructive. Neutron probes count thermalized, actively emitted neutrons, whereas CRNS counts fast neutrons from cosmic radiation. CRNS is restricted to topsoil (10–40 cm), while the averaging area might be in the magnitude of hectares. A detailed intercomparison study in complex terrain on these sensors was performed by [61.126]. The authors developed strate-

gies that improved the accuracy especially in drying periods.

In [61.127], the authors analyze and point out the potential and relevance of new technologies together with methodological progress for understanding and quantifying soil hydrological processes at several spatial scales. In their conclusion, they emphasize the need to better understand hydrological processes at the soil–plant–atmosphere interfaces at the local scale with high spatiotemporal resolution. They underline the potential of combining noninvasive techniques with online stable isotope analysis of gaseous and water fluxes. They further recommend the establishment of networks of hydrological observatories for hypothesis testing and reducing uncertainties in large-scale models.

In this context, we would like to highlight the development of spectroscopic proximal soil-sensing instruments and the increased use of machine learning algorithms in the field of pedometrics. Proximal soil sensing provides information on the observed target without changing it, i.e., without sample destruction. In contrast to remote sensing, the measurement is done from close by (e.g., within 2 m) [61.128]. Diffuse reflectance spectroscopy of soils in the visible to mid-infrared domains has been used to derive several soil properties from spectra of dry or even moist soils, e.g., [61.40, 129]. Combining visible, near-infrared, and X-ray sensors offers new opportunities to acquire soil data rapidly and cost efficiently [61.130, 131].

Soil spectra cannot be used directly to derive soil properties, and a calibration against classical laboratory measurements is required. Because of nonlinear relationships between spectra and soil properties like soil carbon or texture, for example, machine learning algorithms have proved to be very successful. The most prominent ones are random forests [61.132] and partial least-squares regression, e.g., [61.133]. However, with the increasing popularity of deep learning, in particular in remote sensing [61.134], we expect these algorithms from artificial intelligence to be incorporated in soil spectroscopy sooner or later. Indeed, because both remote sensing and soil spectroscopy deal with hyperspectral data, many data analysis steps are similar.

Calibration in soil spectroscopy is one prominent application of pedometrics that is defined as the use of statistical techniques in soil science. Digital soil mapping is another example that is particularly interesting for other disciplines of environmental sciences because it provides spatial soil data like texture, carbon content and even soil hydraulic properties [61.135, 136]. Although it is still challenging to

assess the precision of these data sets and sometimes their meaning (e.g., for soil hydraulic conductivities at 0.25° resolution), standardized and georeferenced

soil data are undoubtedly required in many applications [61.137].

Bernd Huwe

Soil Physics
University of Bayreuth
Bayreuth, Germany
bernd.huwe@uni-bayreuth.de

Bernd Huwe received Habilitation degree in 1991 in Soil Physics. From 1992 to 2017, he was Professor of Soil Physics at the University of Bayreuth. His research addressed theoretical and practical questions of water, heat, and nutrient and pollutant transport in soils. In this context, soil landscape modeling, regionalization of soil processes, effective modeling, and risk and parameter uncertainty analysis were important tools of his research group.

Christina Bogner

Institute of Geography
University of Cologne
Cologne, Germany
christina.bogner@uni-koeln.de

Christina Bogner is Professor of Physical Geography at the Institute of Geography at the University of Cologne in Germany and Head of the Ecosystem Research Group there. She received her PhD in Soil Physics in 2009 and was awarded a Habilitation in Geoecology in 2017. In her multidisciplinary research, she uses experimental techniques and modeling to understand water flow in soils, land use change, and microplastic transport in soils.

Thomas Foken

University of Bayreuth
Bayreuth, Germany
thomas.foken@uni-bayreuth.de

Thomas Foken is a retired Professor of Micrometeorology at the University of Bayreuth. He was the head of Laboratories at the meteorological observatories at Potsdam (1981–1994) and Lindenberg (1994–1997). His research interests include the interaction between the Earth's surface and the atmosphere and the measurement and modeling of energy and matter fluxes, with a strong focus on experimental meteorology. His scientific contributions have been recognized through various international awards.

Water Measure

62. Water Measurements

Volker Mohrholz , Anita Flohr 

Physical properties and fluxes at the lower interface of the atmosphere set important boundary conditions for their dynamics and matter fluxes. Since 70% of this interface is governed by the world ocean, its surface water properties are of high importance. This chapter provides an overview on the measurement techniques of water temperature, salinity, waves, and currents, as well as fluxes of greenhouse and trace gases in surface water. Actual sensors use a wide spectrum of electronic, optical, and acoustic methods. The use of multi-sensor devices is very common in marine science. As example of such a device the conductivity-temperature-depth (CTD) probe is presented in more detail. The methods described are applied in seawater and fresh water environments.

Mainly four major processes at the ocean-atmosphere interface have a strong impact on the state and dynamics of the atmosphere: heat flux, evaporation of water, impulse flux into the ocean, and the exchange of thermal active trace gases. Heat fluxes at the ocean-atmosphere interface are important sources or sinks for thermal energy in the atmosphere. They have a high impact on the stratification and, thus, on the stability of the lower atmosphere. Heat fluxes are also strongly related to the evaporation at the ocean surface, which is the main source of water vapor in the atmosphere. Wind at the ocean surface causes an impulse flux into the ocean that acts like boundary friction and causes the formation of an Ekman layer in the lower atmosphere. In the ocean surface layer, the impulse flux forces currents and turbulent mixing, which, in turn, affect the sea surface

temperature (SST), sea surface salinity (SSS), and the heat and gas exchange with the atmosphere.

The fluxes at the ocean-atmosphere interface depend on the particular conditions in the lower atmosphere, as well as on the properties of the ocean surface mixed layer, which vary on a large range of space and time scales.

Usually, empirical formulas are applied to quantify the fluxes [62.1]. Beside atmospheric parameters information about the SST, SSS, current velocity, waves, and concentration of trace and greenhouse gases in surface water are required to calculate the fluxes. Measurements of these variables are conducted either in-situ or via remote sensing, with various methods and sensors [62.2]. This chapter cannot provide a comprehensive picture of ocean observation methods and focusses

mainly on an overview on in-situ measurement methods of some key parameters in the ocean surface layer.

Atmospheric greenhouse gases absorb and emit thermal energy and, thereby, contribute to warming the Earth's surface. Water vapor is the most abundant greenhouse gas in the Earth's atmosphere, varying strongly between < 1% and 5% and contributing between 60% and 71% to the natural greenhouse effect [62.3, 4] (Chap. 8). Many other long-lived greenhouse gases exist in the Earth's atmosphere, such as carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), chlorofluorocarbons (CFCs), hydrofluorocarbons (HFCs), and others [62.5]. Among these gases, CO₂, CH₄ and N₂O are the only greenhouse gases with both anthropogenic but also natural sources and are, thus, focused on in this chapter. Carbon dioxide contributes ≈ 26% to the greenhouse effect, whereas CH₄

and N₂O jointly account for ≈ 6% of the greenhouse effect [62.3, 6]. Aquatic ecosystems play a major role among the natural sinks and sources of these gases. Regarding CO₂, some (sub)tropical coastal areas are net sources of CO₂ to the atmosphere, but overall the ocean is a net sink for CO₂ [62.7–9]. This is largely due to the fact that CO₂ not only dissolves, but it also reacts with seawater to form the carbonate system. It is the chemical basis for the mitigation of atmospheric CO₂ increase by the ocean [62.10, 11]. Regarding CH₄ and N₂O, aquatic systems are net sources to the atmosphere, accounting for ≈ 27% of natural CH₄ sources and for ≈ 50% of natural N₂O sources [62.8]. Current research largely evolves around identifying the main drivers of the spatial and temporal variability of these greenhouse gas fluxes, including the effect of human perturbations.

62.1 Measurement Principles and Parameters

The standard instrument for in-situ temperature and salinity observation and water sampling in the ocean is the CTD probe (this stands for conductivity-temperature-depth probe). CTD is a measuring platform that combines temperature, conductivity, and pressure sensors with a rosette water sampler for taking samples at selected depth. Nowadays, CTDs are equipped with additional sensors for, e.g., oxygen concentration, turbidity, fluorescence, and pH. CTD is usually deployed on a wire from a vessel. During lowering from the sea surface to the end depth of the profile, data of all sensors are recorded continuously. The classical CTD delivers a vertical 1-D profile at each sampled position. Today, CTDs are also mounted on undulating towed devices (e.g., ScanFish [62.12]) and autonomous operating gliders [62.13, 14], remotely operated vehicles [62.15], and profiling moorings [62.16]. In that case, mostly 2-D datasets are obtained.

The particular CTD sensors use different measurement methods. The temperature is usually obtained with a thermistor or platinum wire resistor. Conductivity is measured either with a multielectrode conductivity cell or with an inductive sensor, and the pressure is usually gathered by a quartz crystal resonator, whose oscillation frequency depends on the pressure-induced stress. Besides vertical profiling CTDs also vessel-mounted underway systems, called thermosalinographs (TSGs), are widely used. They obtain temperature and conductivity in surface water, which is continuously pumped through a temperature and conductivity sensor package.

Current observations in the marine environment are performed mainly with acoustic methods, since mechanical current meters are outdated for the most ap-

plications. The acoustic current meters use either the Doppler effect of a single ultrasound pulse or the phase shift of two subsequent transmitted ultrasound pulses. The transmitted sound pulses are scattered at particles (e.g., zooplankton, suspended matter). The travel time of the backscattered signal is used to determine the distance between the sensor and the measuring volume. Using temporal windowing current profiles can be obtained. For some specialized applications, also the travel time of sound between a fixed transmitter and receiver is used.

There are several methods to measure wave parameters [62.17]. Pressure sensors mounted at a certain depth are very common. Also acoustic methods that obtain the distance to the surface from the travel time of a sound pulse are widely applied. Modern acoustic current meters are also able to estimate wave parameters and directional wave spectra. Wave rider buoys that swim at the sea surface use accelerometers for wave measurements. Radar applications and optical methods are used less often.

The concentration of dissolved greenhouse gases in seawater can be measured from discrete water samples or from continuous sampling systems. Discrete water sampling is usually done to retrieve the vertical distribution of dissolved gases in the water column. Continuous underway measurements are being applied to determine the spatial and temporal distribution of dissolved trace gases in surface water, e.g., to calculate fluxes across the air–water interface. We will focus on this approach, as it is of more relevance from the meteorological perspective. Irrespective of the sampling method, the fundamental principle of analysis involves

Table 62.1 Measured parameters for the calculation of state and fluxes at the atmosphere–ocean interface

Parameter	Description	Unit	Symbol
Temperature	Temperature of the upper mixed layer	K	T
Conductivity	Conductivity of the upper mixed layer	mS cm^{-1} , S m^{-1}	C
Current velocity	Horizontal speed of surface layer	m s^{-1}	u
Significant wave height	Height of wind forced gravity waves at the surface	m	H_s
Mean wave period	Mean wave period of all surface waves in a certain time period	s	T_m
Peak wave period	Period of the most abundant surface waves in a certain period of time	s	T_{peak}
Mole fraction of trace gas	Mole fraction of gas	$\mu\text{mol mol}^{-1}$; ppm (CO_2), nmol mol^{-1} ; ppb (CH_4 , N_2O)	x_{gas}
Mole fraction of water vapor	Mole fraction of water vapor in air	ppm	$x_{\text{H}_2\text{O}}$
In-situ water temperature	Temperature of the water at the intake	K	T_{insitu}
Water temperature in equilibrator	Temperature of water in the equilibrator	K	T_{equ}
Air temperature	Temperature of air usually at 10 m above water surface	K	T_{air}

Table 62.2 Other relevant parameters for the calculation of state and fluxes at the atmosphere–ocean interface

Parameter	Description	Unit	Symbol
Sea pressure	Absolute pressure at depth of measurement reduced by the standard atmosphere pressure	dbar	p
Practical salinity	Salinity of seawater	(psu)	S_p
Reference salinity	Mass of dissolved salt according the reference composition of sea salt.	g kg^{-1}	S_R
Absolute salinity	Derived from sea pressure, temperature, and conductivity Mass of dissolved salt, derived from sea pressure, temperature, conductivity, and local anomaly of salt composition	g kg^{-1}	S_A
Partial pressure of gas	Partial pressure of gas in dry air	atm, ppm (CO_2), atm, ppb (CH_4 , N_2O)	p_{gas}
Atmospheric pressure	Absolute atmospheric pressure	atm	p_{atm}
Partial pressure of water vapour	Saturation vapor pressure of water in equilibrium with the atmosphere	atm	$p_{\text{H}_2\text{O}}$
Solubility	Solubility of a gas in water or seawater	$\text{mol kg}^{-1} \text{atm}^{-1}$	s_{gas}
Concentration	Concentration of a gas in water	$\mu\text{mol kg}^{-1}$ (CO_2) nmol kg^{-1} (CH_4 , NO_2)	c_{gas}
Wind speed	Wind speed at 10 m above the water surface	m s^{-1}	u

Table 62.3 Principles of water measurements and applications

Type of sensor	Measurement principle					Application	
	Mechanical	Electrical	Optical	Acoustic	Chemical	Mean	Turbulent
Temperature sensor		×				×	×
Conductivity		×				×	×
Pressure sensor		×				×	
Current meter	×			×		×	×
Accelerometer		×				×	
Absorption spectrometer			×			×	
GC-MS, GC-ECD		×			×	×	

the extraction of the dissolved gas from the aqueous phase and the analysis of the gas sample by means of absorption spectrometry or gas chromatography coupled to an electron capture detector (GC-ECD) or mass

spectrometer (GC-MS), e.g., [62.17–20] (Sect. 62.4.6). An overview of the most important parameters for the characterization of the sea surface properties is given in Tables 62.1 and 62.2.

62.2 History

Observations of water properties and sea state date back to the early seafarers in antiquity. At that time knowledge about tides, currents, and waves were used mainly for navigation purposes. The scientific interest in ocean dynamics started to grow in the nineteenth century.

62.2.1 History of Water Measurements

The expedition of the HMS Challenger Expedition from 1872 to 1876 marks the start of systematic marine observations on the ocean scale [62.18]. Although this expedition was focused on biological sampling, also physical observations were performed. Prior to this voyage oceanographic data were gathered occasionally by merchant and military ships and were collected by some national authorities, mainly for navigational purposes. Regular time series observations of temperature, salinity and currents have been performed on light ships since the late nineteenth century. At the beginning of the twentieth century the Scandinavian school of oceanographers made substantial progress in the theoretical description of ocean dynamics. Inspired by *Fridtjof Nansen's* (1861–1930) observations of the Arctic ice drift *Walfrid Ekman* (1874–1954) developed a theory of wind-driven currents [62.19]. First hydrographic tables of the state of seawater that define the relation between temperature, salinity, and density were provided by *Martin Knudsen* (1871–1949) [62.20]. The German Meteor expedition of 1925–1927 was the first expedition focused mainly on physical properties of the ocean [62.21]. After the Second World War the frequency and intensity of ocean observations increased considerably. International coordinated programs addressed the understanding of ocean processes on a basin-wide and global scale (e.g., the World Ocean Circulation Experiment WOCE). A dramatic increase in the frequency, coverage, and spatial and temporal resolution of ocean observations was achieved by the development of electronic sensors and the beginning of remote sensing of the Earth's surface using satellite-based sensors.

62.2.2 Historically Relevant Measurement Methods

This section provides a general overview of the most important historical measurement methods for the properties of the ocean surface layer. For more detailed information, please refer to the cited literature.

Temperature

The sea surface temperature is the parameter in the ocean that has been the easiest to measure since the

beginning of scientific ocean observations. The main principle of measuring temperature is the detection of the volume change of a liquid. Simple alcohol and mercury thermometers were widely used in oceanography from the 1700s to the 1980s. During the Challenger Expedition the minimum and maximum temperatures of the water column were recorded with the newly developed Miller–Casella thermometers [62.22]. However, the vertical temperature gradients altered readings from deeper layers, and, consequently, the temperatures from the depth of interest could not be accurately measured. In 1874, the invention of the reversing mercury thermometer [62.23] by Negretti and Zambra overcame this problem. When this thermometer is reversed at the depth of interest, mercury in the stem separates from the reservoir, and the temperature is captured. Reversing thermometers (Fig. 62.1) were used on water sample bottles until the mid-1980s. Comparison measurements using reversal thermometers for in-situ calibration of electronic temperature sensors were performed till the end of the twentieth century.

With the development of semiconductor electronics, mercury thermometers were replaced by platinum-resistance thermometers [62.24] and thermistor-based temperature sensors, which today are the standard sensors for accurately temperature observations in the oceans.

Salinity

The first chemical analysis of seawater composition was performed by *Antoine Lavoisier* (1743–1794). An early method to determine the mass of salt in seawater was boiling a seawater sample until all water vaporized and weighing the remaining salt. Later, the methods to measure salinity were based on the idea that the chemical composition, i.e., the relative abundance of solutes in seawater, is nearly constant in the world ocean. This

Fig. 62.1 Open and closed reversing mercury thermometers (*middle and bottom*) and the reading magnifier (*top*) (photo © V. Mohrholz)

principle dates back to *Alexander Marcet* (1770–1822). Consequently, if the fraction of one particular component on the total mass of salt is known, it is sufficient to measure this component to calculate the salinity. As it is the most abundant substance, chloride (Cl^-) is the best component to use for this purpose. Salinity was determined by titration of seawater with silver nitrate (AgNO_3) till 1978. The chlorinity, or more precisely the total abundance of halogens dissolved in water, is then converted to Knudsen salinity S_K by the empirical relationship [62.20]

$$S_K = 0.03 + 1.805 \cdot \text{chlorinity} . \quad (62.1)$$

In 1967, the formula was slightly modified to the Cox salinity S_C [62.25]

$$S_C = 1.80655 \cdot \text{chlorinity} . \quad (62.2)$$

In the 1970s, the titration method was replaced by measuring the conductivity of seawater to calculate the salinity. In 1978, the Practical Salinity Scale (PSS-78) was introduced [62.26]. It defines the salinity based on the conductivity ratio of a seawater sample to a potassium chloride (KCl) solution with a mass fraction of 0.0324356 [62.27]. This practical salinity S_P is a unitless quantity, since it is defined as a conductivity ratio. In 2010, the new International Thermodynamic Equation of Seawater – 2010 introduced the reference salinity S_R and the absolute salinity S_A , which define the mass of salt in seawater with reference composition and the true salt mass in a seawater sample, respectively [62.28].

Current Meter

Current and wave measurements are among the most difficult measurements to access in the ocean. However, due to their importance for shipping, simple methods for their observation were developed at a very early stage. First measurements of the surface current were carried out with the aid of drift bodies. The path and direction of a drift body is tracked over a certain period of time. Then the averaged velocity is calculated. This method, initially carried out with simple pieces of wood, was further developed over time. With the help of bottle-post experiments and drift cards [62.29], also large currents were investigated until the 1960s. A modern form of drift bodies are the WOCE drifter [62.30] and the Argo float [62.31, 32]. They drift for up to 3 years at the surface or at depths in the ocean and collect data along the pathway. From the drifter position, which is determined by satellites at intervals of some minutes to a few days, the average current velocity and direction is determined.

Point and time series measurements of currents required a different approach, which led to the develop-

ment of the first mechanical current meters at the end of the nineteenth century [62.33]. Initially, the devices were only used to determine the flow velocity. The flow direction was usually observed visually. The flow velocity was determined by means of an impeller or propeller. In the first devices, the number of revolutions of the propeller was counted by an observer. Later, numerous mechanical constructions were developed, which registered the number of revolutions with the help of a clockwork. Also the flow direction could be roughly determined with a drop-ball mechanism [62.34]. These flowmeters only revealed a single average value of the current speed and direction per deployment. In 1926, *Ekmann* developed the first mechanical current meter, which enabled up to 47 individual measurements in one deployment [62.35]. For the start/stop of a single measurement, drop weights, so-called messengers, were used on the wire. The mechanical registration of the flowmeters was further improved to allow continuous measurement of flow velocity and direction. This required a recorder mechanism in a pressure housing that registered on paper or blackened glass plates. At the beginning of the 1970s, mechanical recording was replaced by electronic storage of measured data. The decisive disadvantage of mechanical flowmeters is their susceptibility to contamination and biofouling. Besides the mechanical flow meters, electromagnetic methods for flow measurement were also developed since the 1950s [62.36]. These devices used induction in conductors moving in the Earth's magnetic field. However, due to their high uncertainty, these methods have not been widely disseminated.

The rapid development of microelectronics and electronic signal processing enabled the development and application of acoustic current meters in the late 1970s [62.37]. Acoustic current meters uses the travel time of sound between two points, the Doppler effect, or the phase shift between two subsequently submitted pulses of sound. The latter is the most accurate method, but it has some important limitations [62.38]. Today, acoustic Doppler current profilers (ADCPs) have become the standard instrument for current measurement in marine research. With the availability of accurate remote-sensing data of sea surface elevation large-scale currents in the upper ocean are also estimated using geostrophic equations [62.39].

Long-Lived Greenhouse Gases

The beginning of the study of the impact of greenhouse gases dates back to the early nineteenth century and was initiated by the theory that the Earth's climate had undergone glacial periods in the past [62.40], provoking the question as to what might have caused those climatic variations. *John Tyndall* (1820–1893) was the first to measure the heat absorption of atmospheric gases, emphasizing the importance of water vapor and

CO₂ in maintaining the Earth's current climate [62.41, 42]. In 1896, *Svante Arrhenius* (1859–1927) revived this theory by quantifying the sensitivity of the Earth's climate to changes in atmospheric CO₂ concentrations [62.43]. He further claimed that a substantial amount of the CO₂ emitted from fossil fuel combustion is absorbed by the ocean. This provoked studies aiming to understand the spatiotemporal variability of atmospheric CO₂ concentrations [62.44–46]. Analysis of atmospheric CO₂ concentrations were done mostly by manometric and microgasometric techniques. Using

62.3 Theory

In this section, the theory of basic measurement methods used in the marine environment is briefly described.

62.3.1 Water Temperature

For in-situ measurements of temperature, two basic groups of sensors are applied: platinum resistance thermometers (Chap. 7) and thermistors. Platinum resistance thermometers use the increasing resistance of a platinum wire with increasing temperature. Thermistors are semiconductor elements with a high dependency of their resistance on temperature. The thermistor resistance can be positively or negatively correlated with temperature, called PTC (positively correlated with temperature) and NTC (negatively correlated with temperature), respectively. For further types of temperature sensors the reader is also referred to Chap. 7.

Platinum resistance thermometers have a highly linear characteristic at a wide temperature range. Thus, in the range between 13.8 K (the triple point of hydrogen) and 961.78 °C (the freezing point of silver), the actual International Temperature Scale 90 (ITS-90, Chaps. 5 and 7) is defined by the resistance of a platinum wire [62.57]. The temperature according to this scale is referred to as T_{90} . Before 1990, the temperature scale IPTS-68 was used. In the range between –2 and 40 °C, temperatures measured in IPTS-68 can be converted to ITS-90 by multiplication with a constant factor according to

$$T_{68} [^{\circ}\text{C}] = 1.00024T_{90} [^{\circ}\text{C}]. \quad (62.3)$$

The temperature obtained from platinum resistance thermometers is calculated from the ratio W of the resistance R at the measured temperature T_{90} and the resistance at the temperature of the triple point of pure water (273.16 K).

$$W(T_{90}) = \frac{R(T_{90})}{R(273.16\text{ K})} \quad (62.4)$$

more precise infrared analysis, [62.47] were the first to show and quantify the continuous increase of atmospheric CO₂ concentrations due to the impact of fossil fuel combustion, known as the Keeling curve. This encouraged studies on the processes and timescales governing CO₂ exchange between the atmosphere and the sea [62.48–50]. Likewise, investigations of anthropogenic and natural sources of N₂O and CH₄, mainly based on gas chromatography [62.51–54], confirmed the importance of aquatic systems as sources and sinks of these gases, e.g., [62.54–56].

The temperature in degrees Celsius is derived from the resistance ratio by

$$T_{90} [^{\circ}\text{C}] = D_0 + \sum_{i=1}^9 D_i \left[\frac{W(T_{90}) - 2.64}{1.64} \right]^i. \quad (62.5)$$

The constants D_0 – D_9 are given in [62.57]. Platinum resistance thermometers depict minimal aging effects and a high accuracy. Further details of the properties of platinum resistance thermometers are also given in Chap. 7.

Compared to platinum resistance thermometers, thermistors have the advantage of higher sensitivity, usually about a magnitude higher. However, their characteristic is highly nonlinear and depends on the specific doping of the semiconductor material. Their characteristic can be approximated with

$$R(T) = ae^{b/T}, \quad (62.6)$$

where a and b are material specific constants for the particular thermistor, T is the absolute temperature, and R is the resistance of the thermistor. The temperature characteristic of NTC thermistors can be described by the Steinhart–Hart equation [62.58]. For the typical temperature range of environmental observations, the simplified form of the equation can be used

$$T^{-1} = a_0 + a_1 \ln(R(T)) + a_3 \ln^3(R(T)). \quad (62.7)$$

The Steinhart–Hart coefficients a_0 , a_1 , and a_3 are device specific and are obtained with calibration measurements. The resistance of the thermal active elements is measured with bridge circuits.

Besides the direct measurement with in-situ sensors, the surface temperature can be obtained with remote-sensing techniques from airplanes and satellites. These radiometric methods use a wide spectral range from infrared to microwave radiation. A general overview on temperature measurement methods is given in [62.59].

62.3.2 Surface Salinity

The current definition of salinity of seawater is given by the International Thermodynamic Equation of Seawater – 2010 (TEOS-10) [62.28] (Chap. 5). TEOS-10 defines the properties of seawater as partial derivations of a thermodynamic potential, the so-called Gibbs function. The specific Gibbs function for pure water and its extension for seawater were derived empirically from high precision measurements. TEOS-10 replaces the former Practical Salinity Scale PSS-78 [62.27]. The Practical Salinity (S_p) of seawater is derived from measurements of electrical conductivity. Since it depends also on temperature and pressure, the calculation of S_p also requires an accurate measurement of these parameters. The pressure is given as *sea pressure*, which is the absolute pressure reduced by the standard atmosphere pressure at the sea surface (1013.25 hPa).

PSS-78 defined the S_p as a ratio K_{15} of the conductivity of a seawater sample and the conductivity of a standard potassium chloride solution at temperature of 15 °C and pressure of 101.325 kPa. The mass fraction of the KCl standard solution is 32.4356×10^{-3} . By definition the S_p is 35 for a ratio $K_{15} = 1$. TEOS-10 defines a reference salinity S_R , which is the mass fraction of salt in a seawater sample with a standard composition of salt, given by [62.60]. In contrast to the unitless practical salinity, the reference salinity is given in g kg^{-1} . The conversion from S_p to S_R is given by

$$S_R [\text{g kg}^{-1}] = \left(\frac{35.165047}{35} \right) S_p. \quad (62.8)$$

However, the real sea-salt composition depicts local and regional deviations from the reference composition of standard seawater. Variations in the silicate concentration are the main contribution to this anomaly. In most practical cases, the deviations from the standard composition can be neglected but must be considered if accurate density is required. TEOS-10 provides a global dataset of the salinity anomaly δS_A , derived from available observations. The absolute salinity S_A can be calculated from the reference salinity S_R using the salinity anomaly

$$S_A = S_R + \delta S_A(\varphi, \lambda, p), \quad (62.9)$$

where φ , λ , and p are the latitude, longitude, and sea pressure, respectively. In TEOS-10, the density is defined as a function of sea pressure, temperature, and the absolute salinity. Since most observations use conductivity measurements and reveal the practical salinity, the calculation of density requires the conversion to absolute salinity.

62.3.3 Surface Waves

The wave field at a certain location consists of the swell, which are long waves generated far away, and the wind waves forced by local wind. The most important wave properties that have a significant impact on air sea fluxes are the significant wave height, the mean wave period, and the peak period. The significant wave height H_S is the mean vertical distance between the wave crest and the wave trough of the highest third of all waves. Today, it is also defined as four times the standard deviation of the surface elevation η . For a particular period (t_0 – t_1) H_S can be calculated as

$$H_S = 4 \sqrt{\frac{\int_{t_0}^{t_1} \eta(t)^2 dt}{t_1 - t_0}}. \quad (62.10)$$

The mean wave period T_m is derived from the nondirectional wave spectrum $S(f)$, where f is the wave frequency; T_m is the weighted average of the frequency spectrum

$$T_m = \frac{\int S(f) df}{\int f S(f) df}. \quad (62.11)$$

The peak wave period T_{peak} is the wave period at the energy maximum of the wave spectrum $S(f)$. Together with the significant wave height, the mean wave period and the peak wave period define the sea state. The larger the mean wave period for a given significant wave height, the more energy the wave field contains. A comprehensive theory on wind waves is given in [62.61].

62.3.4 Currents

Today, in-situ current measurements are carried out mainly with acoustic current meters, since they have important advantages for measurements in the marine environment (Table 62.4). Water is much more transparent for sound than for visible light, although the sound attenuation coefficient depends highly on the frequency used and the concentration of some constituents of sea salt, namely magnesium sulfate, borate, and magnesium carbonate [62.62, 63]. Generally, the sound attenuation coefficient is proportional to the square of the sound frequency. Thus, in sea water low-frequency sound has a higher range than high-frequency sound. In contrast to electromagnetic waves, sound waves are longitudinal waves that need a compressible medium for propagation. If the medium is moving, the sound waves are shifted with it. The most acoustic current meters use the frequency range between 38 kHz and 5 MHz.

The simplest method that uses sound for current measurements utilizes the change of travel time along

a defined pathway between a fixed transmitter and a receiver. The theoretical travel time is given by the distance divided through the speed of sound. Deviations from the theoretical travel time can be attributed to the movement of the water between the transmitter and the receiver. The current component along the acoustic beam v_b can be calculated from the distance L between transmitter and receiver, the measured travel time t , and the sound velocity of the water v_s

$$v_b = \frac{L}{t} - v_s. \quad (62.12)$$

The sound velocity depends on the density of sea water, which is not easy to measure. If the travel time along the measuring section is measured in both directions, the velocity v_b can be calculated without information about the sound velocity

$$v_b = \frac{L(t_1 - t_2)}{2t_1 t_2}. \quad (62.13)$$

Also the Doppler effect can be used for measuring current speed. If a sound transmitter and a receiver depict a relative velocity to each other, a frequency shift of the transmitted sound is observed. For nonrelativistic velocities, the frequency shift Δf is proportional to the velocity component v_b along the direction of sound propagation

$$\Delta f = f_s \frac{v_b}{v_s}, \quad (62.14)$$

where f_s is the frequency of the transmitted sound. By measuring the frequency shift and knowing the sound velocity (v_s) in water, the velocity component v_b can be calculated. To measure the current velocity either the transmitter or the receiver must be fixed, whereas the other device moves passively with the mean current. This is not appropriate for most applications.

For practical reasons, the sound transmitter and the receiver are combined in a single device. The sound transmitted as a focused beam is scattered in the water at small particles that move passively with the current. The backscattered sound is used to estimate the current velocity. In that case, the frequency shift is doubled, since the sound waves travel the same path twice. The current component v_b along the sound beam can be calculated from the frequency shift as

$$v_b = \frac{\Delta f v_s}{2f_s}. \quad (62.15)$$

The strength of the backscattered signal depends on the abundance and the acoustic properties of the scatter particles in the water, which are mainly zooplankton but also suspended matter.

A third method that is widely used is the detection of the phase shift of two subsequently transmitted pulses of sound that are backscattered at particles to the receiver. The travel time t_p of two pulses transmitted with a time delay of Δt_{trans} differs if the backscattering target is moving, since the distance between the transmitter and the backscatter target changes between the arrivals of the two pulses. The difference of the travel time Δt_p is proportional to the current component v_b .

$$t_{p1} - t_{p2} = \Delta t_p = \frac{2v_b \Delta t_{\text{trans}}}{v_s} \quad (62.16)$$

Δt_p is not detected directly. Instead, the phase shift between the transmitted pulses is determined. This can be done with high accuracy. However, if the phase shift exceeds 2π , the estimation of the current velocity becomes ambiguous. The maximum velocity v_{b_max} that can be distinctly measured with that method depends on the sound frequency f_s and the time delay Δt_{trans} between pulse transmission

$$v_{b_max} = \frac{v_s}{2f_s \Delta t_{\text{trans}}}. \quad (62.17)$$

To overcome the ambiguity problem the transmitted pulses are modulated to detect phase shifts larger than 2π [62.38].

Most acoustic methods require the knowledge of the actual sound velocity along the pathway of the signal. At oceanic conditions the sound speed of water varies in the upper layer approximately between 1450 and 1550 m s^{-1} . If the actual sound speed is unknown, a constant value of 1500 m s^{-1} can be applied. That results in an uncertainty of 3.5%, which is acceptable for most applications.

Measuring the current velocity along an acoustic beam will only reveal the current component along the beam. To obtain the three-dimensional current vector three and more acoustic beams that point in different space directions are used. From the current components obtained, the true current vector is calculated. If moving platforms, e.g., vessels, autonomous underwater vehicles (AUVs) or gliders, are used the motion of the platform has to be considered additionally.

62.3.5 Dissolved Greenhouse Gases

The solubility of a gas in water depends on the physical and chemical properties of the gas and the water, such as temperature, pressure, and the presence of other chemicals. *William Henry* (1774–1836) was an English chemist who studied the solubility of gases in the

early nineteenth century. He found that at constant temperature the amount of dissolved gas in a solvent is proportional to the partial pressure of the gas phase in equilibrium with the solvent [62.64]. The solubility of gases in liquids according to Henry's law reads as follows

$$c_{\text{gas}} = H p_{\text{atm}} x_{\text{gas}}, \quad (62.18)$$

where c_{gas} is the dissolved gas concentration, H is Henry's law constant, p_{atm} is the atmospheric pressure during equilibration, and x_{gas} is the dry mole fraction of the respective gas in the gas phase. Modifications have been applied, which mainly account for the impact of salinity and temperature on the solubility of the gas and the nonideal behavior of the gas [62.65–67] (Sect. 62.3.5). In addition, some gases like CH_4 and N_2O simply dissolve in water, whereas CO_2 also reacts with water and forms aqueous CO_2 ($\text{CO}_{2\text{aqu}}$) and carbonic acid (H_2CO_3), summarized as H_2CO_3^* , which dissociates to bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}) ions. The sum of all these species is referred to as dissolved inorganic carbon (DIC). This reaction is the fundamental basis for the high inventory of DIC in the oceans. It is the reason why the oceans play an important role in modulating atmospheric CO_2 concentrations both on shorter time scales but also on glacial-interglacial time scales [62.68–73].

Extraction

The basic principle of dissolved gas analysis involves the extraction of the dissolved gas from the aqueous phase and the analysis of the gas sample by means of gas chromatography or laser absorption spectrometry. Extraction techniques include headspace equilibration, adsorbing the gas onto a sorbent, freeze and trap, or purge and trap methods. Headspace equilibration is widely used for continuous measurements used to derive trace gas fluxes between the surface water and the atmosphere. Since the focus of this book is on atmospheric processes, the emphasis of this chapter is on continuous measurements using headspace equilibration.

For continuous measurements, e.g., on board ships, equilibrators are used to convert a liquid phase sample into a gas phase sample. In general, a fixed volume (closed loop) of air passes through and equilibrates with a continuous stream of surface water, which is continuously renewed. The mole fraction of the respective gas (x_{gas}) in air equilibrated with the surface water is then measured. A variety of different equilibrator types have been developed, such as shower or spray-

type, e.g., [62.74–77], bubble-type, e.g., [62.78–80], marble-type [62.81], and Raschig rings-type [62.82]. The recently evolving membrane equilibration techniques, e.g., [62.83–85] allow in-situ extraction of dissolved gases and are, thus, mainly used for vertical profiling of dissolved gases in the water column. However, the aim of these diverse equilibrator designs is to achieve an optimal response time (τ). The response time τ is a measure of how fast the equilibrator setup responds to changes in gas concentrations of the water phase. The response time τ is usually defined as the time (t) it takes until an exponential drop of $1/e$ (36.78%) can be observed for Δp_{gas} , i.e., for the difference between the gas concentration in the gaseous and aqueous phase with respect to its initial value p_{gas}^0

$$\Delta p_{\text{gas}} = p_{\text{gas}}^0 e^{(-t/\tau)}. \quad (62.19)$$

τ has to be determined experimentally because it does not only depend on the gas species and equilibrator setup but also on flow rates in the system, e.g., [62.86, 87]. To determine τ experimentally two batches of water with known p_{gas} , usually one ambient (equilibrated with atmosphere) and one with a high p_{gas} , are prepared. The equilibrator is then flushed first with the ambient p_{gas} batch, followed by the high p_{gas} batch and then ambient p_{gas} batch again. Each time, the change in p_{gas} in the headspace versus time is measured until equilibrium is reached. For guidance on the derivation of τ from the experimental data, the reader is referred to, e.g., [62.80, 86, 87]. Reported τ ranges are ≈ 230 s for CO_2 [62.74, 78, 81, 87, 88], ≈ 680 s for CH_4 [62.87, 89], and ≈ 180 s for N_2O [62.77, 86] implying that *full* equilibration is usually observed after ≈ 6 – 12 min for CO_2 , after ≈ 35 min for CH_4 and after ≈ 9 min for N_2O . Different τ observed for same gases are mainly a result of differences in the equilibration chamber design and the water flow. Different τ between gas species can be explained by their differences in solubility and the extent of disequilibrium between the surface layer and the atmosphere [62.87]. In consequence, equilibrator-based underway measurements (e.g., on board a ship) in regions with a high variability of dissolved trace gas concentrations, will likely not reflect full equilibrium conditions but will represent integrated values. Additionally, they will lag in time, depending on the speed of the vessel. Thus, it is recommended to take discrete water samples on a regular basis from the same water supplying the equilibrator (e.g., from a bypass), to confirm the integrity of the underway results or to correct them if necessary. However, it needs to be noted that, depending on the overall dissolved greenhouse gas variability in surface water and

the speed of the vessel, discrete samples will be affected by a time lag as well. That means that, e.g., discrete triplicates will not be directly comparable to each other.

Calculations

Extraction of the dissolved gas by an equilibrator yields the mole fraction of the respective trace gas (x_{gas}) in the headspace, which is equilibrated with the surface water. The equilibrated headspace air within the equilibration chamber can be assumed to have a humidity of 100%. To reduce the interference of this water vapor in the spectroscopic measurements of a given gas (due to altered partial pressure and band-broadening effects), usually the sample gas stream is dried. Remaining traces of water vapor in the sample gas stream can be detected by most current analyzers and corrected for by the analyzer's internal software. In principle, to calculate the partial pressure of the given gas (p_{gas}) from its mole fraction in dry air (x_{gas}), a correction has to be applied that accounts for the water vapor pressure

$$p_{\text{gas}} = x_{\text{gas}} (p_{\text{atm}} - p_{\text{H}_2\text{O}}) , \quad (62.20)$$

where p_{atm} is the absolute atmospheric pressure, and the $p_{\text{H}_2\text{O}}$ is saturation vapor pressure of water in equilibrium with the atmosphere.

The $p_{\text{H}_2\text{O}}$ from seawater measurements is a function of temperature (T) and salinity (S) and is calculated from [62.66]

$$\ln(p_{\text{H}_2\text{O}}) = 24.4543 - \frac{67.4509 \cdot 100}{T} - 4.8489 \ln\left(\frac{T}{100}\right) - 0.000544S . \quad (62.21)$$

For $p_{\text{H}_2\text{O}}$ from freshwater measurements, the reader is referred to the calculation of E_w discussed in Chap. 8. The isochemical dependence of p_{CO_2} on temperature is about $15 \times 10^{-6} \text{ atm K}^{-1}$, and, thus, accurate measurements of temperature of the seawater in the equilibrator are vital. To account for temperature differences between the in-situ water temperature (T_{insitu}) and the equilibrator water temperature (T_{equ}) the following correction is applied for CO_2

$$p_{\text{CO}_2} = p_{\text{CO}_2 \text{ equ}} \exp[0.0423 (T_{\text{insitu}} - T_{\text{equ}})] , \quad (62.22)$$

using the temperature coefficient 0.0423 K^{-1} determined by [62.90]. The impact of temperature differ-

ences on p_{CH_4} and $p_{\text{N}_2\text{O}}$ is less pronounced. They are calculated as follows

$$p_{\text{CH}_4, \text{N}_2\text{O}} = \frac{s_{T_{\text{equ}}}}{s_{T_{\text{insitu}}}} p_{\text{CH}_4, \text{N}_2\text{O equ}} , \quad (62.23)$$

where $s_{T_{\text{equ}}}$ and $s_{T_{\text{insitu}}}$ are the solubility coefficients ($\text{mol L}^{-1} \text{ atm}^{-1}$) for CH_4 and for N_2O , which can be calculated following [62.66, 91] using T_{insitu} and T_{equ} (both in K). After having applied these corrections, the concentration of the respective trace gas in seawater, (c_{gas}) can then be calculated following Henry's law

$$c_{\text{gas}} = s_{\text{gas}} p_{\text{gas}} , \quad (62.24)$$

where s_{gas} ($\text{mol L}^{-1} \text{ atm}^{-1}$) is the solubility coefficient of the respective gas [62.65, 66, 91], and p_{gas} (atm) is the partial pressure of the respective gas in the headspace equilibrated with seawater.

The gas flux (F_{gas}) across the air–water interface ($\text{mol m}^{-2} \text{ s}^{-1}$) is calculated by

$$F_{\text{gas}} = k(C_{\text{gas}_w} - \lambda C_{\text{gas}_a}) , \quad (62.25)$$

where k is the gas transfer velocity (m s^{-1}), C_{gas_w} and C_{gas_a} are the concentrations of the gas in water and air, respectively (mol m^{-3}) and λ is the dimensionless Ostwald solubility coefficient. Among other factors, k depends strongly on wind speed, i.e., the hydrodynamics of turbulent and molecular processes within the surface layer. For the determination and calculation of k , the reader is referred to specialized literature, e.g., [62.92–95].

For precise calculations of CO_2 air-sea fluxes, the fugacity of CO_2 , f_{CO_2} should be used, which accounts for the nonideal behavior of CO_2

$$F_{\text{CO}_2} = k (f_{\text{CO}_2_w} - \lambda f_{\text{CO}_2_a}) , \quad (62.26)$$

where the term in brackets is the concentration gradient between the sea surface, $f_{\text{CO}_2_w}$, and the atmosphere, $f_{\text{CO}_2_a}$. The f_{CO_2} is derived according to

$$f_{\text{CO}_2} = p_{\text{CO}_2} e^{p(B+\delta)/(RT)} , \quad (62.27)$$

where B is the first virial coefficient, δ is the cross virial coefficient (both in $\text{m}^3 \text{ mol}^{-1}$), and R is the gas constant ($R = 8.314 \text{ J K}^{-1} \text{ mol}^{-1}$). For further details on the calculation of the virial constants, the reader is referred to [62.65].

62.4 Devices and Systems

There exist a large number of sensors and devices that have been developed for marine applications. One can distinguish two main groups. There are sensors and devices that need an external control and power supply, and devices that combine one or more sensors with an internal data logger and power supply for autonomous deployments. Most in-situ sensors and devices consist of a pressure housing that protects the electronics from the high sea pressure, which can amount up to 1100 bar in the case of deep-sea deployments. Different materials are used for pressure housings, depending on their intended depth range. For upper-ocean deployments with depths up to 500 m, plastic housings are common. For depths greater than 500 m, mainly stainless steel or titanium housings are used. Due to the large number of sensors and devices available this chapter cannot provide a comprehensive compilation. Instead, the most important sensors and devices for field observations of sea surface properties are described briefly. For more detailed information, the reader is referred to the cited literature.

62.4.1 Temperature Sensors

Today, mainly two types of temperature sensors are applied for observations of water temperature: platinum resistance thermometers and thermistors.

Platinum Thermometers

Platinum resistance thermometers are used in applications where a high accuracy and long-term stability of the measurement is required. There exist standard sensors PT25, PT100, and PT1000 with an electrical resistance at 0 °C of 25, 100, and 1000 Ω , respectively. The most common in commercial devices for marine applications is the PT100. To measure the resistance a known constant current flows through the sensor. It causes a moderate self-heating of the sensor due to the power loss in the resistor. This effect is minimized by using low measuring currents in the order of 100 μ A and the mechanical design of the particular sensor. Due to the high heat capacity and heat conductivity of water the effect of self-heating on the temperature measurement is lower than in other environments. Sensors that use platinum wires must be designed in such a way that the platinum wire is able to contract and expand with changing temperature without significant strain and deformation. This makes them susceptible to mechanical shocks and vibration. To overcome this problems film sensors have been developed in recent times. These sensors consist of a thin platinum film on a suitable

substrate. Their resistance is often trimmed with laser techniques to the desired value. Compared to sensors with platinum wires, film sensors are much more robust and depict a lower response time. Since film sensors require less effort in the production process, they are often cheaper than wire sensors.

Thermistors

The second important type of temperature sensors, thermistors, are also widely used in oceanographic applications. The higher sensitivity compared to platinum resistance sensors allows highly accurate temperature observations with low response times of the sensors. Thus, thermistors are applied in conditions with high temperature variability, e.g., for profiling measurements and turbulence measurements. However, the long-term stability of thermistors is significantly lower than that of platinum resistance sensors. To overcome this disadvantage many manufactures use only artificially aged thermistors, which depict a low temporal drift. The response times of thermistor temperature sensors depend on the particular type and range between 150 and 10 ms. The absolute precision of the sensor is reciprocal to its response time.

62.4.2 Conductivity Sensors

To calculate salinity in-situ measurements of seawater conductivity are performed. Concurrently, also temperature and pressure have to be measured, since the conductivity of an electrolyte like seawater also depends on these quantities. Today, two different types of sensors are used to measure conductivity: conductivity cells and inductive sensors.

Conductivity Cells

The standard method to measure conductivity is the direct measurement of the electrical resistance between two electrodes that are in direct contact with seawater. Usually, glass tubes with annular electrodes are used. Due to current flow, reactions with the electrolyte occur at the electrodes, resulting in a counter voltage. This effect is called polarization and produces a systematic bias. To minimize this effect, high-frequency alternating current is used to measure the conductivity. The measurement is performed by two additional electrodes located within the linear range of the voltage drop between the two outer electrodes (Fig. 62.2).

Conductivity cells are susceptible to impurities, air bubbles, and biofouling. Thus, for long-term deployment, the use of copper inlets or toxic coatings is

Fig. 62.2 A four-electrode conductivity cell

customary. The response time of a conductivity cell depends mainly on the flushing rate of the cell, which depends on the cell geometry and on the flow field around the sensor. For highly accurate measurements, the seawater is pumped actively with a constant flow rate through the cell. The response time can then be derived from the cell volume and the flow rate. However, sensors for autonomous long-term deployments operate without a pump to minimize power consumption.

Inductive Conductivity Sensors

Inductive conductivity sensors consist of two electrical coils arranged around a tube, which is filled with seawater (Fig. 62.3). An alternating current is applied in the primary coil which generates an alternating magnetic field. A current is induced in the tube and in the surrounding medium. In turn, the current generates a magnetic field, which induces a voltage in the secondary coil of the sensor. The measured current in the secondary coil is a measure for the conductivity of the seawater in the tube.

Fig. 62.3 Sketch of an inductive conductivity cell

The main advantage of inductive conductivity cells is their robustness against biofouling and high loads of suspended matter. They can be easily cleaned, since no electrodes are in direct contact with the seawater. However, a significant part of the measured signal is influenced by the external field of the sensor. The sensor output can be biased if the conductivity in the surrounding water differs significantly from the conductivity of the water inside the cell. This can occur due to small-scale fluctuations in temperature and salinity but also due to adjacent objects, e.g., other sensors, devices, or cables. Thus, the calibration of the sensor has to be done in the particular configuration of the intended deployment. The inductive sensors are not usable in pumped systems because of the high impact of the tube system and the pump on the external field. Inductive sensors are mainly used in autonomous long-term deployments where their robustness against biofouling is important.

62.4.3 The CTD Probe

The conductivity-temperature-depth (CTD) probe is the standard instrument for shipborne in-situ observations of hydrographic parameters. Usually, it combines several sensors with a water sampling system that enables the collection of water samples from selected depths (Fig. 62.4). However, also systems without water samplers are used. Depending on the particular application, a CTD probe can be operated with external or internal power supply and data acquisition. A CTD probe consists at least of temperature, conductivity, and pressure sensors, but today also oxygen concentration, fluorescence, and turbidity sensors are standard sensors on CTD probes. In recent decades, the US company SeaBird Electronics has set the standard regarding accuracy and reliability of CTD probes. Around 1990, SeaBird Electronics invented a pumped CTD system where sensors are arranged subsequently in a tube system to assure that all mounted sensors measure the same water parcel. The temporal delay due to the travel time of the water in the tube is corrected in the postprocessing of the data. This approach could suppress the effect of salinity spiking that occurs during profiling in stratified waters, due to the different response times and flushing rates of the temperature and conductivity sensors in open CTD systems.

CTD probes have been adapted to many different platforms and observation strategies. Besides the standard vertical profiling mode, CTDs are used in undulating towed systems, gliders, free-falling underway systems, moored platforms, and many more.

As an example, the special case of a microstructure profiler is briefly described. Mixing is a key parameter for the state of the ocean. Thus, advanced CTDs

Fig. 62.4 Deployment of a CTD probe on board the research vessel (RV) Meteor. The instrument consisted of the CTD probe with a rosette water sampler, a current meter system (LADCP—lowered acoustic Doppler current profiler), and a video plankton recorder (VPR), mounted in a stainless steel frame (photo © V. Mohrholz)

have been developed that measure temperature, conductivity, and current shear on the scale of turbulence with a spatial resolution of 0.01 m. This requires fast response times of the sensors and a profiling mode that do not disturb the fine structure to be measured. The main difference of a microstructure probe from the standard CTD is the higher sampling rate of up to 1024 Hz and the special streamlined design, which should prevent a tilt and any vibrations during profiling (Fig. 62.5). Microstructure profilers are mainly used in free-falling mode, without tension in the measuring cable. The vertical profiling velocity is controlled by the buoyancy of the instrument, usually about 0.5 m s^{-1} . With a sampling rate of 1024 Hz, the nominal vertical resolution is 0.5 mm. However, the real resolution is determined by the particular sensor size and its specific response time.

62.4.4 Wave-Rider Buoy

Surface waves can be measured with a number of methods. The most common application to obtain information on the wavefield parameters is the wave-rider buoy. The instruments obtain a directional wave spectrum and all important wave parameters. Wave-rider buoys are buoyancy floats that are fixed with an anchor at the sea bottom. The buoyancy float sits at the sea surface and follows its wave-induced displacements. Inside the float, a set of sensors detect the movement of the buoy. The data are processed and stored in a data logger, and/or transmitted online via radio or satellite communication. The movement of the buoy can be detected by accelerometers, motion reference units (MRU) [62.96], and GPS Doppler shift sensors [62.97].

Fig. 62.5 Sensor head of a microstructure probe. The device is equipped with a full set of CTD sensors, pressure, conductivity cell, PT100 temperature sensor, oxygen sensor, and turbidity sensor. Additionally, to measure the microstructure, two shear sensors and a fast FP07 temperature sensor have been mounted (photo © V. Mohrholz)

A comparison between the latter two methods is given in [62.98].

62.4.5 Current Meters

Two major types of current meters for marine applications are available: single-point current meters that measure the 2-D or 3-D current vector as a time series at a single point, and current profilers that obtain time series of 1-D profiles of the 2-D or 3-D current vector from remote backscatter signals of transmitted sound pulses.

Single-Point Current Meters

Although current profilers are the standard instrument for current measurements, single-point current meters are still in use. There are mechanical and acoustic single-point current meters. Mechanical current meters consist of a propeller (or rotor) and, optionally, a wing that aligns the propeller in the current direction. The current speed is obtained by counting the rotations per time unit. The current direction is measured by a compass. This type of current meter gathers only 2-D horizontal current components. Today, mechanical current meters have been replaced almost completely by acoustic devices. Mechanical current meters are still used only in some special applications, e.g., for discharge measurements.

Acoustic single-point current meters split up into 2-D and 3-D devices. An example for a 2-D single point current meter is RCM Blue from Aanderaa Data Instruments AS [62.99]. The device uses four acoustic beams, two each in x and y directions, which radiate in opposite directions. The horizontal current components are derived from the beam velocities and the compass information. The use of two beams for each horizontal

axis increases the accuracy and minimizes the impact of the instrument's own current field on the measurement. 3-D single point current meters operate with at least three beams forming a 3-D vector space, e.g., the AQUADOPP current meter from Nortek [62.100]. Acoustic single-point current meters usually work with high sound frequencies of 1 MHz or more and high sampling rates. Their range is up to 5 m. The gathered velocity data are an average value over the measurement volume, defined by the instrument's specific range and beam geometry. Sound transducers are also used as receivers of backscattered signals. The main advantages of single-point current meters are high accuracy and low power consumption, which make them particularly suitable for long-term deployments.

A special type of single-point current meter is the acoustic Doppler velocimeter (ADV), which is mainly used for small-scale and turbulence measurements [62.101]. In contrast to the instruments described above, where the acoustic beams diverge from the sensor head and span a relatively large sampling volume, ADV measures all three velocity components in a small volume of about 1 cm^3 . An ADV consists of a single sound transmitter and two to four separate sound receivers that measure the scattered sound from different directions (Fig. 62.6).

Profile Current Meters

In recent decades, profiling acoustic current meters have become the standard instrument for current measurements in natural waters. They are available in many different designs and configurations, depending on the intended application and the particular manufacturer. The principal design consists of three or more sound transducers that are combined in a transducer head, similar to the sketch in Fig. 62.6a.

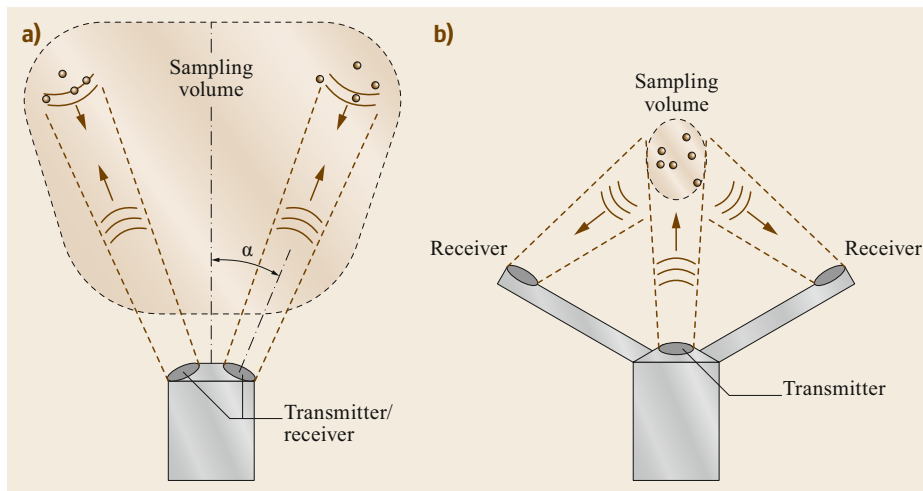

Fig. 62.6a,b

Acoustic beam geometry for an acoustic current meter with diverging beams (a), and an ADV (b). Only two beams are displayed. Usually the instruments consist of three or more acoustic beams, slanted from the vertical axis by the beam angle α

Fig. 62.7a,b Top view of a four-beam ADCP transducer head with acoustic beams (a). The horizontal velocity component u and the vertical velocity w can be calculated from the beam velocities $b^{(1)}$ and $b^{(2)}$ in the x - z plane (b) by simple trigonometric functions. A similar operation is applied to the y - z plane. The difference between the two estimates for the vertical velocity w is used as measure for the uncertainty of the measurement

For many years, the acoustic Doppler current profiler (ADCP) with a four-beam configuration (from Teledyne – RD Instruments) was the most used instrument. Other manufactures use different names for profiling acoustic current meters, like AD2CP (acoustic Doppler dual current profiler) or ADP (acoustic Doppler profiler). However, the main principle of operation is the same, and the acronym ADCP is used in this chapter as a synonym for all profiling acoustic current meters and not as a special brand.

ADCPs deliver a 1-D profile of the 3-D current vector. To measure a profile a sound pulse is transmitted into the water by each transducer. Then the transducer is switched into receive mode and records the backscattered signal for a certain period. The incoming signal is split into time windows of equal length, which are sorted to distances (depth cells) from the transducer head, according to the actual sound velocity and travel time of the sound pulse. From the velocities obtained along the particular beams, a 3-D current vector is calculated for each depth cell (Fig. 62.7). Since the four beams provide an overestimated system, also a measure for the uncertainty of the 3-D current vector can be derived. A detailed description of the principles of ADCP operation is given in [62.102].

The spatial resolution and the length of the current profile depend on the pulse length of the transmitted signal, the sound frequency used, and the abundance and properties of the backscattering particles in the water. There are some general rules. The lower the sound frequency, the larger the range of a profiler. An ADCP with a frequency of 38 kHz can reach ranges of about 1000 m and more. Its spatial resolution is between 16 and 32 m. This ADCP type is mainly used as a vessel-

mounted ADCP. Devices with very high frequencies of about 2 MHz have a range of only some meters and a spatial resolution of a few centimeters. These high-frequency devices are applied for turbulence measurements and observation of small-scale processes, e.g., in boundary layers. For a fixed frequency of sound, the accuracy of an ADCP depends on the selected size of the depth cells. The larger the depth cell, the higher the accuracy and, partly, the total range of the instrument. The accuracy increases also with the number of single-ping current estimates that are averaged. The uncertainty of the averaged velocity value decreases proportionally to the square root of the number of single pings. A precondition for reliable measurements is the availability of suitable scatter particles. Devices with lower sound frequency need larger particles, mainly zooplankton, for backscatter of the transmitted signal. However, the zooplankton distribution depends on the particular environmental conditions at the observation site. Thus, ADCP measurements sometimes fail due to the lack of scatter, e.g., in the winter season with low zooplankton abundance or in large oxygen minimum zones of tropical and subtropical oceans. Another important prerequisite for the calculation of an unbiased 3-D current vector from the beam velocities is the assumption of a homogeneous current field. Due to the diverging acoustic beams, the horizontal distance of the beams increases with increasing distance from the transducer. With a beam angle of 30° the horizontal distance between the beams is equal to the vertical distance from the transducer. For a depth cell that is 100 m off the transducer, the current field should be homogeneous over that distance. Turbulence and small-scale disturbances often violate this condition. However, this can

Fig. 62.8 A four-beam ADCP mounted in a trawl-resistant bottom frame during deployment for long-term observation (photo © V. Mohrholz)

be detected with the error estimate of a four-beam system.

Besides ADCPs with four-beam configuration, also instruments with three and five beams are available. Three-beam ADCPs provide a current profile but no uncertainty estimate for the current measurements. Five-beam devices are used to additionally detect the surface elevation for wave measurements. The fifth beam is also used to measure the vertical current component for turbulence measurements.

A special configuration is an ADCP with a phased array transducer head [62.103]. There the acoustic beam is sent out subsequently in four different directions from a single transducer head. The beam-forming and transmit direction is controlled by a large array of small transducers that are combined in a single sensor head. The advantage of these systems is the smaller size, which is important for devices with low sound frequencies. However, due to the subsequent transmission of the four beams, the sampling frequency is lower than that of devices with four fixed transducers.

Profiling current meters are mainly used to obtain vertical current profiles. They are mounted on a wide range of different platforms, which are moorings, vessels, drifters, AUVs, and many more. For measurements in shallow water, so-called horizontal ADCPs (HADCP) have been developed. They provide a 1-D horizontal profile of the 2-D horizontal current vector and are used to obtain current data in harbors and channels, as well as discharge measurements in rivers [62.104].

62.4.6 Dissolved Long-Lived Greenhouse Gases

Recommendations for the setup of underway $p\text{CO}_2$ measurements have been developed to assure uniform data quality and comparability [62.75, 105]. To the best of our knowledge, no specific recommendations are available for underway CH_4 or N_2O measurements to date, but the Scientific Committee on Oceanic Re-

search (SCOR) Working Group 143 is in the process of developing standard operation procedures for these gases [62.106].

Different setups for surface seawater underway measurements exist, but the fundamental principle is the same, i.e., an underway system usually consists of a *wet unit*, a *dry unit*, and a *deck unit* [62.75, Fig. 1]. The *wet unit* includes the water circulation system, i.e., the equilibrator, water flow meter, and valves controlling the water flow. The electronic parts, i.e., the analyzer, the valves, the power supplies, etc., are part of the dry unit. The deck unit holds the GPS receiver, the pressure transducer, and the iridium satellite modem allowing data transmission.

Seawater is pumped from the ship's bow pump, passing a water filter and then flowing into the equilibrator, which is commonly a shower, spray, or bubble-type equilibrator (Sect. 62.3.5). A bypass chamber fitted with a valve is used for discrete water sampling. The headspace gas equilibrated with the seawater is then dried by passing a condenser, and a Nafion® tube enters the analyzer and is redirected to the equilibrator, thereby forming a closed loop. The equilibrator, analyzer, the condenser, and the deck box are fitted with high-precision temperature sensors and pressure sensors (except for the condenser). A vent maintains ambient pressure inside the equilibrator. A secondary, smaller equilibrator is often used and connected to the main equilibrator by another vent to compensate for any gas loss from the main equilibrator headspace. Flow meters measure the combined flow through both equilibrators: the sample gas flow at the outlet of the analyzer and at the vent that connects the two equilibrators.

For CO_2 analysis, closed-path nondispersive infrared (IR) analyzers have been widely used (e.g., LI-7000; Chap. 8, Fig. 8.25). Conventional methods for the determination of N_2O and CH_4 are mainly based on gas chromatography (following headspace equilibration) coupled to an electron capture detector (GC-ECD) or mass spectrometer (GC-MS), e.g., [62.52, 107, 108]. The recent development and implementa-

Table 62.4 Advantages and disadvantages of the different methods

Devices	Advantages	Disadvantages
Platinum resistance temperature sensors	High accuracy High long-term stability Linear signal characteristic	Larger response time
Thermistor temperature sensors	High sensitivity High accuracy Fast response time	Larger temporal drift Aging effects Highly nonlinear signal characteristic
Conductivity cells	High accuracy Fast response time	Problems with biofouling at longer deployments Low mechanical robustness
Inductive conductivity sensors	High tolerance against bio fouling High mechanical robustness Fast response time	Limited accuracy Not applicable in pumped CTD systems
Wave-rider buoys	High accuracy Directional wave spectra	High maintenance effort
Mechanical single-point current meters	Easy to handle Low power consumption	Limited accuracy Measures only the horizontal velocity Susceptible to contamination
Acoustic single-point current meters	High accuracy Low power consumption	Only single-point measurements
Acoustic Doppler velocimeters	High accuracy High sampling rate	Only single-point measurements
Three-beam acoustic current profilers	Profile measurements	No error estimation possible
Four-beam acoustic current profilers	Profile measurements Error estimation possible	Higher power consumption
Five-beam acoustic current profilers	Profile measurements Error estimation possible Additional wave data	Higher power consumption Complex data processing
Absorption spectroscopy	Low maintenance effort, Cost effective	Analytes are limited
GC-MS and GC-ECD	Highly sensitive	High maintenance effort, labor intensive, costly

tion of near-infrared laser absorption spectroscopy, such as cavity ring-down spectroscopy (CRDS), enhanced integrated cavity output spectroscopy (ICOS), and off-axis integrated cavity output spectroscopy (OA-ICOS) (Chap. 28) provides sensitive, low-maintenance, and cost-effective methods for the measurement of a number of climate-relevant trace gases, including CO₂, N₂O, and CH₄ along with their isotopic signatures. Fourier-transform infrared (FTIR) trace gas analyzers are used for trace gas and isotope measurements as well. Crucially, these methods have enabled scientists to significantly enlarge the spatial and temporal coverage of dissolved greenhouse gas concentrations in surface wa-

ter and associated fluxes across the air–water interface and are increasingly being used for continuous measurements [62.77, 86, 87, 109–112].

62.4.7 Comparison of Methods

In this chapter, only a limited selection of the most important methods for surface water properties is presented. Thus, it is not intended to provide a comprehensive comparison of all available methods for water measurements. Instead, Table 62.4 summarizes the main advantages and disadvantages of the methods described in the previous sections.

62.5 Specifications

Typical values for the range, uncertainty, and response time of temperature, conductivity, and current velocity sensors are given in Table 62.5. The specifications are valid for the most common in-situ sensors. For calibration purposes, special reference instruments with a lower uncertainty are used. The velocity range of

acoustic current meters depends on the frequency of sound used and the principle of operation employed, but instruments for the entire range between 0 and 10 m s⁻¹ exist. However, this requires controlled laboratory conditions. The equilibrator specifications for trace gas measurements are given in Table 62.6.

Table 62.5 Specifications of typical sensors for in-situ measurements of temperature, conductivity wave parameters, and currents

Sensor/Device	Method/active element	Parameter	Range	Typical uncertainty	Response time
PT100	Platinum resistance	Temperature	−2 to 40 °C	≤ 0.003 K	0.15 s
NTC	Thermistor	Temperature	−5 to 40 °C	≤ 0.003 K	0.06 s
NTC FP07	Thermistor	Temperature microstructure	−2 to 40 °C	≤ 0.02 K	0.01 s
Conductivity cell	7-pole cell	Conductivity	0–65 mS cm ^{−1}	0.006 mS cm ^{−1}	0.1 s
Inductive conductivity sensor	Coupled inductive coils	Conductivity	0–65 mS cm ^{−1}	0.01 mS cm ^{−1}	> 0.2 s
Mechanical current meter		Current velocity and direction	0–10 m s ^{−1}	≤ 3%	–
Acoustic current meters	Acoustic Doppler effect and/of phase shift	3-D current vector	0–10 m s ^{−1}	≤ 1%	–

Gas species	Response time (min)	Error (%)	Equilibrator type	Reference
CO ₂	6.1	< 0.2	Shower head	[62.74]
CO ₂	3.8		Bubble	[62.87]
CO ₂	0.7		Column	[62.81]
CH ₄	158.3	≈ 2	Shower head	[62.74]
CH ₄	11.3		Bubble	[62.87]
N ₂ O	6.4	< 0.2	Shower head	[62.74]
N ₂ O	2.4		Shower head	[62.77]
N ₂ O	2.4	< 0.7	Bubble	[62.86]

Table 62.6 Response times and errors (if available) for different equilibrator types and gas species. Equilibrators are usually custom made, i.e., no off-the-shelf-products. Thus, please note that the response times are not directly comparable due to the different designs of the equilibration chamber, as well as background settings, such as the water flow rate. For further information, the reader is referred to the referenced publication ◀

62.6 Quality Control

The particular measurement systems used in water measurements require different strategies to ensure high data quality. Generally, two steps of quality control are performed. Before any sensor deployment most sensors have to be calibrated in the laboratory to correct the sensors for temporal drifts due to aging effects. The interval of calibration differs for the particular sensors. Secondly, during the deployment of the sensors comparison measurements are carried out with independent methods to ensure the data quality and to discover sensor failures.

62.6.1 Sensor Calibration

Temperature and conductivity sensors are usually calibrated in the laboratory at least once a year. Platinum resistance reference thermometers are used to calibrate the temperature sensors at some reference points distributed over the full range of the sensor, usually every 5 K between 0 and 35 °C. The calibration of conductivity is performed with high precision conductivity cells [62.113] and so-called standard seawater that has a reference composition of sea salt [62.60]. Since the conductivity is highly temperature dependent, also the temperature must be measured with high precision.

Current meters are calibrated by the manufacturer before delivery. They can be calibrated in flow chan-

nels, but this requires a high effort and causes high costs. Thus, current meters are usually not calibrated again during their lifetime. This can be accepted, since their principle of velocity measurement is highly robust for temporal drift and aging. However, most current meters consist of a magnetic compass that needs a proper compensation prior to each deployment. This is performed with built-in compass calibration procedures.

For daily calibration procedures of greenhouse gas measurements, secondary standard gases are used, which need to be calibrated against primary standard gases. Primary standard gases for CO₂, CH₄, and N₂O, which are traceable to the World Meteorological Organization Scale, are provided by the National Oceanic and Atmospheric Administration (NOAA) Central Calibration Laboratory (CCL). Calibration procedures to check for long-term drift and for postcorrection of the data differ between types of analyzers and between applications. For Li-COR-based CO₂ measurements, it is recommended to run a set of four reference gases every 3 h. The gases should closely bracket the range of expected gas concentrations [62.75, 105]. In contrast, the OA-ICOS analyzers only need a one-point calibration that is stable for 1–2 weeks, whereas CRDS analyzers need at least three standard gases to perform their calibration. However, standard operation proce-

dures for underway CO₂, CH₄, and N₂O measurements based on near infrared laser absorption spectroscopy are currently being developed by the Scientific Committee on Oceanic Research (SCOR) Working Group 143 [62.106].

62.6.2 Specific Quality Control Methods

During the field deployments of sensors mainly comparison measurements with independent instruments are performed to check the data quality. Temperature sensors can be checked with electronic reversal thermometers or with in-situ platinum resistance reference thermometers. Conductivity sensors are usually compared with independent conductivity measurements of collected water samples. During field expeditions comparison measurements are carried out usually at least once a day. In the case of long-term deployments, comparison measurements are performed immediately after the deployment and prior to the recovery. A new development is the usage of double-sensor packages on CTDs that allow the fast detection of sensor drift and failures by comparison of the data output of two identical sensors. This method has the advantage that the failure of a single sensor does not cause data loss.

Current meters can be compared to each other for a quality check. For example, a current meter that is deployed in a mooring will be checked with the

vessel-mounted ADCP of the ship that performs the maintenance of the mooring. Another opportunity is so-called bottom tracking. An ADCP that measures down to the seabed can estimate its relative movement to the bottom. This is compared to the movement of the measuring platform, derived from independent navigation data (e.g., GPS). With this method, velocity errors and also compass bias can be detected. Further checks are possible if a specific current component is well known. The main axis of a tidal current is very stable and can be used to correct compass bias.

The performance of the equilibrator for trace gas measurements should be checked to determine the gas-specific equilibration time in a set of tests at the home laboratory. In the field, the results of the continuous underway measurements should be checked by taking discrete samples from a bypass connected to the same water flow that supplies the continuous system to confirm the integrity of the underway results or to correct them if necessary. However, it needs to be noted that, depending on the overall variability in surface water and the speed of the vessel, discrete samples will be affected by a time lag as well, and triplicate discrete samples will not be directly comparable to each other. Additionally, regular calibration of the analyzer is needed to check for long-term drift and for postcorrection of the data (Sect. 62.6.1).

62.7 Maintenance

Sensors that are deployed in seawater are exposed to two major stresses: corrosion and biofouling. To prevent serious impacts on sound-sensor operation regular maintenance is required. Although seawater-resistant materials are used for water sensors, the combination of different metals or even plastics, like polyvinyl chloride (PVC), can cause corrosion of the metal parts of sensors. Usually, sacrificial anodes are used to preclude corrosion. Sacrificial anodes have to be checked carefully after each deployment and have to be exchanged if necessary. A particular problem is corrosion on electrical plugs and connectors, especially if they are under power. Any direct contact to seawater must be excluded. For this purpose, special silicon grease is applied to the electrical connections and plugs. Biofouling is another issue. It occurs at the surface as well as at depth. At the surface mainly mussels or barnacles can grow on the instruments and seal, e.g., inlets and tubes of conductivity sensors. They are also able to destroy the coating of acoustic transducers of modern current meters. Copper coatings or tubes are used to minimize biofouling. However, they never prevent it completely. At greater depths biofilms built up by bacteria are very common. Thus, regular

cleaning of instruments is necessary. For conductivity cells, special bleaching solutions are available, since mechanical cleaning would destroy the electrodes. The maintenance interval depends on the particular deployment conditions, but also on battery lifetime and memory capacity for self-contained instruments. Common maintenance intervals reach from 2 weeks in productive surface waters up to 2 years for deep-water deployment.

For maintenance of trace gas systems, care needs to be taken that flow rates of both water and headspace air are monitored and stay constant. Anomalies are indicative of blockage or leakage. Usually, a condenser and Nafion[®] drying tubes, which are low-maintenance parts, are used to dry the gas sample before it enters the analyzer. However, some systems contain additional drying agents, such as magnesium perchlorate (Mg(ClO₄)₂), which need to be replaced regularly. An increase of $x_{\text{H}_2\text{O}}$ readings of the analyzed gas is an indicator for reduced drying efficiency. It is also recommended to back-flush the system to reduce fouling during long measurements and to flush the water filter, tubing, etc., with freshwater after use and before storage to keep it clean and free from blockage.

62.8 Application

Applications of water sensors cover manifold fields, e.g., scientific field observations, environmental monitoring, and waste-water treatment. In this section, two examples for scientific applications are presented.

62.8.1 Variability in the Surface Mixed Layer

The interface between ocean and atmosphere is bounded at the ocean side by the surface mixed layer (SML). The properties of the SML have a high impact on the matter and energy fluxes through the ocean–atmosphere interface. To gather undisturbed data for a process study of the SML an autonomous drifter was deployed during an expedition of RV Meteor (M87/4) in the central Baltic Sea. The drifter consisted of a surface float and a 40-m-long sensor string mounted underneath, which covered the SML. On the sensor string 11 temperature sensors were mounted with a distance of 4 m between the single instruments. At 40 m depth an upward-looking ADCP was fixed to measure the current field in the SML. The deployment covered a period of 10 days. From the time series of the single-point temperature sensors, a Hovmöller plot of the temperature distribution was compiled (Fig. 62.9). It depicts a highly stratified upper layer with a warm surface layer of 10–20 m thickness. Solar radiation has heated the water to a temperature of about 16 °C. The layer below 30 m conserved the late winter temperatures of about 4 °C.

The increasing wind speed during the measuring period led to enhanced mixing in the SML. At the bottom of the mixed layer the thermocline was eroded by the transformation of turbulent kinetic energy into potential energy of stratification. The thickness of the SML increased from 10 m in the beginning to nearly 20 m depth at the end of the time series. This process also increased the vertical temperature gradient between the SML and the cold water layer below.

Wind pulses also generate inertial motions and waves in the SML and below. The current measurements gathered with the ADCP depict the current field of the inertial motions (Fig. 62.10). At the latitude of the observations of 57.3° N the inertial processes have a period of 14.2 h. The observed periodic changes of the surface current fit to this value.

The eastward and northward components of the surface current are phase-shifted by about 90°. This points to inertial motions rather than inertial waves. The strong vertical temperature gradient at the bottom of the SML caused a strong density gradient, which decouples the SML dynamically from the layer below. Thus, the deepening of the SML is also seen in the current field. The deflection of the internal motions at the edges of the basin causes a phase shift of 180° between the currents in the SML and the layer directly below it. At the surface the impact of wind waves on the current measurements is visible as enhanced noise. Since their wavelength is lower than the distance between the particular acoustic beams of the ADCP, which is ≈ 30 m near the surface, the precondition of a homogenous current field is not fulfilled (Sect. 62.4.5). This caused a higher bias in the current measurements gathered in the upper 5 m of the SML. However, this disturbance can be used as an indicator of wave intensity at the surface.

62.8.2 Spatial Variability of Greenhouse Gases off the Coast of Namibia

An example of how the subsurface hydrography links to biogeochemical processes in the surface is illustrated in Fig. 62.11, which shows a cross section through a filament offshore of the Namibian coast [62.115]. This area is part of the Benguela Current Upwelling System and is affected by coastal upwelling of cold, nutrient, and CO₂-enriched subsurface water [62.116, 117]. Fila-

Fig. 62.9 High-resolution time series of SML temperature in the central Baltic Sea, gathered with an autonomous drifter during the RV Meteor expedition M87/4

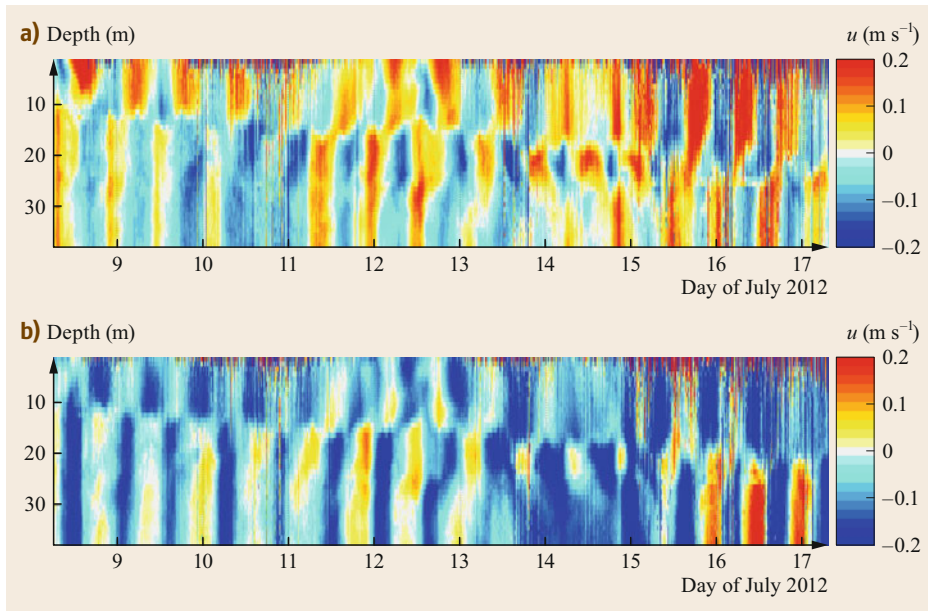

Fig. 62.10a,b
High-resolution time series of currents in the SML in the central Baltic Sea, gathered with an autonomous drifter during the RV Meteor expedition M87/4: (a) current east, (b) current north

Fig. 62.11a,b North-south cross section through a filament offshore of the Namibian coast. (a) Vertical distribution of salinity (color coded, background) is overlain by pH, temperature, and DO saturation, which were measured in surface water along the transect. (b) Vertical distribution of salinity (color coded, background) is overlain by x_{CO_2} , x_{CH_4} , and Chl-*a* fluorescence, which were measured in surface water along the same transect. For reference, atmospheric dry mole fractions of CO_2 and CH_4 measured at the NOAA station in Namibia ranged between 394–397 ppm and 1.76–1.79 ppm at that time (after [62.114])

ments are tongues of cold, upwelled water that separate from the main upwelling front and spread offshore. The filament is indicated by a core of low salinity in the (sub)surface (green and blue colored shading) coinciding with a drop of surface temperature (red line, top panel). The uplift of subsurface water is associated with an increase in x_{CO_2} , as well as x_{CH_4} , but decreased pH and dissolved oxygen (DO) saturation in surface water, which is caused by aerobic decomposition and anaero-

bic methanogenesis of organic matter in sinking organic particles and in the sediments [62.118–120]. The nutrient input associated with the upwelling fuels primary production, which is indicated by a peak in Chl-*a* fluorescence coinciding with a rise in DO saturation and a drop in x_{CO_2} in the center of the filament. In contrast, CH_4 is mainly oxidized in the surface water and is not source for biological primary production and is, thus, not affected by primary production the way that CO_2 is.

62.9 Future Developments

Future in-situ sensors for water measurements will benefit from the rapid development of microelectronics. It will lead to higher integrated systems with lower power consumption, which will enable higher sampling rates and longer autonomous deployment times. The miniaturization of sensors will also allow the faster response times needed for turbulence observations. However, there are physical limits. Since most chemical poisons are banned for in-situ applications, new antifouling concepts have to be developed to ensure data quality during long-term deployments, e.g., on Argo floats. A rapid development of measuring platforms is also expected. The usage of autonomous operating devices, like gliders and AUV, will become a common tool in ocean ob-

servations, although they cannot replace the shipborne observations completely.

Sensors for in-situ trace gas measurements are being developed and are promising tools, e.g., as part of autonomous long-term deployments for monitoring the ocean surface. Sensors for in-situ trace gas measurements are being developed and are promising tools, e.g., as part of autonomous long-term deployments for monitoring the ocean surface. Sensors for in-situ N_2O measurements are not yet commercially available. However, given the strong demand and focus on the development of in-situ sensors to date, the range of available in-situ trace gas sensors, as well as their performance, is likely to improve in future.

Volker Mohrholz

Physical Oceanography and Instrumentation
Leibniz-Institute for Baltic Sea Research
Warnemünde
Rostock, Germany
volker.mohrholz@io-warnemuende.de

Volker Mohrholz is Senior Scientist at the Leibniz-Institute for Baltic Sea Research in Warnemünde, Germany, heading the research group Physical-Biogeochemical Coupling of Marine Systems. He received his PhD in natural sciences in 1995 from the University of Rostock. His work covers the dynamics and variability of circulation in the Baltic Sea, as well as the dynamics of upwelling areas and oxygen minimum zones. His group focuses on high-resolution hydrographic observations and turbulence measurements in the marine environment.

Anita Flohr

Ocean and Earth Science
University of Southampton
Southampton, UK
a.flohr@southampton.ac.uk

Anita Flohr is Postdoctoral Research Fellow at the School of Ocean and Earth Science at the University of Southampton. She received her PhD in Marine Biogeochemistry from the University of Hamburg (2015) for her work on the strength and efficiency of the marine carbon pump of the northern Benguela upwelling system. She is working on a project that develops monitoring strategies for marine carbon capture and storage using tracer gases.

63. Networks of Atmospheric Measuring Techniques

Rolf Philipona 

Networks of atmospheric measuring techniques are fundamental to ensuring the scientific and climatic usefulness of atmospheric measurements. Because air masses can move hundreds of kilometers every day, weather, air pollution, and climate are international issues—they cannot be addressed at the national level alone. However, measurement stations and systems are usually operated and funded at the national level or at even more local levels. To ensure that results are comparable and to address global problems, it is therefore crucial to coordinate goals, operating procedures, stations, systems, standards, traceability, etc. at the international level. International networks allow the implementation of different atmospheric measuring techniques at specifically selected sites and are relevant to all stages of the generation of atmospheric data on physical properties and chemical compositions. The purpose of this chapter is to introduce and describe the history, structure, instruments, methods, and other aspects of these atmospheric observing networks. It chronologically describes the birth and formation of the various atmospheric measurement networks around the globe, which has mainly been driven by the need for atmospheric monitoring that provides long-term climate change observations. The relevance of networks, measurement principles, and the different parameters observed are presented. Quality control, maintenance, and future developments in this field to facilitate various applications are also discussed.

Climate change and its links to various changes in the atmosphere have prompted several initiatives to build networks of atmospheric measuring techniques in recent decades. Global Atmosphere Watch (GAW) is a worldwide system that was established by the World Meteorological Organization (WMO) to monitor trends in the Earth's atmosphere. A forerunner to GAW was conceived as far back as the 1950s, when the WMO began a program that aimed to monitor the atmosphere for trace chemicals and research air pollution from a meteorological perspective. GAW was eventually created in 1989 by combining the Global Ozone Observing System (GO3OS) with the Background Air Pollution Monitoring Network (BAPMoN). In 1991, after five years of planning, the Network for the Detection of Atmospheric Composition Change (NDACC) officially began operating. Originally named the Network for the Detection of Stratospheric Change (NDSC), the goal of NDACC is to observe changes in chemical and physical state in the stratosphere and upper troposphere and to assess the impact of such changes on the lower troposphere and climate. In the early

1990s, the World Climate Research Program (WCRP) initiated a new radiometric network, the Baseline Surface Radiation Network (BSRN), to support climate research. This network provides validation material for satellite radiometry and climate models and detects long-term variations in irradiance at the Earth's surface, which are believed to play an important role in climate change. Around 2010, the Global Climate Observing System (GCOS) Reference Upper-Air Network (GRUAN) moved from concept to reality. The goal of GRUAN is to provide reference-quality in-situ and ground-based remote-sensing observations of important climate variables for the upper air.

The four networks (GAW, NDACC, BSRN, and GRUAN) described above are linked to each other to some extent, and are connected to a number of additional regional, national, and international networks and programs that are also briefly presented below. All of these networks support atmospheric climate monitoring and research as well as broader components of the WMO Global Observing System (GOS), its research, and applications.

63.1 Relevance and Parameters of Networks

Global or Regional GAW stations are operated by WMO members. A *contributing station* is a station that is operated by a WMO partner network or organization that contributes data of known quality to one of the GAW World Data Centres and is linked to the GAW Primary Standard for a particular variable relating to atmospheric physics or chemistry.

63.1.1 Relevance of Atmospheric Measurement Networks

When the origins of atmospheric measurement techniques and research into measuring and understanding changes in the chemical composition of the atmosphere are discussed, two phenomena are usually mentioned. The first is regional air quality and, in particular, the first observations of photochemical *smog*. Hazardous air quality was reported as far back as the nineteenth century, but studies of air pollution generally date back to the 1950s, when the chemical and physical processes that lead to unhealthy urban environments were first identified [63.1]. The second phenomenon is chemical threats to the atmosphere as a whole, which were observed and investigated by scientists during the 1960s and 1970s [63.2–8]. These investigations were inspired by views of our planet from space, and

were boosted by measurement projects initiated during 1957–58: the International Geophysical Year (IGY). During the IGY, background monitoring stations began to measure gases such as carbon dioxide, methane, and total column ozone along with related constituents, many of which were heavily concentrated in the stratosphere. Unlike many short-lived chemical pollutants, carbon dioxide and lower stratospheric ozone have long lifetimes and relatively uniform global distributions. Furthermore, they are related to the radiative properties of the atmosphere. Water vapor and carbon dioxide are primary greenhouse gases, and the thickness of the column abundance of ozone determines the amount of ultraviolet (UV) radiation that reaches the Earth's surface [63.9].

Air quality, photochemical smog, and chemical threats to the atmosphere as a whole were therefore the original drivers for the development of standard procedures for achieving uniform ozone observations and the creation of the Global Ozone Observing System (GO3OS). They also provided the impetus to establish the Background Air Pollution Monitoring Network (BAPMoN) in the late 1960s. These two programs, which were guided by the World Meteorological Organization (WMO) and its Global Atmosphere Watch (GAW) initiative, were ultimately combined into the

GAW program and network in 1989. This network consists of global and regional GAW measurement stations, with additional measurements provided by contributing stations. The global and regional GAW stations are operated by national meteorological services or other national scientific organizations in their host countries. More than 80 countries actively host GAW stations [63.10].

The Network for the Detection of Atmospheric Composition Change (NDACC) is an international global network composed of more than 70 high-quality remote-sensing research stations. NDACC was originally named the Network for the Detection of Stratospheric Change (NDSC), and its goal was to observe changes in the chemical and physical state of the stratosphere and upper troposphere as well as to assess the impact of those changes on the lower troposphere and global climate. While NDACC remains committed to monitoring changes in the stratosphere (with an emphasis on the long-term evolution of the ozone layer), its priorities have broadened considerably to include, for instance, the detection of trends in overall atmospheric composition, understanding the impacts of those trends on the stratosphere and troposphere, and establishing links between climate change and atmospheric composition. Following five years of planning, instrument design, and implementation, NDACC began network operations in January 1991. NDACC is structured around various categories: ground-based observational techniques, timely cross-cutting themes (ozone, water vapor, measurement strategies and emphases), satellite measurement systems, and theory and analysis. To widen its scope, NDACC has established formal collaborative agreements with eight other cooperating networks [63.9].

To support climate research, a new international global radiometric network—the Baseline Surface Radiation Network (BSRN)—was initiated in the early 1990s by the Global Energy and Water Exchanges (GEWEX) project of the World Climate Research Programme (WCRP). This network aims at providing validation material for satellite radiometry and climate models. It also detects long-term variations in irradiance at the Earth's surface, which play an important role in climate change. The network and its instrumentation are designed to (i) cover major climate zones, (ii) provide the accuracy required to meet the objectives, and (iii) ensure homogenized standards far into the future.

The limits on the accuracy of the network that is needed to reach these goals have been defined. Suitable instruments have been determined and the methods to be used for observations and data management have been agreed upon by all (currently 59) stations. The central archive of BSRN is the World Radiation

Monitoring Center (WRMC), which was initiated in 1992 [63.11].

The Global Climate Observing System (GCOS) was established during the Second World Climate Conference in 1992 to ensure that the observations and information needed to address climate-related issues are obtained and made available to all potential users. GCOS is co-sponsored by the World Meteorological Organization (WMO), the Intergovernmental Oceanographic Commission (IOC) of UNESCO, the United Nations Environment Programme (UNEP), and the International Council for Science (ICSU). GCOS is a system that comprises the climate-relevant components of many contributing observing systems and networks. The mission of the GCOS program is to help ensure that these contributing systems, taken as a whole, provide the comprehensive information on the global climate system that is required by users, including individuals, national and international organizations, and institutions and agencies [63.12].

The GCOS Reference Upper-Air Network (GRUAN) is an international reference observing network of sites that measure important climate variables above the Earth's surface in order to fill an important gap in the current global observing system. GRUAN measurements provide high-quality long-term climate data records on, for example, atmospheric water vapor, temperature, wind components, and pressure from the surface through the troposphere and into the stratosphere. These records are used to determine trends, to constrain and calibrate data from more spatially comprehensive observing systems (including satellites and current radiosonde networks), and to provide appropriate data for studying atmospheric processes. GRUAN started in 2008 with about 15 stations, and it is envisaged that it will eventually grow into a global network of 30–40 sites that, if and where possible, builds on existing observational networks and capabilities [63.13].

63.1.2 Measurement Principles and Parameters

The WMO's Global Atmosphere Watch (GAW) program integrates many monitoring and research activities involving the measurement of the chemical composition and physical properties of the atmosphere. The parameters measured by the four main atmospheric measurement networks are shown in Table 63.1.

GAW

GAW serves as an early warning system for further changes in atmospheric concentrations, including the acidity and toxicity of rain as well as the atmospheric burden of aerosols. GAW provides framework design,

standards, intercalibrations, and data collection systems for global monitoring and data evaluation. Its focal areas are aerosols, greenhouse gases, reactive gases, ozone, UV radiation, and precipitation chemistry, and it includes the GAW Urban Research Meteorology and Environment Project (GURME) [63.10].

NDACC

As noted above, NDACC was originally committed to monitoring changes in the stratosphere with an emphasis on the long-term evolution of the ozone layer, but its priorities have recently broadened considerably to encompass issues such as the detection of trends in overall atmospheric composition and understanding the impacts of these trends on the stratosphere and troposphere. Concerns about global ozone intensified with the realization that stratospheric ozone chemistry included catalytic cycles involving reactive halogens, nitrogen, and hydrogen. Early spectroscopic balloon measurements confirmed the presence of trace species such as NO₂, HNO₃, and HCl. Scientists were also beginning to investigate the effects of the growing use of chlorofluorocarbons (CFCs) in myriad applications. Hence, NDACC expanded rapidly, and today it measures total column and vertical profiles of major atmospheric variables (constituents and physical parameters) such as ozone, water vapor, trace species, chlorofluorocarbons, greenhouse gases, reactive gases, aerosols, UV radiation, and temperature up to the mesosphere [63.9].

BSRN

Observations made by BSRN are divided into three main categories: basic, expanded, and other measurements. Because the irradiances in the basic measurement program provide the foundations for the data requirements of BRSM, they have the highest priority in BSRN, and improving their derivation was the focus of development during the initial stages of implementing BSRN. The basic measurements required for these quantities are the direct solar irradiance, diffuse sky irradiance, and longwave downward irradiance. The measurement of global irradiance by a pyranometer is included as part of the basic measurement program to provide closure of the solar radiometer system. Stations with an expanded measurement program provide additional information that is mainly used to improve satellite algorithms and for data interpretation. This includes direct solar spectral irradiance at the specific wavelength, cloud amount and type, vertical distributions of temperature and water vapor, cloud-base height and aerosols, precipitable water, and ozone. During

the course of the project, it was found that measurements of this category are also extremely useful for data quality control. BSRN stations are also encouraged to undertake additional measurements mainly to advance atmospheric radiation research. These include short- and longwave upward irradiance from a tower and low-resolution shortwave and longwave hemispheric spectral irradiance such as UV measurements. These will provide detailed information on radiative effects on the climate system and help to improve parameterization in climate models [63.11].

GRUAN

The GRUAN measurement strategy aims to maintain measurements over several decades in order to accurately quantify trends. It provides data for validating and calibrating measurements from observing systems that are more spatially extensive, such as satellite systems and the global radiosonde network, leading to improved satellite data products. The measurements are performed to fully characterize the properties of the atmospheric column. Major essential climate variables such as atmospheric water vapor, temperature, and wind components are measured using a number of different but complementary techniques to validate derived measurement uncertainties. The final goals are to characterize observational biases and estimate measurement uncertainties, describe measurements using extended metadata, comprehensively document the observing technique, tie measurements to SI units or internationally accepted standards, and ensure the long-term stability of measurement series by managing instrument changes, thus improving the overall upper-air observing network [63.13].

Table 63.1 Important parameters measured by the four main atmospheric measurement networks

Network	Important parameters measured by network
GAW	Greenhouse gases, ozone, aerosols, selected reactive gases, atmospheric deposition, UV radiation
NDACC	Total column and vertical profiles of ozone, water vapor, trace species, chlorofluorocarbons, greenhouse gases, reactive gases, aerosols, UV radiation, and temperature up to the mesosphere
BSRN	Basic measurements include direct solar irradiance, diffuse sky irradiance, and longwave downward irradiance. Global irradiance is measured by a pyranometer to provide closure of the solar radiometer system
GRUAN	Vertical profiles of atmospheric water vapor, atmospheric temperature, and atmospheric wind components

63.2 History

The monitoring of trace atmospheric constituents was originally driven by scientific curiosity. However, it was not long before researchers began to question how closely the observed increases in certain trace chemicals were connected to human activities, and what the consequences would be for humanity if these trends continued unabated. For a discussion of the history of meteorological networks in general, see Chap. 1.

63.2.1 History of Atmospheric Measurement Networks

The WMO played an important role in converting scientifically driven events into regular monitoring by formally embarking on a monitoring program for atmospheric chemistry and meteorological aspects of air pollution during the 1950s. Adequate information on the chemical composition of the atmosphere is needed, and the global consequences of anthropogenic changes to the atmosphere can only be estimated if all measurements of the component of interest are expressed in the same units or on the same scale (i.e., if the measurements performed by different countries are comparable).

GAW

The first step towards the development of atmospheric measurement networks was taken by the WMO, which began to coordinate chemical measurements internationally during the International Geophysical Year in 1957. The WMO took responsibility for developing standard procedures for uniform ozone observations and established the Global Ozone Observing System (GO3OS). GO3OS organized a coordinated Dobson (and later Brewer) spectrophotometer network for measuring total atmospheric ozone, performed ozonesonde intercomparisons, prepared ozone bulletins and assessments, and supported the Ozone Data Centre in Canada.

In the late 1960s, the Background Air Pollution Monitoring Network (BAPMoN) was established. This network focused on precipitation chemistry and aerosol and carbon dioxide measurements. It included regional and background stations and established the WMO World Data Center in the USA.

During the 1970s, three atmospheric issues became increasingly prominent:

- (a) The threat of CFCs to the ozone layer
- (b) The acidification of lakes and forests in large parts of North America and Europe, caused principally by the conversion of sulfur dioxide to sulfuric acid through precipitation processes in the atmosphere

- (c) The global warming caused by the accumulation of greenhouse gases in the atmosphere.

Each of these issues is now the subject of international treaties or conventions. The initial development of these agreements and subsequent assessments of the mitigation measures they specify were heavily dependent on the information provided by the WMO's atmospheric composition monitoring program.

In 1989, the two observing networks BAPMoN and GO3OS were consolidated into the WMO's Global Atmosphere Watch (GAW) program [63.10, 14].

NDSC/NDACC

At a meeting in Geneva in 1989, NASA, NOAA, and the WMO convened a forum in which several international agencies and institutions participated. At that meeting, the organizational structure of the Network for the Detection of Stratospheric Change (NDSC) was formalized [63.15]. Annual Steering Committee (SC) meetings commenced in 1990, and these meetings led to the realization that this research and monitoring program needed to be global. In 1991, after five years of planning, NDSC began official operations. Thus, from its very beginnings, NDSC has been a consortium of countries and sponsoring organizations that is endorsed by the United Nations Environment Programme (UNEP), the WMO, and the International Ozone Commission (IO3C)—a body of the IUGG/IAMAS (International Union of Geodesy and Geophysics/International Association of Meteorology and Atmospheric Science).

NDSC has provided a unique and enduring framework for the international community to perform long-term ground-based measurements of atmospheric composition at the global scale. To celebrate the 10th anniversary of NDSC in 2001, a symposium highlighting its scientific achievements was held in Arachon, France, in conjunction with an international symposium. In 2005, during the 16th Annual SC Meeting in Tenerife, Spain, the name of the Network for the Detection of Stratospheric Change (NDSC) was changed to the Network for the Detection of Atmospheric Composition Change (NDACC) to better reflect the expanded focus of its measurements. For its 25th anniversary, an article on NDACC was featured in *The Earth Observer* [63.16], and a special issue on NDACC was jointly published in the journals *Atmospheric Chemistry and Physics*, *Atmospheric Measurement Techniques*, and *Earth System Science Data*. This special issue included an introductory paper written by the NDACC community [63.9].

BSRN

The radiation budget of the Earth–atmosphere system is a fundamental influence on the thermal conditions and circulation in both the atmosphere and the oceans, and thus shapes the main characteristics of the Earth’s climate. The irradiance at the Earth’s surface is an especially important factor in climate processes, as the Earth’s surface transforms about 60% of the solar radiation it absorbs. This irradiance also plays an important role in the energy budget of the ocean surface, which ultimately influences the major features of ocean currents. While a small change in irradiance at the Earth’s surface may cause a profound change in its climate, until a few decades ago, radiometric networks were not capable of achieving the accuracy required for climate research. Our understanding of the vertical and horizontal radiation distributions was not sufficient to understand the climate. The results of simulations of previous and future climate fluctuations induced by changes in solar radiation flux had high uncertainties. This was the background for the World Climate Research Programme (WCRP) to initiate a new radiometric network to support the research projects of the WCRP and other scientific programs.

In October 1988, the World Meteorological Organization/International Council of Scientific Unions (WMO/ICSU) Joint Scientific Committee for the WCRP proposed the international Baseline Surface Radiation Network (BSRN), with the following goals:

- (1) To perform irradiance measurements at the Earth’s surface that can be used to validate satellite-based estimates of the surface radiation budget and radiation transfer through the atmosphere
- (2) To provide the irradiance data needed to validate and improve radiation codes of climate models
- (3) To monitor long-term changes in the irradiance at the Earth’s surface.

To achieve these goals, it is necessary to ensure that the entire network adheres uniformly to the highest achievable standards of accuracy, observation procedures, and calibration methods. Consequently, sustained efforts to develop more accurate and stable instruments, more reliable weather protection, and more uniform calibration procedures are a necessary component of BSRN. It is also important to carry out radiometry concurrently with measurements of relevant atmospheric characteristics such as temperature, water vapor, ozone, aerosol, and clouds. The initial proposal for the network included about 20 strategically located stations. A working group for the implementation of the project

was formed in 1989. The group was charged with the following tasks:

- (1) To identify the optimal sites and the organizations to carry out the observations
- (2) To formulate the observational requirements and procedures, including instrument selection (or development if necessary), method deployment, and calibration processes
- (3) To develop the data administration scheme, including quality control, permanent archiving, and data retrieval [63.11].

BSRN began operating in 1992, utilizing nine sites and an archive at the WCRP World Radiation Monitoring Center (WRMC) in the Swiss Federal Institute of Technology (ETH) in Zurich. To facilitate attainment of the target accuracy and to ensure the standardization of observations and data handling, the working group published manuals for observational procedures [63.17] and for data management and quality control [63.18]. The fully automated data administration and data access system has been operational at ETH Zurich since June 1995. Since 2008, the WRMC has been operated by the Alfred Wegener Institute for Polar and Marine Research (AWI), Germany. The data this network provides are hugely important for the validation and confirmation of satellite and computer model estimates of surface radiation quantities. At an increasing number of stations (currently 59) in contrasting climatic zones that range in latitude from 80° N to 90° S, solar and atmospheric radiation is measured with instruments of the highest available accuracy and with high time resolution (1–3 min).

In 2004, BSRN was designated the global baseline network for surface radiation for the Global Climate Observing System (GCOS). BSRN stations also contribute to Global Atmospheric Watch (GAW). In 2011, BSRN and NDACC reached a formal agreement to become cooperative networks.

GRUAN

The GCOS Reference Upper-Air Network (GRUAN) is an international reference observing network that was specifically designed to meet the needs of climate monitoring and to fill a major void in the current global observing system. The key aspects of GRUAN were developed during three workshops. The first, held at NOAA in Boulder (CO, USA) in February 2005, identified the requirements of a reference upper-air network for climate observations. The second, held at the University of Washington in Seattle (WA, USA) in May 2006, explored potential technologies and net-

works that could meet the stated requirements. Details on these two workshops were reported by GCOS in 2007 [63.19]. The third workshop, held at the Lindenberg Meteorological Observatory in Germany in February 2008, reached decisions on issues relating to instrumentation, observation protocols, management, and the relationships between GRUAN and other programs and organizations [63.20], all of which were needed to initiate the program [63.21].

GRUAN was designed to:

- Comprise several dozen stations that would become operational in a phased process. This network serves primarily as a long-term reference for other networks. GRUAN is not intended to include stations in every region of the world; instead, it samples major climatic regimes, latitudes, altitudes, and surface types. Each station is associated with a host institution that has the necessary scientific and technical expertise and a commitment to the long-term operation of the site.
- Adhere to the climate monitoring principles of GCOS, such as ensuring the quality and the long-term continuity and homogeneity of observations (and the metadata needed to interpret them), the use of the data in research and assessments, establishing the requirements at the outset of system design and implementation, and incorporating data management systems that facilitate data access.
- Measure the *essential climate variables* identified by GCOS in 2003, with a particular focus on the highest priority upper-air variables. High-quality instruments are employed to provide the most accurate data possible.
- Perform ongoing real-time and retrospective cross-validation of different measurements of the same parameter and evaluate measurement accuracies and drifts.
- Include a strong lead center that provides scientific leadership and oversight, manages the network, trains operators, and ensures proper data archival

and free dissemination. The Meteorological Observatory Lindenberg (Richard Aßmann Observatory) serves as the GRUAN Lead Centre due to the German Meteorological Service (DWD) offer of substantial financial, scientific, and technical support in response to a call for interest issued by the GCOS Secretariat.

- Incorporate a strong commitment to coordinate with other existing networks and observing systems and to provide a scientifically robust service to the user community. Achieving coordination among networks is recognized to be a challenge, but it is seen as critical to the long-term success of GRUAN and other networks.

These concepts help to clarify what GRUAN is, but it is also important to clearly articulate what GRUAN is not. It is not a set of identical stations; some will be more comprehensive than others, although all will obtain a core set of first-priority observations. It is not a replacement for the existing radiosonde network, which has a higher spatial density (necessary for some weather observations), nor for the GCOS Upper-Air Network (GUAN). The 30- to 40-station GRUAN network aims to provide reference observations, i.e., the long-term anchor points that comprehensively characterize the atmospheric column based on the best measurements currently available. The basis of the system is the complete global upper-air observing system, which serves a wide variety of purposes (primarily weather prediction), includes the operational radiosonde network, aircraft and satellite observations, etc., and embraces model-assimilated upper-air datasets and reanalyses.

GRUAN is a key component of GCOS, and GCOS is, in turn, the formal climate component of the Global Earth Observing System of Systems (GEOSS) [63.22]. GRUAN contributes to GEOSS's goal to "understand, assess, predict, mitigate, and adapt to climate variability and change" [63.23]. GRUAN is also a crucial element of the Global Space-Based Inter-Calibration System [63.21, 24].

63.3 Network Structure

Research at GAW is focused on conducting observations to document changes in atmospheric composition, continuously improving the observational and data management infrastructure, analyzing the data to improve our understanding of the processes that lead to changes in atmospheric composition, and developing GAW products and services.

63.3.1 The WMO/GAW International Network and Stations

The backbone of the GAW program is its network of measurement stations. Three types of stations are identified in the GAW strategic plan for 2008–2015: global GAW stations, regional GAW stations, and contribut-

Fig. 63.1 Map showing the locations of global GAW stations (after [63.25])

ing stations operated by contributing networks. Both the global and the regional stations are operated by national meteorological services or other national scientific organizations in their host countries. More than 80 countries actively host GAW stations.

Currently, GAW coordinates activities and data from 31 global stations, more than 400 regional stations, and around 100 contributing stations operated by contributing networks (Fig. 63.1).

Any station that contributes to GAW must satisfy the following requirements:

- For the variables measured, the station location must be regionally representative and generally free of any influences from local sources of significant pollution.
- The station must have adequate power, air conditioning, communications, and building facilities to sustain long-term observations with greater than 90% data capture (i.e., <10% missing data).
- Technical support at the station must be trained in the operation of the equipment.
- The agency responsible must commit to carrying out long-term observations of at least one variable relating to one of the six focal areas of GAW (ozone, aerosols, greenhouse gases, reactive gases, UV radiation, and precipitation chemistry).
- GAW observations must be of known quality and linked to the GAW Primary Standard.
- The data (and associated metadata) should be submitted to one of the GAW World Data Centres no later than one year after the observation was made. Changes to the metadata (including instrumentation, traceability, observation procedures) should be reported to the responsible WDC in a timely manner.
- If required, data should be submitted to a designated data distribution system in near real time.
- Standard meteorological in-situ observations that are required for the accurate determination and interpretation of GAW variables should be made with known accuracy and precision.
- The station characteristics and observational program must be updated in the GAW Station Information System (GAWSIS) on a regular basis.
- A station logbook (i.e., a record of observations made and activities that may have affected the observations) should be maintained and used in the data validation process.

Additional characteristics are also required for a global GAW station:

- The station must measure variables in at least three of the six focal areas of GAW (see previous list)
- It must have a strong scientific support program with appropriate data analysis and interpretation within the host country as well as—if possible—the support of more than one agency.

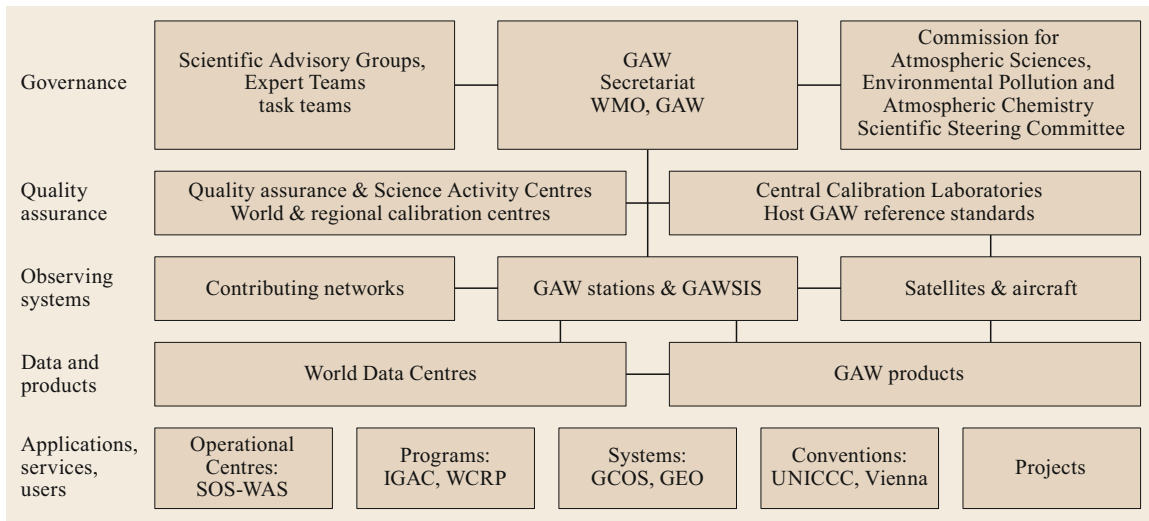

Fig. 63.2 The organizational structure of GAW (after [63.26] with the permission of the WMO)

- The station should measure other atmospheric variables that are relevant to weather and climate, including variables measured with upper-air radiosondes at the station site or in the same region.
- The station should provide a facility where intensive campaign research can be performed to augment long-term routine GAW observations, and where the testing and development of new GAW methods can be undertaken.
- 6 World Data Centres that archive the observational data and metadata, which are integrated by the GAW Station Information System (GAWSIS).

Several organizations operate a number of CCLs and WCCs at the same time (Fig. 63.2).

In recent years, satellite programs have yielded important measurements of atmospheric compounds and related parameters that complement GAW network measurements. When highly accurate local measurements from ground-based GAW stations are coupled with the near-global coverage of satellite measurements, a more complete picture of atmospheric composition and processes at the global scale can be achieved, and this approach also allows complementary checks of instrument calibrations. The Committee on Earth Observation Satellites (CEOS) has developed a strategy for achieving this cooperation within an integrated system for monitoring the atmosphere [63.27].

Since its inception in 1992, GAW has matured and developed into a program supported by a large number of WMO members. More than 100 countries have registered more than 800 stations with the GAW Station Information System (GAWSIS).

There are various GAW expert groups and central facilities that are overseen by the WMO Commission for Atmospheric Sciences (CAS) and its Environmental Pollution and Atmospheric Chemistry Scientific Steering Committee (EPAC SSC, as of CAS-16 Session). As of January 2014, these comprise:

- 7 Scientific Advisory Groups (SAGs) to organize and coordinate GAW activities by parameter and Expert Teams on World Data Centres (ET-WDC) and Near-Real Time Chemical Data Transfer (ET-NRT CDT).
- 4 Quality Assurance/Science Activity Centres (QA/SACs) that perform network-wide data quality and science-related functions.
- 35 Central Calibration Laboratories (CCLs) and World and Regional Calibration Centres (WCCs, RCCs) that maintain calibration standards and provide instrument calibration and training to the stations.

63.3.2 The NDACC International Network

The international Network for the Detection of Atmospheric Composition Change (NDACC) consists of more than 70 globally distributed, ground-based, remote-sensing research stations (Table 63.2) with over 160 currently active instruments. These instruments provide high-quality, consistent, standardized, long-term measurements of atmospheric temperatures and trace gases, particles, spectral UV radiation that reaches the Earth's surface, and physical parameters. The availability of such data allows trends in overall atmospheric composition to be detected, and the impacts of these trends on the stratosphere, troposphere, and mesosphere

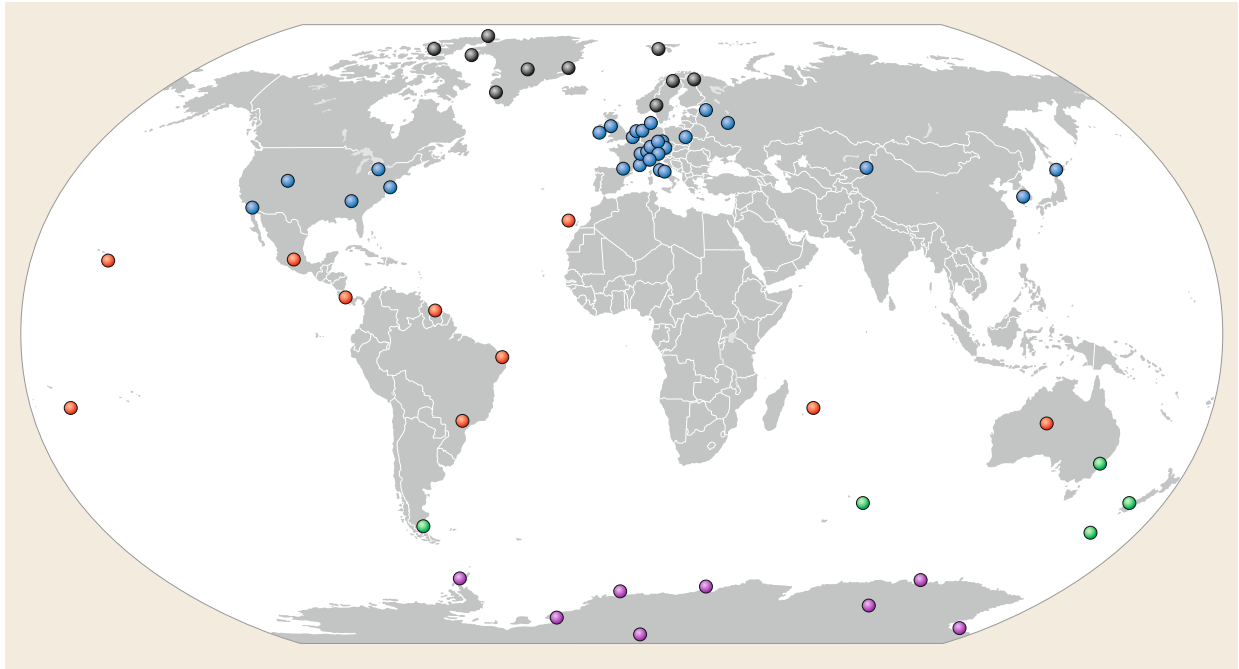

Fig. 63.3 Locations of currently active NDACC stations: *black dots* Northern Hemisphere (NH) high-latitude (> 60° N) stations, *blue dots* NH mid-latitude stations, *red dots* tropical & subtropical stations, *green* Southern Hemisphere (SH) mid-latitude stations, *purple* Antarctic stations (after [63.28])

Table 63.2 Currently active NDACC stations (stations are color-coded as defined for Fig. 63.3)

NH high-latitude stations	NH mid-latitude stations		Tropical & subtropical stations	SH mid-latitude stations	Antarctic stations
Alert	St. Petersburg	Bern	Izana	Wollongong	Palmer
Eureka	Onsala	Zimmerwald	Hilo	Lauder	Dumont dUrville
Ny Alesund	Zvenigorod	Payerne	Mauna Loa	Kerguelen	Neumayer
Thule	Bremen	Arosa	Altzomoni	Rio Gallegos	Concordia Dome-C
Summit	Legionowo	Jungfrauoch	San Jose	Macquarie	Arrival Heights
Scoresbysund	Aberystwyth	OHP (Observatoire de Haute Provence)	Paramaribo		Scott Base
Kiruna	Lindenberg	Toronto	Natal		Belgrano II Station
Sodankylä	DeBilt	Rikubetsu	Cape Matatula		South Pole
Sendre Stromfjord	Valentia	Midi-Pyrénées	La Réunion		
Harestua	Uccle	Issk-Kul	Bauru		
	Villeneuve dAscq	Rome	Alice Springs		
	Praha	Potenza			
	Gross-Enzerdorf	Boulder			
	Hohenpeissenberg	Wallops			
	Garmisch	Seoul			
	Zugspitze	Huntsville			
	Hoher Sonnblick	Table Mtn			

to be elucidated; it also makes it possible to identify links between climate change and atmospheric composition, to test and validate atmospheric measurements from satellites, to support process-focused scientific field campaigns, and to test and improve theoretical models of the atmosphere (Fig. 63.3).

The principal goal of NDACC is to allow the earliest possible identification of long-term changes to the stratospheric ozone layer and to establish the causes of such changes. This aim is achieved by performing high-quality measurements of a wide range of stratospheric chemical species and parameters using instru-

ments operated at a number of ground stations around the world.

More specifically, the network aims to:

- Study the temporal and spatial variability of atmospheric composition and structure in order to provide early detection and subsequent long-term monitoring of changes in the physical and chemical state of the stratosphere and upper troposphere; in particular, the aim is to provide the means to discern and understand the causes of such changes
- Establish the links between changes in stratospheric ozone, UV radiation at the ground, tropospheric chemistry, and climate
- Provide independent calibrations and validations of space-based sensors of the atmosphere, and supply complementary measurements
- Support field campaigns focusing on specific processes that occur at various latitudes and during various seasons
- Produce verified data sets for testing and improving multidimensional models of both the stratosphere and the troposphere.

NDACC has been endorsed by national and international scientific agencies, including the United Nations Environment Programme (UNEP) and the International Ozone Commission of the International Association of Meteorology and Atmospheric Sciences. NDACC is a major contributor to the GAW program of the WMO, and a key component of the Integrated Global Atmospheric Chemistry Observation (IGACO) initiative.

63.3.3 The BSRN International Radiation Network

The objective of BSRN is to provide observations of the best possible quality for short- and longwave surface radiation fluxes with a high sampling rate. These readings are taken from a small number of selected stations in contrasting climatic zones, together with collocated surface and upper-air meteorological data and other supporting observations.

The uniform and consistent measurements obtained throughout the BSRN network are used to:

- Monitor the background (least influenced by immediate human activities) shortwave and longwave radiative components and their variations using the best methods currently available
- Provide data that can be used to validate and evaluate satellite-based estimates of surface radiative fluxes

- Produce high-quality observational data that can be used for comparison with global climate model (GCM) calculations and for the development of regionally representative radiation climatologies.

At present, 48 BSRN stations are in operation and 11 stations are temporarily or permanently closed (Fig. 63.4). The stations measure different sets of radiation values. Some stations carry out only *basic measurements* [63.16]. Other stations carry out *other measurements* in addition to the basic measurements. Some stations also perform synoptic observations, upper-air soundings, ozone measurements and *expanded measurements*.

Additional stations are also being prepared; some of these stations should begin operating within the next few years.

63.3.4 The GRUAN International Upper-Air Network

GRUAN is envisaged as a network of 30–40 observing stations (Fig. 63.5). It builds on existing observational networks and operational capabilities and is expected to be complemented by ground-based state-of-the-art instrumentation. The task of GRUAN is to provide long-term, highly accurate measurements of the atmospheric profile, particularly the upper troposphere and lower stratosphere (upper air). The particular aim of this network is to define and assure reference quality for data and data products. The essential climate variables (ECVs) defined by GCOS—temperature, wind speed and direction, water vapor, cloud properties, and the Earth’s radiation budget (including solar irradiance)—are prioritized. High data reliability—which necessarily includes well-estimated uncertainties, thus enabling different techniques to be compared—is required to fully characterize the properties of the atmospheric column and quantitatively explore climate change and its underlying causes (e.g., to separate the long-term change signal from natural variability).

The definition of reference quality includes the full traceability of all measurements to SI units or internationally accepted standards in a consistent way, uncertainty analyses that distinguish the contributions from systematic and random errors, comprehensive documentation, data validation, and metadata collection and management. Due to the high quality of the data from GRUAN, results from more spatially comprehensive global observing systems, including satellites and current radiosonde networks, can be constrained and calibrated.

GRUAN is a heterogeneous network that includes sites supported by both research institutes and national

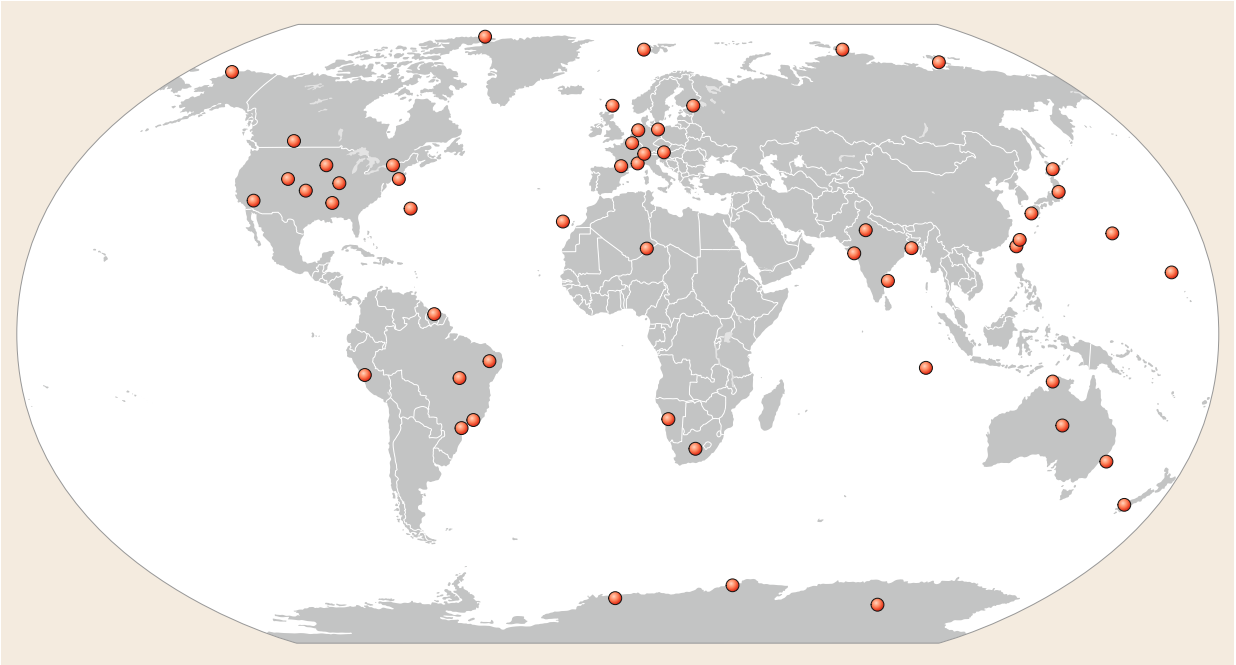

Fig. 63.4 Locations of BSRN global sites (stations that were active in 2019 (after [63.29]))

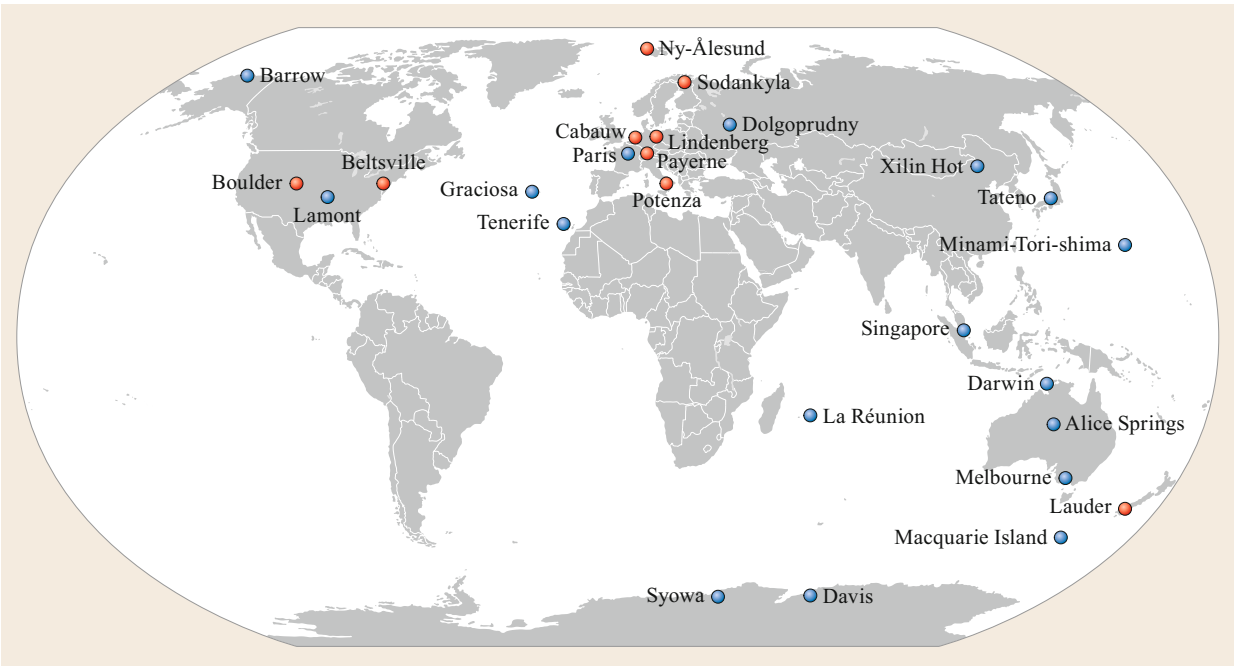

Fig. 63.5 Map of GRUAN global sites in 2017: *red* sites that are certified, *blue* sites that are yet to be certified (after [63.30])

weather services. With this in mind, the GRUAN governance structure (Fig. 63.6) was finalized in 2012 at a WMO Integrated Global Observing System (WIGOS) pilot project meeting. This structure enables the WMO,

through its technical commissions, to guide GRUAN on operational practices and procedures; to assist GRUAN in extending its operations to include a near-real-time operational mode of data delivery; and, in doing so, to

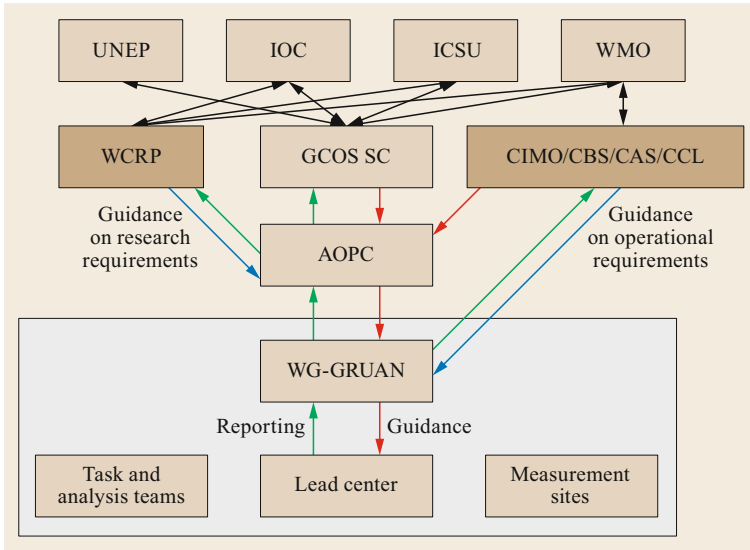

Fig. 63.6 The GRUAN heritage and governance structure. *Green arrows* show reporting responsibilities while *red arrows* show guidance responsibilities. *Blue arrows* show specific paths for guidance from the World Climate Research Programme (WCRP) and from the WMO’s technical commissions to GRUAN. *Gray arrows* show how GRUAN is linked to the highest governing bodies. The *gray box* encompasses what is referred to as GRUAN (after [63.13] © American Meteorological Society, used with permission)

help nurture additional participation of WMO members in the desired GRUAN expansion. The emergence of sites from both the research and operational measurement communities requires careful management and recognition of competing demands on different stations. Through the GRUAN Lead Centre (located in Lindenberg, Germany), the task team of site representatives, and the Working Group on GRUAN (WG-GRUAN),

efforts are being made to provide appropriate support and guidance to all sites. The WG-GRUAN and its task teams, including ex-officio members and invited experts, gather annually at GRUAN Implementation and Coordination Meetings (ICMs), which provide a forum for communication, coordination, WG-wide decision-making, community building, and the sharing of ideas and expertise.

63.4 Other Important Networks

The most important international networks of atmospheric measurements are likely the four programs discussed above, GAW, NDSC/NDACC, BSRN, and GRUAN. These four programs are strongly promoted and supported by the WMO and other international organizations. While these four programs collaborate with each other, each also collaborates with a number of additional regional, national, and international networks and programs, as described below.

63.4.1 Networks Contributing to the GAW Program

A GAW contributing network is one that has signed a letter of agreement (LoA) with the WMO. Any such agreement contains a list of the stations that are included in the GAW network as contributing stations as well as their characteristics. The list of stations that con-

tribute to the individual GAW contributing programs is available on the internet.

TCCON

The Total Carbon Column Observing Network (TCCON [63.31]) is a ground-based network of high-resolution Fourier-transform spectrometers (FTSs) that record the near-infrared solar absorption spectrum and retrieve column-average mixing ratios of CO₂, CH₄, N₂O, and several other gases with high precision and accuracy. TCCON data are a valuable complement to in-situ surface data and can be included in global inversions and other models of greenhouse gases, including studies of the carbon and nitrogen cycles. Furthermore, the column measurements serve to validate measurements from the currently active satellites GOSAT (Greenhouse Gases Observing Satellite) and SCIAMACHY (Scanning Imaging Absorption Spectrometer for Atmospheric

Chartography), and will serve the same role for data from future satellite missions such as OCO-2. TCCON also contributes to the NDACC program (see further information in Sect. 63.4.2).

EARLINET

The European Aerosol Research Lidar Network (EARLINET [63.32]), which was established in 2000, is the first aerosol lidar network. Its main goal is to provide a comprehensive quantitative database of the three-dimensional time-dependent distribution of aerosols over Europe. The network currently comprises 28 sites that are broadly distributed across Europe. Network-wide observations take place on a fixed schedule. Lidar surveillance adheres to a regular timetable of once per week at around noon, when the boundary layer is usually well developed, and twice weekly at night under low background light conditions in order to perform Raman extinction measurements. Other network activities include monitoring extraordinary events such as Saharan dust outbreaks, forest fires, photochemical smog, and volcanic eruptions. EARLINET is expected to contribute to defining and standardizing the aerosol-related products within GRUAN.

IMPROVE

The Interagency Monitoring of Protected Visual Environments (IMPROVE) program is a cooperative measurement effort governed by a steering committee composed of representatives from federal and regional-state organizations [63.33]. The IMPROVE optical monitoring network uses open-air nephelometers to measure particulate scattering hourly in primarily rural environments. In addition, the temperature and relative humidity are measured hourly at each site. These data are used in conjunction with IMPROVE aerosol data to assess light scattering status and trends and to better understand the optical properties of aerosols.

AD-Net

The Asian Dust and Aerosol Lidar Observation Network (AD-Net [63.34]) is an Asian coordinated lidar network that was established in 2001. It measures aerosol backscattering and depolarization for Asian dust and performs regional air pollution studies over East Asia.

LALINET

The Latin America Lidar Network (LALINET, a.k.a. ALINE [63.35]), is a Latin American coordinated lidar network that was established in 2001 to measure

aerosol backscatter coefficients and aerosol extinction profiles for climatological studies of the aerosol distribution over Latin America, as well as other atmospheric species such as ozone and water vapor. This federated lidar network aims to establish a consistent and statistically sound database that can enhance understanding of the aerosol distribution over the continent and its direct and indirect influences on the climate.

NADP

The US-based National Atmospheric Deposition Program (NADP) is a long-term measurement cooperative composed of representatives from federal, state, tribal, and national agencies, universities, private companies, and nongovernmental organizations. Most NADP stations are located in the United States, but several are located in Canada and in other nations. NADP operates three precipitation chemistry networks: the National Trends Network (NTN), the Atmospheric Integrated Research Monitoring Network (AIRMoN), and the Mercury Deposition Network (MDN). It also operates two gaseous atmospheric chemistry networks: the Atmospheric Mercury Network (AMNet) and the Ammonia Monitoring Network (AMoN). A central office coordinates program activity and oversees field and lab operations, data management, and quality assurance for each network. Each monitoring network follows well-defined protocols to measure acidic compounds, nutrients, base cations, and mercury in precipitation (NTN, AIRMoN, and MDN) as well as ambient concentrations of ammonia and mercury for estimating dry deposition (AMoN and AMNet). Program data are used to assess the geographic patterns and long-term temporal trends in the concentrations and deposition of major ions and mercury in precipitation, and to better understand the cycling of these chemicals in a variety of physical environments for a multitude of applications.

The IDAF (IGAC/DEBITS AFRICA) Project

The international Deposition of Biogeochemically Important Trace Species (DEBITS) program started in 1990 as part of the IGAC/IGBP (International Global Atmospheric Chemistry/International Geosphere–Biosphere Programme) core project. The aim of this project is to assess the wet and dry atmospheric deposition in tropical regions.

The IDAF (IGAC/DEBITS AFRICA) project for tropical Africa started in 1994 and is implemented in partnership with INSU (Institut National des Sciences de l'Univers, France) and the CNRS (Centre National de la Recherche Scientifique, France) as a part of the

Observatory Service (SO, France) networks. The aim of SO/IDAF is to establish a long-term measuring network to study the atmospheric composition and wet and dry atmospheric processes. As such, IDAF performs high-quality measurements of atmospheric chemical data (gaseous concentrations and the chemical composition of precipitation) in a multiyear monitoring scheme. This project has established ten monitoring sites in the major African ecosystems over West and Central Africa and South Africa: dry savanna (Niger, Mali, South Africa), wet savanna (Côte d'Ivoire and Benin), and equatorial forest (Cameroun, Congo). The sites in West and Central Africa are coordinated by the Laboratoire d'Aérodologie in Toulouse (France) and sustained by a French national proposal funded by INSU/CNRS. The South African sites are coordinated by the North West University in Potchefstroom (South Africa) and sustained by national and/or private South African projects.

The NASA Micro-Pulse Lidar Network (MPLNET)

The NASA Micro-Pulse Lidar Network (MPLNET) is a federated network of micro-pulse lidar (MPL) systems that measure aerosol and cloud vertical structure continuously, day and night, over long time periods. The resulting data are utilized in climate change studies, related aerosol and cloud research, and to provide ground validation of satellite sensors in the Earth Observing System (EOS). MPLNET also contributes to the NDACC program (see further information in Sect. 63.4.2).

The Clean Air Status and Trends Network (CASTNET)

The Clean Air Status and Trends Network (CASTNET) is a well-established national air quality monitoring network in the US that provides data which is used to assess trends in air quality, atmospheric deposition, and ecological effects due to changes in air pollutant emissions. CASTNET began collecting measurements in 1991, following the incorporation of 50 sites from the National Dry Deposition Network, which had been in operation since 1987. The National Park Service (NPS) operates more than 20 CASTNET sites within national parks and Class 1 areas. The Bureau of Land Management, Wyoming State Office joined CASTNET in 2012 when they converted five Wyoming Air Resource Monitoring System (WARMS) sites to CASTNET protocol sites. CASTNET provides long-term monitoring of air quality in rural areas so that trends in regional atmospheric nitrogen, sulfur, and ozone concentrations and deposition fluxes of sulfur and nitrogen pollutants can be discerned, thus allowing the effectiveness of national and regional air pollution control programs to be evaluated. CASTNET operates more than 85 regional sites throughout the contiguous United States, Alaska, and

Canada. Sites are located in areas where urban influences are minimal. Data from these stations therefore ideally complement the measurements of regional and global GAW stations in North America.

In-service Aircraft for a Global Observing System (IAGOS)

The European Research Infrastructure IAGOS (In-service Aircraft for a Global Observing System [63.36]) operates a global-scale monitoring system for atmospheric trace gases, aerosols, and clouds that utilizes existing global civil aircraft. This new monitoring infrastructure builds on the heritage of the research projects MOZAIC (Measurement of Ozone and Water Vapour on Airbus In-service Aircraft) and CARIBIC (Civil Aircraft for the Regular Investigation of the Atmosphere Based on an Instrument Container). The CARIBIC project is still active within IAGOS, and acts as an important airborne measurement reference standard within the wider IAGOS fleet. IAGOS is a major contributor to the in-situ component of the Copernicus Atmosphere Monitoring Service (CAMS), and provides data for users in science, weather services, and international policy-making relating to atmospheric composition. IAGOS is unique in that it makes regular in-situ observations of reactive gas and greenhouse gas concentrations and aerosol properties in the upper troposphere and lowermost stratosphere (UTLS) at high spatial resolution. It also provides routine vertical profiles of these species in the troposphere over continental sites or regions, many of which are undersampled by other networks, particularly in Africa, Southeast Asia, and South America. These stations ideally complement the measurements of GAW regional and global stations. In combination with MOZAIC and CARIBIC, IAGOS has provided long-term observations of atmospheric chemical composition in the UTLS since 1994.

63.4.2 NDACC Cooperating Networks

The Network for the Detection of Atmospheric Composition Change (NDACC) recognizes the importance of new measurement capabilities and of existing capabilities that were developed externally to NDACC. In many cases, the NDACC Steering Committee has encouraged proposals that such measurements should be formally affiliated, and has often designated measurement locations as NDACC sites. To achieve NDACC measurement status, the proposing investigators must affiliate with a specific NDACC instrument working group and agree to comply with the various NDACC protocols (measurements, intercomparisons, validation, and data). Documentation of the measurement capability and operational scope, instrument validation, and

the data quality must appear in a proposal requesting designation as an NDACC measurement. The appropriate working group is responsible for evaluating the proposal and recommending a course of action to the Steering Committee.

However, in some cases where there are regional, hemispheric, or even global networks of instruments that operate independently of NDACC, strong measurement and scientific collaboration between these networks and NDACC is of mutual benefit. Such networks have often established their own quality assurance guidelines, operational requirements, and data archiving policies, and they have national or international recognition. In such cases, bringing the complete network under the NDACC umbrella is neither practical nor desirable.

To collaborate with such networks, NDACC established the concept of a *NDACC cooperating network* to formalize its mutually beneficial relationships with regional, hemispheric, or global networks. Each cooperating network may request ex-officio representation on the NDACC Steering Committee in order to provide information on collaborative activities at the Annual NDACC Steering Committee Meeting. Where appropriate, NDACC may request representation on the corresponding oversight group of the cooperating network. Aside from BSRN and GRUAN, the six independent networks discussed below have finalized agreements that will designate them as cooperating networks, allowing them to collaborate with NDACC.

AERONET

The AERONET (Aerosol Robotic Network) program [63.39] is a federation of ground-based, remote-sensing aerosol networks established by NASA and the University of Lille that has greatly expanded due to collaborators from national agencies, institutes, universities, individual scientists, and partners. The program provides a long-term, continuous, and readily accessible public domain database of aerosol optical, microphysical, and radiative properties for aerosol research and characterization, the validation of satellite retrievals, and synergism with other databases.

The AERONET collaboration provides globally distributed observations at over 500 sites of spectral aerosol optical depth (AOD), inversion products, and precipitable water in diverse aerosol regimes (Fig. 63.7 [63.37]).

AGAGE

The Advanced Global Atmospheric Gases Experiment (AGAGE) performs real-time, high-frequency measurements of approximately 50 trace gases at stations around the world (Fig. 63.8), and interprets these measurements using three-dimensional models and inverse theory to further understand ozone depletion and climate change and to address verification issues arising from the Montreal (ozone) and Kyoto (climate) protocols. AGAGE utilizes the Medusa gas chromatography with mass spectrometry (GC-MS) and

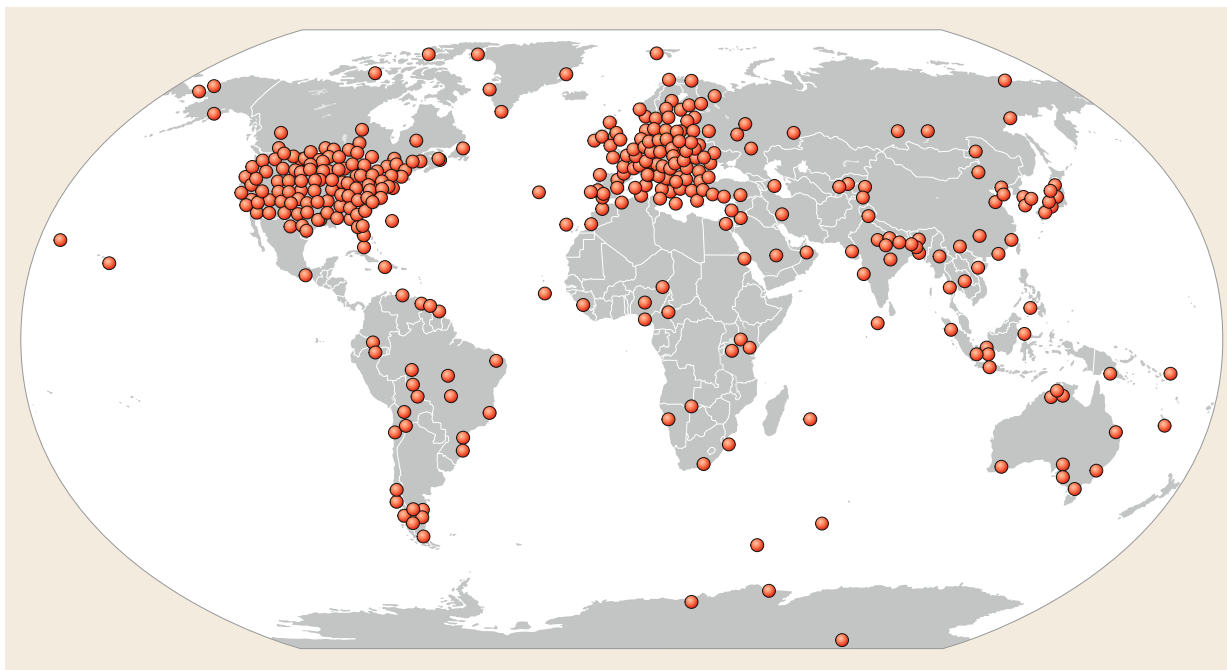

Fig. 63.7 AERONET site distribution in 2014 (after [63.37])

Fig. 63.8 AGAGE measurement sites (after [63.38])

GC-multidetector instruments, and is distinguished by its ability to measure all the important species in the Montreal Protocol and all non-CO₂ gases in the Kyoto Protocol with high frequency. The scientific objectives of AGAGE are important for furthering understanding of global chemical and climatic phenomena [63.38].

HATS

The Halocarbons and other Atmospheric Trace Species (HATS) program is a global in-situ and flask network for the measurement and analysis of halocarbons and other atmospheric trace gases that is maintained by the National Oceanic and Atmospheric Administration's Earth System Research Laboratory (NOAA/ESRL) (Fig. 63.9). The network began operating in 1977 with measurements of three trace gases (nitrous oxide, CFC-11, CFC-12) at five flask locations, and has grown to include observations of over 40 trace gases at over 30 locations as well as airborne campaigns that include both flask and in-situ monitoring. The purpose of this work is to study atmospheric trace gases that affect climate change, stratospheric ozone depletion, and air quality based on observations at NOAA and cooperating stations. Some atmospheric trace gases (e.g., SF₆) are used as atmospheric clocks to retrieve important information on atmospheric transport [63.40].

MPLNET

The NASA Micro-Pulse Lidar Network (MPLNET) [63.41] is a ground-based network of micro-pulse lidar

(MPL) [63.41] instruments collocated with sun photometers in AERONET [63.25]. These joint supersites provide both column and vertically resolved aerosol and cloud information such as optical depths, single-scatter albedos, size distributions, aerosol and cloud heights, planetary boundary layer (PBL) structure and evolution, and extinction and backscatter profiles. Principal investigators for individual sites may be from NASA, other US government agencies, universities, or foreign research groups. MPLNET is a federated network consisting of NASA sites and others run by, or run with the help of, partner research groups from around the world (Fig. 63.10 [63.42]).

SHADOZ

The Southern Hemisphere Additional Ozonesondes (SHADOZ) is a project that aims to augment balloon-borne ozonesonde launches and to archive data from tropical and subtropical operational sites (Fig. 63.11). This project was initiated in 1998 by the NASA/Goddard Space Flight Center along with NOAA and international coinvestigators in Europe, South America, Asia, and Africa. There are currently 13 operational stations in the network. The collective dataset provides the first profile climatology of tropical ozone in the equatorial region, enhances validation studies aimed at improving satellite remote-sensing techniques for tropical ozone estimation, and serves as an educational tool for students, especially in the participating countries. SHADOZ is a flexible archive that has grown and evolved as scientific

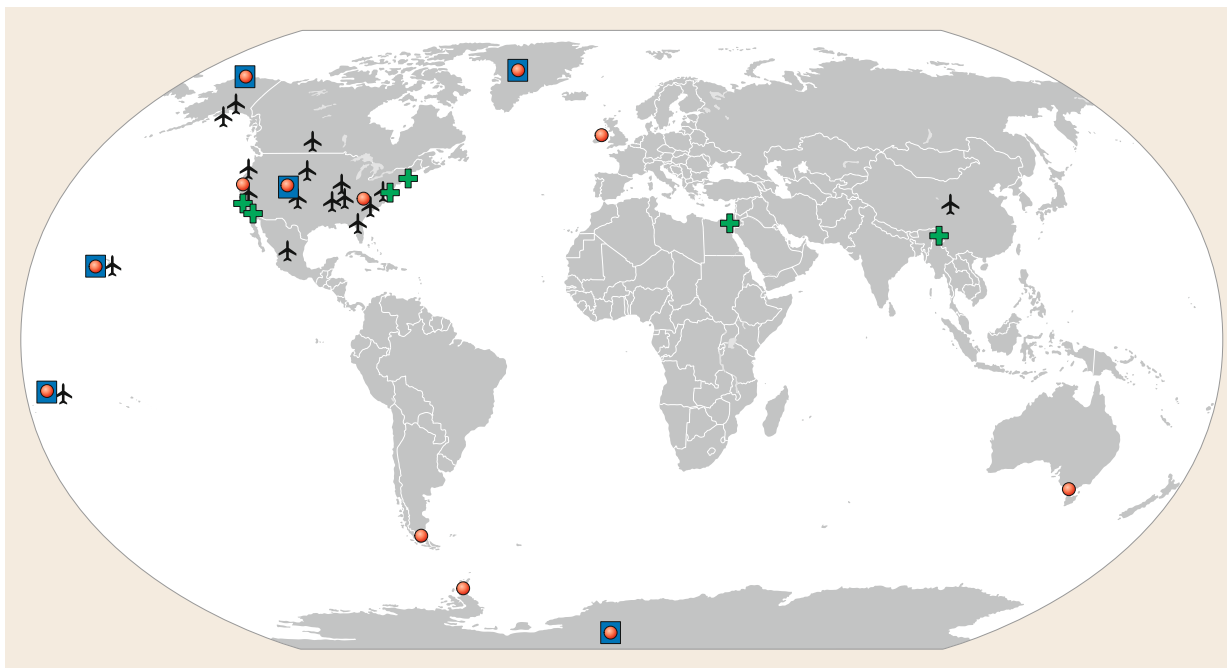

Fig. 63.9 HATS stations: *circles* flask sites, *boxes* in-situ sites, *planes* airborne sites, *crosses* flasks at airborne sites (after [63.40])

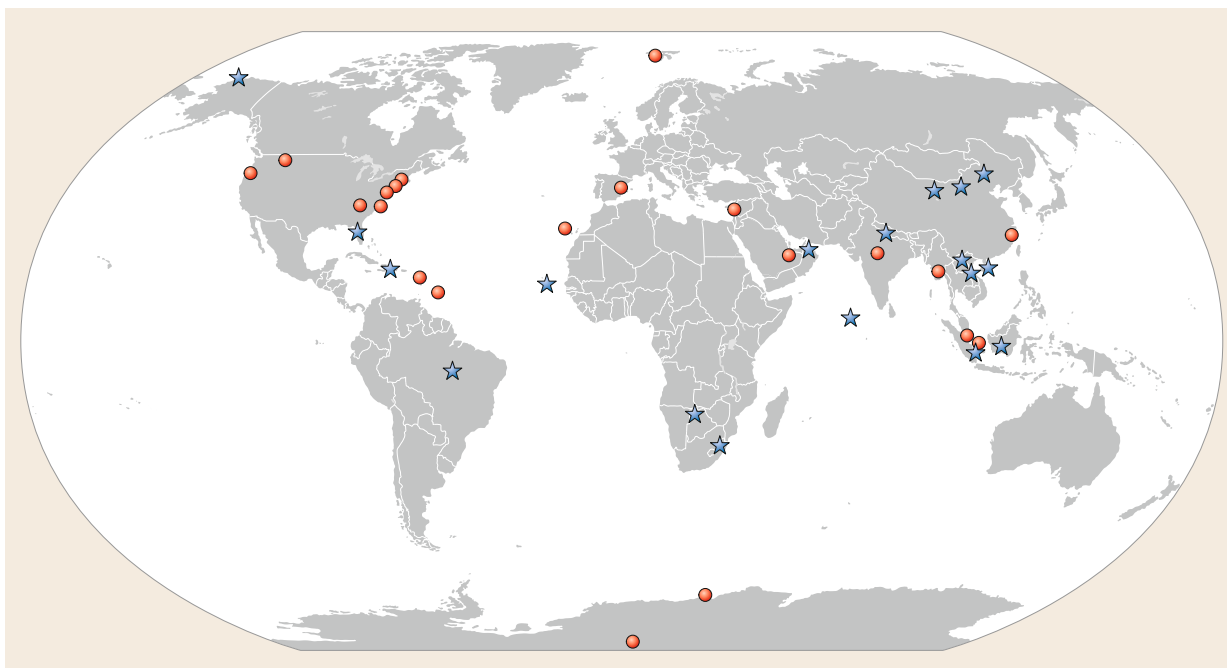

Fig. 63.10 Long-term MPLNET stations (*circles*) and field campaigns (*stars*) (after [63.43])

needs and research questions have changed. In addition to the NDACC link, SHADOZ data are transmitted regularly to the World Ozone and Ultraviolet Radiation

Data Centre (WOUDC) and archived in Hierarchical Data Format (HDF) for the satellite user community at the Aura Validation Data Center.

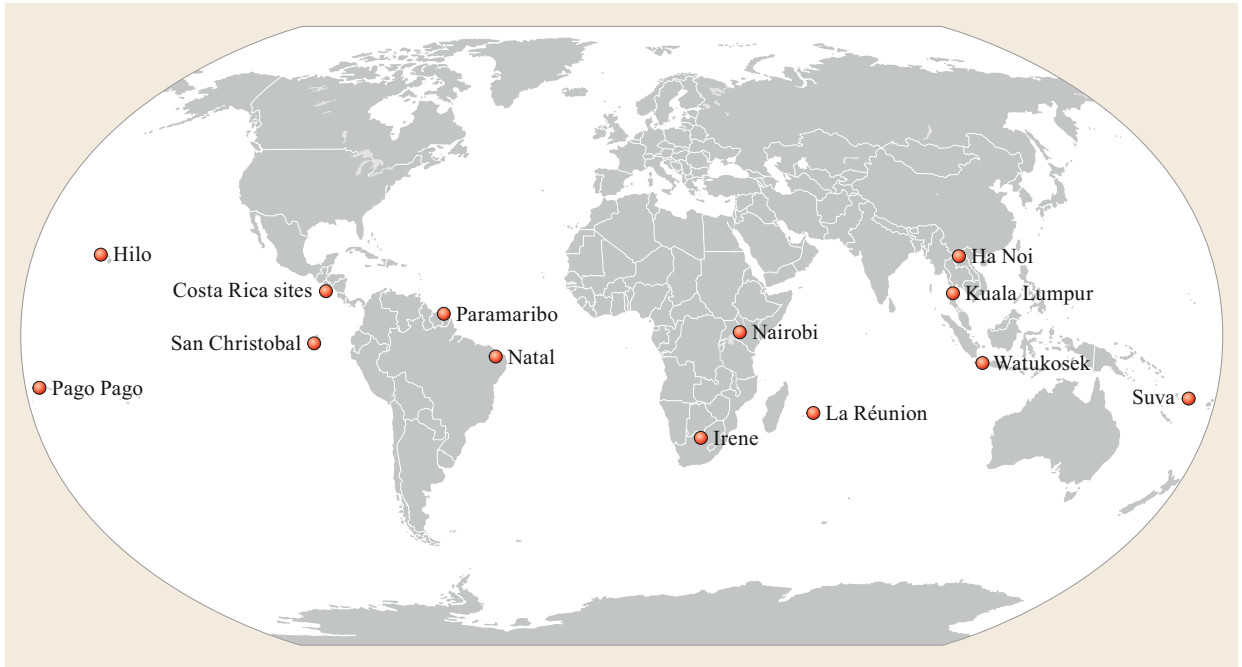

Fig. 63.11 SHADOZ stations (after [63.44])

TCCON

The Total Carbon Column Observing Network (TCCON) is a network of ground-based Fourier-transform spectrometers that record direct solar spectra in the near-infrared spectral region. The project was initiated in 2004 with support from National Institute of Water and Atmospheric Research (NIWA) (New Zealand) and NASA. It has expanded to include international coinvestigators around the world. The primary data products are high-precision total columns of CO_2 and CH_4 . Other gases, including HDO, CO, and N_2O , are also retrieved and archived. Sites for the network span the globe and thus provide diverse and targeted data to validate observations from the GOSAT and OCO-2 CO_2 -monitoring satellites as well as to probe the seasonal cycles and long-term trends in CO_2 and CH_4 (Fig. 63.12). The network shares common methodologies and technical issues with, and is a member of, the NDACC Fourier-transform infrared spectroscopy (FTIR) Working Group [63.31].

63.4.3 BSRN Collaborating Networks

BSRN is closely linked to NDACC in that atmospheric composition is a primary determinant of the nongeometric variability of the surface irradiances observed by BSRN. BSRN encourages, but does not require, simultaneous observations of aerosol optical depth, water vapor, and ozone close to its sites. Some sites belong to both networks, but most do not.

In the mid-1990s, BSRN was included in the WCRP program called The Global Energy and Water Cycle Experiment (GEWEX). By the late 1990s, BSRN had been designated a contributing network for the WMO Global Atmospheric Watch (GAW) program, and in the early 2000s it was designated the global baseline surface radiation network of the Global Climate Observing System (GCOS).

63.4.4 Collaborations of GRUAN with Other Networks

The GRUAN guide states that GRUAN shall not operate in isolation of existing networks and is not intended to replace existing networks in any way. Many GRUAN sites already belong to existing networks such as GUAN, GAW, NDACC, BSRN, and SHADOZ. For GRUAN to be successful, it must coordinate closely with the user community, and many of these networks are also likely to be users of GRUAN data. Similarly, complementary measurements from these other networks should be collated in a database to enable cross-comparisons and to quantitatively link GRUAN measurements to similar measurements made within other networks. As a result, close coordination between the governing bodies of these networks and WG-GRUAN is required on a continuous basis. This close coordination can be achieved by having members of WG-GRUAN attend steering group meetings of partner networks, and by inviting co-

Fig. 63.12 Operational TCCON stations (after [63.45])

chairs or steering group members from partner networks and projects to attend WG-GRUAN meetings.

Several currently active networks perform measurements that fall within the scope of GRUAN (e.g., sites that obtain upper-air measurements of parameters that are not the temperature, pressure, or water vapor content). Many of these networks, including the GCOS Upper-Air Network (GUAN), have developed systems for assuring the quality of their measurements. Where the systems that are currently in place are sufficient to meet the operational requirements of GRUAN, they should be used by GRUAN. Where networks are working towards QA/QC procedures, GRUAN should partner with these networks to develop systems that meet the operational requirements of both parties. In some cases, sites within these partner networks may also become GRUAN sites. This is encouraged since it promotes a traceable link between GRUAN measurements and measurements obtained at all other sites within the partner network (if the measurements within the partner network are traceable and can be quantitatively linked). Existing networks and potential resources from within those networks that are likely to be of value to GRUAN are discussed below.

GOS (Global Observing System)

The GOS provides a coordinated system of methods and facilities for making meteorological and other environmental observations at the global scale in support

of all WMO programs. The system comprises operationally reliable surface-based and space-based subsystems. The GOS includes observing facilities on land, at sea, in the air, and in space. These facilities are owned and operated by the member countries of the WMO, each of which undertakes to meet certain responsibilities in the agreed global scheme so that all countries can benefit from the consolidated efforts. Since GRUAN is intended to be an important component of the GOS, GRUAN operations must be cognizant of, and engage with, all related components of the GOS.

GUAN

As noted above, GRUAN will provide a reference backbone for GUAN. The greater the number of GUAN sites that become GRUAN sites, the more efficient the transfer of outcomes from GRUAN to GUAN. New measurement methodologies developed at GRUAN sites operating as NMHS (National Meteorological and Hydrometeorological Services) sites should efficiently propagate to other GUAN sites operated by the same NMHS.

WOUDC

The World Ozone and UV Data Centre (WOUDC) is part of the GAW program of the WMO. The WOUDC, which is operated by the Experimental Studies Section of Environment Canada in Toronto, is not so much a network as an international repository for ozone

and UV data. Many of the practices employed within the ozone measurement community are likely to be useful to GRUAN. For example, the management of the Dobson spectrophotometer and Brewer spectroradiometer networks, both of which provide data to the WOUDC, demonstrate many of the principles upon which GRUAN is founded.

SHADOZ

The Southern Hemisphere Additional Ozonesondes (SHADOZ) project was initiated to remedy the lack of consistent tropical ozonesonde observations. This was done by increasing the frequency and improving the quality of ozonesonde launches at selected tropical ozone observation sites. Rather than establishing an entirely new network, SHADOZ aims to enhance ozonesonde launches at existing facilities on a cost-share basis with international partners. The geographical coverage of the network was specifically designed to address targeted research questions.

AERONET

AERONET also contributes to the NDACC program (see Sect. 63.4.2).

EARLINET

EARLINET also contributes to the GAW program (see Sect. 63.4.1).

ARM

The goal of the US Department of Energy Atmospheric Radiation Measurement (ARM) program is to study alterations in climate, land productivity, oceans or other water resources, atmospheric chemistry, and ecological systems that may alter the capacity of the Earth to sustain life. This includes improving the atmospheric datasets used in regional and global climate models. A primary objective of the ARM user facility is improving scientific understanding of the fundamental physics of interactions between clouds and radiative feedback processes in the atmosphere. Five of the current GRUAN sites are also ARM sites, in part because the radiation measurements made at these sites satisfy many of the ECV measurement requirements within GRUAN.

Cloudnet

The Cloudnet project aims to provide systematic evaluations of clouds in forecast and climate models by comparing the model output with continuous ground-based observations of the vertical profiles of cloud properties. In the models, the properties of clouds are simplified and expressed in terms of the fraction of the model grid box filled with cloud together with the liq-

uid and ice water content of the clouds [63.46, 47]. The Cloudnet project produces vertical profiles of cloud and aerosol properties at high temporal and spatial resolution for the following reasons:

- To optimize the use of existing datasets in the development and validation of new cloud remote-sensing synergy algorithms
- To continuously evaluate the representation of clouds in climate and weather forecast models
- To demonstrate the potential of an operational network to improve the representation of clouds in models.

Partnership with Meteorological Agencies

Meteorological agencies that produce global real-time analyses (e.g., UK Met Office (UKMO), German Meteorological Service (DWD), European Centre for Medium-Range Weather Forecasts (ECMWF), National Centers for Environmental Prediction (NCEP), NOAA, and Japan Meteorological Agency (JMA)) or historical reanalyses (e.g., NCEP/NCAR (National Center for Atmospheric Research), NCEP/DOE (Department of Energy), NCEP-CFSR (Climate Forecast System Reanalysis), ECMWF, JMA, NOAA, and NASA) are likely to use the high-quality data produced by GRUAN. There are well-developed systems for monitoring the quality of operational observations, whether it is the performance of individual radiosonde sites or the bias corrections required by current satellite observations. Therefore, diagnostics obtained from the various assimilation schemes used in such activities provide valuable metadata on the consistency of the GRUAN measurements with other data used in the operational analyses (thereby facilitating comparisons of GRUAN measurements with, for example, satellite-based measurements) and on the representativeness of the estimated uncertainty in the GRUAN data. If GRUAN data are to be used in 4-D Var assimilation schemes for ingestion or validation purposes, the precise 4-D (latitude, longitude, altitude, and time) coordinates associated with any measurement must be available. Reference sites will be essential aids when characterizing observational biases and the impact of observing system changes and when attempting to understand model errors, all of which are important aspects of high-quality reanalysis. Studies which demonstrate the value that GRUAN measurements add to numerical weather prediction (NWP) and to meteorological reanalyses are currently lacking. Some GRUAN sites may also be National Meteorological Service (NMS) sites, or they may be paired with a NMS site to extend the variety of measurements performed, with the result that NMSs are likely to provide partial or full support for a site.

63.5 Quality Control

Quality control of atmospheric measurement techniques and the data measured at network stations was first addressed in the WMO GAW program. Other networks that overlap considerably with the GAW network follow the same quality assurance routines as used in GAW. See also Chap. 3, which specifically addresses quality control.

63.5.1 Objectives of Quality Control

The primary objectives of the GAW QA system are to ensure that the data in the World Data Centres (WDCs) are consistent and are of known and adequate quality, and that they meet GAW data-quality objectives and are supported by a comprehensive description of the methodology. They must be supported by comprehensive metadata and should be sufficiently complete to describe global atmospheric states with respect to spatial and temporal distributions. The QA system involves quality assurance and calibration centers that ensure the quality of observations through adherence to measurement guidelines established by the Scientific Advisory Groups and through calibrations that are traceable to World Calibration Standards.

The GAW quality assurance (QA) system impacts all aspects of atmospheric physics and chemistry observations, including:

- The training of station personnel
- The assessment of infrastructure, operations, and the quality of observations at the sites
- The documentation of data submitted to the WDCs
- Improvements in the quality and documentation of legacy data at the WDCs.

Five types of central facilities dedicated to six groups of measurement variables are operated by WMO members and form the basis for quality assurance and data archiving in the GAW global monitoring networks (Fig. 63.13). They include Central Calibration Laboratories (CCLs) that host Primary Standards (PS), Quality Assurance/Science Activity Centres (QA/SACs), World Calibration Centres (WCCs), Regional Calibration Centres (RCCs), and World Data Centres (WDCs) that are responsible for archiving and providing access to GAW data.

63.5.2 Regulations for Quality Control

The principles of the GAW QA system are to:

- Fully support the GCOS climate monitoring principles
- Use only one reference standard or scale (the Primary Standard) across the network, meaning that

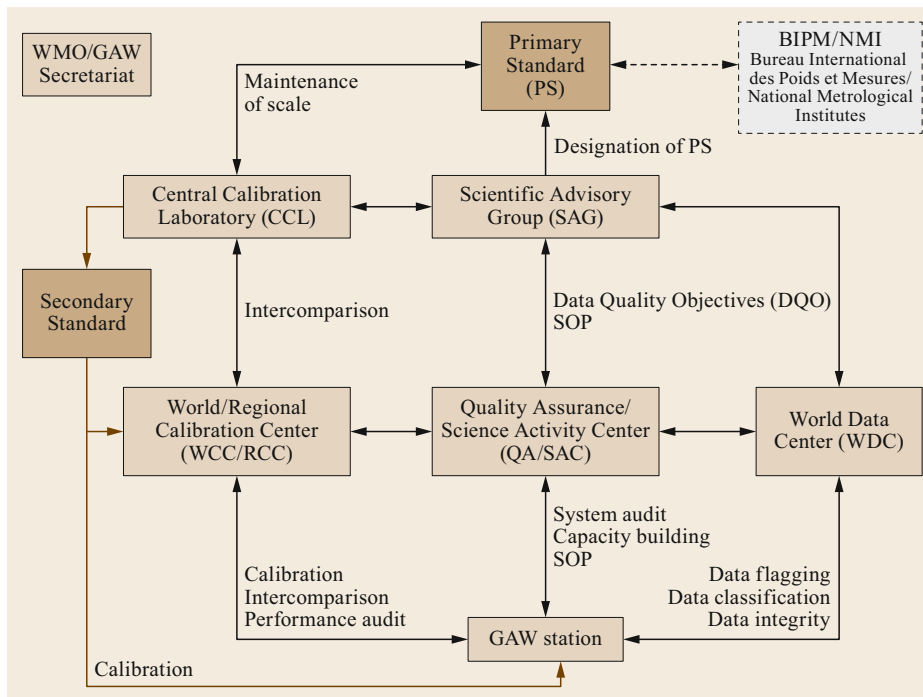

Fig. 63.13 Conceptual framework of the GAW quality system (after [63.48] with the permission of the WMO)

there is only one institution that is responsible for this standard

- Ensure full traceability of all measurements made by GAW global, regional, and contributing stations to the primary standard
- Define data quality objectives (DQOs)
- Provide established guidelines on how to meet these quality targets, i.e., harmonized measurement techniques based on measurement guidelines (MGs) and standard operating procedures (SOPs)

- Establish MGs or SOPs for these measurements
- Use detailed logbooks for each parameter that contain comprehensive metadata relating to the measurements, maintenance, and *internal* calibrations
- Perform regular independent assessments (system and performance audits)
- Submit data and associated metadata to the responsible World Data Centre in a timely manner in order to facilitate independent reviews of the data by the wider community.

63.6 Maintenance

Long-term education, training, workshops, calibration station audits/visits, and twinning are provided to build capacity in the atmospheric sciences in the GAW network. These capacity-building activities have become increasingly important as many GAW stations in developing countries have initiated operations.

63.6.1 Regulations for Maintenance

GAW procedures address the quality of an observation through the maintenance of components of the entire measurement process, ranging from operational procedures at stations to the submission of appropriately quality-controlled data to the World Data Centre. The recommended GAW principles are as follows [63.49]:

- Harmonize the measurement methodologies used at all stations using measurement guidelines and standard operating procedures
- Conduct regular intercomparison campaigns.

In addition, certain measurement principles are parameter specific:

- Use data-quality objectives that specify tolerable levels of uncertainty, as well as completeness, comparability, and representativeness
- Maintain full traceability to the World Reference Standard for all measurements performed by GAW global and regional stations
- Establish standard operating procedures for the measurements
- Maintain a detailed *logbook* of measurement methodologies and procedures for instruments, maintenance, and *internal* calibration.

63.7 Application

The main task of the WMO and other networks of atmospheric measuring techniques is to obtain continuous information on the physical state and chemical composition of the atmosphere at a detailed scientific level. The corresponding World Data Centres provide long-term records of a wide variety of atmospheric data for scientific research and climate change investigations, which help to improve our understanding of interactions between the atmosphere and the Earth's surface.

63.7.1 Modeling Applications of GAW Data

The GAW Scientific Advisory Group (SAG) on Modelling Applications (SAG-APPs) was established in 2016 by the WMO Congress to enhance exchange between the GAW observational community, the modelling communities, and other end users of atmospheric

composition data. Near-real-time data applications such as air quality forecasting require timely access to observations. Therefore, one of the main objectives of this group is *to demonstrate the usefulness of exchanging chemical observational and modeling data in near real time (NRT: hours to days) to support monitoring and forecasting applications.*

Members of SAG-APPs represent a broad range of disciplines and a variety of research and user communities. SAG-APPs promotes current and envision future applications that (will) make use of NRT data delivery at regional to global scales. It is a collaborative effort between GAW, the World Weather Research Programme (WWRP), and the World Climate Research Programme (WCRP). This SAG also works closely with WIS/WIGOS—the WMO's Integrated Global Observation System.

An important service that is already operational is the Copernicus Atmosphere Monitoring Service (CAMS; <https://atmosphere.copernicus.eu/about-cams>, Accessed 24 July 2021), which provides near-real-time data analyses of and forecasts for multiple atmospheric chemical constituents that are relevant to air quality and other environmental issues at global and regional scales. The Sand and Dust Storms Warning Advisory and Assessment System (SDS-WAS; <https://sds-was.aemet.es/>, Accessed 24 July 2021) provides health-relevant information relating to sand and dust storms. A schematic of potential GAW services is given in a figure under (WMO; <https://community.wmo.int/activity-areas/gaw/science/modelling-applications>, Accessed 24 July 2021).

63.7.2 Objectives and Membership of SAG-APPs

The main objective of SAG-APPs is to develop a portfolio of modeling products and services relating to atmospheric composition, and more specifically to

demonstrate the benefits of exchanging observational chemical data in near real time to support monitoring and forecasting applications. The rationale for creating SAG-APPs is the WMO's strategy of providing advice and support to meteorological institutions who wish to broaden their services and products from conventional weather forecasting to services that include aspects of the atmospheric environment. The idea is that developing a portfolio of demonstration projects (i.e., designing concepts, endorsing initiatives, and stimulating communities to develop these projects) will provide the necessary impetus to speed up the emergence and expansion of such services. These developments will not only benefit NRT applications but also provide a closer link to assessment activities such as those currently performed by the Task Force on Hemispheric Transport of Air Pollution (TF HTAP) and partner organizations in the health (e.g., World Health Organization (WHO)), agriculture/vegetation (e.g., Convention on Long-Range Transboundary Air Pollution (CLRTAP)), and climate (e.g., Chemistry Climate Model Initiative (CCMI)) communities.

63.8 Future Developments

The WMO Global Atmosphere Watch (WMO-GAW) program recognizes the need to develop up-to-date GAW products and services for a variety of user communities as well as the need to support cross-cutting research activities relating to the forecasting of atmo-

spheric composition changes and the environmental phenomena induced by them. In this context, ensuring that observations are made available to modeling activities in a timely manner is crucial [63.14].

63.9 Further Reading

Much of the content of this chapter is also available on the Internet. The WMO, GAW, and all the networks that were created after them have websites that can be consulted for further reading. Internet links for differ-

ent networks are provided in this chapter and in the following references: GAW [63.14], NDACC [63.45], BSRN [63.29], GRUAN [63.30].

rolf.philipona@gmail.com

Rolf Philipona's research interests are radiation and upper-air measurements and related climate change. He was a senior scientist at the World Radiation Center at Davos and at the Federal Office of Meteorology and Climatology (MeteoSwiss). He lectured at the Institute for Atmospheric and Climate Sciences at ETH Zurich. He received the 2002 WMO Prof. Dr. Vilho Vaisala Award and 2007 WMO-Norbert Gerbier-Mumm International Award. He retired from MeteoSwiss in 2017.

Integration

64. Integration of Meteorological and Ecological Measurements

Hans Peter Schmid , Corinna Rebmann 

Recent developments in both environmental measurement technology and numerical modeling have cleared the way for integrative approaches to Earth system science. Modern Earth system models can now account for interactions and feedback between the atmosphere, oceans, the cryosphere, and ecosystems at global to regional scales and over timescales ranging from hours to decades or longer. In turn, such models call for integrated data fields from observations in each of these Earth system compartments as well as their interactions. The nature, spatial scale, and data structure of ecological measurements (soil and vegetation parameters, ecosystem–atmosphere exchange fluxes) are distinctly different from those of most meteorological measurements. This chapter summarizes the basic notions of ecological measurement networks and addresses the challenges of integrating data from ecological and meteorological networks.

Ecology is the branch of biology that studies the interactions between organisms and their environment [64.1]. A community of living organisms that interact with each other and with the inanimate components of their environment is known as an *ecosystem* [64.2]. All organisms on Earth depend on the availability of water, energy, carbon, and nutrients, and ecosystems typically evolve to optimize the way these *life elixirs* are exchanged and cycled between their biotic and abiotic components. These interactions can involve biological, chemical, physical, and—depending on the timescale—geological processes. Thus, one speaks of biogeochemical or biogeophysical cycling. With these definitions in mind, it is quite obvious that the relationship between ecology and meteorology must be an intricate one. For most terrestrial organisms, the primary source of water is precipitation (directly or indirectly); for plants, the primary source of energy is solar radiation and the most important source of carbon is atmospheric CO₂. While the basic distribution of nutrients (mostly compounds containing N, P, or S) is governed over the long term by geological and hydrological processes, a significant amount of nutrients is

redistributed by the atmosphere (as cloud condensation nuclei, dissolved in precipitation water, as aerosols, or as trace-gas admixtures). The kinetics of biochemical reactions that both create and decompose organisms are directly dependent on temperature [64.3] and the stability of enzymes. The biological catalysts that make metabolic processes possible [64.4] are only functional within specific ranges of temperature. Clearly, plant growth and ecosystem development are largely governed by meteorological processes and the state of the atmosphere over timescales ranging from seconds to decades or longer.

On the other hand, the earliest regular meteorological observations (performed in India around 5000 years ago [64.5]) were likely motivated by agriculture and the need for crop yield optimization. So, interest in identifying the parameters that control ecosystem function drove the earliest development of meteorological instrumentation [64.6].

This chapter on the integration of meteorological and ecological measurements only addresses terrestrial ecosystems. Much of what is mentioned here is also relevant to aquatic (freshwater and marine) ecosys-

tems, but the spatial and temporal scales as well as the relevant parameters and measurement techniques for aquatic ecosystems can differ quite strongly from those of terrestrial ecosystems. Thus, the challenges involved in integrating meteorological and ecological measurements for terrestrial ecosystems are likely different from those involved in similar measurement integration for aquatic systems. The principal focus is

on regional or global networks of ecological measurements.

Historically, the first ecological measurements occurred at agricultural crop sites, and many of the most important measurement techniques (e.g., the eddy-covariance technique for CO₂ flux measurements and the eddy accumulation technique) were first developed for agricultural or agronomy applications [64.7, 8].

64.1 Relevance and Parameters of Networks

The establishment of meteorological and aerological measurement networks was driven by two primary motivations (see Chap. 63). One was to gain information on the temporal evolution of the weather or air quality in a given location or region. Measurements outside the region of interest (especially upstream) provided data on possible advection into the region. Networks, especially global networks, formalized and generalized this utilization of *upstream* information. One of the primary uses of modern meteorological and aerological measurement networks is thus to initialize and reanalyze global and regional prediction models.

The other motivation for creating meteorological and aerological networks derives from the increasing interest in global climate variability and climate change, which first gained public attention in the 1960s [64.9, 10]. Measurement networks have proven crucial to the detection of atmospheric variability (both spatial and temporal), short-term disturbances (e.g., due to volcanic eruptions, major industrial accidents, and wildfires), and long-term trends in the state of the atmosphere.

As outlined in Chap. 63, atmospheric networks are commonly not only networks of measurements but also networks of scientific exchange for the development and coordination of observational methods, techniques, quality control, and instrument calibration. Standardization of calibration routines and data quality control ensures that network datasets are internally consistent. In order to fulfill their purpose as meteorological and aerological networks that monitor a given region or the whole globe, the distance between neighboring measurement stations must be small enough to ensure that the variables sensed by different stations are correlated to some extent [64.11, 12]. Provided that condition is satisfied, continuous atmospheric fields can be estimated and reanalyzed to, for instance, generate regular grids using data assimilation techniques. Therefore, one requirement of such a measurement network is that it should represent the spatially explicit variability and temporal evolution of atmospheric fields [64.13].

In contrast, networks of ecological measurements do not, and probably cannot, represent the spatially ex-

PLICIT variability or temporal evolution of ecosystem characteristics or processes. To begin with, many ecological parameters (e.g., soil and vegetation properties such as soil texture, phenological data) are not physical field variables—they are neither continuous in space nor differentiable everywhere. Further, the spatial variability of terrestrial ecological variables typically manifests not as smooth gradients but as discrete boundaries over scales that are much smaller than those of the variations relevant to atmospheric networks (excluding turbulence scales, which become irrelevant after Reynolds averaging).

Thus, network design for ecological networks must serve objectives that are very different from those of atmospheric networks. Ecological measurement networks are usually collections of observation sites (often comprising extended areas with diameters of several tens of meters to several hundred meters) arranged over a given region (perhaps the entire globe) according to various network design approaches, with specific objectives in mind. Such network design approaches include:

- (i) Monitoring the most important ecosystem types in a given region [64.14, 15]
- (ii) Monitoring similar ecosystem types using stations arranged along gradients of climate, soil type/soil moisture, or elevation [64.16, 17]
- (iii) Monitoring similar ecosystem types with different ages or at different successional stages under similar climatic and substrate conditions [64.18, 19].

However, in contrast to atmospheric measurement networks, the behavior of ecological variables at one station cannot be expected to be spatially correlated to their behavior at a neighboring station. Long time series of data from individual stations are often used to develop and evaluate parametric or mechanistic process models, and it is only through such models that measurements from different sites in ecological networks can be objectively and systematically connected [64.20]. The latter two approaches to network design are often used in a quasi-experimental fashion

to simulate effects of, for example, climate change or stand age using a space-for-time analogy [64.21, 22]. In conjunction with models evaluated against station data, the first approach serves to integrate ecosystem processes over a region or for the entire globe [64.23].

Just as they are for atmospheric measurement networks, knowledge exchange among network scientists and technicians, coordination and standardization of observational methods, quality control, and calibration are key to the successful operation of ecological networks. Because of the larger number of variables that need to be measured at ecological sites (both meteorological and ecological variables), and because of the vast differences between ecosystem types (from Arctic tundra to tropical rainforest), standardization of ecological measurements is more difficult than it is for atmospheric measurements; indeed, it is a formidable challenge (see [64.24] and other papers in the same issue [64.25, 26]).

The increased knowledge of and interest in complex interactions and feedback loops between Earth system compartments in recent decades have led to considerable advances in observation and modeling techniques: higher resolution both spatially and temporally, improved precision and stability of measurement systems, and the inclusion of more detailed process interactions in models [64.27]. These developments have enabled models to track more complex interactions at increasingly fine scales in an integrated approach across Earth system compartments, and over larger spatial domains for longer time periods. The general tendency continues to be to move beyond offline compartment-specific atmospheric, oceanic, and dynamic ecosystem modeling to integrated Earth system modeling. The newest additions to Earth system modeling over the last two decades have been the inclusion of atmospheric chemistry, the carbon cycle, the nitrogen cycle, and dynamic vegetation [64.28, 29]. The results obtained using these new modeling capabilities have prompted a plethora of questions that need to be evaluated by independent observations. To serve this purpose, such observations also need to be integrated Earth system observations, with concerted measurement programs across all Earth system compartments. The integration required for regional assessments over the continents is essentially between long-term atmospheric and ecological measurement networks.

64.1.1 Ecological Measurement Networks

General environmental sensor networks are described and discussed in [64.30], where the authors differentiate between *large-scale single function* (LSSF) networks, *localized multifunction sensor* (LMS) networks,

biosensor (BS) networks, and *heterogeneous sensor* (HS) networks (hybrid forms that possess characteristics of all of the previously mentioned networks). The classic LSSF network is the network of thousands of standardized meteorological and climatological stations worldwide. Their primary purpose is to provide a data field for initializing or evaluating weather forecasts or for climatological statistics, and they commonly encompass a limited set of standardized sensors (see Chaps. 4 and 43). LMS networks cover smaller areas with greater density and serve multiple applications. Examples include the Oklahoma Mesonet (Chap. 45), which is designed to characterize the state of the environment over the domain and duration of mesoscale weather and hydrological events, and urban observation networks (Chap. 52), which observe the spatial and temporal variability of diverse parameters (including meteorological and hydrological parameters, the energy balance, air quality, and greenhouse gases) over an urbanized area. Biosensors are typically miniaturized devices with biochemical or biophysical detectors as well as data storage and transmission capabilities [64.31]. In ecological systems, biosensors are used to measure or derive physical or chemical properties of the soil, water, or organisms (e.g., the water, carbon, or nitrogen content in soils or sap flow in trees). Some BS networks employ a large number of biosensors of a similar type to cover an entire ecological unit (e.g., the soil and trees in a forest stand) or a small region; others include a variety of sensor types to monitor multiple aspects of the state of an ecosystem over time.

Ecological measurement networks that address biogeochemical cycling, biodiversity, and climate mitigation services by ecosystems are generally hybrid sensor networks (HS, see [64.32] for a review). As defined in [64.30], heterogeneous sensor networks integrate the characteristics of LSSF, LMS, and BS networks. Such integrated ecological measurement networks tend to cover large regions (countries, continents, or the entire globe). Their nodes are often arranged in clusters that can be considered LMS networks themselves, and sites within the clusters contain BS networks with specialized sensing or sampling structures. The variability of biogeochemical cycling processes covers a vast range of spatial scales, ranging from the size of intracellular organelles ($\approx 10^{-6}$ m) to the continental and global scales ($\approx 10^7$ m). For instance, when assessing the role of terrestrial ecosystems in the global carbon cycle, atmospheric transport by the global circulation is important, but the limiting processes to be captured are photosynthesis by chloroplasts inside the mesophyll cells of plant leaves, the diffusion of CO_2 molecules through their stomatal openings, and respiration by microbes in the soil. The range of timescales to be covered

is similar: the photosynthesis of leaves inside a forest canopy reacts to transient sunflecks within milliseconds, phenological changes (e.g., the springtime onset of plant growth, or leaf senescence in fall) respond to seasonal weather anomalies, and rising temperatures and atmospheric CO₂ levels affect plant physiology over climatic timescales. Thus, ecological measurement networks are commonly designed in a hierarchical way: principal nodes aim to represent the most important biomes and climatic zones [64.14], and some of these nodes are developed into supersites [64.33, 34] to collocate measurements for a variety of objectives. Supersites can be augmented by clusters of lower-grade sites to upscale observations from site to region [64.35] or to evaluate ecosystem function responses to gradients in elevation or climate [64.16].

64.1.2 Measured Parameters

Ecological networks commonly measure parameters and processes that characterize the thermal, physical, chemical, and biological conditions in soils, vegetation, the canopy airspace, and the atmospheric boundary layer, as well as exchanges between these Earth system compartments. Thus, all of the chapters in Part

B (focusing on in-situ measuring techniques) of this Handbook may be relevant, depending on the specific foci of individual networks or sites. Recently, many of the principal sites have also integrated ground-based remote-sensing techniques into their portfolio (see Part C), especially sensing systems for the thermal and dynamic structure of the atmospheric boundary layer (Chaps. 23–27) or to integrate across spatially heterogeneous landscapes (Chaps. 28, 34, 35, 48–50). Of primary importance from an ecological perspective are exchange fluxes of heat, trace gases, and aerosols over small, well-defined plots (Chaps. 53, 58, 59–61) or a turbulent flux footprint (Chaps. 1, 55, 56).

Of particular importance for all measurements in ecological networks is the detailed characterization of measurement sites by the BADM (Biological, Ancillary, Disturbance, and Metadata) protocol [64.25, 36–38]), as epitomized by the words of the late Australian micrometeorologist *Ray Leuning* (1948–2016): *know thy site!* (personal communication). Regularly updated BADM information is crucial for data interpretation across sites and for use as driving parameters in models.

An example of a well-established data management system for an ecological measurement network is described in [64.26, 39].

64.2 History

Since their inception in the mid-1970s, ecological measurements organized into networks have focused on long-term observations. In 1977, the US National Science Foundation (NSF) organized a workshop in Woods Hole (MA, USA) to discuss fundamental issues concerning long-term ecological measurements [64.40]. Discussions evolved around the recognition that all ecosystems are in a process of long-term change, including cyclic or irregular variability and long-term trends. Both trends and changes in variability can be due to natural processes or may have anthropogenic causes. The conclusion of the conference was a call to form a network of long-term ecological observations. As a result, the first Long-Term Ecological Research (LTER [64.41]) Network, with 28 sites across the United States, was established in 1980 by the National Science Foundation to support research on long-term ecological phenomena.

Over the last three decades, a growing need for observational data on ecosystem functions and biogeochemical cycling (primarily of water, carbon, nitrogen, and heat) in response to the so-called *missing carbon sink* problem [64.42, 43] has motivated the formation and expansion of large-scale and long-term ecological measurement networks that focus on carbon exchange and function in terrestrial ecosystems. Examples of

these (FLUXNET, AmeriFlux, NEON, and ICOS) will be briefly presented in the following.

64.2.1 History of Ecological Measurements

Likely the most important developments in the observational capabilities of ecological measurement networks are associated with the eddy-covariance technique (see Chap. 55) for the direct derivation of reliable ecosystem–atmosphere exchange fluxes of heat, water vapor, and CO₂, which can be operated continuously over long periods (up to decades).

There were four events that made this technique possible:

- The development of the infrared gas analyzer for the optical detection of CO₂ and water vapor concentrations. The first IRGA was patented in Germany in 1938 by two physicists working for a chemical company in Ludwigshafen [64.44] and was published in 1943 [64.45]. Soon after (in 1949), this principle was adopted for enclosure measurements of CO₂ exchange by plants at the University of Heidelberg [64.46]. In 1950, *Bruno Huber* (1899–1989) reported on the first use of an IRGA to estimate

- an ecosystem-scale CO₂ flux via a micrometeorological technique [64.47], albeit with a flux-profile approach based on a simple but unrealistic exchange coefficient.
- The principle of the eddy-covariance technique was pioneered by *William Christopher Swinbank* (1913–1973) [64.48] (see Chap. 55). The first successful CO₂ flux measurement by eddy-covariance (using an IRGA) was reported by *Ray Desjardins* (*1940) in 1974 [64.7].
- Arguably the first usable sonic anemometer for eddy covariance was developed by *J. Chandran Kaimal* (1930–2021) and *Joost Businger* (*1924) in the early 1960s [64.49].
- Stable continuous CO₂ flux measurements became available only after microprocessor technology and data storage capacity had advanced sufficiently in the 1980s and 1990s. See [64.50] for a personal anecdotal account of the history of eddy-covariance measurements by *Dennis Baldocchi* (*1955).

64.3 Structures of Notable Networks

FLUXNET is a global network of regional (CO₂) flux measurement networks [64.53] but does not operate measurement stations. Currently, its main function is to act as a global data portal for ecosystem-atmosphere exchange flux stations [64.54]. Over the years, more than 900 flux sites have been registered with FLUXNET, but many of those operated for relatively short periods and are now inactive. FLUXNET is thus mainly an organization that comprises scientists and experts, and as such it facilitates the discussion and formulation of measurement and data standards and the creation of quality-controlled synthesis datasets for flux stations around the globe. The latest synthesis data

release (FLUXNET2015, see Fig. 64.1) includes 212 sites. Over the years (up to 2016), the networks that participate in FLUXNET have included 914 sites, representing a total of 7479 site-years. In 2016, 459 of those sites were reported to be active. As is clearly evident in Figs. 64.1 and 64.2a, the geographical distribution of FLUXNET sites is very inhomogeneous and is highly correlated with the availability of funds to operate and maintain the flux stations. Among the major biomes represented in FLUXNET (Fig. 64.2b), sites in forests (of all kinds) are particularly well represented.

FLUXNET consists of a large number of regional networks [64.56], the largest of which is Ameri-

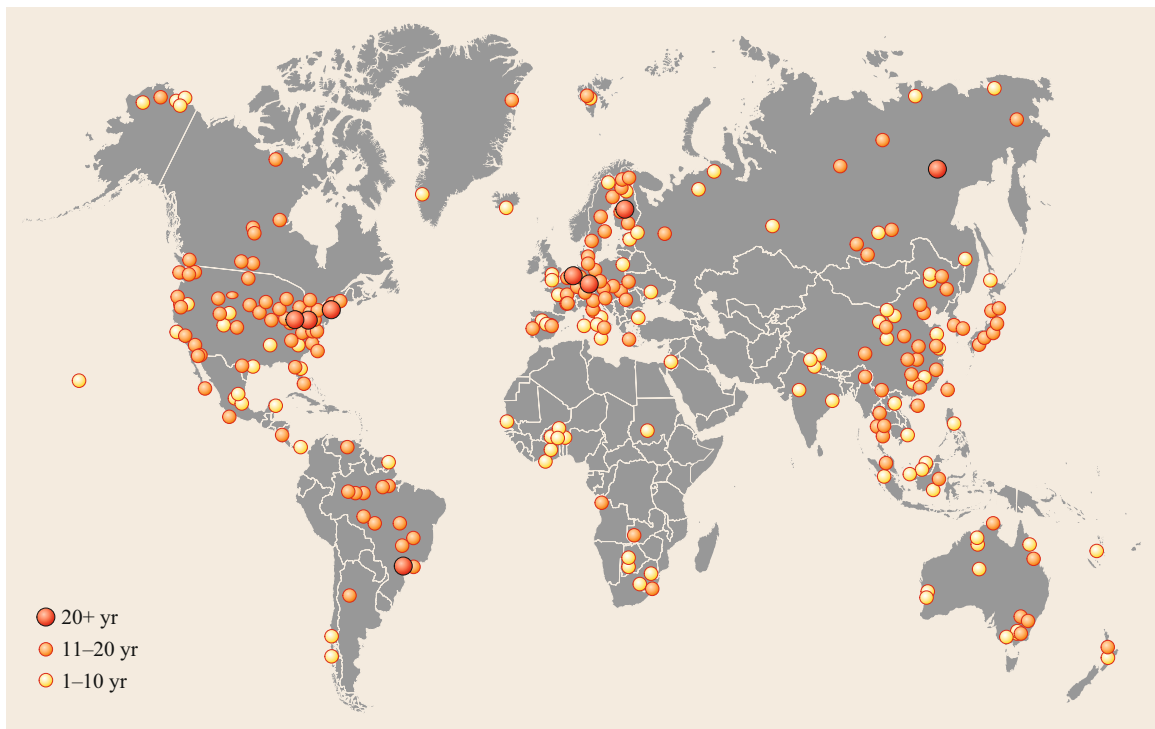

Fig. 64.1 Global distribution of the 212 eddy-covariance stations that contribute to the FLUXNET2015 synthesis dataset, including an indication of the years of data contributed (after [64.51])

Flux [64.57, 58]. Until recently, AmeriFlux sites had no central funding structure. For this reason, AmeriFlux evolved slowly; it consisted of only a handful of sites in 1996 when it was launched following a noted international workshop in La Thuile, Italy, in 1995 [64.59]. In part through necessity, AmeriFlux has adopted diversity of site design, instrumentation, and analysis methods as its *modus operandi*. However, this diversity developed during a period when the concept of long-term flux measurement campaigns was still in its infancy and standardization was based on arbitrary decisions. By establishing and deploying a mobile reference eddy-covariance system, the so-called *roving system*, it was possible to perform intranetwork field calibrations and comparisons between systems, which formed the basis for the emergence of standardized *best practices*, estimates of uncertainty, and cross-site compatibility of data [64.60]. Currently, AmeriFlux is coordinated by a long-term management project and consists of 276 sites across the Americas that are active or have provided data in the past (Fig. 64.3). About 80% of all registered sites are located in the United States, 16% are in Canada, and the remaining 4% are distributed among a number of countries throughout the Americas (see [64.57]).

Fig. 64.3 Site distribution of the AmeriFlux network (after [64.55]) ▶

Fig. 64.2a,b Temporal development of FLUXNET sites: (a) distribution among continents; (b) distribution among major biomes. In (b), *other* includes, for example, tundra and urban areas (after [64.52] with the permission of Housen Chu)

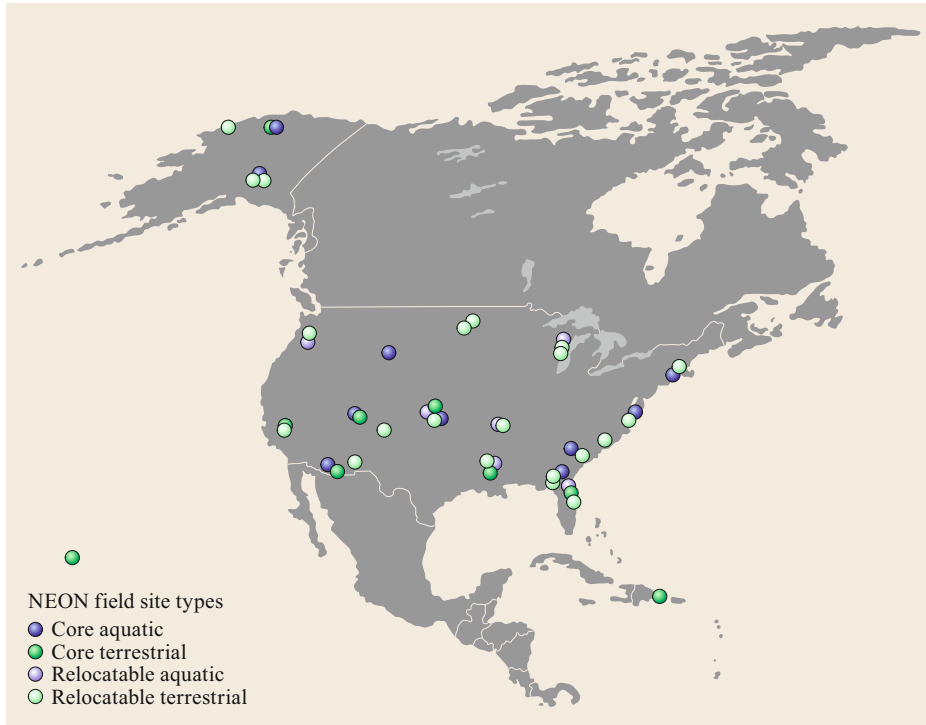

Fig. 64.4 NEON field site map; NEON core sites have a strong emphasis on aquatic environments (after [64.61])

Of the AmeriFlux sites within the United States, 44 (2018) have been selected as *core sites*, with assured long-term funding support for concerted operation and a more standardized maintenance schedule.

At the other end of the site design diversity spectrum is NEON (US National Ecological Observatory Network [64.62, 63], Fig. 64.4). The observational scope of NEON is broader than that of AmeriFlux, but it also has a strong focus on ecosystem-atmosphere exchange flux measurements. NEON is centrally funded and is highly standardized in terms of station design, instrumentation hardware, and methods of data analysis [64.26]. NEON is not currently contributing data to AmeriFlux or FLUXNET, but is moving towards that goal [64.26].

In terms of standardization and funding structure, ICOS (Integrated Carbon Observation System [64.64]) is somewhere between AmeriFlux and NEON. ICOS is a distributed European research infrastructure with independently funded national networks in 12 countries at present. ICOS consists of three parallel observation systems that concentrate on the atmosphere, the oceans, and (terrestrial) ecosystems. ICOS Ecosystems (see Fig. 64.5) is far along the road to establishing standardized instrumentation, data analysis, and quality

Fig. 64.5 The ICOS Ecosystem station network (after [64.64])

control protocols (see [64.24] and other contributions in the same issue).

All three of the ecological flux measurement networks featured here are intended to be operated over the

long term (> 20 years). They benefit from each other by frequently exchanging ideas and experience as well as collaborating in the preparation of synthesis projects and intercomparisons.

64.4 Temporal and Spatial Scales

For general questions about the temporal and spatial scales of environmental measurements, see Chap. 1. Ideally, the temporal and spatial scales that an ecological measurement network needs to cover correspond to the scales of the relevant processes that govern the development of the ecosystem of interest [64.65]. Spatial scales can be covered by positioning the nodes of the network strategically [64.15] and making use of satellite remote-sensing and ecosystem models [64.23, 66]. Temporal scales of ecological processes are limited only by the age of the ecosystem (including soils). At mid- and polar latitudes, this often corresponds to the time since the last glaciation, or about 10^4 years. Similarly, the spatial scales over which ecosystem processes can develop correspond to the size of the ecosystem (up to several 10^3 km), because an ecosystem is defined by similarity of processes and function. Of course, a timescale of 10^4 years cannot be covered directly by any ecological measurement network, but, as mentioned, long temporal scales can sometimes be spanned indirectly through a space-for-time analogy or chronosequence approach [64.21, 22].

An important aspect of the ecosystem–atmosphere interaction is that there are concurrent effects of a large number of interlinked processes that operate over vastly different timescales, ranging from, say, sunflecks that last for less than a second but affect the photosynthesis in a leaf to soil development processes that last for thousands of years. Therefore, it is clearly not practicable to include the entire spectrum of timescales for such a complex dynamic system when performing ecological observations. A more relevant approach is suggested by the concept of *ecological resilience* [64.67, 68], and by realizing that any natural ecosystem generally develops by experiencing successive disturbances and recovering from them, not under the influence of

equilibrium conditions. In its broadest sense, resilience describes [64.69]

the capacity of a system to absorb disturbance and reorganize while undergoing change so as to still retain essentially the same function, structure, identity, and feedbacks.

A more measurable concept of resilience is borrowed from engineering, where it is the timescale associated with the return of a system to equilibrium or a steady state after it has been disturbed [64.68]. A particular type of resilience timescale was proposed in [64.70] for a spruce forest ecosystem in the Bavarian Forest (Germany) after a stand-replacing disturbance by a windthrow as “the timescale over which all post-disturbance emitted carbon will have been fixed again by the ecosystem”. Based on observations of carbon exchange fluxes for several years after the windthrow and the projections of an ecosystem model, this resilience timescale was estimated to be about 20 years for that particular Norway spruce forest. A consequence for ecological measurements is that observation periods which are shorter than the resilience timescale may exhibit a systematic bias because they provide an incomplete representation of the dynamics of the ecosystem and its interaction with the atmosphere. Stand-replacing disturbances (e.g., caused by wind storms, fires, logging) are important but relatively rare occurrences; smaller disturbances are the norm in natural ecosystems. Thus, given the complex dynamic behavior of the system, identifying an observation timescale for ecological measurements that has the chance of capturing a full cycle of ecosystem development is a difficult problem, and is the subject of active research. The chronosequence (space-for-time) approach mentioned above may be of some help if a model is used to fill the gaps in the ecosystem stages captured by the chronosequence.

64.5 Quality Control of Ecological Measurement Networks

For general quality control issues associated with measured data, see Chap. 3. Similar to measurements in atmospheric networks (Chap. 63), the objectives of quality control in ecological measurement networks are

to make measured data within the network consistent and comparable.

Consistency refers to the aim that the quantities measured at different sites in a network should repre-

sent the same process or system state. For instance, if soil temperatures are measured at different depths in different locations, the ensuing dataset is not consistent. But if more than one depth is sampled at every location, the dataset may be made consistent by interpolating a given soil temperature profile at every location. Thus, the assessment of measurement consistency (and its assurance) in a network depends largely on the documentation of metadata detailing the circumstances of the measurements or observations [64.71]. As mentioned, a framework that is commonly used to report the biological, ancillary, disturbance, and metadata (BADM) is presented in [64.39].

Comparability is achieved by quantifying the random uncertainty in the measurements and by identifying and quantifying systematic biases. For some of the most important ecological observations (e.g., flux measurements obtained via chambers or eddy covariance; see Chaps. 55, 59, 60), there is no absolute standard instrument or measurement method. Moreover, for such instruments, their performance is highly dependent on the measurement setup, including the chamber or mast design, aerodynamic exposure, juxtaposition with other instruments, obstacles, etc. [64.72, 73]. Thus, the identification and avoidance of systematic biases are achieved

through checks of physical plausibility (e.g., no photosynthesis at night), internal consistency (e.g., balance closure requirements), and long-term integral requirements (e.g., negligible storage change integrated over daily or annual cycles).

In the absence of absolute standards, it is not possible to perform an absolute instrument calibration to estimate the error. For eddy flux measurements of CO₂, practical methods of estimating various types of random measurement uncertainties are presented in [64.74–76].

A useful, but costly, approach to ensuring network-wide consistency in field calibrations and enabling comparison against a reference standard (if not an absolute standard) is the use of a *roving system* [64.77]. In this approach, a mobile system of laboratory-calibrated component instruments is deployed and operated in close proximity to a comparable measurement system in the network. The two systems are operated in parallel over a duration of 10 days or 2 weeks, and the data are used to assess the random uncertainty and systematic deviations from the roving standard. Costs arise from maintaining the roving standard system and the personnel needed to operate and move the system. An example of using a roving-standard eddy-covariance flux system in the AmeriFlux network is described in [64.76].

64.6 Maintenance

For instrument maintenance strategies, see the individual chapters on instrumentation in this Handbook. To minimize data gaps during instrument maintenance in a network, it is advisable to perform minor routine maintenance in the field without removing instruments. If it is necessary to send instruments back to a lab-

oratory or the manufacturer, it is useful to deploy a temporary replacement system to bridge the gap. If several similar stations can be serviced in a rotation scheme, it is possible to implement a round-robin strategy with one redundant system.

64.7 Applications

The principal applications of integrated meteorological and ecological measurement networks involve the use of synthesis datasets, after standardized quality control and data analysis, to perform spatial and temporal integrations (e.g., of CO₂, water vapor, or

energy fluxes [64.53]) or to assess ecophysiological characteristics (e.g., water-use efficiency [64.78, 79]). See [64.80] for more examples of publications relating to applications of the FLUXNET synthesis datasets.

64.8 Further Developments

Developmental trends for meteorological and ecological measurement networks are primarily for further integration, data sharing, and standardization of instruments, analyses, and methods across various networks (including AmeriFlux, NEON, and ICOS [64.58]). Sites that serve multiple networks and objectives develop

into supersites [64.34] or meteorological–ecological observatories (e.g., the SMEAR I and II stations at the Hyytiälä site in Finland [64.33], the Niwot-Ridge AmeriFlux and LTER site in Colorado [64.81], the Harvard Forest site in Massachusetts [64.82], and the Fendt TERENO/ICOS/ScaleX site in Germany [64.16, 83]).

Hans Peter Schmid

Institute of Meteorology and Climate Research – Atmospheric Environmental Research
 Karlsruhe Institute of Technology (KIT)
 Garmisch-Partenkirchen, Germany
hape.schmid@kit.edu

Hans Peter (HaPe) Schmid (Ph.D., UBC Vancouver, Canada, 1988) is a Swiss micrometeorologist. He has headed the Institute of Meteorology and Climate Research (Department of Atmospheric Environmental Research) at the Karlsruhe Institute of Technology since 2007. He is also Professor of Atmospheric Environmental Research at the TU Munich. His research focuses on the atmosphere–land surface interaction. Before moving to Germany, he was full Professor at Indiana University, Bloomington (USA).

Corinna Rebmann

Department Computational Hydrosystems
 Helmholtz Centre for Environmental Research
 Leipzig, Germany
corinna.rebmann@ufz.de

Corinna Rebmann is a research scientist at the Helmholtz Centre for Environmental Research in Leipzig (Germany). Since finishing her PhD, she has worked on methodological development for the eddy-covariance method and procedures for quality assurance and control. Within TERENO and ICOS-RI, she is responsible for the coordination and scientific evaluation of ecosystem stations in central Germany. Corinna has chaired the ecosystem monitoring station assembly of ICOS-RI until June 2020.
