the emissions of anthropogenic or biogenic VOCs and, in the case of cities, NO_x are high), models are often unable to reproduce observations of radicals [16.126, 127]. Figure 16.6 highlights the tendency of a model to underestimate RO_2 radicals under high NO_x conditions and HO_2 under low NO_x conditions. The observations of radicals were performed during the 2012 ClearLo project in London, UK [16.127].

16.8.2 Measurements of Halogenated Gases in Remote Regions

The precise quantification of trace levels of halogen radicals is required to understand the global budget for O_3 . Cycling between atomic halogens and their oxides X and XO (X = Cl, Br, I) is an efficient mechanism for O_3 destruction. The magnitude of this mechanism depends on the ambient levels of halogen radicals, which are present at mixing ratios of a few pptv at most in the lower atmosphere. These species, particularly BrO and IO, can be measured by visible absorption spectroscopy. Figure 16.7 shows the diel cycles of measured BrO and IO at the Cape Verde Atmospheric Observatory in the Atlantic Ocean for 8 month periods in 2006 and 2007 [16.128]. Measurements were obtained from UV and visible DOAS at a time resolution of 30 min over a 12 km path, most of which was across a bay (i.e., over water) adjacent to the Cape Verde Atmospheric Observatory. The O_3 loss associated with these levels of halogen oxides, as predicted by a chemical transport model, was about 50% greater than the predictions of the model that was unconstrained by observations of these species.

16.8.3 Measurements of VOC Emissions From Oil and Gas Development

Emissions of methane and volatile organic compounds (VOCs) from oil and gas development strongly influence regional air quality and climate. Particularly in the US, where oil and gas production has increased significantly since 2005, there is considerable interest in quantifying these emissions [16.129]. The development of spectroscopic instruments that can measure ethane (C_2H_6) rapidly and precisely have contributed to this effort. Figure 16.8 shows C_2H_6 measurements over the Barnett Shale, an oil- and gas-producing area in the US state of Texas, in 2013 [16.130]. Measurements were carried out with a Herriott-cell-based tunable diode laser spectrometer operating at $3.3\ \mu\text{m}$. This system produced 1 Hz C_2H_6 data, making it suitable for use in

**Fig. 16.6a,b**

Average diel observed (*colored lines with error bars*) and MCM (master chemical mechanism) box model (*black line*) OH, HO₂, RO_{2i}, and RO₂ profiles during (a) south-westerly and (b) easterly flows ([OH]_{PSS} is indicated by the orange line). The error bars represent the 1σ variability in the observations. The average diel observed NO (*brown line*) and NO₂ (*green line*) are displayed in the bottom panels. The observations of radicals were performed during the 2012 ClearLo project in London (after [16.127] © L.K. Whalley et al., licensed under CC-BY)

aircraft. Enhanced levels of C₂H₆ and their correlation with CH₄ enables the precise attribution of emissions of both species from various sources, including oil and gas.

16.8.4 Long-Term Monitoring of Climate Gases and Urban Pollutants and Links to Policy

As noted above, CRDS measurements of CO₂ and CH₄ have become a new standard for greenhouse gas mea-

surements globally, augmenting previous networks that were based on lower-frequency measurements such as flask sampling. Figure 16.9 shows one example of aircraft measurements in Alaska performed over three years from 2009–2011 aboard a US Coast Guard C-130 aircraft [16.131]. Comparisons between flask samples, the previous CO₂ standard measurement, and CRDS CO₂ are shown. Results from the assessment suggest that the CRDS measurements are accurate to within 150, 1.4, and 5 ppbv for CO₂, CH₄, and CO, respectively.

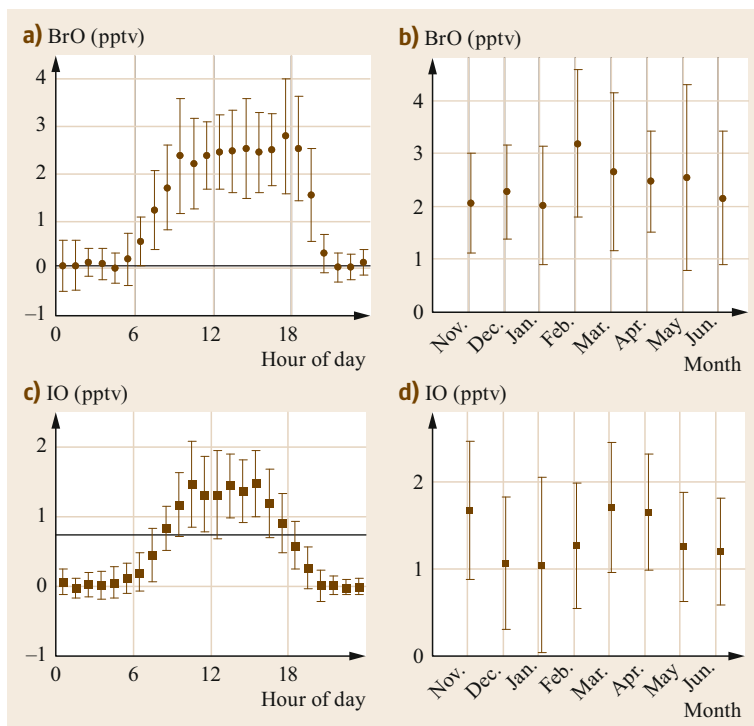

Fig. 16.7 Average diel cycles and seasonal averages of the halogen oxides BrO and IO, as measured at the Cape Verde Atmospheric Observatory in 2006–2007 (after [16.128])

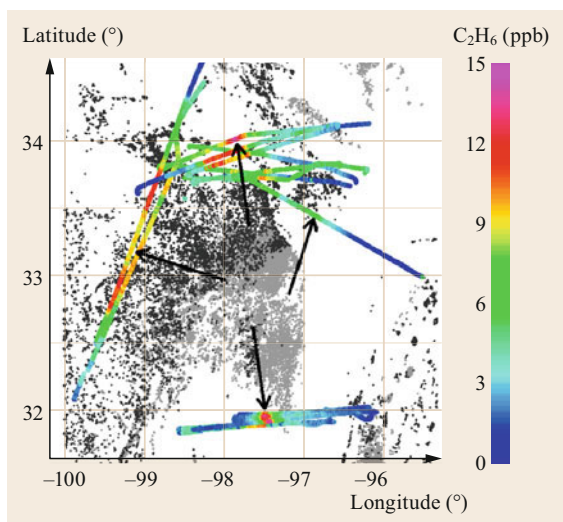

Fig. 16.8 Map of ethane measured along a research aircraft flight track over the Barnett Shale in the US state of Texas in 2013. Ethane mixing ratios along the flight track are color coded according to the key shown on the right, while the dots represent oil and gas wells (after [16.130] reprinted with permission, © American Chemical Society 2015)

Fig. 16.9 Comparison of CO₂ measurements obtained using a CRDS instrument and flask samples for three years of aircraft sampling (2009–2011) over Alaska (after [16.131] © A. Karion et al., licensed under CC-BY)

16.9 Future Developments

Spectroscopic methods have advanced continuously over the last 50 years, from the onset of routine atmospheric measurements and monitoring in the 1970s to the highly distributed networks and detailed aircraft-based measurements that occur today. This advance is likely to continue with developments in light sources and measurement technology. In recent years, the development of robust mid-IR light sources based on quantum cascade and interband cascade lasers has had a notable impact. New broadband technologies such as optical frequency combs [16.132] may facilitate the next generation of such instruments.

The number of species detected by LIF, either directly or following their conversion to another species, is growing. Laboratory detection of CH_3O_2 by LIF following chemical titration to CH_3O has shown that this method has the sensitivity required for ambient de-

tection [16.70], offering the opportunity to detect an individual organic peroxy radical rather than a measure of the total RO_2 .

The sensitivity, time resolution, and robustness of the latest generation of NO chemiluminescence analyzers facilitates measurements in environments remote from local emissions, thus enabling long-term changes in background concentrations to be studied. In addition, the increasingly high time resolution of these analyzers will permit further flux measurements to be made for a suitable footprint, so that emissions inventories—for example of important pollutants or greenhouse gases—can be validated.

Acknowledgments. Thanks are given to Bob Yokelson (University of Montana) and Scott Herndon (Aerodyne) for helpful discussions.

16.10 Further Reading

The following is a comprehensive textbook that covers the main techniques used to monitor the gas-phase composition of the atmosphere, with substantial chapters on absorption, fluorescence, and chemical conversion with chemiluminescence:

- Heard, D.E. (Ed.), *Analytical Techniques for Atmospheric Measurement*, Blackwell Publishing Oxford, 2006.

For a textbook on differential optical absorption spectroscopy and its methods and applications, please refer to:

- Platt, U. and J. Stutz, *Differential Optical Absorption Spectroscopy*. 2008, Berlin: Springer-Verlag.

The following textbook on cavity-ring down spectroscopy illustrates this technique and a variety of its applications, including those in atmospheric science and other fields:

- Berden, G. and R. Englen, *Cavity Ring-Down Spectroscopy: Techniques and Applications*. 2009, West Sussex, UK: John Wiley & Sons.

Dwayne Heard

School of Chemistry
University of Leeds
Leeds, UK
d.e.heard@leeds.ac.uk

Dwayne Heard is Professor of Atmospheric Chemistry at the University of Leeds, UK. He received a DPhil in physical chemistry in 1990 from the University of Oxford and was awarded the Royal Society of Chemistry's Environment Prize in 2017. His research focuses on atmospheric chemistry, especially field measurements of hydroxyl and other radicals, reaction kinetics and photochemistry, and aerosols and heterogeneous chemistry, as well as planetary and interstellar chemistry.

Lisa K. Whalley

School of Chemistry
National Centre for Atmospheric Science,
University of Leeds
Leeds, UK
l.k.whalley@leeds.ac.uk

Lisa Whalley is a senior research scientist at the National Centre for Atmospheric Science (NCAS) at the University of Leeds. She received a PhD in atmospheric chemistry in 2004. Her research interests involve atmospheric measurements, modeling studies, and laboratory experiments, and focus on understanding the chemistry responsible for the processing of trace gases in the atmosphere through field observations and comparison of these observations with detailed chemistry models.

Steven S. Brown

NOAA Chemical Sciences Laboratory
Boulder, USA
steven.s.brown@noaa.gov

Steven S. Brown is a Research Chemist at the Chemical Sciences Division of the NOAA Earth System Research Laboratory in Boulder, Colorado, and an Adjoint Professor of Chemistry at the University of Wisconsin-Madison in 1996. His research interests include the chemistry of nitrogen oxides in the Earth's atmosphere and the development of high-sensitivity spectroscopic instruments for atmospheric sensing.

17. Measurement of Stable Isotopes in Carbon Dioxide, Methane, and Water Vapor

Ingeborg Levin , Matthias Cuntz 

Instrumentation for the continuous measurement of stable isotopes in atmospheric trace substances such as carbon dioxide (CO₂), methane (CH₄), and also water vapor (H₂O), has grown tremendously in the last decade. This is due to the development of new highly sensitive infrared spectroscopic techniques such as Fourier transform infrared spectroscopy, or laser-based systems like quantum cascade laser absorption spectroscopy and cavity ring-down spectroscopy. These systems are not only applied for precise continuous concentration measurements, but have also recently been used for high-frequency isotope measurements of net ecosystem-atmosphere exchange fluxes. Similar development of isotope ratio mass spectrometry systems led to successful application of the spectrometers in quasicontinuous mode at field stations. The currently available continuous measurement systems for CO₂, CH₄, and H₂O stable isotopic compositions are described here and information about calibration, maintenance, and quality assurance requirements of these systems is given.

From the classical biogeochemist's point of view, molecules containing different isotopes, known as isotopologues, have equal chemical and biochemical properties. However, tiny differences of often only one mass unit lead to small variations in their physical behavior, such as in molecular diffusion, e.g., dur-

ing uptake of CO₂ through stomata of leaves, or during phase changes, e.g., evaporation or condensation of water vapor [17.1]. These fractionation processes cause measurable differences in the isotope ratios of, most prominently, light atoms, such as hydrogen (²H/¹H), carbon (¹³C/¹²C), nitrogen (¹⁵N/¹⁴N),

or oxygen ($^{17}\text{O}/^{16}\text{O}$, $^{18}\text{O}/^{16}\text{O}$) in the biogeochemically most relevant molecules like H_2O , CO_2 , CH_4 , and N_2O [17.2–5], but also in more rare atmospheric trace substances such as ozone (O_3) or molecular hydrogen (H_2) [17.6–8]. Isotopic fractionation of various processes can be measured in nature or in the laboratory, and may be uniquely associated with one particular process, leaving a so-called fingerprint on the isotope ratio of the molecules involved [17.1]. For example, CO_2 released from ocean surface water is about 16‰ more enriched in the rare ^{13}C isotope than CO_2 respired from the roots or leaves of a tree [17.9]. Also in the case of CH_4 , its production by incomplete combustion car-

ries almost the same isotopic signature as the originally burned carbon, and is thus about 40‰ more enriched in ^{13}C than CH_4 originating from anaerobic decomposition of organic material, e.g., in wetlands [17.10]. As emissions from various sources (and removal by fractionating sinks) cause not only concentration changes but also leave measurable isotopic signals in the atmosphere, the measurement of trace gases' isotopologues, in combination with their concentration measurement in the atmosphere, thus allows for insights into the relevant exchange processes and sometimes even provide quantitative information on their different source components (see Sect. 17.8).

17.1 Measurement Principles and Parameters

Differences in the isotopic composition of natural samples are normally small, i.e., on the order of a few percent; therefore, isotope ratios (R) are measured and reported relative to internationally agreed standard material in the so-called delta notation [17.1],

$$\delta = \frac{R_{\text{Sample}} - R_{\text{Standard}}}{R_{\text{Standard}}} \quad (17.1)$$

with, for example $^2\text{H}/^1\text{H} = ^2R$, $^{13}\text{C}/^{12}\text{C} = ^{13}R$, and $^{18}\text{O}/^{16}\text{O} = ^{18}R$. ^2H is commonly called *deuterium*.

The term δ is most often expressed in per mille. Here, ^2H , ^{12}C , etc. are atom concentrations rather than molecule concentrations. The international standard for hydrogen and oxygen isotope ratios is the Vienna Standard Mean Ocean Water (VSMOW), while for carbon

it is the Vienna Pee Dee Belemnite (VPDB) [17.1] carbonate. All laboratories report their data relative to these standards in order to be comparable to each other. The delta notation is written as the δ symbol followed by the rare isotope, for example $\delta^{18}\text{O}$ for the relative deviation of an $^{18}\text{O}/^{16}\text{O}$ ratio from the VSMOW standard. The substance containing the isotopic composition is often appended to the delta notation, either with a hyphen, e.g., $\delta^{18}\text{O}-\text{H}_2\text{O}$, or in parentheses, e.g., $\delta^{18}\text{O}(\text{H}_2\text{O})$. The hyphen notation is used throughout this chapter.

The classical way to measure isotope ratios is by isotope ratio mass spectrometry (IRMS) [17.20] see Table 17.1. For mass spectrometer (MS) analysis of the isotope ratios in atmospheric carbon dioxide, CO_2 has to be quantitatively separated from the air sample. This

Line strengths are in absorbance units (cm^2 per molecule cm^{-1}), adjusted for the natural abundance of each isotopologue. The y-axes scale with the isotopologue abundance ratios. Possible lines for laser spectroscopy are indicated by *arrows* (after [17.19] with permission from Elsevier)

is done either cryogenically or by gas chromatography. The CO_2 sample is then injected into the ion source of the mass spectrometer, ionized, accelerated, and separated in a magnetic field, with the separated ion beam currents of the different isotopologues measured with three Faraday cups, i.e., for mass 44, 45 and 46 [17.1].

Stable isotope measurements in water vapor by IRMS require preprocessing, firstly as water is condensable and very sticky, sitting as thin films on instrument walls, and secondly as the relevant masses of water overlap with those of oxygen atoms (^{18}O), e.g., originating from traces of dissociated molecular oxygen. The oxygen isotopic composition is often measured via equilibration of the water with CO_2 , measuring then the isotopic composition of CO_2 as above. The water is catalytically reduced to hydrogen gas for hydrogen isotopic measurements using a separate MS with Faraday cups for masses 2 and 3. Therefore, particularly in the case of water isotopologues, optical systems that directly measure both oxygen and hydrogen isotopic compositions create new possibilities to study this important greenhouse gas in the climate system.

Mass spectrometry measurements of the stable isotope ratios in atmospheric methane are often done by separation and preconcentration of CH_4 from other air

constituents and subsequent oxidation of CH_4 to CO_2 and H_2O . Carbon dioxide can then be measured directly in the mass spectrometer while water is reduced to hydrogen before it is injected into the ion source of the mass spectrometer (Sect. 17.2.2).

Optical spectroscopy measurements of isotope ratios use the fact that isotopologues have different characteristic absorption spectra due to small differences in the infrared (IR) rotational–vibrational energy states (see Fig. 17.1). The ratios can thus be measured directly in an air sample without preprocessing, given that the potential overlap of their spectra with those of other trace substances can be corrected for (most prominently absorption lines of water vapor). For CO_2 and CH_4 detection, air samples are therefore most often dried before analysis. Some instruments also measure samples at reduced pressure to limit pressure broadening of the absorption lines. Two principally different methods are in use: Fourier transform infrared spectroscopy (FTIR) and laser-based systems (see also Chap. 28). FTIR uses an infrared light source covering the important range of greenhouse gas (GHG) absorption lines (i.e., from 2000 to 4000 cm^{-1}). An alternative method uses laser systems specifically tuned for the absorption lines of the species to be detected.

17.2 History of Stable Isotope Measurements in Atmospheric CO₂, CH₄ and H₂O

One can determine the source/sink strength of a trace gas when measuring its atmospheric abundance. The atmosphere, however, integrates different sources and sinks and only the net flux density can be determined. The fluxes to and from the atmosphere carry isotopic signatures. This can help disentangle the individual sources and sinks if their isotopic signatures are distinct. A famous example uses the ¹³C-isotopic composition of atmospheric CO₂ to determine ocean versus land uptake of carbon (Sect. 17.8).

17.2.1 Carbon Dioxide

The first systematic stable isotope measurements on atmospheric CO₂ were published by *Charles David Keeling* (1928–2005) in 1958 [17.3]. Carbon dioxide from flask air samples were extracted cryogenically and then measured directly by IRMS. Following this work, isotope measurements were extended to the entire global flask sampling network of the Scripps Institution of Oceanography (SIO). The carbon isotope data provided important new insights into the global distribution of atmospheric CO₂ sources and sinks [17.21–23]. Following that pioneering work, the Commonwealth Scientific and Industrial Research Organisation (CSIRO), the National Oceanic and Atmospheric Administration/Global Monitoring Division (NOAA/GMD), and other groups world-wide extended these flask observations at globally distributed background stations [17.24, 25]. Air drying was introduced, which is essential for maintaining the original CO₂ oxygen isotope ratio in the sample. Now the ¹⁸O isotopic signals can also be used for carbon cycle investigations [17.26–30]. Routine analysis of stable isotope ratios in atmospheric CO₂ from flask samples still uses similar extraction and IRMS analysis methods [17.31–33]; however, sample sizes are now reduced to a few hundred milliliters of air, and extraction and analysis systems in the lab are automated in order to allow for effective measurement of thousands of samples per year from globally distributed networks. Additionally, the newly established European Integrated Carbon Observation System Research Infrastructure (ICOS RI) atmospheric station network uses this methodology for flask analysis [17.32].

17.2.2 Methane

Early stable isotope observations in atmospheric CH₄ are from the 1980s [17.5, 34–37]. They provided important new insights into the relative contributions of natural and anthropogenic sources to the global budget of atmospheric CH₄ [17.10, 38].

Due to the low atmospheric abundance of CH₄, precise measurements in the past used large sample volumes (i.e., CH₄ from several hundreds of liters of air), and special care was needed to fully separate CH₄ from other carbon-containing gases, such as CO₂ and CO, but also trace amounts of hydrocarbons. The purified and preconcentrated CH₄ then had to be converted to CO₂ and H₂O with H₂O being further reduced to H₂ for IRMS measurements [17.37, 39]. An alternative way to extract the hydrogen from CH₄ for IRMS measurement is by pyrolysis [17.32]. As an optical detection method, a tunable diode laser absorption spectrometer was introduced by *Bergamaschi* et al. in the 1990s [17.40] to analyze ¹³C and ²H directly on purified and preconcentrated CH₄ samples without the additional step of conversion to CO₂ and H₂. In particular for $\delta^2\text{H-CH}_4$ this system yielded more precise measurements than IRMS [17.40]. Today, due to the development of continuous-flow mass spectrometry, much smaller sample amounts of a few 100 mL are needed for precise measurements of both stable isotopes in CH₄, so that $\delta^2\text{H-CH}_4$ trends in the atmosphere also become available [17.32, 39, 41–43].

17.2.3 Water Vapor

Atmospheric water vapor stable isotope measurements were traditionally conducted cryogenically on samples collected in-situ [17.44, 45]. As for CO₂ and CH₄, extraction from ambient air must be quantitative in order to avoid isotope fractionation. This is particularly important when sampling in cold areas with ambient dewpoints well below 0 °C. Not much systematic data on water vapor exists in the literature, due to the fact that information on the global water cycle can more readily be obtained from precipitation samples [17.46], which are much easier to collect, e.g., by rain collectors carefully avoiding evaporation [17.47]. Since very sensitive optical systems have recently become available, new systematic quasicontinuous observational records of water vapor isotopologues are established [17.48].

17.3 Theory

The traditional methodology for isotope analysis was by isotope ratio mass spectrometry, which requires the pure substance (CO_2 , CH_4 , H_2O , and others) to be separated from the air sample and, for CH_4 and H_2O , transformation into a measurable molecule, such as CO_2 or H_2 before injection into the mass spectrometer. Respective fractionation-free sample preparation was, therefore, often the most demanding part in the analysis system. Since optical methods have become more sensitive and substance-specific, care has to be taken to avoid spectral interference with other species. For gases with very low abundances, there is also the need for pre-concentration of the component in the sample to be analyzed. Entire analysis systems including sample preparation will be presented in Sect. 17.4. Here we first describe the fundamental background of the different detection systems for atmospheric isotopologue measurements that have been published and are currently in use.

17.3.1 Isotope Ratio Mass Spectrometry (IRMS)

As mentioned earlier, only $\delta^{13}\text{C}\text{-CO}_2$ and $\delta^{18}\text{O}\text{-CO}_2$ can be measured directly on pure CO_2 extracted from whole-air samples. Three Faraday cups are used in the spectrometers, one for collecting mass 44 ($^{12}\text{C}^{16}\text{O}_2$) ion beams, one for mass 45 ($^{13}\text{C}^{16}\text{O}^{16}\text{O}$, $^{12}\text{C}^{16}\text{O}^{17}\text{O}$) and one for mass 46 ($^{12}\text{C}^{16}\text{O}^{18}\text{O}$, $^{13}\text{C}^{16}\text{O}^{17}\text{O}$, $^{12}\text{C}^{17}\text{O}^{17}\text{O}$). Since mass 45 and mass 46 ion beams both contain a mixture of two and three isotopologues, respectively, an assumption of a relation between $^{18}\text{O}/^{16}\text{O}$ and $^{17}\text{O}/^{16}\text{O}$ in ambient samples must be made [17.20]. This is done by assuming that the ratio is only modified by mass-dependent fractionation during related exchange and transformation processes. This then allows for the estimation of accurate $^{13}\text{C}/^{12}\text{C}$ and $^{18}\text{O}/^{16}\text{O}$ ratios of CO_2 . Different correction functions have been suggested ([17.49] and references therein) and were implemented in IRMS software/programs used in individual laboratories, which can lead to biases between measurements in different laboratories that potentially exceed repeatability errors achieved by modern IRMS analytics.

Moreover, when CO_2 is extracted cryogenically at -196°C (with liquid nitrogen) from ambient air samples, atmospheric N_2O is trapped together with the CO_2 and respective N_2O ions generated in the MS ion source are collected on the mass 44 ($^{14}\text{N}_2^{16}\text{O}$) and mass 45 ($^{15}\text{N}^{14}\text{N}^{16}\text{O}$) Faraday cups. This interference also needs to be corrected for; it requires measurement of the N_2O ionization efficiency in the ion source of the IRMS used [17.50].

The $^{17}\text{O}/^{16}\text{O}$ ratio in atmospheric CO_2 (and water) samples, although at first glance assumed to have a fixed relation to its $^{18}\text{O}/^{16}\text{O}$ ratio (see above), has been shown to be anomalously enriched in the stratosphere, due to mass-independent photochemical reactions [17.51]. The measurement of the $^{17}\text{O}/^{16}\text{O}$ ratio of CO_2 , however, requires chemical transformation of the oxygen in the CO_2 , due to the overlap at mass 45 with the relatively large signal of $^{13}\text{CO}_2$. Note that the typical $^{13}\text{C}/^{12}\text{C}$ ratio of CO_2 is on the order of 1%, while the $^{17}\text{O}/^{16}\text{O}$ ratio is only $\approx 0.04\%$. In some applications, the oxygen is fully extracted from the CO_2 [17.52, 53] and then measured as O_2 by IRMS. Alternatively, the $^{17}\text{O}/^{16}\text{O}$ ratio of the CO_2 is modified by isotope exchange with water to a known value to allow for the correct determination of the $^{13}\text{C}/^{12}\text{C}$ ratio of the sample (that stays unchanged during the oxygen equilibration reaction). The $^{17}\text{O}/^{16}\text{O}$ ratio of the original sample can then be determined from the original measurement [17.54, 55].

Quasicontinuous CO_2 isotopologue measurements can be conducted when the mass spectrometer is coupled with a gas chromatograph that separates CO_2 from the ambient air (and N_2O) and subsequently injects the CO_2 peak into the MS [17.56]. This methodology, continuous-flow isotope ratio mass spectrometry (CF-IRMS), although less precise than offline extraction and IRMS analysis, has been applied in the field, for example to study CO_2 exchange processes in ecosystems [17.11].

Mass spectrometric analysis of stable isotopes in atmospheric water vapor (and precipitation) requires well-established preprocessing of the (cryogenically) collected samples. For the ^{18}O isotope ratio, the water sample is equilibrated at a predefined temperature with CO_2 , which is then measured by IRMS. As discussed above for CO_2 , the measurement of ^{17}O on water samples by IRMS is not possible solely via CO_2 equilibration due to mass interference with $^{13}\text{C}\text{-CO}_2$, and this also requires particular preprocessing [17.57]. For hydrogen isotope analysis, the water is catalytically reduced to hydrogen gas, which can then be measured by IRMS on two Faraday cups, one for mass 2 (H_2) and one for mass 3 ($^1\text{H}^2\text{H}$). The measurement is complicated by the fact that in the ion source, H_2 combines with one H^+ and forms an H_3^+ ion, thus contributing to the mass 3 ion beam. A respective instrument-dependent correction needs to be made to account for this effect [17.1].

The development of CF-IRMS has greatly improved the measurement capacity of methane isotopologues [17.32, 42, 43, 58, 59]. Compared to former off-line extraction and preconcentration systems, this methodology requires a smaller sample size and allows automation to be run autonomously in the field [17.18].

Still, the preconcentrated and cryo-focused CH_4 samples need to be converted to CO_2 and H_2 in order to be measured by IRMS.

17.3.2 Optical Methods

The different isotopologues of gaseous species have different absorption lines in the infrared. Hence, one measures absorption strengths at specific wavelengths for heavy and light isotopologues. There are currently two measurement principles in use, either using monochromatic light specific to the species of interest (tunable diode laser absorption spectroscopy, quantum cascade laser absorption spectroscopy, cavity ring-down spectroscopy, off-axis integrated cavity output spectroscopy, difference frequency generation laser spectroscopy), or a broadband light source that passes an interferometer analyzing all wavelengths (Fourier transform infrared spectroscopy).

Tunable Diode Laser Absorption Spectroscopy (TDLAS)

Light in tunable diode laser absorption spectroscopy (TDLAS) comes from tunable diode lasers, which are the most common type of lasers produced. They are semiconductor devices similar to well-known light-emitting diodes. The diode lasers can be tuned by changing the temperature of operation or by changing gain current. The latter allows tuning only in a limited range of only a few cm^{-1} but this can be achieved quickly and with step sizes $< 0.01 \text{ cm}^{-1}$. Different trace gases therefore need different diode lasers because their absorption bands are too far apart. Different absorption bands of isotopologues, however, can be close together so that a small tuning range is sufficient. TDLAS thus tunes its laser through its narrow wavelength range, sampling the absorption spectrum along the wavelengths [17.60] (see Fig. 17.1 for suitable spectral ranges for CH_4 and CO_2 isotope analysis). To limit pressure broadening of the absorption lines, and hence overlap of the lines of the different isotopologues, most systems reduce pressure in the sample gas cell. But, absorption strength depends on the amount of gas the light passes through, which is much less in reduced pressure. These systems therefore use multipass cells, such as White or Herriott cells, where light gets mirrored multiple times, effectively increasing the path length of the light beam through the sample gas by about two orders of magnitude.

Quantum Cascade Laser Absorption Spectroscopy (QCLAS)

Quantum cascade lasers (QCL) are a special kind of semiconductor laser where thin layers of semiconducting materials are periodically stacked. The emitted

wavelength does not depend on the band gap between conduction and valence band of the material, but rather on the physical layer thicknesses. Quantum cascade lasers can therefore be produced for a large variety of wavelengths but also having several emission lines with the same laser system. Using external cavities with later diffraction gratings makes QCLs highly tunable [17.61]. One electron, transitioning from the conduction band to the valence band, can emit more than one photon in QCLs because of the layered organization. QCLs can hence produce higher output powers than laser diodes. Both, the highly tunable wavelengths and the high power output make QCLs very popular in currently available laser spectrometers [17.62].

Cavity Ring-Down Spectroscopy (CRDS)

Cavity ring-down spectroscopy (CRDS) differs from the above absorption techniques in that it uses a time-based measurement rather than an intensity-based measurement. External cavities are used with most absorption spectroscopies. While most systems use multipass cells, extending effective path length by about two orders of magnitude, one can also use resonance cells that have much higher reflectivity, extending the effective path length by about four orders of magnitude. Traditional absorption spectroscopy measures the attenuation of the incident signal given a known path length. CRDS, on the other hand, measures instead the time it takes that a pulsed signal gets attenuated to a threshold level inside the cavity, the so-called ring-down time. This time is in the order of microseconds and depends on the resonance cavity and the amount of trace gas in the cavity (Fig. 17.2). By pulsing different wavelengths with tunable lasers, one samples the wavelengths of the different isotopologues and thus determines their concentrations [17.63]. Laser systems can be any tunable system such as the above diode lasers or quantum cascade lasers used in pulsed mode.

Off-Axis Integrated Cavity Output Spectroscopy (OA-ICOS)

Similar to QCLAS, OA-ICOS uses continuous-wave mid-IR quantum cascade laser absorption spectroscopy. However, the laser enters the measurement cell at an off-axis angle in OA-ICOS, causing excitation of many transverse modes of different orders and a more efficient averaging of the cavity output, thus improving sensitivity through reduced noise [17.65]. Compared to CRDS, OA-ICOS is orders of magnitude less sensitive to internal alignment due to its geometry. Extremely long pathways (kilometers in a cell of a few centimeters length) through multireflection between the two mirrors of the cavity result in high detection sensitivity and precision. OA-ICOS can be operated at any wavelength

Fig. 17.2a,b Measurement principle of cavity ring-down spectroscopy (CRDS). For each wavelength of the absorption line selected by the wavelength monitor (a), the time development (decay time, (b)) of the beam intensity in the cavity after multireflection is measured (Fig. 17.6). This decay time on the order of microseconds depends on the trace gas concentration in the cavity. The area under the absorbance curve (a) is proportional to the trace gas concentration (after [17.64] with permission from Picarro)

from UV through IR, allowing detection of many different trace gas species and their isotopic ratios.

Difference Frequency Generation (DFG) Laser Spectroscopy

The DFG laser spectrometer of Thermo Fisher Scientific utilizes a simple multipass cell design and laser radiation covering the strong absorption bands in the mid-IR [17.65, 66] (i.e., $2310.1\text{--}2311.0 \text{ cm}^{-1}$, Fig. 17.1). Mid-IR laser radiation is produced by difference frequency generation (DFG) where the beams of two laser diodes are introduced into a nonlinear crystal made from periodically poled lithium niobate (PPLN), generating emission of wavelengths that correspond to the difference of the two fundamentals. One laser is frequency-stabilized, while the other is a tunable distributed feedback laser that is used to tune the difference frequency, in order to cover the spectral range of $2310.1\text{--}2311.0 \text{ cm}^{-1}$. The laser light then enters a multipass cell where it is reflected between two curved mirrors yielding a total effective optical path length of $\approx 5 \text{ m}$. The laser scans over the absorption lines at 500 Hz and the signal is averaged over 1 s before the absorption spectrum is fitted and isotope ratios are calculated from the spectrum fit [17.67].

Fourier Transform Infrared Spectroscopy (FTIR)

Instead of single-wavelength tunable lasers, Fourier transform infrared (FTIR) spectroscopy uses the broadband infrared (IR) radiation from a blackbody light source that covers the entire IR spectrum. The FTIR

uses a Michelson interferometer where the beam of radiation, after having passed the absorption cell, is split with one part directed to a fixed and the other to a movable mirror, introducing a path length difference between the two beams. After recombination of the reflected beam parts, an interference pattern of intensity, depending on the position of the movable mirror is observed at the detector; this is called interferogram [17.14, 68, 69]. Thus, instead of stepwise changing the wavelength of the light source to analyze the transmitted spectrum that has passed the sample cell, the transmission spectrum is calculated via Fourier transformation from the measured interferogram. This way FTIR spectroscopy principally covers the entire mid-infrared (MIR) spectrum of the blackbody light source, where the strong fundamental rotation–vibration bands of many important greenhouse gases, such as H_2O , CO_2 , CH_4 , and N_2O are located. If the interferometer has sufficient resolution to distinguish overlapping absorption bands (e.g., $\leq 0.01 \text{ m}^{-1}$), gas concentrations of several trace gases and, in the case of H_2O and CO_2 also some of their isotopologues, can be measured simultaneously [17.14]. A typical transmission spectrum from an FTIR spectrometer is shown in Fig. 17.3. The relatively weak absorption signals due to the blackbody radiation source being less bright than that of a laser is counteracted by using long multipath sample cells in the interferometer. Precision is also improved by including many absorption lines of the analyzed species. The obtained transmission spectrum is evaluated by a fitting algorithm that calculates

Fig. 17.3 Mid-infrared absorption spectrum of clean air in a 24 m FTIR multipass cell. *Brown:* undried air, *black:* dried air. Positions of main absorption bands of H₂O, CO₂, CH₄, CO, and N₂O are indicated by *horizontal lines* (after [17.14] © D. W. T. Griffith et al., licensed under CC-BY)

the specific absorption coefficients of the different gas components in the sample. Using the individual characteristic absorption bands of the gases (taken from the HITRAN database [17.70]) the algorithm generates a theoretical spectrum based on estimated concentration

values. It then recalculates the concentration values in an iterative way until the best fit to the measured spectrum is achieved [17.71] to determine the final GHG concentrations.

17.4 Devices and Systems

While prototypes of the above-described instrumentation were developed in various research institutions, measurement systems are now commercially available from a number of specialized companies. In many cases, air intake pumping and drying systems are already included in these off-the-shelf devices. Often, however, modifications are introduced by users to reach the required high precision for continuous atmospheric observations. Here we describe some of these dedicated devices, which have been recently or still are successfully applied in the field.

17.4.1 Continuous Isotope Observations with Tunable Diode Laser Absorption Spectroscopy

Tunable diode laser absorption spectroscopy (TDLAS) has been used for trace gas measurements since the late 1980s [17.72, 73]. A classic design of a compact, robust and portable TDLAS monitor was introduced by *Edwards et al.* [17.74] and is now commercialized by Campbell Scientific, Inc., Logan, UT, USA. *Bowling et al.* [17.75] describe the first generation of

Campbell's so-called trace gas analyzer (TGA) and its modifications for atmospheric isotope measurements (Fig. 17.4).

The tunable diode laser is controlled simultaneously for temperature and current to produce a linear wavelength scan centered around single selected absorption lines of the isotopologues of the target gas. The original lead-salt diode lasers needed strong cooling, most often with liquid nitrogen that needed refilling as much as twice per day at the beginning (1993) down to once per week with the TGA200 in 2008. A new room-temperature thermoelectrically cooled interband cascade laser has been used since 2014, making the TGAs more autonomous instruments. The laser beam is split passing through single-pass reference and sample cells. Single-pass cells are chosen to avoid alignment and contamination problems associated with multipath absorption cells. A prepared reference gas having a known composition is flown through the reference cell. The reference signal provides a template for the shape and position of the absorption spectrum, avoiding the need for precise temperature and pressure measurements in the sample cell.

Fig. 17.4 Diagram of Campbell's TGA100 tunable diode laser absorption system (after [17.75] with permission from Elsevier)

17.4.2 High-Resolution Isotope Observations with Quantum Cascade Laser Absorption Spectroscopy

Laser absorption spectroscopy can use principally any laser that can be tuned over a certain wavelength. Popular devices using pulsed quantum cascade lasers (QCL) are the so-called laser trace gas monitors of Aerodyne Research, Inc., Billerica, MA, USA (Fig. 17.5). A key feature of these instruments is a dual-path multipass cell. This is an astigmatic Herriott cell, where the path length depends on the angle the beam enters the cell [17.76]. The ratio of the path lengths is chosen to be similar to the abundance ratio of the different isotopologues, yielding similar absorption depths for both isotopologues [17.19]. For carbon dioxide, the two paths correspond to 2 (e.g., $^{12}\text{CO}_2$) and 174 (e.g., $^{13}\text{CO}_2$) passes within the cell of 0.32 m length. Hence, temperature and pressure are identical for both measurements, i.e., the major and minor isotopologue, because the two measurements are simultaneous within the same cell. Absorption lines are chosen so that they can be detected within a single spectral scan (over 0.5 cm^{-1}) obtained by a current ramp, which modulates laser temperature and thus its spectral frequency. Differences in absorption spectra due to pulse-to-pulse energy variations are reduced by normalizing the pulses via a special reference path within the optical base (Norm. path in Fig. 17.5). Very short pulses ($\approx 10\text{ ns}$) are used to minimize linewidth, but linewidth and associated line shape stability remain precision limiting issues.

The laser trace gas monitors also exist with two QCLs working in parallel. It takes advantage of the astigmatic Herriott cell, which can have not only two but multiple path lengths. The two lasers sweep over two different wavelength ranges, using different angles of attack on the sample cell, which implies different

path lengths within the cell. This allows, for example, measuring methane and carbon monoxide simultaneously, using transitions at 1271 and 2180 cm^{-1} , respectively [17.78].

17.4.3 Stable Isotope Observations with Cavity Ring-Down Spectroscopy

The most common instrument measuring stable isotope ratios with cavity ring-down spectroscopy (CRDS) are manufactured by Picarro, Inc., Santa Clara, CA, USA ([17.12], Fig. 17.6). They use a patented wavelength monitor, which is used threefold:

- (1) It monitors the wavelength from the incoming laser
- (2) It locks the laser to the wavemeter, and
- (3) It can be tuned to different wavelengths, hence actively scanning the absorption line (Fig. 17.2a).

The near-IR laser diode is tuned by changing its drive current and temperature. The relationship between current and wavelength is, however, not stable over time and between individual lasers, which is solved by using the wavelength monitor. The Picarro CRDSs use a ring resonator, i.e., a three-mirror cavity (triangular, Fig. 17.6) resulting in a traveling wave compared to standing waves in two-mirror cavities, providing better signal-to-noise ratio. The cavity is temperature-stabilized to within 20 mK, using active and passive thermal stabilization. The instrument further controls the pressure in the sample cell to within 5 Pa around its nominal pressure of $\approx 187\text{ hPa}$. The stabilization of wavelength, temperature, and pressure allows for precise measurements of isotope ratios [17.15] down to $\approx 0.02\text{ ‰}$ in water and 0.1 ‰ in CO_2 for averages over a few minutes (Table 17.4).

17.4.4 Continuous Atmospheric $^{13}\text{C}\text{-CO}_2$ Observations by Fourier Transform Infrared Spectroscopy

After development and publication of a new in-situ FTIR system for precise greenhouse gases concentration and CO_2 (and H_2O) isotopologue measurements by Griffith et al. [17.14], a FTIR system was installed and is still continuously run at the Institut für Umweltphysik, Heidelberg University, to analyze ambient air

on the University campus in Heidelberg, Germany. This system has been slightly modified for better pressure and flow stabilization in the cell and is further equipped with additional air intakes for calibration gases and for regular measurement of so-called target gases for quality assurance [17.79] (Sect. 17.6). A schematic of the Heidelberg in-situ FTIR system is displayed in Fig. 17.7. Ambient or tank air is admitted via a multiport selection valve with the flow rate being stabilized by a mass flow controller (MFC). The sample air then

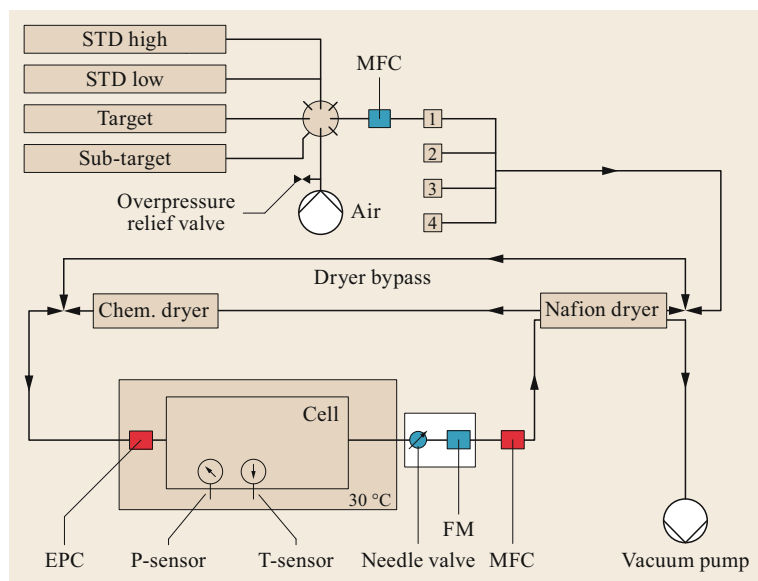

Fig. 17.7 Schematic setup of the in-situ FTIR analyzer of Hammer et al. [17.79]. The blue parts of the original setup of Griffith et al. [17.14] have been replaced with the red parts in the final setup. The modifications include mass flow controllers (MFC) and electronic pressure controllers (EPC) and replace the original needle valve–flow meter (FM) unit (after [17.79] © S. Hammer et al., licensed under CC-BY)

passes a Nafion predrying unit (operated in counter flow mode) and is further chemically dried to an H₂O vapor pressure of < 4 ppm. Excellent drying is necessary to avoid too much overlap of water vapor absorption bands with those of the trace GHGs and CO₂ isotopologues to be monitored (Fig. 17.3). The dry air then passes the 3.5 L multipass cell with 24 m optical path length. An electronic pressure controller at the inlet together with a second MFC at the outlet of the cell keep pressure constant at a slight over-pressure above ambient. A vacuum pump at the air outlet allows evacuation of the cell before admittance of tank air (calibration or target gases). This reduces flushing time of the cell and, thus, the amount of calibration gases needed to fully replace the air of the rather large cell volume (3.5 L). The multipass cell itself is equipped with an in-situ PT100 resistance temperature detector as well as with a pressure sensor. The housing of the cell including the interferometer (IRCube, Bruker Optics, Germany) is temperature stabilized to better than ± 0.1 °C and is permanently flushed with high-purity nitrogen (99.999%) to avoid absorption of GHGs between cell and interferometer.

After modification, Hammer et al. [17.79] performed careful characterization of the entire in-situ FTIR system, including determination of the instrument response function as well as residual interspecies cross-sensitivities. These effects stem from incomplete separation of partly overlapping absorption bands due to imperfect spectral information in the HITRAN [17.70] database as well as from imperfect fitting routines. Further, sensitivity towards residual temperature and pressure variations, i.e., imperfect determination of the sample density in the cell, but also imperfect infor-

mation on these parameters in the HITRAN database determining the line shape required for fitting were determined. Cross-sensitivities turned out to be relevant for CO₂, ¹³C-CO₂, and N₂O, and need to be corrected for if the interlaboratory compatibility goals agreed on by WMO experts (Table 17.3) shall be reached. The instrument was proven to be linear for all GHGs and ¹³C-CO₂ in their ambient air ranges.

The short-term stability of all components was tested with tank air and turned out to be excellent, i.e., reaching the WMO compatibility goals for all GHGs mole fractions and the extended WMO compatibility goal for $\delta^{13}\text{C-CO}_2$ [17.80]. A weekly calibration frequency of the instrument was recommended. $\delta^{18}\text{O-CO}_2$ measurements in ambient air turned out to be possible too, as was shown in a subsequent study by Vardag et al. [17.17]. However, the precision of $\delta^{18}\text{O-CO}_2$ of 0.2–0.3 ‰ turned out not to meet the WMO compatibility goals, neither for regional nor for background air (Table 17.3, from [17.80]).

The FTIR instrument originally developed by the University of Wollongong, Australia, is now commercially available through ECOTECH (Spectronus Trace Gas and Isotope Analyser). In order to reduce the amount of calibration gases, one of the major disadvantages of the instrument, the cell volume was reduced to 2.5 L and it is now manufactured from aluminum and internally gold coated. The latter is to reduce interaction of the measured gases with cell walls. Also, temperature measurement in the cell and its control in the housing was improved. Advantages and disadvantages of FTIR and the other instrumentation presented in this chapter are listed in Table 17.2.

Table 17.2 Comparison of the isotopologue measurement methods

Devices	Advantages	Disadvantages
Isotope ratio mass spectrometry (IRMS)	High sensitivity Applicable to all isotopologues	Pretreatment of air sample required Interfering masses Low temporal resolution
Tunable diode laser absorption spectroscopy (TDLAS)	Availability of wide range of lasers Precise and wide tuning High temporal resolution	Smaller output power than QCL thus less sensitive Some systems do not operate at room temperature
Quantum cascade laser absorption spectroscopy (QCLAS)	Precise tuning with external cavity and diffraction gratings High temporal resolution Large output power High mode purity and wavelength stability	Pulsed mode not optimal and under active development Higher noise thus less sensitive than OA-ICOS
Cavity ring-down spectroscopy (CRDS)	Large range of gas concentrations Insensitive to vibrations Measures and corrects for water vapor	Absolute value of laser wavelength needed Cavity sensitive to temperature and pressure Ring-down time limits sampling frequency Possible interferences of organic molecules
Off-axis integrated cavity output spectroscopy (OA-ICOS)	High sensitivity Large range of gas concentrations Precise beam alignment not critical	No quantitative information on precision and long-term stability available for isotopes in atmospheric CO ₂ and CH ₄
Difference frequency generation laser spectroscopy (DFG)	High precision if referencing is frequently performed Standard gas concentrations adjusted to measured concentration	Standard has different matrix gas than measured sample Frequent referencing strongly reduces time for ambient measurement Current systems have insufficient internal drying units (dewpoint > -20 °C) and not all sample ports are equipped with mass flow controllers
Fourier transform infrared spectroscopy (FTIR)	Many air components measured simultaneously Re-evaluation of spectra possible if interest in additional trace gas or if improved spectral information becomes available	Large sample cell requiring large amounts of sample and calibration gases Low temporal resolution Strong cross-sensitivities of many trace gases with water vapor, requires drying to < 8 ppm for precise measurement of GHGs other than H ₂ O

17.4.5 Atmospheric Observations of Methane Isotopologues by Continuous-Flow Mass Spectrometry in Comparison to Quantum Cascade Laser Absorption Spectroscopy

An interesting study, comparing atmospheric methane isotopologue observations by continuous-flow dual-isotope ratio mass spectrometry with optical measurements by QCLAS at the Cabauw meteorological tower in the Netherlands, has been published by *Röckmann et al.* [17.18]. Both systems use CH₄ preconcentration units but do not require liquid nitrogen, an important advantage for field applications.

Figure 17.8 displays the IRMS setup for $\delta^{13}\text{C}$ and $\delta^2\text{H}$ analysis of atmospheric CH₄, which is based on the integrated System for Analysis of Atmospheric Constituents (ISAAC) developed for flask sample analysis at the Max Planck Institute for Biogeochemistry (MPI-BGC) in Jena, Germany [17.32]. Predried air is collected either from an ambient intake line or from a reference gas tank and is pumped through a preconcentration trap filled with molecular sieve (HaySep D) and cooled down to a temperature below -132 °C.

For cooling, the preconcentration trap is mounted in a copper bloc, cooled with a Polycold compact cooler compressor (Brooks Automation Inc., USA). In the same device a focus trap is mounted. Preconcentration and focus traps can be kept at different temperatures to allow, for example, transfer of the sample from the preconcentration trap (then heated to -30 °C) to the focus trap (kept at below -132 °C).

After complete sample transfer to the focus trap, it is heated up to release the CH₄, which is then either passed on (with He as carrier gas) to a combustion oven, where CH₄ is oxidized to CO₂ and H₂O, then passed through a Nafion dryer for H₂O removal and further through a gas chromatographic column to eliminate interfering co-trapped krypton before it is injected into the MS (Delta plus XP, Thermo Fisher Sci.) for $\delta^{13}\text{C}$ analysis. For $\delta^2\text{H}$ analysis, the CH₄ sample is converted to H₂ and carbon in a pyrolysis tube furnace and, after passing a CarboPLOT column and a Nafion dryer, the H₂ is introduced into the MS for deuterium analysis.

The laser-based QCLAS system run at Cabauw in parallel to the IRMS system introduced above was described in detail by *Eyer et al.* [17.81]. The optimal con-

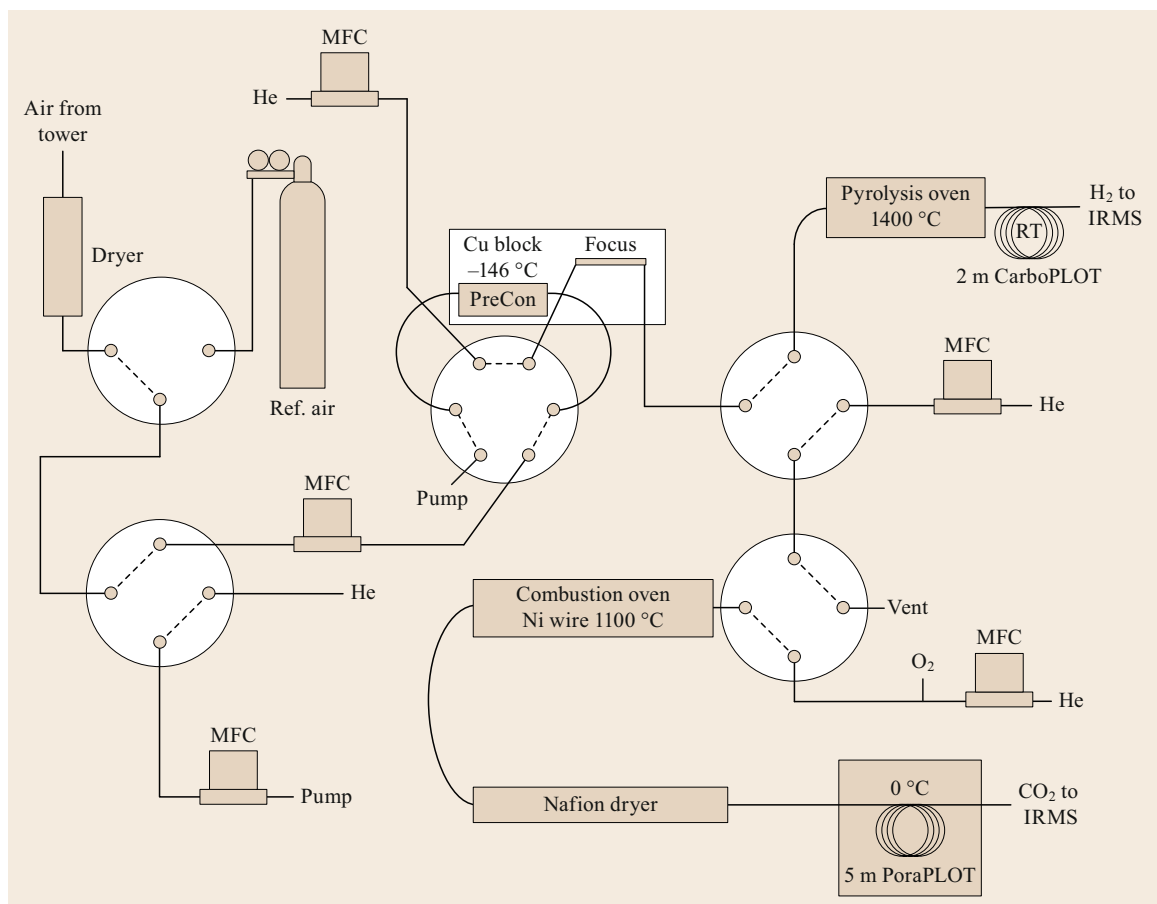

Fig. 17.8 Schematics of the pre-concentration and extraction system developed for the IRMS technique (after [17.18] © t. rückmann et al., licensed under CC-BY)

ditions for analyzing both stable isotope ratios of CH_4 with the commercially available quantum cascade laser system QCL-76-D (Aerodyne Inc., USA) at 20–60 hPa are at a mole fraction range of 600–1000 ppm CH_4 , requiring pre-concentration from ambient mole fraction by a factor of 300–400. A schematic of this trace gas extractor (TRES) is displayed in Fig. 17.9. Similar to the pre-concentration unit used in the IRMS setup above (Fig. 17.8), it requires cooling to very low temperatures. This is achieved with a Stirling cooler. The adsorption trap, filled with HaySep D to selectively retain CH_4 from the air sample, is cooled down to about -175°C (Fig. 17.9, left part) when attached to the copper plate while it gets warmed up stepwise after being detached from the cooler plate (Fig. 17.9, right part) for release of volatile bulk gases. When the temperature reaches -15°C , CH_4 also desorbs from the trap and is transferred to the previously evacuated cell of the QCLAS with synthetic air as purge gas. This process is finished when the pressure in the cell has reached ≈ 40 hPa; the

accumulated sample is then analyzed. The laser spectrometer is based on the QCL-76-D system (Aerodyne Res. Inc., USA) with an optical path length of 76 m and a cell volume of 0.5 L. Hardware electronics have been modified as described by Eyer et al. [17.81] in order to meet the required precision.

Comparability of isotopologue observations between the two systems when measuring ambient air at the Cabauw tower was restricted by lack of synchronization of the analysis cycles (84 min for the IRMS system and 54 min for the TRES-QCLAS system) and air sample integration periods, which were 10 min for the IRMS and 15 min for the TRES-QCLAS. The overall difference between the two systems (QCLAS – IRMS) was $(0.25 \pm 0.04)\text{‰}$ for $\delta^{13}\text{C}$ and $(-4.3 \pm 0.4)\text{‰}$ for $\delta^2\text{H}$. This is slightly outside the extended WMO compatibility goals for stable isotopes in CH_4 (compare Table 17.3) but demonstrates the current state-of-the-art ability of quasicontinuous ambient air CH_4 isotopologue measurements.

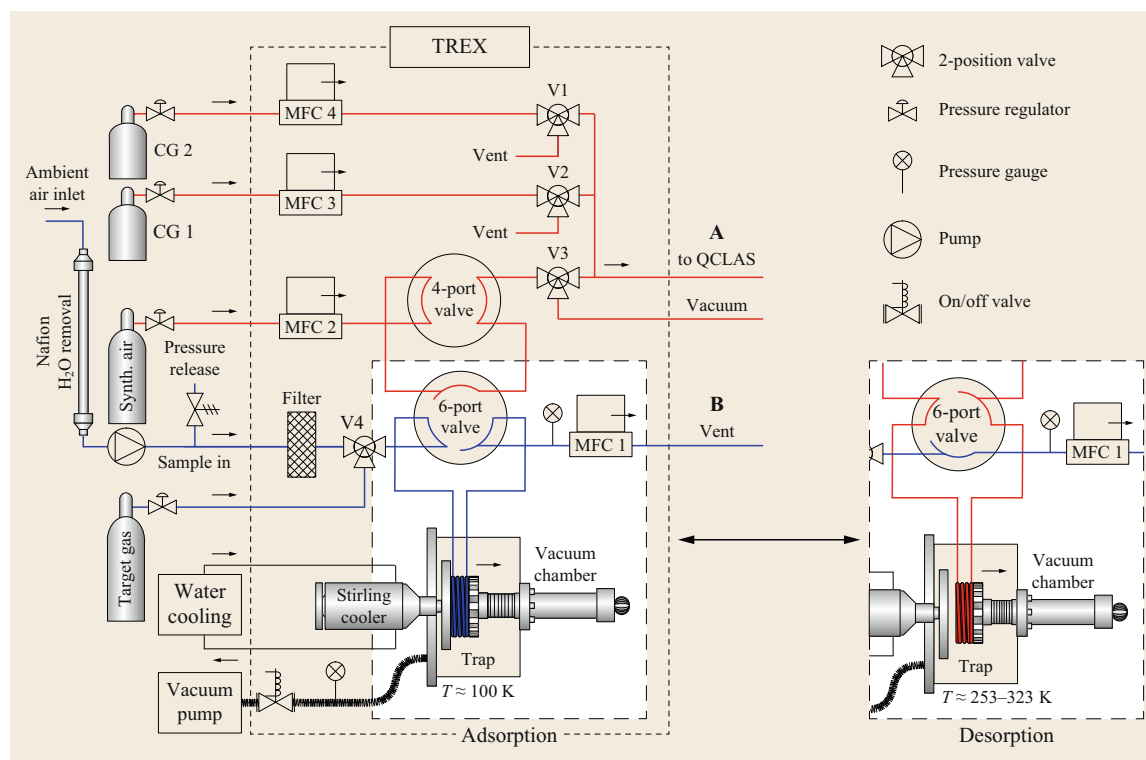

Fig. 17.9 Schematics of the preconcentration unit (TREX) used by Röckmann et al. [17.18]. The blue lines indicate the flow of sample air and target gas, i.e., ambient air CH_4 mole fractions, while red lines represent the flow of calibration gases and desorbed air, i.e., high CH_4 mole fraction (after [17.81] © S. Eyer et al., licensed under CC-BY)

Table 17.3 WMO recommendation for compatibility of measurements of GHGs [17.80]

Component	Compatibility goal 1-sigma	Extended compatibility goal ^{a)}	Range in unpolluted troposphere (approximately range for 2015)	Range covered by the WMO scale
CO_2 (ppm)	± 0.1 (NH ^{b)} ± 0.05 (SH ^{b)})	± 0.2	380–450	250–520
CH_4 (ppb)	± 2	± 5	1750–2100	300–5900
$\delta^{13}\text{C}-\text{CO}_2$ (‰)	± 0.01	± 0.1	–9.5 to –7.5 (VPDB)	
$\delta^{18}\text{O}-\text{CO}_2$ (‰)	± 0.05	± 0.1	–2 to +2 (VPDB-CO2)	
$\delta^{13}\text{C}-\text{CH}_4$ (‰)	± 0.02	± 0.2		
$\delta^2\text{H}-\text{CH}_4$ (‰)	± 1	± 5		

^{a)} Extended compatibility goal is provided as a guideline for studies in which the highest precision and accuracy is not required, for example a regionally focused study with large local fluxes, or services related to urban air quality.

^{b)} NH Northern hemisphere; SH Southern hemisphere.

17.4.6 Overall Evaluation of Available Isotope Measurement Systems

Thanks to the development of new optical instrumentation, precise quasicontinuous field observations of stable isotope ratios in atmospheric CO_2 , CH_4 , and H_2O have become possible. Some characteristics of different commercially available systems are listed in Table 17.2. Continuous isotope measurements are most relevant for

continental or regional applications, where the temporal variability of GHGs is large and where many different source components are associated with different catchments. In the case of CH_4 with atmospheric mole fractions of $< 2 \mu\text{mol mol}^{-1}$, preconcentration is necessary before analysis, which limits time resolution of observations. In some cases, e.g., with FTIR systems, relatively large cell volumes of more than 1 L are also limiting factors for the temporal resolution on one hand,

but also, for example, for their application on stations at tall towers, where fast switching through different levels is required to measure vertical profiles in the atmospheric boundary layer. Although absolute isotope

ratio measurements are principally possible with optical methods, frequent calibration against internationally agreed standards is important for accuracy and compatibility of observations (Sect. 17.6).

17.5 Specifications

Most optical systems have very short response times on the order of milliseconds. One can average several measurements to derive more precise estimations of concentrations. Hence, precision of the different measurement systems depends on the averaging time, which might be given by specific application requirements (high temporal resolution, e.g., for application of eddy-covariance techniques to calculate energy and matter fluxes, see Chap. 55). Atmospheric trace gas concentrations generally do not need temporal resolution of less than one minute and a large number of high-frequency observations can be averaged for more precise mean observations. The averaging time that leads to more precise observations might be limited due to instrument stability such as instrument drifts and temperature effects. This is often investigated with Allan–Werle plots (Fig. 17.10, for $\delta^{13}\text{C-CO}_2$ from [17.17]): the Allan variance (or Allan standard deviation) of the individual high-frequency observation in a certain averaging time interval is plotted against the length of the averaging time [17.82]. The minimum of this curve shows the maximal attainable precision. This is not to be mistaken as the accuracy of the observations. The precisions given in Table 17.4 depend on how the instrument is employed, and which averaging time the specific application demands. Resolutions are given approximately for the fastest instruments in the literature.

Some isotopic species such as deuterated methane are so rare that precise ambient air measurements require preconcentration systems (Sect. 17.4.5) [17.81]. This limits time resolution severely, particularly for continuous-flow IRMS, but even optical instruments might only give one observation per hour (Sect. 17.4.5).

As part of the WMO Global Atmosphere Watch GHG monitoring program (see also Chap. 63), WMO organizes, together with the International Atomic Energy Agency (IAEA), biennial meetings to review the scientific understanding of greenhouse gas sources and sinks, evaluate the network development, review the best practices for quality assurance and quality control, and examine data quality objectives and measurement techniques. The WMO regularly updates their recommendations based on the proceedings from these meetings as WMO Reports [17.80]. These recommen-

ations also include compatibility goals for the various GHGs and their isotopologues, to allow for merging data from different laboratories or networks for global or regional model evaluation. These goals mainly concern compatibility of observations in the background atmosphere where gradients from which, e.g., hemispheric source or sink strengths are deduced, are small (column 2 in Table 17.3). Compatibility goals are slightly relaxed for regional applications named *extended compatibility goal* and listed in column 3 of Table 17.3.

17.6 Quality Control

As noted above, the very low abundances of some GHG isotopologues and the small spatial and temporal variations of these abundances in the atmosphere require precise measurements. Moreover, data from different laboratories must be highly compatible in order to allow for combining them into global data sets for global GHG budgeting. Calibration relative to internationally agreed standard material as well as ongoing quality control measures are, thus, essential for meaningful data evaluation.

17.6.1 Calibration

As indicated in Sect. 17.1, none of the described instrumentation for stable isotope analysis in GHGs provides accurate absolute isotope ratios from which δ -values can be calculated. Therefore, all instrumentations need calibration gases, which are regularly analyzed to monitor accuracy and long-term repeatability. Depending on instrument response characteristics, two to four calibration points, covering the range of ambient air abundances, are regularly measured for calibration. In many cases, depending on the stability of the instrument, a working gas is frequently analyzed and used as an ongoing reference while the entire response curve for calibration is only measured once per week or even at lower frequency.

The primary standard material was internationally agreed upon during times when (precise) stable isotope measurements were exclusively made by IRMS. In the case of carbon isotopes, the VPDB carbonate standard has to be processed to yield pure CO₂ gas before being analyzed by dual-inlet mass spectrometry [17.20, 50]. Likewise, VSMOW standard water is equilibrated with CO₂ under preset stabilized conditions to allow analysis

as CO₂ gas by IRMS, which carries the ¹⁸O signal, or it has to be reduced to H₂ for deuterium analysis. In the case of CO₂, reference materials, which are linked to the primary scale, are available from the International Atomic Energy Agency [17.86, 87]. This allows for direct calibration of mass spectrometers without chemical processing of the primary carbonate standard VPDB.

As many laboratories in the world that contribute to the global network of atmospheric GHGs isotopologue observations do not have facilities for primary standard preparation, a Central Calibration Laboratory for consistent stable isotope calibrations for CO₂ was established at the Max Planck Institute of Biogeochemistry in Jena, Germany [17.88]. This laboratory provides CO₂-in-air gas mixtures, the so-called JRAS (Jena Reference Air Set) calibration gases that are directly linked to the international stable isotope scale (VPDB for $\delta^{13}\text{C}$) [17.80]. For stable isotopes in CH₄, no such central calibration laboratory currently exists. Laboratories performing these measurements thus have to establish and maintain their own internal standard scale. International compatibility of ambient CH₄ isotopologue measurements is thus not yet fully achieved. Comparison activities are conducted to determine scale offsets between laboratories [17.89] or co-located measurements are compared as an attempt to combine globally distributed observations, e.g., for global modeling efforts [17.90].

17.6.2 Cross-Sensitivities

Precision (and accuracy) may be limited due to the interference of GHGs absorption lines with those of water vapor or other atmospheric components. Moreover, GHGs concentrations are generally reported as mole fractions

Table 17.5 Maintenance of continuous isotopologue measurement systems

Maximum interval	Isotope ratio mass spectrometer (IRMS)	Laser systems (TDLAS, QCLAS, CRDS, OA-ICOS)	Fourier transform infrared spectroscopy (FTIR)
1 day	Full scale calibration of response curve	Target gas analysis for quality control (QC)	Target gas analysis for QC
1 week		Full scale calibration of response curve	Full scale calibration of response curve
1–3 month			Change of chemical drying agent Change of N ₂ flushing gas
1 year	Vacuum pump	Pump	Vacuum pump

in dry air. Therefore, sample air is often dried or corrections need to be made, e.g., based on the parallel analysis of water vapor (or other gases) in the sample air.

As line shape and gas concentrations strongly depend on temperature (and pressure), optical instruments are generally temperature stabilized, and cell pressures and flow rate are controlled (or at least continuously monitored for correction). Typical stabilization requirements are ± 0.01 °C for cell temperature, ± 0.01 hPa for cell pressure, ± 0.2 $\mu\text{mol mol}^{-1}$ for moisture level, and ± 0.01 slpm for sample flow rate. As the air matrix, i.e., the concentration of major air components such as nitrogen, oxygen, and argon, is important for calculating

line shapes, calibration gases need to have the same composition as the ambient air samples. Therefore, standards of artificial gas mixtures should be avoided as they may lead to considerable calibration biases.

17.6.3 Specific Quality Assurance Measures

To monitor the quality of the continuous measurements and the stability of the instrument response, analysis of a so-called target gas, e.g., once per day has been recommended [17.80]. The accuracy and the variability of the target gas results provides an important measure for uncertainty estimates of the ambient air data.

17.7 Maintenance

Instrumentation maintenance for stable isotope ratio measurements mainly involves regular calibration with frequency depending on the stability of the instrument response curve, which itself depends on parameters such as temperature and pressure stabilization in the cell. However, frequent calibration (or referencing) as found in the DFG system (Sect. 17.3.2), even though it has the advantage of avoiding cross-sensitivity or non-linearity over a large concentration range, may take up too much of the time for ambient measurements, in particular if high precision or accuracy are needed [17.66]. Besides temperature and pressure, atmospheric water

vapor is the most influential ambient parameter (if not to be analyzed itself as an unknown variable). To keep water vapor at a constant low level, the drying system requires maintenance such as manual change of cooling traps or drying agent. Furthermore, air pumping systems need to be regularly maintained and checked for leakages, and special care is required to keep all tubing air-tight and free of contamination (e.g., with room air).

In general, optical devices require less maintenance than, e.g., continuous-flow IRMS systems, and are thus often easier and maintained with less effort for continuous observation under field conditions (Table 17.5).

17.8 Application

As introduced in Sect. 17.2, isotopic observations of greenhouse gases can be useful for disentangling contributions of different sources to the total net flux, while the concentration signal or regional gradient alone provide only information on the total net flux.

Principally, two fluxes can be distinguished if their associated isotopic fluxes, so-called isofluxes, are different. The global net ocean and land fluxes of carbon,

for example, have similar magnitudes on the order of 2 Pg C a^{-1} . The ocean flux carries an isotopic signature of around -2% while the land flux is on the order of -18% , leading to very distinct isofluxes [17.91]. Another possibility for different isofluxes is that two large fluxes carry isotopic signatures that are not very different but still distinguishable. The large fluxes then amplify the little differences in the isotopic signatures.

This is the case for ^{18}O in atmospheric CO_2 , where the carbon gross fluxes photosynthesis and respiration are on the order of 100Pg C a^{-1} , globally, and have close isotopic signatures of 14‰ and 15‰, respectively [17.27, 92]. Hence, small variations in the large carbon gross fluxes will lead to rather large differences in the isofluxes of photosynthesis and respiration [17.30].

17.8.1 Ecosystem Observations

The ^{13}C isotopic signature of photosynthesis and respiration have pretty similar magnitudes because the respired CO_2 was fixed by photosynthesis. It was therefore argued that it is impractical to use $\delta^{13}\text{C}$ - CO_2 to determine photosynthesis and respiration separately [17.93]. The tremendous improvements in laser-based spectroscopy, however, have made it possible that one can actually use high-frequency observations of CO_2 together with $\delta^{13}\text{C}$ - CO_2 to disentangle photosynthesis and respiration from the observed net ecosystem exchange [17.94, 95].

$\delta^{18}\text{O}$ - CO_2 , on the other hand, has larger differences in the source signatures of photosynthesis and respiration than $\delta^{13}\text{C}$ - CO_2 . Measuring $\delta^{18}\text{O}$ - CO_2 was therefore projected to have a higher potential for determining the two gross biosphere fluxes [17.93] and the approach was pursued with traditional isotope analysis in the laboratory [17.96]. The enormous potential of in-situ laser-based spectroscopy of $\delta^{18}\text{O}$ - CO_2 has yet to be harvested because of the isotopic equilibration of CO_2 with water, and thus the convolution with a second isotopic cycle.

The water isotopes themselves were, however, used on an ecosystem scale to describe the water cycle in forest ecosystems [17.29, 97]. The isotopic compositions of water evaporated from the soil and transpired by plants are very distinct because evaporating water is fractionated while transpired water is not (in steady state) [17.98]. However, these assumptions have to be tested carefully in the ecosystem because the isotopes will otherwise overpredict the fraction of transpiration in the evapotranspiration signal [17.99]. The obligation to precisely measure two isotopic cycles might be the reason why the considerable potential of $\delta^{18}\text{O}$ - CO_2 has yet to be unleashed.

17.8.2 Atmospheric Observations

Monitoring of GHG isotopologues for global budgeting is still dominated by analysis of grab samples collected at remote stations in the marine realm and analysis in the laboratory at the highest possible precision (Sect. 17.5). Continuous measurements are more fre-

quently applied at continental stations, where the contributions from different regional sources (and sinks) in the immediate catchment shall be identified and quantified on the diurnal time scale, based on their different isotopic signatures.

Concerning atmospheric CO_2 , one important aim is to distinguish regional ecosystem CO_2 fluxes from those of fossil fuel burning. Both CO_2 source categories, ecosystem and fossil, are principally distinguishable by their $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ signatures [17.1, 100]. Using the Keeling plot approach [17.3, 101] (see also Chap. 56), their varying ^{13}C imprint on atmospheric CO_2 has, for example, been monitored via a significant seasonality of the mean $\delta^{13}\text{C}$ source signature at a polluted station in Germany [17.84]. However, when it comes to quantitatively separating the different source contributions, uncertainties are often large. This is because the fossil fuel and ecosystem CO_2 signatures partly overlap for $\delta^{13}\text{C}$ [17.84, 101]. Additional information might then be necessary such as given by the radioactive isotope ^{14}C [17.102]. For ^{18}O , although the fossil fuel CO_2 has a distinct imprint on the (regional) ^{18}O signature of atmospheric CO_2 [17.17, 103], isotopic equilibration of CO_2 with water reservoirs needs to be additionally modeled for any quantitative CO_2 budget [17.92, 96].

Concerning CH_4 , a number of different source categories, such as emissions from natural wetlands, agriculture, waste management, or energy production and distribution contribute to the continental and global atmospheric methane burden [17.104]. Their individual (regional) share is often mainly estimated from bottom-up inventories. Therefore, top-down source attribution from isotopic observations are a promising application of CH_4 isotopologue measurements [17.105, 106]. An open question concerns, e.g., the causes of the stagnation of the CH_4 concentrations after 1999, following its increase since preindustrial times due to increasing emissions from anthropogenic sources such as agriculture as well as energy production and distribution. Further, since 2006, CH_4 is increasing again at a rate similar to the 1990s. This development in the last two decades has not been fully understood because the CH_4 budget is still largely underconstrained if only $\delta^{13}\text{C}$ - CH_4 trends are taken into account [17.107–109]. More $\delta^2\text{H}$ - CH_4 measurements may help in solving this issue.

A recent proof-of-concept study in the Netherlands at the Cabauw tower site compared a continuous IRMS with a QCLAS-based technique (Sect. 17.4.5) and provided promising results for the regional scale that have a clear potential, together with regional modeling, to test the reliability of bottom-up emission inventories [17.18].

17.9 Future Developments

New and improved measurement techniques for combined ^{18}O and ^{17}O isotopes in CO_2 may allow estimates of carbon exchange fluxes with the biosphere [17.110, 111]: a small signal of the enrichment of rare oxygen isotopes in the stratosphere (due to mass-independent photochemical reactions) should be transferred to the troposphere. To which extent this signal is re-equilibrated with tropospheric water reservoirs, such as leaf water, depends on the gross CO_2 exchange with the terrestrial biosphere. Therefore, triple oxygen isotope observations in tropospheric CO_2 could potentially be used as a tracer for gross primary productivity, an important but not so well-known component in the global carbon cycle [17.110]. Some laboratories, e.g., [17.57] equilibrate CO_2 with water of known composition and then fluorinate CO_2 to produce O_2 . Measuring the masses 36, 37, 38 allows then for the determination of the $\delta^{17}\text{O}$ and $\delta^{18}\text{O}$ isotopic compositions. There are also first optical instruments that allow measuring both oxygen isotopes in CO_2 . Prototypes were delivered to research groups in 2017 and promise improved estimation of photosynthesis on regional scales.

Another interesting development is the measurement of so-called clumped isotopes, with the first optical instrument in its final development. Clumped

isotopes are, for example, double- or triple-substituted CO_2 molecules such as $^{13}\text{C}^{16}\text{O}^{18}\text{O}$ [17.112]. The most prominent example of clumped isotopes applications is the carbonate system, where the clumped isotope signal depends solely on temperature while the individual isotopes such as $\delta^{18}\text{O}$ depend on temperature and on the $\delta^{18}\text{O}$ of waters from which carbonates grew. But clumped isotopes might also constrain the atmospheric budget of trace gases such as CO_2 [17.113]. This signal is not yet fully understood, but might help in the future to improve applications of single isotopes such as $\delta^{18}\text{O}$ [17.114, 115].

In polluted areas, continuous observations of co-located atmospheric CO_2 mole fraction and deuterium excess in atmospheric water vapor [17.116] may be used to estimate combustion-derived water vapor. Measurements at a monitoring station in the Salt Lake City basin in Utah, USA, during winter implied that the particularly low deuterium excess values of water from fossil fuel combustion significantly influenced the isotopic signature of atmospheric water vapor. This effect is most significant during cold temperatures when atmospheric humidity is generally low and stable inversion situations allow combustion-derived emissions (CO_2 and H_2O) to accumulate in a shallow atmospheric boundary layer [17.117].

Matthias Cuntz is Directeur de Recherche at the Institut National de Recherche pour l’Agriculture, l’Alimentation et l’Environnement (INRAE) in Nancy, France. He received a PhD in physics in 2002, subsequently working in atmospheric physics (Paris), biology (Canberra), biogeochemical cycles (Jena), and hydrology (Leipzig). He combines measurements and modeling to understand and describe mathematically the processes behind the exchanges of the atmosphere with the biosphere.

18. Measurement of Fundamental Aerosol Physical Properties

Andreas Held, Alexander Mangold 

Measurements of physical and optical particle properties are essential for evaluating the impact of atmospheric aerosols on atmospheric chemistry, climate, and health. This chapter describes the fundamental equations and conventions pertinent to particle detection and to the measurement of particle number, size, optical properties, and mass. Optical and electrical detection techniques are presented for particle number measurements. An overview of particle light scattering and absorption measurement methods is given. Various measurement principles for determining particle size are introduced, including those based on the optical interaction, aerodynamic behavior, or electrical mobility of particles. Particle mass measurement methods include gravimetric analysis, the vibration of a piezoelectric crystal, harmonic oscillation, and the attenuation of beta radiation. This chapter introduces sensors for measuring particle number, size, light scattering and absorption, and mass, while analysis of the chemical composition of particles will not be covered. General aspects of calibration and quality control are also described, typical technical specifications of the instrumentation are given, and recommendations for the maintenance of atmospheric particle sensors are presented. Finally, the chapter provides examples of applications and current developments in particle measurement techniques.

The atmospheric aerosol is a mixture of solid particles and liquid droplets suspended in air. The nongaseous part of this mixture is typically referred to as particles.

These particles play an important role in atmospheric physics and chemistry. Atmospheric particles are relevant in the climate system because they scatter and ab-

sorb solar radiation, directly influencing the temperature at the surface and within the atmosphere, and exerting a positive or negative radiative forcing. Further, atmospheric particles are essential for the formation of clouds and their microphysical properties and lifetime, which indirectly influence climate. In addition, particles provide surfaces for and take part in (photo)chemical reactions in the atmosphere. A particle size fraction with an aerodynamic diameter $< 10\ \mu\text{m}$ can be readily inhaled and may contain toxicologically relevant substances that can lead to adverse human health effects. Finally, airborne particles contribute to the atmospheric transport

of both nutrients and pollutants, to the advantage or disadvantage of ecosystems. This chapter describes the measurement principles for the fundamental physical and optical properties of atmospheric particles (number, size, mass, light scattering, and absorption) and the respective measurement sensors. Such measurements are essential for assessing the effects of aerosols on climate, health, and atmospheric chemistry. For information about additional aerosol instrumentation and measurement principles, including sensors for the chemical composition of atmospheric particles, the reader is referred to the literature, for example, [18.1, 2].

18.1 Measurement Principles and Parameters

The ability to accurately measure the physical properties of atmospheric particles is essential in order to describe and quantify their impact on climate, atmospheric chemistry, human health, and biogeochemical cycles. This section gives a brief overview of measurement principles for fundamental physical and optical particle parameters (particle number, size, mass, light scattering, and absorption coefficients) and of the respective measurement sensors. The chapter does not cover measuring principles and sensors for the chemical analysis of atmospheric particles, and the reader is referred to the literature, for example, [18.1, 2].

18.1.1 Physical Properties of Atmospheric Particles

Atmospheric particles are produced both by natural sources (e.g., desert dust, biomass burning, sea salt, volcanoes) and anthropogenic sources (e.g., industry, traffic, agriculture) [18.3]. Particles can be emitted directly into the atmosphere as primary emissions (e.g., dust, sea salt, soot) or can be formed by gas-to-particle conversion of precursor gases as secondary emissions (e.g., sulfates, ammonium nitrate, secondary organic aerosol). Once in the atmosphere, particles are transformed by coagulation (i.e., collision and coalescence), condensation growth (gas molecules condense on existing particles) or shrinkage (volatile compounds evaporate from existing particles), are transported by advection and turbulence, and are finally removed from the atmosphere by dry or wet deposition. Accordingly, the particle size range (Fig. 18.1) covers several orders of magnitude and may be subdivided into the *nucleation mode* (diameter $< 20\ \text{nm}$), the *Aitken mode* (diameter $20\text{--}100\ \text{nm}$), the *accumulation mode* (diameter $100\text{--}1000\ \text{nm}$), and the *coarse mode* ($> 1\ \mu\text{m}$). There are various definitions of the exact diameter ranges of

the modes, and the given ranges follow [18.4]. The atmospheric residence time is longest in the accumulation range of $0.1\text{--}1.0\ \mu\text{m}$, because smaller particles quickly grow to larger sizes by condensation and coagulation, and larger particles are efficiently removed by gravitational settling. Depending on the measurement principle, particle size is typically given as an equivalent diameter of a spherical particle with similar behavior as the particle of interest (Sect. 18.3.9).

Due to the high variability of particle sources and sizes, multiple parameters are necessary to comprehensively characterize atmospheric particles (see Tables 18.1–18.4). Measurements of total particle number concentrations and particle sizes are fundamental (Table 18.1). Particle size is measured in specific size bins, covering one or more of the above-mentioned size modes, and is typically connected to a sensor for particle number measurement. This results in particle number size distributions, which are the basis for calculating particle surface, volume, and mass size distributions (Sect. 18.3.9 and Table 18.2). Particle mass concentrations are important for studies in which mass-related particle properties are relevant (e.g., health or mass-specific optical parameters). Particle mass concentrations are typically given for specific size ranges, e.g., PM_{10} as the particle mass concentration of particles $< 10\ \mu\text{m}$ or $\text{PM}_{2.5}$ as the particle mass concentration of particles $< 2.5\ \mu\text{m}$. The highest number concentrations are typically found in the size range $< 100\ \text{nm}$. The highest mass and volume concentrations are found in the coarse mode, because the volume, and thus the mass, of spherical particles scales with the third power of the diameter. The highest surface concentrations are typically found in the accumulation mode.

To further characterize the environmental impact of atmospheric particles, their optical properties must be measured. Radiation will be attenuated by atmospheric

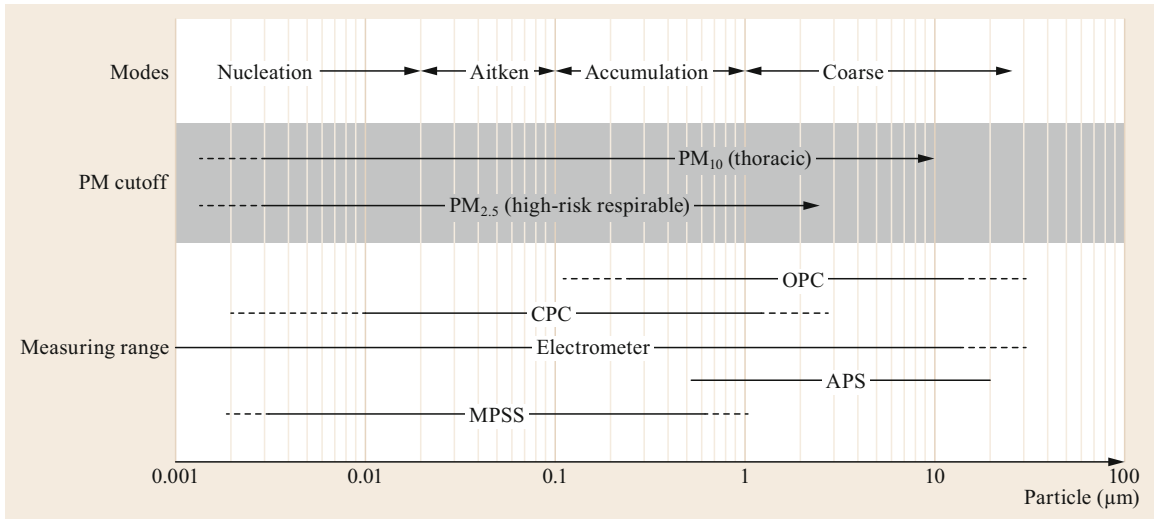

Fig. 18.1 Size ranges of the nucleation, Aitken, accumulation, and coarse modes, the PM₁₀ and PM_{2.5} conventions, and typical measuring ranges of particle instrumentation (OPC: optical particle counter; CPC: condensation particle counter; APS: aerodynamic particle sizer; MPSS: mobility particle size spectrometer). Further details in the text

Table 18.1 Fundamental physical parameters of atmospheric particles; units and symbols are commonly used for atmospheric particles

Parameter	Description	Unit	Symbol
Particle number concentration	Number of particles in a volume of air	cm ⁻³ or m ⁻³	<i>N</i>
Particle mass concentration	Mass of particles in a volume of air	μg m ⁻³	<i>M</i>
Particle size	Particle size typically given as equivalent diameter of a spherical particle	nm or μm	<i>D</i> , <i>D_p</i>

Table 18.2 Derived physical parameters of atmospheric particles

Parameter	Description	Unit	Symbol
Particle surface concentration	Particle surface derived from measurements of particle number and size in a volume of air; shape of particles usually assumed to be spherical	μm ² cm ⁻³	<i>S</i>
Particle volume concentration	Particle volume derived from measurements of particle number and size in a volume of air; shape of particles usually assumed to be spherical	μm ³ cm ⁻³	<i>V</i>
Mass concentration of light-absorbing particles	Particle mass of light-absorbing particles in a volume of air; derived from measurements of particle absorption coefficients and calibration with particles with known mass absorption cross section	μg m ⁻³	<i>M_{LAP}</i>

particles. This attenuation (termed extinction) consists of two parts, particle scattering and absorption (Table 18.3). Based on particle scattering and absorption coefficients, additional optical parameters can be derived (Table 18.4), such as the complex refractive index, the single-scattering albedo, or the particle phase function, which are essential for studies of the radiative forcing of atmospheric particles or for radiative transfer modeling.

18.1.2 Principles of Measurements

Measurement principles for fundamental physical particle properties introduced in Sect. 18.1.1 are summarized in Table 18.5, together with the respective mea-

surement sensors, some of which are also important for sampling trace substances in air (Chap. 19). The particle number can be measured either optically by particle light scattering, or electrically by measuring the electrical charges carried by particles. Particle sizing methods make use of optical properties of particles (light scattering), their aerodynamic behavior, or their electrical mobility. Particle mass is measured by gravimetric methods, absorption of beta radiation, harmonic oscillation of a microbalance, or the vibration of a piezoelectric crystal. Particle light scattering is measured with nephelometers. For the measurement of light absorption, either filter-based instruments are used (which measure the attenuation of light by particles collected on a fil-

Table 18.3 Fundamental optical parameters of atmospheric particles

Parameter	Description	Unit	Symbol
Particle scattering coefficient	Wavelength-dependent attenuation of incident radiation by particle scattering	m^{-1}	σ_{sp}
Particle backscatter coefficient	Wavelength-dependent attenuation of incident radiation by particle scattering, considering only the backward direction	m^{-1}	σ_{bsp}
Particle absorption coefficient	Wavelength-dependent attenuation of incident radiation by particle absorption	m^{-1}	σ_{ap}

Table 18.4 Derived optical parameters of atmospheric particles

Parameter	Description	Unit	Symbol
Particle extinction coefficient	Sum of the particle scattering coefficient and the particle absorption coefficient	m^{-1}	σ_{tot}
Single-scattering albedo	Ratio of the particle scattering coefficient and the particle extinction coefficient	–	ω
Forward scattering coefficient	Attenuation of incident radiation by particle scattering, considering only the forward direction	m^{-1}	σ_{fsp}
Particle phase function	Angular distribution of the particle scattering coefficient	–	p
Asymmetry parameter	Average cosine of the scattering angles, taking into account the scattering intensities of the particle phase function	–	g
Complex refractive index	Optical particle properties with respect to the surrounding medium; consists of a real part (describing scattering) and an imaginary part (describing absorption)	–	m

Table 18.5 Measurement principles and sensors for fundamental physical properties of atmospheric particles

Sections	Measurement principle	Type of sensor	Parameter

ter), or instruments exploiting the conversion of the energy of light absorbed by particles into an acoustic wave are used. In addition, the particle chemical composition has a distinct impact on their optical properties. Therefore, measurement techniques to determine the chemical composition of particles are highly complementary to the ones described in this chapter.

18.1.3 Measurement Site

Measurements of atmospheric particles are typically colocated with measurements of meteorological parameters such as air temperature, relative humidity, wind speed and direction, precipitation, and solar radiation. In a fixed sampling site, the instrumentation is placed in a temperature-controlled shelter, and the particle sam-

ple is directed to the sensor(s) through an inlet and tubing system. The sampling height for particle measurements close to direct sources such as traffic is between 1.5 and 4 m AGL, while sampling heights of 5–10 m AGL are used for process studies of the undisturbed atmospheric particle population. The sampling location should not be directly influenced by topography, vegetation, or buildings.

Particle measurement sensors are placed not only in laboratory-like setups, but also on platforms such as towers or ships (ground-based, Chap. 6), aircraft (airborne platforms, Chap. 37), or balloons (aerology, Chap. 46), or under extreme conditions with respect to temperature, air pressure, or pollution. It is therefore very important to choose the appropriate instrument and method for the application under question.

18.2 History

Already in historical times, atmospheric particles were linked to air pollution. For example, in 1273 King Edward I prohibited cooking of food over coal fires in England, and proclaimed a ban on coal burning in London in 1306. In 1661, *John Evelyn* (1620–1706) addressed the *inconveniencie of the aer and smoak of London* in his *Fumifugium* tract on air pollution to *King Charles II* [18.5]. The development of particle sensors has its roots in the 19th century with the invention of the nepheloscope, an early cloud chamber, by *James Espy* (1785–1860) in 1841, the discoveries and inventions of *John Tyndall* (1820–1893) in the 1850s and 1860s, and the groundbreaking work on atmospheric condensation nuclei of *Paul-Jean Coulier* (1824–1890) [18.6] and *John Aitken* (1839–1919) [18.7, 8], which led to the development of the first portable particle counter by Aitken. Still today, the design of this instrument is the basis for modern condensation particle counters to measure the number concentration of atmospheric particles by growing individual particles into visible droplets by

condensation of supersaturated water vapor. Only in the 20th century did scientists begin to consider the atmosphere as a colloid, and the term *aerosol* was coined in the early 20th century by *Frederick G. Donnan* (1870–1956) and *August Schmauß* (1877–1954) [18.9]. Seminal work that set the stage for the development of modern aerosol science included *The Mechanics of Aerosols* [18.10] (first published in Russian in 1955 by *Nikolai Fuchs* (1895–1982)), *Air Chemistry and Radioactivity* [18.11] by *Christian Junge* (1912–1996), and *Smoke, Dust and Haze* [18.12] by *Sheldon Friedlander* (1927–2007). Important developments in the field of atmospheric particle measurement techniques were made for example in France by *Jean Bricard* (1907–1988; particle counters and diffusion batteries), in England by *Charles Norman Davies* (1910–1994; particle sampling techniques), in Japan by *Kouichi Iinoya* (1917–1998; particle sampling techniques), and in the USA by *Kenneth Whitby* (1925–1983; electrical aerosol analyzer, differential mobility analyzer).

18.3 Theory

The physical properties of atmospheric particles are measured based on a variety of principles including the interaction of particles with light, electrical mobility, diffusivity, aerodynamic behavior, and particle mass (Sect. 18.1.2 and Table 18.5). Here, we will introduce fundamental equations and conventions pertinent

to particle detection and the measurement of particle optical properties, particle size, and particle mass. This section also describes the specific requirements for the setup of the particle sampling system. Additional theoretical background on particle collection can be found in Chap. 19.

18.3.1 Particle Light Scattering

Due to the interaction of light with molecular dipoles of particles, light is scattered by particles at various scattering angles θ , described as the angle between the direction of propagation of the incident light and the scattered light. For a mathematical description of the scattering process, three different regimes are typically considered, depending on the ratio of particle circumference and wavelength of incident light, $\pi D/\lambda$ (Fig. 18.2). The Rayleigh scattering regime is applicable for particles much smaller than the wavelength of the light ($\pi D/\lambda \ll 1$), the Mie scattering regime for particle sizes of the order of the wavelength of the light, and the geometric scattering regime for particles much larger than the wavelength of the light ($\pi D/\lambda \gg 1$), where scattering is due to diffraction, reflection, and refraction.

Thus, optical detection of individual particles by light scattering strongly depends on particle size and the wavelength of the incident light. This limits the practical use of optical particle detection with visible light to particles $\gtrsim 100$ nm. With condensation particle counters, smaller particles are grown to optically detectable sizes by condensation of a supersaturated vapor. The size of the smallest particles that can still be activated to grow by condensation and the growth rate depend on the vapor supersaturation, which can be evaluated by classical Köhler theory or nano-Köhler theory [18.13].

For an individual particle in the Rayleigh scattering regime, the angular distribution of the scattered light intensity, i.e., the so-called particle phase function $p(\theta)$, is given by

$$p(\theta) = \frac{\lambda^2}{8\pi^2} \left(\frac{\pi D_p}{\lambda} \right)^6 \left| \frac{m^2 - 1}{m^2 + 2} \right|^2 (1 + \cos^2 \theta) I_0, \quad (18.1)$$

with the scattering angle θ , the wavelength of light λ , the particle diameter D_p , the refractive index of the particle m , and the intensity of the incident light I_0 . Obviously, the scattering properties in the Rayleigh regime are strongly dependent on the ratio of the particle diameter and light wavelength as well as the refractive index of the particle. In the Mie scattering regime, the scattering properties are calculated based on approximations of Mie theory [18.14], given for example by [18.15].

Based on Mie theory, dimensionless scattering efficiencies Q_{sp} can be calculated for individual particles. For an ensemble of particles of diameter D_p with number density N , the particle scattering coefficient σ_{sp} is related to Q_{sp} by

$$\sigma_{sp} = N \frac{\pi D_p^2}{4} Q_{sp}. \quad (18.2)$$

The particle scattering coefficient σ_{sp} is given in units of m^{-1} , and can be interpreted as the relative reduction in light intensity per unit length due to scattering.

Optical particle spectrometers directly link the scattering intensity of individual particles to the so-called optical equivalent diameter D_o , defined as the diameter of a spherical particle that exhibits the same optical properties as the studied particle. Therefore, the optical equivalent diameter is particularly useful for characterizing particles in terms of their effect on atmospheric visibility or direct climate effects.

If there is more than one particle in the viewing volume of an optical particle counter, coincidence of particles has to be taken into account. This process can be described by Poisson statistics, and the probability that particle coincidence occurs is

$$P_{\text{coinc}} = 1 - e^{-N_p t_d}, \quad (18.3)$$

Fig. 18.2 Idealized representation of the relative scattering intensity of light at a wavelength of $\lambda = 0.5 \mu\text{m}$ as a function of particle diameter in the Rayleigh, Mie, and geometric scattering regimes; in the Rayleigh regime, the relative intensity increases in proportion to D_p^6 (18.1); in the Mie regime, the relationship follows a complex, not strictly monotonic pattern; in the geometric regime, the relative intensity is proportional to the particle cross section, i.e., $\propto D_p^2$

with the probability of coincidence P_{coinc} , the particle count rate N_p , and the residence time of an individual particle in the viewing volume t_d . Based on this equation, the actual particle count rate N_a is related to the measured particle count rate N_m [18.16] by

$$N_a = N_m e^{N_a t_d} . \quad (18.4)$$

A common approximation for solving this equation is to substitute N_a with N_m in the exponent on the right-hand side of the equation.

18.3.2 Particle Light Absorption and Extinction

The particle absorption coefficient σ_{ap} characterizes the relative reduction in light intensity due to absorption. Directly measured values of the particle absorption coefficient σ_{ap} can be converted to equivalent mass concentrations of light-absorbing particles M_{LAP} if the mass absorption cross section of the light-absorbing particle population α_{LAP} at the measurement wavelength is known

$$M_{\text{LAP}} = \frac{\sigma_{\text{ap}}}{\alpha_{\text{LAP}}} . \quad (18.5)$$

The particle extinction coefficient σ_{tot} is the sum of the particle scattering coefficient σ_{sp} and the particle absorption coefficient σ_{ap} ,

$$\sigma_{\text{tot}} = \sigma_{\text{sp}} + \sigma_{\text{ap}} . \quad (18.6)$$

The particle extinction coefficient is either calculated from measurements of the scattering and absorption coefficients, or directly measured with extinction meters. The extinction of light by a particle population, including both scattering and absorption of light, can be described by the Bouguer–Lambert–Beer’s law

$$I = I_0 e^{-\sigma_{\text{tot}} L} , \quad (18.7)$$

with the light intensity after interaction with the particle population I , the incident light intensity I_0 , the particle extinction coefficient σ_{tot} , and the path length of interaction L between the particle population and the incident light.

The single-scattering albedo ω , i.e., the ratio of the particle scattering coefficient and the particle extinction coefficient

$$\omega = \frac{\sigma_{\text{sp}}}{\sigma_{\text{tot}}} , \quad (18.8)$$

is a dimensionless measure of the scattering properties with a value of 1 for purely scattering particles, and a value of 0 for purely absorbing particles.

Based on work by [18.17], the particle extinction coefficient at a wavelength $\lambda = 550 \text{ nm}$ can be used to estimate the atmospheric visual range VIS in m,

$$\text{VIS} = \frac{3.9}{\sigma_{\text{tot}}^{550 \text{ nm}}} = \frac{3.9}{\sigma_{\text{sp}}^{550 \text{ nm}}} \omega^{550 \text{ nm}} . \quad (18.9)$$

The complex refractive index of a particle, $m = n + ik$, summarizes the optical properties of a particle. The real part n represents scattering by the particle, while the imaginary part k describes absorption by the particle. The refractive index is not directly measured but rather typically derived from measurements of the particle scattering and absorption behavior.

18.3.3 Photoacoustic Spectroscopy

A direct method for measuring the particle absorption coefficient is photoacoustic spectroscopy. Photoacoustic spectroscopy [18.18] exploits the fact that the absorbed energy of a modulated light source of a specific wavelength will heat up a particle. The dispersed heat of the particle is associated with a thermal expansion of the surrounding gas. The periodic expansion of the gas yields a standing pressure wave that can be detected in an acoustic resonant chamber with a sensitive microphone. The amplitude of the acoustic wave is proportional to the amount of absorbed energy, which again is proportional to the amount of the absorbing particle ensemble.

18.3.4 Electrical Detection and Mobility of Particles

For electrical detection of particles, all particles or a well-defined fraction of the particle population must be electrically charged. Particles are exposed to a high concentration of either positive or negative ions (unipolar charging) or both positive and negative ions (bipolar charging) for a sufficiently long time, typically in the absence of an electric field. For particle detection, unipolar charging with high efficiency is desirable in order to obtain robust electrometer measurements even at low particle concentrations.

In the presence of an electric field, charged particles will migrate through a medium with an electrical mobility Z , defined as the ratio of the velocity of an electrically charged particle in an electric field, v_e , and the electric field strength E that accelerates the particle to that velocity,

$$Z = \frac{v_e}{E} = \frac{neC_c}{3\pi\eta D_m} , \quad (18.10)$$

with the number n of elementary charges e carried by the particle, the slip correction factor C_c that accounts

for noncontinuum effects when considering small particles in the transition regime between free molecular and continuum flow, the dynamic viscosity of air η , and the mobility diameter D_m . Following [18.19], the slip correction factor C_c is calculated as

$$C_c = 1 + \frac{2\lambda_{\text{mfp}}}{D_p} \left[1.165 + 0.483 \times \exp\left(-0.997 \frac{D_p}{2\lambda_{\text{mfp}}}\right) \right], \quad (18.11)$$

with the mean free path at 296.15 K and 1013.25 hPa, $\lambda_{\text{mfp}} = 67.3$ nm, and D_p in nm.

The so-called mobility diameter D_m is defined as the diameter of a spherical particle with the same electrical mobility as the studied particle. D_m is measured with mobility particle size spectrometers, typically in the submicron size range. Particle populations are neutralized by exposing the particle population to a large number of bipolar ions in order to achieve so-called Boltzmann charge equilibrium. Diffusion charging theories as proposed by [18.20, 21] have been experimentally validated for submicron particles [18.22], and are commonly approximated by an empirical polynomial function introduced by [18.23].

18.3.5 Diffusivity of Particles

Diffusion is a key transport and deposition mechanism for atmospheric particles smaller than 100 nm, caused by Brownian motion. Particle diffusivity or the particle diffusion coefficient D_{diff} is given by the Stokes–Einstein equation [18.24]

$$D_{\text{diff}} = \frac{kTC_c}{3\pi\eta D_p}, \quad (18.12)$$

with the Boltzmann constant k , temperature T , the slip correction factor C_c , the dynamic viscosity of air η , and the particle diameter D_p . D_{diff} increases with temperature and is strongly dependent on particle size. For small particles with $C_c \gg 1$, the particle diffusion coefficient is approximately proportional to D_p^{-2} .

18.3.6 Aerodynamic Behavior of Particles

For a particle that is accelerated by the gravitational force, a counteracting drag force described by Stokes' law for the general case of laminar flow around atmospheric particles will lead to a terminal settling velocity v_s in equilibrium [18.24], given by

$$v_s = \frac{\rho_p D_a^2 g C_c}{18\eta}, \quad (18.13)$$

with the gravitational acceleration g , the slip correction factor C_c , the dynamic viscosity of air η , and the aerodynamic equivalent diameter D_a . The aerodynamic equivalent diameter is defined as the diameter of a spherical particle of unit density (particle density $\rho_p = 1 \text{ g cm}^{-3}$) that exhibits the same terminal settling velocity as the studied particle. The aerodynamic diameter is applicable when using the aerodynamic particle sizer or impactors. For an impactor with nozzles of width W (diameter of circular nozzle or half-width of slit) and a particle velocity of v_n through the nozzle, particle collection depends on the dimensionless Stokes number St [18.24] expressed as

$$St = \frac{\rho_p D_a^2 C_c v_n}{9\eta W}. \quad (18.14)$$

Solving this equation for the aerodynamic diameter D_a when the collection efficiency is 50% yields the cutoff diameter of an impactor stage. The resulting size information is directly linked to the deposition behavior of particles in the human body, and therefore, important for the evaluation of particle health effects.

18.3.7 Particle Microbalances

Direct gravimetric measurement of the particle mass concentration after collection of particles with a filter or an impactor requires knowledge of the collection efficiency for different particle sizes. In the case of filtration, collection by molecular diffusion is efficient only for particles < 100 nm, while gravitational settling and sieving is efficient only for supermicron particles. In the range of 100 nm to 1 μm , inertial impaction and interception are the relevant processes for particle collection on the filter. For a quantitative discussion of these collection processes, the reader is referred to Chap. 19 and [18.25].

The deposition of particles on piezoelectric crystals increases the resonant frequency f_0 of the oscillating system. The frequency change Δf (in Hz) of the resonant frequency can be related to the mass change Δm (in kg) using the Sauerbrey equation [18.26],

$$\Delta f = -\frac{2f_0^2}{\sqrt{\rho_c \mu_c A_c}} \Delta m, \quad (18.15)$$

with the density of the crystal ρ_c , the modulus of rigidity of the crystal μ_c , and the deposition area of the crystal A_c .

For quartz crystals, where the quartz is cut at an angle of $\approx 35^\circ$ to the optical axis of the crystal (AT cut), with $\rho_c = 2.648 \times 10^3 \text{ kg m}^{-3}$ and $\mu_c = 2.95 \times$

$10^{10} \text{ kg m}^{-1} \text{ s}^{-2}$, we obtain

$$\Delta f = -2.26 \times 10^{-6} f_0^2 \Delta m. \quad (18.16)$$

Analogously, in a tapered element oscillating microbalance, the particles are deposited on an exchangeable filter, which is part of the microbalance. The sampled air continues through a hollow, tapered tube. The specific design of this tapered element and surrounding component cause the tube to oscillate at its specific frequency. The oscillating frequency changes in proportion to the change in deposited particle mass.

18.3.8 Attenuation of Beta Radiation

Particles attenuate beta radiation (0.01–0.1 MeV energy range) due to inelastic scattering by atomic electrons of particles. The particle mass concentration can be evaluated from an increase in attenuation as more particles are collected on a filter tape.

18.3.9 Representation of Particle Size Distributions

Particle size is typically reported as equivalent diameter, i.e., the diameter of a spherical particle that exhibits the same behavior as the studied particles. Depending on the measurement principle, the frame of reference can be the optical properties of a particle, the aerodynamic behavior of a particle, or the mobility of a particle in an electric field.

For a nonspherical particle, a dynamic shape factor χ [18.10] accounts for the increased drag on the particle due to its irregular shape. It is defined as the ratio of the drag force on the nonspherical particle of interest to the drag force on a volume-equivalent spherical particle moving at the same velocity relative to the surrounding gas. The dynamic shape factor χ allows us to relate the volume-equivalent diameter D_v , the aerodynamic equivalent diameter D_a , and the mobility diameter D_m ,

$$D_v = \sqrt{\chi \frac{\rho_0 C_c(D_a)}{\rho_p C_c(D_v)}} D_a = \frac{1}{\chi} \frac{C_c(D_v)}{C_c(D_m)} D_m, \quad (18.17)$$

with the particle density ρ_p , unit particle density $\rho_0 = 1 \text{ g cm}^{-3}$, and the slip correction factor C_c .

Particle size distribution is measured by parallel or subsequent measurement of the particle number concentration in finite size bins. For atmospheric particles, size distributions show characteristic peaks in certain size ranges, the so-called size modes. Whitby [18.27] proposed that atmospheric particle size distributions can be parameterized by a trimodal model representing the nucleation mode, the accumulation mode, and

the coarse mode, and are mathematically expressed as a superposition of log-normal distributions that represent the different modes,

$$N(\log D_p) = \sum_{i=1}^n \frac{N_i}{\sqrt{2\pi} \log \sigma_i} e^{-\frac{\log D_p - \log \text{GMD}_i}{2 \log^2 \sigma_i}}, \quad (18.18)$$

with the number of particles of diameter D_p N , the number of particles in mode i N_i , the geometric standard deviation σ_i , and the geometric mean diameter (GMD) of each mode i . Thus, each mode of the size distribution is uniquely characterized by the three parameters N_i , σ_i , and GMD_i .

Because atmospheric particles cover a diameter range over several orders of magnitude, the particle size distribution is presented on a logarithmic diameter scale. In order to make graphical representations of particle size distributions independent of the number and width of size bins, the number of particles in each size bin divided by the width of the size bin on a logarithmic scale, $dN/d \log(D_p)$, is plotted against the particle diameter D_p on a logarithmic scale (Fig. 18.3).

Particle surface size distribution dS , particle volume size distribution dV , and particle mass size distribution dM are often calculated from measured particle number size distribution dN assuming spherical particles with a representative diameter D_i in each size bin, and an assumed particle density ρ_p

$$dS = \pi D_i^2 dN, \quad (18.19)$$

$$dV = \frac{\pi}{6} D_i^3 dN, \quad (18.20)$$

$$dM = \rho_p \frac{\pi}{6} D_i^3 dN. \quad (18.21)$$

18.3.10 Setup Requirements of the Particle Sampling System

When sampling atmospheric particles, special attention has to be paid to the design of the inlet and tubing system. The ambient air flow to the inlet must be as free as possible from any disturbance. The inlet itself has to be omnidirectional, i.e., ensuring that ambient air from all wind directions can equally enter the sample tube. If only particles up to a certain size are collected, specific inlets or cyclones with defined cutoffs are needed, which are valid for a specific sample flow only. In order to avoid particle losses to the tubing wall, the tubing should follow a straight path to the measurement chamber, as short as possible, and be of conductive material (e.g., stainless steel, avoiding electrostatic charging and subsequent particle loss). The flow rate should be optimized. High flow rates are advised when sampling

Fig. 18.3 Example of a particle number size distribution; measurement in 18 size bins (*open diamonds*), with three fitted log-normal distributions (*dotted lines*) and the resulting superposition (*solid line*)

low particle concentrations. Low flow rates are recommended for applications that detect single particles in the measurement cell, or in environments with high particle concentrations. According to the sample flow, the tube diameter also has to be adapted. The sample flow should be laminar to avoid losses of small particles due to diffusion and turbulent inertial deposition. To identify an adequate combination of tube diameter and flow rate, the Reynolds number should be calculated [18.28]. Further theoretical background on sampling systems can be found in Chap. 19.

Stable temperature and humidity conditions are very important for atmospheric particle measurement, and therefore temperature and humidity in the measurement cell should be controlled or, if not possible, at least be monitored. For particle sensors operating within the WMO GAW (World Meteorological Organization Global Atmosphere Watch) program, it is recommended that relative humidity in the measurement cell be controlled to < 40% [18.29]. It is important that the temperature of the measurement cell be above

the dewpoint temperature of the sample air in order to avoid contamination by the condensation of water vapor. Drying of the sample air is done by removing water vapor upstream with water traps or dryers, diluting the sample air with dry particle-free air, or heating the tubing system. It must be taken into account that drying might lead to the loss of semivolatile components of the particles. Besides monitoring temperature and humidity, the atmospheric pressure at the measurement site also has to be recorded in order to report particle concentrations at either standard or ambient atmospheric conditions.

Further, the inlet must be protected against the intrusion of insects, rain droplets, or ice crystals. In cold and relatively humid environments, obstruction of the inlet system by riming must be prevented, while taking into account effects of potential heating on the ambient aerosol. For detailed descriptions of inlet system design, including specific applications such as measurements on board aircraft or under extreme environmental conditions, the reader is referred to the literature [18.24, 28].

18.4 Devices and Systems

For the measurement of atmospheric particles, there is no one ideal instrument that can provide information about all relevant properties, but rather a large number of devices and systems that measure one or several specific properties. In the following, relevant instruments for the measurement of particle number, size, mass, and optical properties are summarized according to the respective measurement principles. Due to their widespread use and various specific features, condensation particle counters and mobility particle size

spectrometers are covered in greater detail. Further, the added benefit of particle sensor combinations will be illustrated, and finally, the advantages and disadvantages of the different methods will be compared.

18.4.1 Particle Light Scattering

Optical particle counters (OPC) detect particles by measuring scattered light produced by individual particles crossing a focused light beam (Fig. 18.4). The first

Fig. 18.4 Schematic setup of optical particle detection; particles are focused through a nozzle and illuminated by a light beam; scattered light is directed to a sensitive photodetector through collecting lenses, while the direct light beam is trapped

OPC was introduced by [18.30, 31]. In general, a narrow air sample stream is illuminated by an intense beam of light, which is scattered by individual particles. The scattered light is collected through lenses at a specified angle with respect to the incident light beam, and directed to a photodiode. Here, light is converted into an electric current based on the inner photoelectric effect, and the typical output is a voltage pulse with a magnitude proportional to particle size. Individual pulses are counted for a specified time period, and together with the known sample volume passing through the illuminated region during that time period, the particle number concentration can be calculated.

There is a practical lower detection limit of optical particle detection depending on the wavelength and intensity of illumination and the dark current of the detector. Common OPC light sources operate in the visible wavelength range, including either monochromatic laser light or broadband white light. Laser intensities are typically much larger than those from white light sources and thus preferable for the detection of smaller particles. Most commercially available OPCs use laser diodes, enabling lower-diameter detection limits < 100 nm (but more typically ≈ 200 nm), while white light OPCs typically cannot detect particles with diameters < 300 nm [18.32].

The intensity and angular distribution of the scattered light can also be exploited to determine particle size and shape. Optical particle spectrometers (OPS) evaluate the pulse height of scattered light in order to determine the number concentration in distinct size bins. The relationship between particle size and pulse height is affected by the instrument design and the optical properties of the particle. For practical purposes, a calibration curve for particles of known shape and composition, such as spherical water droplets or polystyrene spheres, is required to determine the optical equivalent diameter. A particle size distribution derived from optical particle spectrometers then describes the

ensemble optical properties of the particle population, i.e., its interaction with light.

The angular distribution of the scattered light intensity exhibits complex patterns (Sect. 18.3.1). In most optical particle spectrometers, scattered light is collected either in an angular range of about 5° – 25° in the forward direction of the incident light (forward-scattering instruments) or in a broad angular range including the perpendicular direction (wide-angle instruments). In both configurations, the relationship between pulse height and particle size is not strictly monotonic, and assigning a particle to a unique size bin is not always possible. Generally, the response of instruments with monochromatic light sources shows stronger oscillations than that of instruments with white light sources. For detailed studies of particle size and shape, the angular distribution of the scattered light intensity can be measured with multiple detectors for various angular regions [18.33].

Condensation particle counters (CPC, also condensation nucleus counters CNC) are widely used for the optical detection of particles < 100 nm. Here, prior to optical detection, individual particles are grown by condensation of a supersaturated vapor to droplets with diameters of several μm , which can be easily detected. There are different methods for producing the supersaturated vapor, including adiabatic expansion, heat transfer, and mixing of warm and cold air streams, as well as different working fluids such as water or *n*-butanol. The earliest instruments, including the original expansion-type instrument [18.8], used water as working fluid and adiabatic volume expansion or pressure release to cool the aerosol sample in a chamber saturated with respect to water vapor, which leads to condensation of water vapor onto the particles, and growth to optically detectable sizes. A major drawback of expansion-type CPCs is the discontinuous measurement cycle. Most modern continuous-flow CPCs use forced convection heat transfer to produce supersaturation, typically with

Fig. 18.5 Schematic setup of a condensation particle counter; the aerosol sample is mixed with saturated vapor of the working fluid in a heated saturation chamber, followed by condensation of the vapor onto particles in the cooled condensation chamber and detection of the grown droplets in an optical chamber

n-butanol or water as working fluids. The first instruments of this type were introduced by [18.34–36]. In a butanol-based CPC (Fig. 18.5), the aerosol sample is introduced into a temperature-controlled saturation chamber, which is filled with saturated butanol vapor. Then, the aerosol sample together with the saturated vapor enters a colder, temperature-controlled condensation chamber, where the butanol vapor becomes supersaturated and condenses onto the particles. The temperature conditions in the saturation and condensation chambers determine the supersaturation of the butanol vapor, and thus the smallest size of particles that are still activated to grow by condensation of butanol. High supersaturation is desirable in order to achieve activation of particles insensitive to the chemical composition of the particles. However, nucleation of particles from the butanol vapor, which can occur if the supersaturation is too high, must be avoided. In a water-based CPC, the aerosol sample first flows through a cold, humid chamber, where the particles are cooled and water vapor is saturated. The aerosol then enters a warm, wet-walled growth tube, where water vapor becomes supersaturated and condenses onto the cold particles in the center of the tube, because diffusion of water vapor from the wall to the center is faster than heat transfer and warming of the particles. Another method for achieving supersaturation of the working fluid vapor involves mixing of saturated air streams at different temperatures. While heat transfer instruments are operated in laminar flow and exhibit a limited response to concentration changes, mixing-type instruments have been designed with fast response times [18.37, 38].

Whereas particle detection in early instruments was accomplished by manual counting of droplets under a microscope after collection on a grid, today indi-

vidual particles are automatically detected by light scattering. This direct single-particle counting method is limited to particle number concentrations on the order of 10^4 – 10^5 cm^{-3} , when scattering signals do not overlap. At higher concentrations, coincidence, i.e., the simultaneous detection of multiple particles, occurs and has to be corrected (Sect. 18.3.1). At very high concentrations, particle number concentrations may be derived indirectly by evaluating the light attenuation caused by the particle ensemble in the light path of the instrument.

The working fluid in a CPC should have sufficiently high vapor pressure to grow particles to sizes of several μm within a period of several tenths of a second as the particle population passes through the condensation chamber. At the same time, the supersaturation should not lead to nucleation of particles. In addition to water and butanol, various other working liquids have been used in both research and commercial CPCs, most notably isopropanol, ethylene glycol, and diethylene glycol [18.39].

A key characteristic of each CPC is the lower cutoff diameter, the size of particles that are still activated to grow by condensation of the working fluid. The lower cutoff diameter is defined as the particle diameter with a 50% detection efficiency, which can be derived from detection efficiency curves giving the fraction of activated particles relative to the total particle number as a function of particle size. The nominal lower cutoff diameter of different CPC models depends on various factors including the instrument design, the sampling pressure, and the vapor supersaturation achieved for the specific working fluid. It should be noted that the true lower cutoff diameter may also vary for individual instruments of the same CPC model. Only over the

Fig. 18.6 Schematic setup of a nephelometer; particles are pumped through the measuring volume, which is defined by the volume illuminated by a light source and the sensing volume of the detector; the backscatter shutter can restrict the illuminated volume to the backscattering part; a chopper opens and closes the sensing volume to the detector, which may consist of several photomultipliers for different wavelengths selected with bandpass filters

past decade have lower cutoff diameters < 3 nm been achieved. One notable example approaching the molecular regime is the Particle Size Magnifier [18.40], which makes use of diethylene glycol as working fluid to grow particles as small as 1 nm.

Nephelometers (Fig. 18.6) measure light scattering by particles. Integrating nephelometers [18.41, 42] quantify the scattering over all directions, and the signal contribution due to both scattering by gases and instrument noise is subtracted by periodic background measurements of particle-free air. Well-calibrated nephelometers can measure scattering coefficients $< 2 \times 10^{-7} \text{ m}^{-1}$. Commercially available nephelometers include single-wavelength instruments using light in the visible or near-infrared range, as well as multiwavelength instruments that measure scattering of light at different wavelengths (typically 450, 500, 650–700 nm). In addition to the total scattering measurement, some instruments also use a backscatter shutter in the optical path to quantify the hemispheric backscattering. By varying the position of the backscatter shutter, the angular distribution of scattering can be measured with polar nephelometers.

Relative humidity $> 40\%$ strongly influences the scattering measurement due to particle growth and shrinkage, depending on particle composition. It is recommended that nephelometer measurements be performed under *dry* conditions, i.e., at a relative humidity $< 40\%$, and that the measured *dry* value be related to ambient relative humidity by empirical calibration functions. Because of technical limitations, the scattering angles covered for the total and backscatter measurements are truncated. Two commonly used nephelometers, the TSI Model 3563 (TSI Incorporated, St. Paul, MN, USA) and the Ecotech Aurora 3000 (Ecotech, Melbourne, Australia), cover scattering angles from 7° to 170° and 9° to 170° , respectively. Both

humidity effects and truncation must be corrected for accurate scattering measurements.

18.4.2 Particle Light Absorption and Extinction

In *filter-based absorption monitors*, light absorption by particles is characterized by collecting particles on a filter and measuring the transmission or reflection of light with a photometer. Transmission and reflection of light is affected not only by absorption, but also by scattering and multiple scattering of light by both the filter material and the particle sample, which must be accounted for. In the integrating sphere method, a filter is illuminated in an integrating sphere. The difference between light detected with particles on the filter and a clean filter is attributed to the light absorbed by the particles. A simplification of this technique is the integrating plate method [18.43], where a glass plate is placed between the particle filter and the detector. For continuous absorption measurements, particles are collected on a filter or a filter tape and illuminated. In aethalometers [18.44], the light attenuation with particles on the filter tape is measured and compared with the light attenuation by the unloaded filter tape as a reference. The difference is considered to be the absorption due to the collected particles. For automated operation, the filter tape is advanced as soon as the measured attenuation is above a threshold value. Measurements are made either at a single wavelength or at multiple wavelengths. For example, the Magee Scientific aethalometer model AE33 (Magee Scientific, Ljubljana, Slovenia) measures the light attenuation at seven different wavelengths from the UV-A to the near-IR and performs internal corrections for the filter-loading effect (artificial increase in attenuation due to multiple scattering by particles). The particle soot absorption photometer (PSAP, [18.45]) measures

the differential transmittance through a glass fiber filter with and without particle loading, either at a single wavelength of 550 nm or at three wavelengths. The multi-angle absorption photometer (MAAP; [18.46]) measures both the light transmitted through and scattered back in two different angles from particles collected on a glass fiber filter tape. The absorption coefficient is derived with a two-stream approximation radiative transfer model that takes into account multiple scattering and reflection effects. Correction recommendations for the MAAP and the PSAP instruments are given in [18.29], and also for the aethalometer. However, there is presently no consensus on how to correct aethalometer measurements in a consistent way [18.29].

For all filter-based absorption photometers, the absorption coefficient measured at a specific wavelength can be converted to yield the mass concentration of light-absorbing particulate compounds, typically reported as equivalent black carbon, i.e., the mass concentration of black carbon that would yield the measured absorption coefficient.

In a different approach, light extinction can be measured by cavity attenuated phase shift (CAPS) spectroscopy due to a change in the waveform of a square-wave-modulated light-emitting diode coupled to an optical cavity, depending on the particle light extinction in the optical cell [18.47]. Complementing equivalent black carbon measurements by filter-based absorption measurements, the single-particle soot photometer (SP2) measures soot mass in individual particles by laser-induced incandescence [18.48].

18.4.3 Photoacoustic Spectroscopy

An alternative to filter-based absorption measurements is photoacoustic spectroscopy [18.18, 49, 50], where light absorption heats up particles and the surrounding gas. Various photoacoustic sensors have been developed for light absorption measurements of atmospheric particles [18.51–53], including the commercially available three-wavelength photoacoustic soot spectrometer PASS (Droplet Measurement Technologies, Longmont, CO, USA). The photoacoustic extinctions PAX (Droplet Measurement Technologies, Longmont, CO, USA) combines a photoacoustic cell to measure light absorption by particles and a reciprocal nephelometer to measure light scattering by particles in one instrument, yielding particle light extinction.

18.4.4 Electrical Detection and Mobility of Particles

Electrometers are used to determine the number concentration of an ensemble of particles by collecting

electrically charged particles on the electrode of an electrometer and measuring the electric current induced by the deposition of electrical charges. In a Faraday cup electrometer, charged particles are collected on a filter placed in a metal housing (Faraday cup), and the induced charge is measured with a highly sensitive electrometer (0.1–1 fA). For quantitative information, the charging state of the particle ensemble has to be known. In order to charge the sample with high efficiency, unipolar diffusion chargers, where unipolar positive ions are produced by corona discharge, are commonly used. However, the efficiency of the diffusion charging process is dependent on a large number of factors, and the accuracy of the particle number concentration from electrometer measurements is limited by the variability in the particle charging probability as a function of particle size and chemical composition. For example, multiple charged particles deposit more than one elementary charge to the electrometer. Compared with single-particle counting of CPCs, electrometers require a minimum number concentration for reliable quantification, but as an advantage, particles of all sizes will be detected as long as they carry an electrical charge and are captured in the Faraday cup. A typical application of electrometers is the calibration of CPCs by independent measurement of the particle number concentration in a controlled laboratory setup [18.54].

Mobility particle size spectrometers (MPSS) classify submicron particles according to their electrical mobility, i.e., the behavior of charged particles in an electric field. In the first commercial mobility spectrometer, the electrical aerosol analyzer (EAA) [18.55] based on a design developed by [18.56], particles are electrically charged with a unipolar positive charger and then coaxially introduced into a cylindrical classifier with a well-defined electric field. It is recommended that a positive voltage be applied, i.e., measuring the mobility of negatively charged particles. Depending on the flow rate and the electric field, particles with high mobility are removed by deposition to the classifier walls, while larger particles with sufficiently low electrical mobility are detected with a Faraday cup electrometer. By applying different voltages to the classifier, the electric field is adjusted to remove different mobility fractions of the particle population in order to obtain particle size distributions. In typical applications, the EAA covered a size range of about 10 nm to 1 μm in ten size bins.

The differential mobility particle sizer (DMPS) is an improvement over the EAA with much higher size resolution. A DMPS (Fig. 18.7) consists of a particle neutralizer [18.56], a differential mobility analyzer (DMA) [18.57], and a particle detector, e.g., a CPC or an electrometer. In the neutralizer, particles are exposed

Fig. 18.7 Schematic setup of a mobility particle size spectrometer; the particle sample enters a pre-impactor to remove supermicron particles, a neutralizer to achieve charge equilibrium, and the DMA for mobility classification; the central rod is biased to a variable high voltage to establish an electric field in which particles within a small mobility range are deflected to an annular slit and transferred to a CPC; the *dashed arrows* indicate the particle-free sheath flow

to bipolar ions for a sufficient length of time to achieve Boltzmann charge equilibrium. Most commonly, radioactive neutralizers based on Kr-85, Am-241, or Po-210 are used to establish a bipolar ion cloud. As an alternative, nonradioactive neutralizers based on soft x-ray ionization [18.58] and bipolar corona discharge are available. After passing the neutralizer, the average charge of the particle population is close to zero, and the size-dependent probability of each particle carrying one or multiple positive or negative charges is well defined. A commonly used approximation for particle charge distribution was published by [18.23]. In the DMA, particles are introduced into an electric field between two electrodes. In most cases, a cylindrical design with a metal rod as inner electrode and a metal cylinder as outer electrode is used. The aerosol sample with charged particles enters the annular region between the electrodes in a laminar flow of particle-free sheath air. The geometry of the DMA and the applied voltage determine the trajectory of particles as a function of their electrical mobility. A particle fraction with a defined electrical mobility is deflected to a slit in the inner electrode (which is typically biased to a positive voltage up to several kV), while all other particles are deposited to the walls or removed with the excess air flow. Thus, instead of measuring a particle fraction with an electrical mobility above a certain threshold integrally as in the EAA, the DMA extracts particles differentially within a small range of electrical mobility. To obtain particle size distributions, different voltages are applied in discrete time steps, and the particles are detected with a CPC or an electrometer. A typical measurement cycle for a full DMPS particle size distribution measurement

takes 15–30 min. In order to reduce the time required to complete a full measurement cycle, [18.59] proposed the scanning mobility particle spectrometer (SMPS), where the voltage is ramped up and down continuously instead of applying discrete voltage steps in the DMPS. In addition, various modifications to the design of the cylindrical DMA, and the radial DMA design [18.60] have been developed to improve the DMA transmission efficiency of nucleation mode particles. An overview of the recommended setup and the performance of various currently available MPSS can be found in [18.29, 61].

In order to study fast changes in particle size distribution, e.g., close to particle emission sources or directly in engine exhaust, mobility spectrometers with electrometer detection such as the engine exhaust particle sizer (EEPS) or the fast mobility particle sizer (FMPS) are commercially available. In addition, for size and mobility distribution measurements of molecular clusters and nucleation mode particles, the neutral cluster and air ion spectrometer (NAIS) [18.62] classifies particles and air ions based on their mobility and parallel detection with an array of 21 electrometers. Depending on the operating mode, the NAIS instrument works similarly to the electric aerosol spectrometer [18.63] or to the air ion spectrometer (AIS), which only detects naturally occurring air ions.

18.4.5 Diffusivity of Particles

In a laminar flow field, the diffusivity of ultrafine particles (diameter < 100 nm), and thus the probability of deposition to surfaces, increases with decreasing size. In *diffusion batteries*, this differential diffusion behav-

ior can be exploited to obtain particle size distributions. In practice, there are tube-type (or channel-type) diffusion devices, such as a series of fine capillaries [18.64], and screen-type diffusion devices, where particles flow through a series of fine mesh screens [18.65]. While diffusion batteries have been replaced by MPSS for size distribution measurements, diffusion screens are still in use today for controlling the lower size limit of a particle population, e.g., to modify the lower cutoff diameter of a CPC. Also, *diffusion size classifiers* [18.66], where particles are electrically charged and deposited in consecutive stages depending on their diffusive behavior, have become available as robust portable instruments to infer particle number concentrations, the lung deposited particle surface area concentration, and the mean particle diameter.

18.4.6 Aerodynamic Behavior of Particles

The *aerodynamic particle sizer* (APS) measures the aerodynamic diameter by accelerating the airflow in a nozzle and measuring the time of flight of individual particles after acceleration. Each particle is detected twice by light scattering with two laser beams separated by a fixed distance, e.g., 200 μm . The time delay between the two detection pulses divided by the known distance of the laser beams yields the particle velocity. Due to their inertia, larger particles with a higher mass are accelerated less than smaller particles with lower mass. Thus, the particle velocity and the associated time of flight over a given distance are directly related to particle mass. For a spherical particle of unit density, as used in the definition of the aerodynamic diameter (Sect. 18.3.6), this enables a unique determination of the aerodynamic diameter. Aerodynamic particle sizers cover a nominal aerodynamic diameter range of about 0.5–20 μm , although [18.67] found large instrument-to-instrument variability of up to 60% for particle diameters < 0.9 μm in an intercomparison study of 15 aerodynamic particle size spectrometers. In practice, the aerodynamic diameter derived from the APS is adjusted for particle sphericity, particle and gas density, and air viscosity. For interpretation of the APS, it should also be taken into account that particles may be affected by a pressure and temperature drop after expansion through the nozzle.

Impactors are widely used to collect size-fractionated particle samples based on acceleration of the air flow through nozzles and inertial impaction on collection plates (Chap. 19). The acceleration is determined by the air flow rate and the nozzle size. Depending on the aerodynamic behavior of particles, the fraction of the particle population that cannot

follow the streamlines around the collection plate will impact on the plate. In cascade impactors, size fractions are subsequently collected on several impaction stages with well-characterized cutoff diameters, i.e., the aerodynamic diameter of particles with a collection efficiency of 50%. However, particle bounce effects, potentially leading to a transfer of particles to subsequent stages, have to be avoided, and interstage particle losses have to be characterized. In order to minimize particle bounce-off and transfer to subsequent stages, a thin layer of grease can be applied to the impaction substrates. Each impactor stage is associated with a pressure drop due to expansion through the nozzles. For typical 5-stage or 12-stage cascade impactors such as the Berner-type low-pressure impactor (LPI), covering a diameter range of 50 nm to 10 μm , a pressure drop to ≤ 50 mbar is reached in the final impaction stage.

The electrical low-pressure impactor (ELPI) [18.68] measures particle size distribution by separating particle size fractions according to aerodynamic diameter in a cascade impactor, and electrical detection of the collected particles. Before entering the impactor, the particle population is electrically charged with a unipolar corona charger, and collected particles deposit their charge on the impaction stages, which is measured as electric current with an electrometer. With volume flow rates of 10 or 30 L min^{-1} , the ELPI can provide particle size distribution with high time resolution. The commercial ELPI+ has also been used for size-resolved particle flux measurements [18.69].

A prominent feature of impactors is the physical collection of size fractions of a particle population. The collected particles may be analyzed for particle mass or chemical composition. For gravimetric analysis of the collected particle mass, aluminum impaction substrates are widely used. There are various impactor designs for specific purposes. For example, rotating drum impactors [18.70] collect particle samples continuously on a slowly rotating drum, which allows both size-resolved and time-resolved analysis of the collected particles. In the micro-orifice uniform deposit (MOUDI) impactor [18.71], the collection plates are rotated in order to deposit particles uniformly on the plates. MOUDI impactors can reach a lower cutoff diameter of 10 nm. A quartz crystal microbalance MOUDI has recently been developed, allowing real-time size-resolved mass measurements [18.72] (cf. piezoelectric crystal microbalance in Sect. 18.4.7).

In virtual impactors, the impaction plate is replaced by a second airflow of different velocity, so that the particle population is separated into two size fractions with a specified size cut, and both particle fractions remain suspended. Cyclones also make use of inertial

impaction to separate larger particles from a particle population by deposition on the cyclone wall from the circular path of the airflow in a vortex.

18.4.7 Particle Microbalances

Particle mass concentrations can be directly determined by quantitatively collecting particles from a known volume of air on filters (Chap. 19), and using *microbalances* to measure the particle mass. There is a large variety of filter material for atmospheric particle sampling with well-characterized collection efficiency, including fiber filters made of quartz, glass, cellulose, or metal, and membrane filters [18.73]. Deposition of particles to the filter is caused by different mechanisms, including diffusion (efficient for smaller particles), impaction and interception (important for accumulation mode particles), and gravitational settling and sieving (efficient for larger particles). For collection, filters are placed in filter holders that can be open-faced, integrated in a sampling line (inline), or stacked in filter cassettes. The volume flow rate through the filter holder is typically $> 1000 \text{ L min}^{-1}$ in high-volume samplers, or $< 20 \text{ L min}^{-1}$ in low-volume samplers. Because particle mass concentration is legislatively regulated, it is sometimes necessary to collect a specified size fraction of atmospheric particles on filters by preceding the filter holder with cyclones or impactor-based inlets with a defined cutoff, such as the PM_{10} or $\text{PM}_{2.5}$ standards for particles with diameters < 10 and $2.5 \mu\text{m}$, respectively, with a 50% transmission efficiency for the cutoff sizes. Impactors can also be used for size-resolved particle collection and subsequent gravimetric analysis. Before and after particle collection, the filter is conditioned for 24 h in a temperature- and humidity-controlled room, weighed on a microbalance, and the mass increase is divided by the total volume of sampled air to obtain the particle mass concentration.

A *piezoelectric crystal microbalance* for automated particle mass concentration measurements [18.74] is based on the change in the resonant vibration frequency of a piezoelectric crystal when particle mass is added to the crystal. Typically, quartz crystal microbalances with resonant vibration frequencies of 5–10 MHz are applied, and the change in the vibration frequency due to the deposition of particles from a known volume of air is registered. Piezobalances can resolve absolute mass changes as small as 1 ng, but due to a nonlinear relationship between the change in mass and the change in the vibration frequency, the crystal has to be cleaned when $\gtrsim 10 \mu\text{g}$ of absolute mass has been deposited.

The *tapered element oscillating microbalance* (TEOM) [18.75] consists of a hollow tapered tube with a replaceable particle filter at the narrow tip. Particles

collected on the filter cause a decrease in the natural oscillation frequency of the tapered element. Temperature fluctuations and condensation of water have to be avoided because the oscillation frequency will be affected, and therefore the housing of the microbalance is temperature-controlled, typically to a constant temperature (30 or 50 °C, depending on research objectives or legislative regulations). This can lead to evaporation of volatile or semivolatile compounds, which must be accounted for. With the filter dynamic measurement system (FDMS), the measurement alternates between the sampling of ambient particles and a reference cycle with particle-free air. The mass loss measured during the reference cycle is used as an estimate to compensate for the evaporative mass loss during the ambient measurement.

18.4.8 Attenuation of Beta Radiation

Beta attenuation monitors or beta gauges [18.76] are used for continuous measurement of the particle mass concentration. Particles are collected on a filter tape, and beta radiation (energy range 0.01–0.1 MeV) directed through the filter tape is attenuated due to inelastic scattering by atomic electrons of the filter material and the collected particles. The particle mass concentration is evaluated from the increase in attenuation as more particles are collected on the filter tape. Depending on the ambient particle concentration and the user-selectable intervals of filter tape change, continuous measurements are possible for several months. For the typical composition of atmospheric particles, beta attenuation is only weakly dependent on the chemical composition, and beta gauges are widely used as equivalent methods for the measurement of PM_{10} particle mass concentrations.

18.4.9 Combination of Particle Sensors

The combination of two or more particle sensors allows for additional measuring capabilities, and several examples are briefly presented to illustrate this potential.

Atmospheric measurements of ultrafine particle size distributions typically carried out with mobility spectrometers are limited either by the relatively slow measuring cycle of SMPS or DMPS instruments or by the sensitivity and accuracy of fast mobility spectrometers. In order to measure the temporal evolution of the nucleation mode very quickly and accurately, the condensation particle counter battery and the DMA train have been proposed. The condensation particle counter battery [18.77] is a combination of several separate CPCs with different lower cutoff diameters operated in parallel. The differences in particle number concentration measurements of two CPCs can be attributed to the size

range between the two lower cutoff diameters. In this way, concentration changes in several size bins of the nucleation mode can be measured with the time resolution of the CPCs. For narrower and more precise size bins, the DMA train [18.78] employs six differential mobility analyzers and CPCs in parallel to measure rapid changes in sub-10 nm particles with high time resolution.

The hygroscopic tandem differential mobility analyzer (HTDMA) is a combination of two DMAs, a conditioning unit for humidity and a CPC in order to measure the hygroscopic properties of particles, i.e., how particles respond to changes in relative humidity [18.79]. With the first DMA, a particle size fraction is selected and subsequently exposed to controlled humidity conditions. Depending on size and chemical composition, some or all particles may grow due to water uptake. This size change is measured with the second DMA and the CPC. As a result, HTDMA measurements yield size-resolved hygroscopic growth factors and information about the mixing state of a particle population, i.e., the variability in the chemical composition of individual particles. A variation of this principle is the volatility tandem differential mobility analyzer (VTDMA), where a particle size fraction is selected with the first DMA and exposed to elevated temperatures in a controlled volatility conditioning unit. The loss of volatile compounds at different temperatures can then be determined from the reduced size of the particles measured with the second DMA. Again, by measuring a physical property, i.e., the size change in particles, indirect information about the chemical composition of the particle population can be derived. The hygroscopic growth factors and volatility losses from HTDMA and VTDMA measurements are important in many practical measurement situations, for example when atmospheric particles are sampled through a heated inlet or dried before the measurement.

Considering the relationship between different particle equivalent diameters, the simultaneous measurement for example of aerodynamic and mobility diameters with an electrical low-pressure impactor and an SMPS can be used to estimate particle properties such as the effective density [18.80] or the fractal dimension of particle agglomerates [18.81]. Similarly, a size distribution measurement together with an independent particle mass measurement, for example a combination of SMPS and quartz crystal microbalance measurements [18.82], yields the effective density of a particle population.

18.4.10 Comparison of Methods

For a comprehensive characterization of atmospheric particles, the combination of many complementary

measurement techniques and instruments is necessary. Here, the major advantages and limitations of instrumentation used to measure particle number, particle size, particle mass, and optical properties will be briefly discussed and summarized in Table 18.6.

For particle detection and particle number concentration measurements, single-particle counting is possible with both OPCs and CPCs. However, particle coincidence at high number concentrations has to be taken into account, and the smallest particle size that can be directly detected with an OPC restricts its use for ultrafine particles. In contrast, electrometers can detect particles over a wide size range and with a fast time response, but particles have to be electrically charged, and the sensitivity is not sufficient to count individual particles. Therefore, the CPC is the preferred instrument for accurate measurement of total particle number concentrations over a wide size range. For the determination of the particle number concentration in ambient air according to the technical specification CEN/TS 16976:2016 [18.83], *n*-butanol is required as the working fluid of the CPC.

When evaluating the scattering signal of individual particles in optical particle spectrometers, particle size distributions can be obtained for particles ≥ 100 nm with a time resolution on the order of seconds. The resulting optical equivalent diameter is directly related to the interaction of the particle with light, pertinent to the direct climate effect. When evaluating human health effects and the deposition of particles in the human body, direct measurement of the aerodynamic diameter with the aerodynamic particle sizer or with impactors is more appropriate. An additional benefit of impactor measurement is the physical collection of size-resolved particle samples, which can be analyzed for chemical composition. However, the APS sizes only particles ≥ 0.5 μm , and the size resolution of impactors is limited. For submicron particles, mobility spectrometers such as the DMPS and the SMPS are very popular. These instruments combine good size resolution and sensitive particle detection. However, a minimum scanning time of 2 min is recommended for the SMPS [18.61], and thus the time resolution is typically on the order of minutes. Also, compliance with licensing requirements for radioactive neutralizers in mobility spectrometers typically requires additional administrative effort. Diffusion size classifiers [18.66] are commercially available as portable handheld instruments and yield average size information and particle number concentration. While they are easy to use, their accuracy and fields of application are limited.

Nephelometers can measure the particle scattering coefficient very precisely. When measuring in environments with particles predominantly in the diameter

Table 18.6 Advantages and disadvantages of devices for atmospheric particle measurements

Type of Sensor	Advantages	Disadvantages
OPC	Single-particle counting, information about equivalent diameter	Not applicable for ultrafine particles, size information dependent on particle shape and chemical composition, particle coincidence
CPC	Single-particle counting, wide size range	Particle coincidence
Nephelometer	Direct measurement of particle scattering coefficient	Careful calibration needed
Filter-based absorption sensor	Very low detection limit	Several correction schemes, no definitive standard correction yet; no standard reference calibration material
Photoacoustic sensor	Direct measurement of particle absorption coefficient	Sensitive to noise perturbation; difficulties at low particle concentrations; careful calibration needed
Electrometer	Wide size range, fast response	No single-particle counting, dependent on particle charging probability
MPSS	Mobility diameter measurement in the submicron size range, good size resolution	Limited time resolution (typically several minutes), licensing required for radioactive neutralizers
Diffusion size classifier	Portable instruments, information about ultrafine particles	Limited accuracy
APS	Aerodynamic diameter measurement, no calibration of scattering intensity required	Lower particle diameter cutoff ≈ 500 nm
Impactor	Size-dependent particle collection	Particle bounce in impactor stages, limited size resolution
Filter microbalance	Direct mass measurement, chemical analysis of collected sample possible	Time-consuming due to manual operation
Piezoelectric crystal microbalance	Very low detection limit	Requires frequent routine maintenance
Oscillating microbalance	Continuous measurements of particle mass concentration	Potential loss of (semi)volatile compounds
Beta attenuation monitor	Continuous measurements of particle mass concentration	Particle mass is derived indirectly

range < 100 nm, the scattering intensities are very low. Under these conditions, besides careful calibration, instruments with high flow rates are recommended.

The particle absorption coefficient can be measured by either filter-based methods or the photoacoustic method. Whereas the filter-based photometers require corrections in order to derive the particle absorption coefficient, the photoacoustic photometer yields a direct measurement of the particle absorption coefficient. The photoacoustic method, however, is sensitive to disturbance by noise and vibrations (e.g., pumps) and has a relatively high lower detection limit. With multi-wavelength instruments, the spectral dependency of the particle absorption coefficient can be investigated. Depending on the application, the possible time resolution of the instrument is important. In clean environments, long integration intervals up to 60 min or greater are recommended, while measurement intervals as short as 1 min are typical in polluted environments.

For particle mass concentration measurements, discontinuous techniques, such as sample collection with

filters or impactors and subsequent gravimetric analysis, and continuous techniques with varying degrees of automation exist. Long-term routine measurements are facilitated by continuous techniques such as beta attenuation monitors and piezoelectric crystal or oscillating element microbalances. Here, the quartz crystal microbalance and tapered element oscillating microbalance exploit the direct relationship between a change in vibration frequency and collected particle mass, while beta attenuation monitors rely on the assumption that the attenuation of beta radiation is only a function of particle mass and independent of particle chemical composition. The piezoelectric crystal microbalance requires frequent maintenance, and the oscillating microbalance is prone to loss of semivolatile compounds from the collected sample at the elevated temperatures inside the instrument. Given the limitations of the continuous particle mass measurement techniques, they are often complemented in regular time intervals by filter collection and gravimetric analysis, which is costly in terms of time and labor.

18.5 Specifications

The most important recommendations and general specifications for the different instrument types were described in Sect. 18.4. In this section and in Table 18.7, typical values for accuracy, measurement range, and time resolution are given. For most instrument types, there are several models of several manufacturers available, each with distinct specifications. The values given are therefore guided by the values of standard-quality instruments, installed for example at WMO GAW measurement sites.

For particle number concentration measurements in ambient air, according to [18.83], a condensation particle counter with *n*-butanol as working fluid must provide a lower cutoff diameter (50%) of (7 ± 0.7) nm and counting efficiency $> 90\%$ for $1 \mu\text{m}$ particles. The dynamic range should cover at least three orders of magnitude from $< 100 \text{ cm}^{-3}$ to $> 10\,000 \text{ cm}^{-3}$,

and with a zero filter the zero count rate should be $< 1 \text{ min}^{-1}$. Many commercial CPCs are in compliance with these specifications; however, the actual performance of individual instruments must be checked regularly (Sect. 18.6).

Commercial electrometers for atmospheric particles are sensitive to electrical currents of $\pm 1 \times 10^{-16}$ to 10^{-15} A (0.1–1 fA) at 1 Hz time resolution. This is important in order to quantify small particle number changes even at low particle number concentrations. A comparison of particle size and concentration measurements with electrometers from European national metrology institutes and expert laboratories [18.84] showed a typical instrument-to-instrument variability within $\pm 3\%$ for particle diameters from 20 to 200 nm. For particle diameters < 20 nm and at low concentrations, instrument comparison is more challenging.

Table 18.7 Typical specifications of standard particle sensors; further details in text

Type of sensor	Measurement range	Accuracy	Response time
Sensors detecting particle number			
OPC	Size range: ≈ 0.2 to 10 or $20 \mu\text{m}$; Concentration range: 1×10^{-3} to $1 \times 10^4 \text{ cm}^{-3}$	$< 10\%$ $< 10\%$	< 5 s
CPC	Size range: ≤ 7 nm to $\approx 3 \mu\text{m}$; Concentration range: 1×10^1 to $1 \times 10^5 \text{ cm}^{-3}$;	$< 10\%$; $< 10\%$	< 5 s
Electrometer	Size range: < 10 nm to $\approx 10 \mu\text{m}$; Electric current range: 1×10^{-15} to 1×10^{-11} A	$\pm 1 \times 10^{-15}$ A	< 5 s
Sensors detecting particle size			
MPSS	Several models exist, covering size ranges from < 5 nm to $1 \mu\text{m}$	Depending on size range, e.g., 10% for 20 – 200 nm	2 – 5 min
APS	Size range: ≈ 0.5 to $20 \mu\text{m}$; Concentration range: 1×10^{-3} to $1 \times 10^4 \text{ cm}^{-3}$	$< 2\%$ $< 10\%$	< 5 s
Impactor	Several models exist, covering size ranges from 16 – 56 nm to $10 \mu\text{m}$	$< 10\%$	Depending on sampling interval
Sensors detecting particle light scattering and absorption coefficient			
Nephelometer	2×10^{-7} to $2 \times 10^{-3} \text{ m}^{-1}$	2 to $3 \times 10^{-7} \text{ m}^{-1}$	< 10 s
Filter-based absorption sensor	Lower bound: MAAP: $8 \times 10^{-8} \text{ m}^{-1}$ PSAP: $5 \times 10^{-8} \text{ m}^{-1}$ Aethalometer: $1 \times 10^{-7} \text{ m}^{-1}$ Upper bound: $1 \times 10^{-2} \text{ m}^{-1}$	1 to $5 \times 10^{-7} \text{ m}^{-1}$	1 min
Photoacoustic sensor	1×10^{-6} to $1 \times 10^{-2} \text{ m}^{-1}$	$1 \times 10^{-6} \text{ m}^{-1}$	< 1 min
Sensors detecting particle mass			
Oscillating microbalance	$0.1 \mu\text{g m}^{-3}$ to 1 g m^{-3}	Precision: $0.5 \mu\text{g m}^{-3}$ (24 h average); $2 \mu\text{g m}^{-3}$ (1 h average)	< 1 min; because of reference cycles effectively 6 min
Beta attenuation monitor	$< 1 \mu\text{g m}^{-3}$ to 1 g m^{-3}	Precision: 0.3 – $1.0 \mu\text{g m}^{-3}$ (24 h average); 3 – $5 \mu\text{g m}^{-3}$ (1 h average)	1 min; because of reference cycles effectively ≈ 15 min

Particle number size distributions in the diameter range of 0.2–20 μm are typically measured with aerodynamic or optical particle size spectrometers. Large instrument-to-instrument variability has been reported for concentration measurements in the size range close to the lower cutoff diameter [18.67]. Direct intercomparison in the diameter range around 1 μm often shows lower concentration measurements with optical particle spectrometers compared to aerodynamic particle spectrometers. The number of sizing channels varies between the available models and should be taken into account with respect to the final application.

Following [18.85], number size distribution measurements of particles < 1 μm with carefully calibrated mobility particle size spectrometers should comply with the following specifications. The particle size measurement of a certified polystyrene particle size standard, preferably in the diameter range of 100–350 nm, should be within $\pm 3\%$ of the nominal value of the standard. The particle number size distribution should be within $\pm 10\%$ of a reference mobility particle size spectrometer in the diameter range of 20–200 nm, and within $\pm 20\%$

in the diameter range of 200–800 nm. The particle number concentration derived from the particle size distribution measurement should be within $\pm 10\%$ of a reference CPC. The lower cutoff diameter of the CPC used should be within 1 nm of the nominal value.

Most nephelometers record a measurement value internally each second (or even higher frequency), but integrate to values of 1 min or longer. Depending on the model, the values at high frequency might be accessible. However, the realistic response time is between 1 and 10 s. When choosing a model, the finite bandwidth of each measurement wavelength should be as narrow as possible.

The instrument noise of filter-based light absorption sensors depends on the wavelength, the flow rate, the filter spot size, and the averaging time. In an intercomparison study, [18.86] report typical instrument noise levels for the MAAp, the PSAP, and the aethalometer for different wavelengths and averaging intervals. The lower bounds given in Table 18.7 can vary slightly as a function of wavelength, and longer averaging intervals can yield lower detection limits.

18.6 Quality Control

For most particle sensors mentioned in this chapter, there are standard operating procedure manuals of the scientific community containing guidelines for quality assurance, quality control (QA/QC), and calibration [18.29, 61, 87]. The general QA/QC procedures given in Chap. 3 should be considered. In addition, instructions by the manufacturer for specific calibration procedures should be taken into account. Further, if the particle sensor is used under specific environmental conditions ranging outside the nominal instrument operating conditions, e.g., at high altitude or at very low temperatures, its calibration should take into account these conditions, thus calibrating at low pressure or in a cold chamber. This section summarizes the most important aspects with respect to specific sensor types and presents in Table 18.4 an overview of quality assurance measures.

Instruments for measuring particle number such as CPCs are calibrated by using monodisperse silver particles, size-selected with a DMA. The efficiency of the CPC is then evaluated against a reference electrometer [18.88]. For example, the electrometer used at the World Calibration Center for Aerosol Physics (WCCAP) [18.29] is calibrated to a femtoampere source at the German national metrology institute. Technical specifications for the determination of the number concentration of atmospheric particles in ambient air are given in [18.83].

The accuracy of particle size measurements must be evaluated by providing particles with known or very narrow geometric standard deviation from the particle sizing instrument. Often, polystyrene latex spheres (PLS) are used. They are commercially available in sizes from 20 nm to super-micrometer sizes, and are approved and traceable by the US National Institute of Standards and Technology (NIST). The sizing accuracy can also be validated by producing a quasi-monodisperse particle population (e.g., ammonium sulfate particles with a DMA system). For MPSS, the calibration and QA/QC procedures are described in great detail in [18.29, 61, 85].

Nephelometers are calibrated by sampling a particle-free reference gas with known values of the scattering coefficient for several wavelengths. With this gas, the *span point*, or the upscale part of the calibration curve, is determined. Typically, pure CO₂ (purity grade 4.8 or 5.5) is used. If the nephelometer is applied in environments with very high scattering coefficients, a gas with a higher scattering coefficient is recommended (e.g., heptafluoropropane HFC-227ea, which is however a halocarbon gas). For the zero-point determination, the internal zero-air filter is switched on in order to sample particle-free air. As the zero point defines the effective lower detection limit of the measurements, the quality of the zero-air filter and

Table 18.8 Calibration methods and quality assurance measures of particle sensors; further details in text

Type of sensor	Calibration method; QA/QC measure	Time interval	Remarks
OPC	Application of DMA-size-selected monodisperse particles; Application of NIST-traceable polystyrene spheres; Count efficiency validated with simultaneous CPC measurement	Yearly	See [18.29, 61, 85] for details
CPC	Application of DMA-size-selected monodisperse silver particles and count efficiency validated with reference electrometer	Yearly	See [18.83, 88] for details
Nephelometer	Full calibration with reference gas; Zero-point determination and adjustment of calibration curve	Yearly; Weekly to daily	More often during field campaigns; Zero point determines effective lower detection limit
Filter-based absorption sensor	No standard calibration method available, ongoing research; Application of equivalent black carbon mass; Determination of site-specific mass absorption cross section; Simultaneous scattering measurements	Once at production; Yearly; Yearly	See [18.29, 89]; Includes particle-filter interaction; Chemical analysis necessary; Takes into account particle-filter interaction [18.45, 90]
Photoacoustic sensor	Full calibration with reference gas; Zero-point determination and adjustment of calibration curve	Yearly; Daily to hourly	More often during field campaigns; Zero point determines effective lower detection limit
Electrometer	Calibration to a femtoampere source at reference metrology institutes	Yearly	See also [18.83]
MPSS; Diffusion size classifier; APS; Impactor (size)	Application of DMA-size-selected monodisperse particles; Application of NIST-traceable polystyrene spheres; Count efficiency validated with simultaneous CPC measurement	Yearly	See [18.29, 61, 85] for details
Particle microbalances	Application of NIST-traceable reference weights and standards	Yearly	See [18.29, 87] for details; Filters have to be conditioned before and after collection
Beta attenuation monitor	Application of NIST-traceable reference weights and standards	Yearly	See [18.29, 87] for details

of the zero-point measurement defines the precision with which the instrument's background signal is measured. Therefore, a zero-point measurement should be performed at least weekly to daily, and even hourly when sampling in very clean environments.

The specific characteristics of filter-based particle absorption photometers were described in Sect. 18.4. References [18.29, 87] give more details on potential calibration of these instruments. A calibration of the filter-based methods needs to take into account the interaction of the measurement light beam with the filter media and the deposited particles, which also have scattering properties. References [18.45, 90] describe calibrations with the help of simultaneous nephelometer measurements. For example, the aethalometer has been calibrated using an *equivalent* mass of black carbon with a respective mass absorption cross section, which however includes the particle-filter interaction.

In order to derive mass concentrations representing real ambient air equivalent black carbon concentrations, the respective mass absorption cross sections have to be experimentally derived for each measurement site by chemical analyses. However, there are currently no procedures commonly agreed upon as to how to calibrate filter-based particle absorption photometers and how to convert the attenuation measurements into mass concentrations in a consistent way [18.29, 89].

Photoacoustic absorption sensors can be calibrated using a gas with known absorption coefficients (e.g., NO₂), likewise for nephelometers and the light scattering coefficient. The photoacoustic sensors are sensitive to any disturbance by ambient noise, e.g., from pumps, and the instrument should therefore be insulated. As with nephelometers, a careful zero-point measurement is essential, performed at least daily, and even hourly when sampling in very clean environments.

Calibration and QA/QC procedures for particle mass measurements are described in [18.29, 87] and in the user manuals of the manufacturers. For the calibration of filters to be used with the gravimetric method, NIST-traceable reference weights must be used. The calibration con-

stant of an oscillating microbalance system can be verified with a preweighed calibration filter. Sensors applying the beta attenuation method usually use an internal membrane mass as a reference, which has been calibrated by the manufacturer with NIST-traceable standards.

18.7 Maintenance

The standard operating procedure manuals of the scientific community contain guidelines for the maintenance of particle instruments [18.29, 61, 87]. If available, instructions from the manufacturer (operating manuals) should also be taken into account, in particular concerning specific parts of instruments such as cleaning of optical parts or flow-regulating pieces.

Particle sensors should be calibrated yearly. If the sensor is used within a measurement campaign, it should be calibrated both at the beginning and at the end. When calibrating the instrument, one should not forget to calibrate the internal sensors as well for temperature, relative humidity, and pressure.

A general measure of QA/QC is continuously maintaining and saving log-files of all relevant complementary measurement parameters, such as sample and sheath flow, temperature of housing, sample cell or inlet tubing, relative humidity in the sample cell, the ambient and sample pressure, and current or voltage of light sources. If spurious signals continue to appear, they are a sign that some maintenance is necessary. Most often, the instrument manuals give advice on the type of maintenance required.

For particle concentration measurements, verification of the sample flow rate is essential. The flow rate given by the instrument should be validated with a quality flow meter, which gives the flow rate at both standard atmospheric conditions and the actual volumetric flow. A flow rate check should be done at least every three months, and in the case of measurement campaigns at least once at the beginning.

Many particle sensors apply a specific light source and have an elaborate optical measurement system (e.g., mirrors, filters, windows). Depending on the evolution of the respective parameters in the log-files, replacement of the light source or cleaning of optical parts is necessary.

It is important to check the inlet system regularly and to keep it clean. The inlet and tubing system should

be checked at least weekly with respect to physical integrity and to ensure that the protection against intrusion of insects and water is in good order. The inlet itself and the tubing should be cleaned in regular intervals, including impaction plates in cutoff cyclones and inlets. The time interval of cleaning depends on particle concentrations at the sample location. However, at least a visual check should be done weekly. Cleaning can be done by using lint-free tissues, either dry or wetted with ethanol. For the tubing itself, small, thin brushes can be used or flushing the tubing with purified synthetic air. Tubing parts that are not stainless steel and that are situated outside should be replaced after one to two years, to take into account the aging by the impact of radiation, temperature, and humidity.

Many instruments apply internal filters for regular particle-free reference measurements. These filters should be exchanged in regular intervals, depending on particle concentrations at the sample location. Regular leak checks of the measurement setup are important. The sample flow circuit must not show any leak, in order to avoid potential sample contamination. Typically, absolute particle filters or high-efficiency particulate air (HEPA) filters are placed in front of the instrument and the count rate is observed, which should show zero over at least several minutes. Such a check should be conducted once a month, and in the case of measurement campaigns at least once at the beginning and once in the middle. In addition, an exchange of zero filters or another leak check may be necessary when the zero measurements show a drift. Note that there are different classes of filters for different efficiencies of blocking particles.

It is also important to regularly check the internal clock of each instrument, and adjust it if necessary. If the internal clock or other electronic parts are powered by a separate battery, this battery should be replaced regularly. In Table 18.9, an overview of the most important maintenance procedures is presented.

Table 18.9 Maintenance of particle sensors; further details in text; for devices not explicitly listed, the generally maintenance recommendations apply

Type of sensor	Kind of maintenance	Time interval
All instruments	Full calibration; Calibration of temperature/pressure/humidity sensors; Validation of flow rate (standard and volume flow); Cleaning of inlet system; Zero-air and leak check; Keeping track of metadata log-files	Yearly; Yearly; 3-monthly; Depending on particle concentrations; At least monthly; Weekly
OPC	Replacement of light source and cleaning of optical components	Depending on evolution of respective parameters in log-files
CPC	Exchange of working fluid, also in the internal tubing system; Cleaning or exchange of saturator wick	Yearly; Yearly
Nephelometer	Replacement of light source; Cleaning of optical components	Depending on evolution of respective parameters in log-files
Filter-based absorption sensor	Replacement of filter tape; Precise measurement of filter spot area (PSAP)	Depending on particle concentration; Yearly
Electrometer	Zero measurements compensating for drift in current measurement	Daily – Weekly
MPSS	See [18.29, 61, 85]	
Impactor	Cleaning of impaction plates	Depending on sampling interval, particle concentration
Piezoelectric crystal sensor	Cleaning of piezoelectric crystal	When limit of $\approx 10 \mu\text{g}$ mass deposition is reached
Oscillating microbalance	Replacement of microbalance filter; Replacement of reference filter	Depending on particle concentration

18.8 Application

Atmospheric particle measurements are crucial for a large number of applications in science and technology. This section outlines four examples of particle measurements applied to current atmospheric research challenges, and is neither exhaustive with respect to the many potential applications nor with regard to the various particle sensor types. The choice of the below-mentioned examples is guided by current research about the environmental impact of atmospheric particles, such as the effects on human health and climate. Accordingly, important particle sources such as secondary particle formation and particle removal by dry deposition, air quality impairment due to particles, and the effect of particles on the atmospheric radiation budget must be quantitatively described using particle sensors.

18.8.1 Secondary Aerosol Formation

Particles are emitted into the atmosphere as primary particles from various natural and anthropogenic sources,

such as sea spray or mineral dust, and formed by gas-to-particle conversion in the atmosphere as secondary particles. Until recently, elucidating the reaction mechanisms leading to atmospheric secondary aerosol formation has been limited by the available particle instrumentation. Nucleation, the initial step in secondary aerosol formation, leads to extremely small particles in the size range of 1–20 nm, the nucleation mode. Only over the past 10–15 years, improved condensation particle counters (Sect. 18.4.1) with sufficiently low cutoff diameters to detect freshly nucleated particles and advanced mobility spectrometers to follow the temporal evolution of particle size distributions have been developed, which are capable of characterizing the growth dynamics of the nucleation mode due to coagulation and condensation. New particle formation events are typically identified by a strongly enhanced concentration of nucleation mode particles measured with CPCs, and a characteristic growth behavior as measured with MPSS (Sect. 18.4.4). At the same time, advanced instrumentation for the measurement of the chemical composition of

particles such as the Aerodyne aerosol mass spectrometer (AMS) [18.91], the atmospheric pressure interface time-of-flight mass spectrometer (APi-TOF) [18.92] for atmospheric ions, and the proton-transfer-reaction mass spectrometer (PTR-MS) [18.93] for the measurement of organic precursor gases have provided detailed insight into the mechanisms of atmospheric secondary organic aerosol (SOA) formation. For example, understanding the role of extremely low-volatility organic compounds (ELVOC), which are highly oxidized multifunctional molecules (HOM), in SOA formation helped to better constrain the total contribution of SOA to the atmospheric particle burden. Understanding secondary aerosol formation and SOA properties is also essential for evaluating the impact of atmospheric particles on climate (Sect. 18.8.4).

18.8.2 Vertical Particle Flux Measurements

Dry deposition (Chap. 54) is an important removal process for atmospheric particles. The dry deposition of nutrients and pollutants can be to the advantage or disadvantage of ecosystems, crops, or residential areas. In order to quantify particle dry deposition, vertical particle flux measurements are carried out either directly using CPCs and OPCs (Sect. 18.4.1) in eddy-covariance systems (Chap. 55) or by indirect methods such as flux-gradient relationships. However, there are several limitations to estimating the particle dry deposition. Changes in particle number concentrations occur not only due to turbulent transport but also due to coagulation of particles, particle growth to sizes outside the measuring range of the particle sensor, or secondary aerosol formation, and it is difficult to take into account these processes separate from turbulent transport. For particle number and mass concentration, the assumption of steady-state conditions, which is a requirement for eddy-covariance calculations, is often violated. Also, most particle sensors are not sufficiently fast to provide independent particle number or mass concentration measurements for eddy-covariance with a time resolution of 10 Hz. For example, the response time of laminar-flow condensation particle counters to a number concentration change is typically a few seconds, and the associated loss of high-frequency flux contributions is commonly estimated from a spectral loss model. This is also true for size-segregated particle number flux measurements with optical particle counters [18.94–96] and the electrical low-pressure impactor [18.69, 97]. Particle mass fluxes have been calculated from size-segregated particle number flux measurements or measured directly and

chemically resolved using aerosol mass spectrometers in eddy-covariance measurements [18.98, 99].

18.8.3 Atmospheric Particles and Air Quality

In many studies, airborne particulate matter has been associated with adverse health effects, for example [18.100]. As a result, legislative measures for monitoring and evaluating the PM₁₀ and PM_{2.5} concentrations, i.e., the mass concentrations of all particles with diameters < 10 μm (corresponding to the thoracic convention) or 2.5 μm (corresponding to the high-risk respirable convention) [18.101], have been introduced in Europe and worldwide. Continuous measurements of the particle mass concentration are carried out using oscillating microbalances and beta attenuation monitors (Sects. 18.4.7 and 18.4.8) and validated by filter sampling and gravimetric analysis. However, advanced particle instrumentation is required to identify particle sources and quantify their relative contributions to the atmospheric particle burden, to understand the atmospheric transport and transformation processes of particles, and to evaluate their effect on human health. For example, there is concern that exposure to ultrafine particles with diameters < 100 nm is more detrimental to human health than exposure to larger particles [18.102]. However, the contribution of ultrafine particles to particle mass is negligible due to their small size, and assessing their health effects requires particle number-based metrics and size-resolved measurements. Further, in order to develop effective mitigations strategies in areas with elevated particle concentrations, the identification and evaluation of particle sources and their relative contributions by source apportionment is typically based on measurements of the particle chemical composition [18.103].

18.8.4 Climate Effects of Atmospheric Particles

Atmospheric particles affect the radiation budget both directly, by scattering and absorbing solar radiation, and indirectly by modifying cloud formation and cloud properties. The direct radiative effect of atmospheric particles can be evaluated by characterizing the optical properties of the particles. A key parameter for estimating the direct radiative forcing of particles is the single-scattering albedo (Table 18.4 and Sect. 18.3.2). It is important to note that the scattering and absorption properties of particles exhibit a strong dependence on wavelength. The wavelength dependence of the scattering, absorption or extinction coefficients, and

the single-scattering albedo can be expressed by the Ångström exponent α , which relates the ratio of these parameters at two different wavelengths λ_1 and λ_2 and the ratio of the two wavelengths, for example, for the single-scattering albedo by

$$\frac{\omega_{\lambda,1}}{\omega_{\lambda,2}} = \left(\frac{\lambda_1}{\lambda_2}\right)^{-\alpha} \quad (18.22)$$

This equation can be used to estimate the direct radiative effects of particles from a measurement of scattering and absorption at a single wavelength, and validated by measurements at different wavelengths. In practice, in-situ measurements with nephelometers and filter-based absorption photometers complement remote-sensing techniques such as sun photometers in the Aerosol Robotic Network (AERONET) [18.104, 105] that determine the spectral aerosol optical depth (AOD) and derived products including the refractive index, the particle phase function, and the single-scattering albedo. The AOD is an integral measurement of the combined particle absorption and scattering (thus extinction) over the total atmospheric column and is widely used to represent the atmospheric particle

concentration in global chemistry or transport modeling [18.106, 107].

The indirect climate effect of atmospheric particles, i.e., a change in the formation, distribution, and radiative properties of clouds due to atmospheric particles, is the single largest uncertainty of the global radiative forcing estimate [18.108]. Therefore, major efforts are made to improve our understanding of aerosol–cloud–climate interactions, including in-situ measurements of aerosol–cloud relationships, for example the potential of particles to act as cloud condensation nuclei (CCN) or as ice nuclei (IN). The CCN concentration can be measured with a CCN counter, in which a particle sample is exposed to a well-defined supersaturation of water vapor, and activated particles are detected with an OPC. For size-segregated CCN measurements, a differential mobility analyzer is used to preselect a certain particle size fraction, and then compare the number of activated particles measured with the CCN counter and the total number of particles in this size fraction measured with a CPC. To give an example, based on such measurements, [18.109] suggest that particle size might be more important for the ability of particles to act as CCN than their chemical composition.

18.9 Future Developments

Studying atmospheric particles and their environmental impact is a highly dynamic and interdisciplinary field of research. The development of new measuring capabilities is driven both by fundamental research questions to improve our understanding of the sources, transport, transformation, and sinks of atmospheric particles, and by applied research questions, for example in the fields of nanotechnology and materials sciences. In recent years, miniaturized sensors for atmospheric particles have become very popular. For example, handheld instruments are used for spatially resolved measurements at multiples sites in air quality studies, on mobile platforms such as bicycles and unmanned aerial systems

(Chap. 49), or for personal exposure sampling to assess health risks such as in workplaces. Miniaturized particle sensors are also used in citizen science projects, e.g., studying particle optical properties using low-cost spectropolarimeters attached to smartphones [18.110], or studying urban air quality using low-cost PM_{10} sensors. While the performance of such low-cost sensors is typically not comparable to established particle instrumentation, their development and application promises to open up many opportunities in atmospheric research, as long as the limitations of these sensors are well characterized and taken into account in the interpretation of the resulting data.

Andreas Held

Environmental Chemistry and Air Research
Technische Universität Berlin
Berlin, Germany
held@tu-berlin.de

Andreas Held, Professor of Environmental Chemistry and Air Research at Technische Universität Berlin, studied Geoecology at the University of Bayreuth, received his PhD at the University of Münster, and was Junior Professor/Professor of Atmospheric Chemistry at the University of Bayreuth from 2009 to 2018. His research interests include the formation and transport of atmospheric aerosols. He is currently co-chair of the European Aerosol Assembly's Aerosol Measurement Techniques working group.

Alexander Mangold

Scientific Service Observations
Royal Meteorological Institute of Belgium
Brussels, Belgium
alexander.mangold@meteo.be

Alexander Mangold is a Senior Scientist at the Royal Meteorological Institute of Belgium within the Scientific Service Observations. He received the Dipl.-Geoecology degree from the University of Bayreuth and his PhD in Natural Sciences at the University of Wuppertal, Germany. He is responsible for the atmospheric composition research program of his institute at the Belgian Antarctic research station and of the institute's atmospheric aerosol in-situ measurements in Brussels.

19. Methods of Sampling Trace Substances in Air

Christopher Pöhlker , Karsten Baumann , Gerhard Lammerl 

Trace gases are commonly collected via accumulative sampling, employing sorbents and cryotrap that utilize passive (diffusive) or active sampling principles. For semivolatile substances such as ammonium salts as well as oxygenated and halogenated organics, the particulate and gas phases must be collected separately—either side by side or in a sample train. Aerosol particles are collected using a broad spectrum of samplers that rely on physical principles such as inertia-based particle sampling, diffusive particle transport and adsorption to surfaces, particle migration and deposition in external fields, and filter sampling. Dedicated inlet systems with minimized particle losses must be used to ensure that sampling gives representative results, particularly for the particle size distribution. Note that artifact-free sampling is not yet available for a number of target compounds.

Poor air quality affects both human and ecosystem health [19.1, 2]. It is therefore important to monitor air quality to ensure that anthropogenic emissions are within the limits specified by national regulations and international agreements. Due to the diversity of natural and anthropogenic emissions, air pollutant concentrations in the atmosphere can vary significantly. In addition to primary pollutants (i.e., those that have long atmospheric lifetimes and remain unaltered after being released), many air pollutants are formed via secondary processes involving photochemical reactions during atmospheric transport. Due to these complexities, it is very difficult and costly to monitor air quality at ad-

equate spatial and temporal resolution. Ground-based monitoring stations provide good temporal coverage in real time but are too expensive to be operated at sufficient spatial resolution. Airborne monitoring via aircraft or satellite platforms provides good regional to global coverage but is extremely costly and very limited in terms of its temporal coverage and the number of pollutant species measured. The integrated sampling methods described here provide a valuable compromise between the two ideals of high spatial and temporal resolution. Furthermore, the sampling of atmospheric trace substances provides the basis for in-depth laboratory investigations of their physical, chemical, and/or biological

cal properties, as well as the changes in their properties upon atmospheric processing. The approaches used to integrate samples of trace substances over prolonged

time periods must be carefully evaluated for systematic artifacts that are quantified in the analytical procedures employed following sample collection.

19.1 Measurement Principles and Parameters

The analysis of trace substances in the atmosphere through sampling occurs indirectly in most cases, namely through a combination of trace substance sampling and the subsequent laboratory analysis of the analyte. The atmospheric abundances of gaseous and semivolatile species are typically quantified as mixing ratios or concentrations (Table 19.1) [19.3]. Since regulations for air pollutants specify limits on mass concentrations or volumetric mixing ratios, the volume of sampled air is the most important quantity aside from the amount of analyte found in the sample. Due to inherent differences in air density at different measurement locations, the atmospheric pressure p and the temperature t must also be known in order to facilitate site comparability and to check for compliance with regulatory standards. In addition, the ambient relative humidity R plays an important role in the partitioning of semivolatile gases, whether they sorb onto droplets or particles, and the hygroscopicity and viscosity of a particle/droplet determine if the sorbed gas stays in the particle phase unaltered or undergoes further chemical transformations.

The abundance of aerosol particles in the atmosphere is typically quantified as a number concentration or mass concentration [19.3]. Mass concentrations are typically obtained from the gravimetric analysis of filter samples [19.4]. It should be noted, however, that a multitude of other properties of the collected particles are also investigated, using various laboratory techniques.

For instance, a wide range of spectroscopic [19.5, 6], microscopic [19.7, 8], chromatographic [19.9, 10], and/or mass spectrometric [19.11, 12] analyses are conducted on aerosol samples. Due to the huge variety of methods used for analyses of aerosol samples, a comprehensive overview of all of the parameters measured in aerosol analysis—such as molecular compositions, aerosol mixing states, light absorbance, and the taxonomic diversity of bioaerosol organisms—is beyond the scope of Table 19.1.

19.1.1 Sampling of Trace Gases

Active and passive sampling are two fundamentally different approaches to the collection of ambient trace gas samples. Passive sampling is based on the molecular diffusion of analyte molecules from the ambient air to a sampling medium due to a gradient in chemical potential. Most passive sampling devices utilize gas diffusion across a well-defined diffusion barrier—in other words, permeation through a membrane, with subsequent deposition onto a sorbent material. This approach is also known as diffusive sampling. Passive sampling is advantageous compared to active sampling in that it requires less operational support (e.g., for flow control and calibration), less maintenance of pumps and other moving parts, and it is more flexible in terms of deployment as it does not require electricity. After sample collection, the analytes are extracted from the

Table 19.1 Parameters measured through the sampling of trace substances in air

Parameter	Description	Unit	Symbol
Molar concentration of gases or semivolatiles	Amount of substance i in a volume of air	mol m^{-3}	c_i
Mass concentration of gases or semivolatiles	Mass of substance i in a volume of air	$\mu\text{g m}^{-3}$	m_i
Mixing ratio or mole fraction of gases or semivolatiles	Ratio of amount of substance i , c_i , in a volume of air to amount of all constituents, c_{total} , in that volume	Parts per million (ppm, $\mu\text{mol mol}^{-1}$), parts per billion (ppb, nmol mol^{-1}), or parts per trillion (ppt, pmol mol^{-1})	ξ_i
Aerosol particle number concentration	Number of aerosol particles in a specified diameter (D) range (e.g., $D > 10 \text{ nm}$ or $D = 1\text{--}10 \mu\text{m}$) in a volume of air	cm^{-3} or m^{-3}	N_D
Aerosol particle mass concentration	Mass of aerosol particles in a specified diameter (D) range (e.g., $D > 10 \text{ nm}$ or $D = 1\text{--}10 \mu\text{m}$) in a volume of air	mg m^{-3} , $\mu\text{g m}^{-3}$, or ng m^{-3}	M_D

sorbent by solvents (usually deionized water for inorganic gases, and often dimethylchloride or alcohols for semivolatile organics) or desorbed thermally, and are then analyzed in the laboratory. Thus, passive sampling methods have a number of advantages: their *small size*, allowing mobile and unobstructed operation in tight spaces such as personal breathing zones; their *low cost* in terms of material and labor, permitting multiple deployments that combine geographical mapping with the capacity to probe long-term data trends; their *integrative nature*, as they provide pollution levels representing weeks, months, or even seasons of accumulation; and their *low impact*, which enables unsupervised operation without any sound or odor emissions, meaning that they can be used in both urban and remote environments. However, passive samples require relatively laborious postprocessing in analytical laboratories, and such sampling typically provides a very low temporal resolution, so it is not possible to access information on dynamic atmospheric relationships or the sensitivities of analytes to changes in the atmosphere or receptor response [19.13]. Active sampling of trace gases requires a pump and flow control to actively draw the ambient air sample over pretreated surfaces that take the form of a tube, multiple concentric tubes (annuli), or a honeycomb structure. These structures are called denuders, and their surfaces are coated with materials that are known to be particularly efficient at retaining (via absorption or adsorption) the specific compounds of interest. In most applications, at least two denuders are used in series to measure compound-specific retaining efficiencies or artifacts. The analytical procedures implemented in the laboratory after active sample collection are the same as those used after passive sampling.

19.1.2 Sampling of Semivolatile Substances

In the two-phase system of an atmospheric aerosol (at ambient temperature and pressure), the semivolatility of the substance causes it to be significantly distributed across both phases, which is known as gas–particle partitioning [19.14].

19.1.3 Sampling of Aerosol Particles

An aerosol is a two-phase system of liquid or solid particles suspended in a gas. Throughout this chapter, we will use the terms *particulate matter* and *aerosol particles* synonymously. Since aerosols are of considerable scientific interest in various research fields [19.15–17],

many techniques for aerosol analysis have been developed, including *offline* techniques, which involve the collection of particles on substrates and subsequent laboratory analysis, and *online* techniques, which allow in-situ and near-real-time particle characterization (Chap. 20). This chapter reviews the principles and applications of aerosol sampling—in other words, the separation and collection of airborne particles from the gas phase, followed by the offline analysis of those particles. However, the gas phase should not be ignored, as the particles typically contain both non-volatile compounds (e.g., salts, mineral dust, and soot) and semivolatile compounds (e.g., nitrates and organics) that partition between the gas and particle phases (Sect. 19.1.2) [19.18].

Particle size plays a key role in the physicochemical properties and atmospheric dynamics of aerosols. Hence, particle size is also highly relevant to the design and application of sampling strategies. In addition to size, the particle shape and density influence the aerodynamic motion of the particles and must therefore be considered in sampling applications. Figure 19.1 provides an overview of the characteristic particle sizes of aerosols from selected sources as well as their health effects. The aerosol particle size range, which spans from ≈ 1 nm to ≈ 100 μm , is typically subdivided into ultrafine (< 0.1 μm), fine (0.1–1 μm), and coarse (> 1 μm) particles. Furthermore, the pronounced modes in the multimodal atmospheric aerosol size distribution are defined as the nucleation mode (1–25 nm), the Aitken mode (25–100 nm), the accumulation mode (0.1–1 μm), and the coarse mode (> 1 μm) [19.3, 19, 20]. Note that different definitions for the thresholds between the modes exist. Particle size is determined by various measurable properties of the particles (e.g., electromobility, aerodynamic mobility, and geometric or optical size); variations in these parameters result in different *equivalent particle diameters* [19.3, 21].

Given the large number and high diversity of commercial and noncommercial devices and systems for aerosol sampling [19.27–29], this chapter cannot provide a comprehensive overview of all of them. Instead, it aims to present the key concepts and characteristics of the most widely used sampling strategies. Moreover, the main designs and operating principles of relevant sampling devices are summarized. The sampling of cloud droplets is treated as a special case of large particle sampling in the relevant sections. Throughout this chapter, we provide multiple references to text books, journal articles and other resources for further reading and in-depth research on this subject.

Fig. 19.1 Aerosol particle size scales for selected particle categories and characteristic modes of multimodal particle size distributions. The aerosol particle size distributions (the volume distribution in *blue* is calculated from the number distribution in *red*) are characteristic multimodal cases as frequently observed in the atmosphere. The definitions of the nucleation, Aitken, accumulation, and coarse modes were obtained from [19.3, 19, 20]. Different definitions of the coarse mode exist (> 1 , > 2 , or > 2.5 μm); here, coarse-mode particles have been defined as > 1 μm . The size ranges of the selected particle types (*brown*)—most of which are taken from [19.22]—are generalized and meant for overall orientation here. Typical size ranges for bacteria, fungal spores, and pollen can be obtained from [19.23, 24], the typical size range for mineral dust can be found in [19.25], and that for soot is presented in [19.16, 26]. *Gray bars* refer to the widely monitored particulate matter (PM) mass concentrations PM_1 , $\text{PM}_{2.5}$, and PM_{10} as well as the ultrafine particle (UFP) fraction below 100 nm.

19.2 History

As in most fields of natural science, our current knowledge of aerosol physics and chemistry is based on the curiosity of individual researchers who continuously advanced our understanding through new discoveries. The following summarizes a few highlights of the development of this field without claiming to be a complete reflection of all recent progress made.

19.2.1 Sampling of Trace Gases

The first records of the development and use of a passive sampler date back to the year 1853, when potassium iodide (KI)-impregnated filter papers were used to detect and quantitatively collect ambient ozone (O_3) [19.30]. This method followed on from the discovery of ozone in 1839 by *Christian Friedrich Schönbein* (1799–1868), a professor of chemistry at the Univer-

sity of Basel. He reported to the Swiss National Nature Research Society that a smell developed at the positive electrode during the electrolysis of water, and that this smell was strikingly similar to that obtained when electricity flowed across electrodes [19.31]. By the late 1840s, he had developed Schönbein paper, a mixture of starch, KI, and water spread on filter paper and dried. Ambient ozone oxidizes the KI on the paper, producing iodine (I_2) that reacts with the starch, staining the paper violet. The intensity of the color depends on the amount of ozone present: more ozone leads to a darker color.

Attempts by *Chester S. Gordon* and *James T. Lowe* to quantitatively measure carbon monoxide (CO) using palladium chloride salts as a passive sampler yielded US patent 1644014, filed on 3 December 1925 and granted on 4 October 1927 [19.32]. Early examples of successful passive sampling in outdoor air included the determina-

tion of gaseous oxides of sulfur and nitrogen [19.33, 34]. Several passive samplers were also developed to evaluate and monitor different types of environmental pollution. Most of those studies monitored indoor air pollution [19.35]. *Edward D. Palmes* (1916–2004) and *Albert F. Gunnison* (at the Department of Environmental Medicine, New York University) [19.36] used a mercury chloride sorbent in a Palmes tube to capture sulfur dioxide (SO₂), which was subsequently quantified via colorimetric analysis [19.37]. This design was later modified to trap nitrogen dioxide (NO₂) on a stainless-steel grid coated with triethanolamine [19.34]. The collecting grid was located at the closed end of an acrylic tube that was ≈ 8 cm long and had an inner diameter of 1 cm. Analytical quantification followed spectrophotometric nitrite analysis using sulfanilamide and naphthylethylenediamine as reactants.

The *Swedish Environmental Institute* [19.38] significantly advanced the use of passive sampling of selected air pollutants in remote air quality monitoring applications by demonstrating that high data quality could be attained through the application of dedicated analytical laboratory and rigorous quality control procedures. *Mazur et al.* [19.39] developed one of the first ammonia (NH₃) samplers using an acid-impregnated glass fiber pad resting behind a potassium hydroxide (KOH)-pretreated, charcoal-impregnated glass fiber front filter. The purpose of the charcoal was to remove (adsorb) interfering amines, while the alcoholic KOH with 0.1% wetting agent prevented the occurrence of a negative artifact arising from the irreversible adsorption of NH₃ along its diffusive path to the collecting glass fiber pad. *Christian-Thomas Monn* and *Markus Hangartner* (at ETH Zürich and Dübendorf, respectively) [19.40] developed one of the first passive samplers for ozone, which was based on the Palmes tube mentioned above. The aldehyde resulting from the hydrolysis of the ozonide formed by the reaction of the adsorption medium 1,2-di(4-pyridyl)ethylene with ambient O₃ was measured spectrophotometrically, and the results correlated well with those from collocated reference monitors [19.41]. Parallel applications (which are, however, less widely used) were also developed for carbon dioxide (CO₂) [19.42], hydrogen sulfide (H₂S) [19.43], polyaromatic hydrocarbons (PAHs) [19.44], volatile organic compounds (VOCs) [19.45], and chlorinated semivolatile organic pollutants [19.13, 46].

Researchers from the United States Department of Agriculture (USDA) Forest Service and the University of California (Riverside) developed a passive sampler for atmospheric nitric acid (HNO₃) that was both simple and inexpensive to deploy across USDA-managed landscapes [19.47]. The sampler utilized HNO₃ diffusion through a Teflon filter membrane with a pore size

of 2 μm and a diameter of 47 mm and subsequent adsorption onto a nylon backup filter of the same size (Nylasorb, Pall Corporation). *Bytnerowicz et al.* [19.48] showed that HNO₃ concentrations determined using the nylon filters closely agreed with those measured by a collocated active sampler employing calcium carbonate (CaCO₃)-coated honeycomb annular denuders under both random ambient and controlled experimental conditions. The pair of filters were exposed in a 50 mm round commercial polycarbonate petri dish held in place by Teflon rings and protected from the elements by a generic polycarbonate cap. The original design was susceptible to artifacts from high winds that caused uncontrolled turbulent flow and disrupted the laminar airflow that controls the HNO₃ deposition onto the nylon filter.

19.2.2 Sampling of Semivolatile Substances

Gaseous semivolatile chlorinated organics are not sufficiently retained in adsorbents that are suitable for volatiles. Therefore, since the 1970s, gaseous chlorinated organics have been sampled using polyurethane foam instead [19.49–51]. Since then, polyurethane foam has been employed in many monitoring and research applications across the world to collect various classes of semivolatile organic compounds (SVOCs) [19.52].

19.2.3 Sampling of Aerosol Particles

Historically, the development and application of aerosol sampling strategies were stimulated by increasing awareness of the adverse effects of inhaled aerosols on human health [19.29, 53, 54]. Indeed, the history of the development of sampling strategies for airborne microorganisms stretches back to the work of *Louis Pasteur* (1822–1895), *Christian Gottfried Ehrenberg* (1795–1876), and other pioneers who conducted the first bioaerosol samplings and analyses in the middle of the nineteenth century [19.54–58]. Another strand of development in this field also reaches back to the late nineteenth and early twentieth century, when the protection of public health in the context of increasing industrial and combustion pollution became an important societal issue. Such monitoring is particularly relevant to occupational settings (e.g., workplace exposure for industrial workers and miners) and ambient settings in strongly industrialized and hence particularly polluted cities [19.29, 59]. Evidently, the development of sampling instrumentation is closely linked to the requirements of analytical techniques for subsequent aerosol analysis, such as gravimetric, microscopic, or mineralogical investigations on the one hand and practical and physical constraints on the other.

Moreover, sampling and analytical strategies have developed in concert as knowledge of the physical and chemical properties of aerosols has increased, leading to the definition of criteria for health-relevant sampling standards (e.g., respirable fractions and mass standards such as PM_{10} and $PM_{2.5}$ (particulate matter); see Fig. 19.1) [19.60].

Some milestones in early aerosol sampling include

1. the development of the first impactor by *M.F. Pouchet* in 1860 [19.61],
2. systematic bioaerosol investigations since the 1880s that have been based on sampling with culture media and have focused in particular on the health effects of bioaerosols [19.54],
3. systematic filter sampling for gravimetric analysis to quantify the total mass of collected particulate matter (e.g., in underground mining) [19.62, 63], as performed since the 1900s,

4. the development between the 1900s and 1930s of different designs of thermophoretic precipitators, electrostatic precipitators, and impactors to deposit particles on glass slides or other suitable substrates for subsequent optical microscopy to count smaller, respirable (and hence more relevant to health) particle size fractions [19.64–69],
5. the development of sampling devices with aerodynamic particle size segregation, such as cascade impactors and cyclones, since the 1940s [19.70, 71], and
6. the creation in the 1960s of wearable miniaturized samplers that allowed the exposure of individuals (e.g., miners) to be monitored [19.72].

Since those early days, the developments in this field have progressed rapidly and have yielded a diverse set of partly sophisticated techniques that are now applied routinely in aerosol sampling and analysis.

19.3 Theory

The abovementioned developments and technological progress were achieved largely due to advances in our understanding of their underlying physicochemical principles, which are described below.

19.3.1 Sampling of Trace Gases

The theory behind active and passive sampling has been extensively reviewed elsewhere [19.13, 73–76], so we focus here primarily on issues related to NH_3 and HNO_3 , the two most important reactive gases in the Earth's nitrogen balance. In addition to its acidifying effects, HNO_3 (a member of the reactive nitrogen complex) is involved in the initial soil fertilization process, which increases the growth, productivity, and reproduction of terrestrial plants. It also influences plant community structure, causing shifts from nitrophobic to nitrophilic species and promoting biodiversity. Furthermore, atmospheric deposition of nitrate can result in surface water eutrophication and hypoxia, impacting wildlife habitats and diversity [19.77].

In the context of passive air sampling, diffusional mass transfer through either a static layer of ambient air or across a membrane can be described by Fick's first law of diffusion. This law states that, for a given analyte, the sampling rate v_i (the volumetric amount of analyte collected by the sampler per unit time at constant concentration in the surrounding medium) is given by

$$v_i = D_i \frac{A}{\Delta x}, \quad (19.1)$$

where D_i is the diffusion coefficient and $A/\Delta x$ is the sampler-specific geometric constant.

The $A/\Delta x$ ratios for the Ogawa and Radiello samplers, for example, are specified by the manufacturer as 2.23 and 14.2 cm, respectively. For NH_3 , Radiello [19.78] specifies a constant sampling rate v_{NH_3} of 235 mL min^{-1} for an ambient t of $2\text{--}39^\circ\text{C}$, $R = 10\text{--}90\%$, and a wind speed u of $0.1\text{--}10 \text{ m s}^{-1}$. The NH_3 sampling rate for the Ogawa sampler is 32.3 mL min^{-1} [19.79]. Neither the literature nor the manufacturer provide sampling rates for HNO_3 when utilizing the Ogawa-type passive sampler. Therefore, employing (19.1), a value of 15.8 mL min^{-1} can be used, assuming a constant HNO_3 diffusion coefficient of $0.118 \text{ cm}^2 \text{ s}^{-1}$ [19.80] and an $A/\Delta x$ ratio of 2.23 cm.

In most applications, the D_i values of both HNO_3 and NH_3 vary little within the typical ranges of ambient temperature and pressure, so v_i mainly depends on the sampler geometry, which is given by the effective diffusive surface (cross-section) A and the diffusion path length Δx (the distance between the diffusive and adsorbing surfaces). Knowledge of the relationship between the sampling rate and analyte concentration allows the time-weighted (integrated) average ambient concentration of analyte i to be determined from the difference in mass between the analyte on the exposed sampler (M_i) and a field blank ($M_{i,0}$) divided by the analyte-specific and exposure time (t_{exp})-dependent air volume (V_i), i.e.,

$$C_i = \frac{M_i - M_{i,0}}{V_i}, \quad (19.2)$$

where

$$V_i = v_i t_{\text{exp}} \quad (19.3)$$

At least three main conditions have to be met when using this approach.

1. The receptor medium must act as a so-called *zero sink*; that is, it must not release any of the adsorbed molecules even if the concentration of the analyte in the ambient environment decreases to zero.
2. The trapped molecules must be either inert to variations in the ambient conditions and chemically reactive species, or they must change their state to a measurable quantity consistently and with 100% efficiency.
3. The sampling rate must remain constant throughout the sampling period. This is accomplished when the analyte is absorbed (e.g., into a liquid receiving phase) or *chemisorbed* (e.g., in the case of HNO_3 on a NaCl-coated surface). However, problems occur when physical *adsorption* governs analyte collection, as it does for HNO_3 on nylon. In this case, the linear portion of the adsorption isotherm should be used exclusively throughout the entire sampling process.

This is typically accomplished by using low mass loadings of high-capacity sorbents that are far from thermodynamic equilibrium. However, since adsorption is a competitive process, the linear range of the adsorption isotherm can easily be exceeded whenever other molecules are trapped in large amounts along with the analyte molecules. The adsorption of HNO_2 and NO_2 onto nylon is a good example of this mechanism, as described above.

19.3.2 Sampling of Semivolatile Substances

Many inorganic and organic substances are semivolatile under ambient conditions (i.e., they partition significantly between the particulate and gas phases) [19.81–83]. This behavior corresponds to a vapor pressure in the range 10^{-6} – 10^{-2} Pa (at $t = 293$ K, $p = 1$ bar [19.84]). Higher particulate mass fractions occur at higher altitudes, during the cold season, or at night. The influence of temperature alone is, however, insufficient to explain the partitioning process: it is understood to result from a number of attractive interactions at the molecular level that influence adsorption onto aerosol surfaces and absorption into liquid or semisolid particulate organic matter [19.85, 86]. Accordingly, the slope of the empirical equation

$$\log K_p = -m \log p_L^0 + b, \quad (19.4)$$

which relates the partitioning coefficient $K_p = c_p / (c_g c_m)$ (where c_p and c_g are the substance concentrations in the two aerosol phases, respectively) to the saturation vapor pressure of the supercooled liquid p_L^0 , usually deviates significantly from -1 [19.87].

Observations of the partitioning ($\log K_{\text{oa}} > 11$) of very lipophilic substances indicate that kinetic limitations may cause deviations from phase equilibrium [19.88]. This issue is being addressed in ongoing research. For substances that significantly partition to both aerosol phases, separate sampling media are applied for both phases in parallel. For the respective sampling theory, see Sects. 19.3.1 and 19.3.3.

19.3.3 Sampling of Aerosol Particles

Aerosol samplers are generally active sampling techniques that use a pump to draw air into a device in which aerosol particles within a certain size range are deposited on substrates. The particle deposition process can be governed by different *particle collection mechanisms*, which can be categorized as follows:

1. inertia-based particle separation and sampling;
2. particle transport via Brownian motion and gradient-induced diffusion;
3. particle migration and deposition under the influence of gravitational and electric fields; and
4. particle filtration (which is dominated by the processes of diffusion, impaction, and interception).

All of these processes can be used *intentionally* in aerosol sampling strategies, but they also occur *unintentionally* in aerosol inlets and tubes, leading to sampling artifacts. Thus, the following section summarizes the relevant theoretical background for aerosol sampling techniques, as well as strategies for minimizing aerosol sampling artifacts. More detailed information on the physical background for aerosol properties and dynamics beyond the summary presented below can be found elsewhere [19.3, 27–29].

Inertia-Based Particle Size Separation and Sampling

Inertial sampling is widely used for aerosol particle collection and size separation in numerous devices, such as impactors and cyclones [19.18, 29, 89]. The theoretical basis for inertial sampling presented here is applicable within the Stokes regime, characterized by a Reynolds number $\text{Re} < 1$. The Reynolds number is a dimensionless number that reflects the ratio of inertial forces of the particles to viscous forces of the gas [19.28], and is defined as

$$\text{Re} = \frac{\rho_g U d}{\eta}, \quad (19.5)$$

Fig. 19.2 (a) Schematic design of a conventional impactor, showing gas-flow streamlines and characteristic particle trajectories. (b) The corresponding particle collection efficiency curve, showing a comparatively sharp cutoff that approaches an ideal step function. The nozzle diameter D_{nozzle} , the dimensionless jet-to-plate distance S/D_{nozzle} , and the dimensionless nozzle throat length T/D_{nozzle} , as specified in (a), are important parameters in the design of jet impactors [19.90] (after [19.89] with permission from John Wiley & Sons, Inc.)

where ρ_g is the density of the gas, U is the velocity of the gas relative to the object of interest, d is the characteristic dimension of the object, and η is the viscosity of the air.

In aerosol sampling, Re is a key parameter in two fluid flow aspects. First, it describes the fluid flow around a suspended particle (i.e., d is the diameter of the particle and U is the velocity of the gas in relation to the particle), in which case it is called the *particle Reynolds number* Re_p . Second, it describes the fluid flow inside an inlet tube (i.e., d is the diameter of the tube and U is the fluid flow velocity in the tube), in which case it is called the *flow Reynolds number* Re_f . Re is used to predict transitions from laminar to turbulent flow regimes. For a discussion of sampling strategies employed in different Re_f regimes, see Sect. 19.6.3.

The condition $Re_p < 1$ applies to most aspects of aerosol motion, which is predominantly defined by the motion of the gas, given that the inertial forces of particles are relatively weak (because the particle masses and velocities are rather low). Inertial particle classification utilizes the curvilinear motion of the gas flow (e.g., the gas is redirected or deflected using obstacles) to capture the particles with sufficiently high inertia to remain on their original trajectory (or a trajectory close to it). These particles therefore cross the streamlines of the air and collide with a collection body, such as the sampling substrate. On the other hand, smaller particles with less inertia follow the gas flow and remain airborne (Fig. 19.2). The key parameters in inertial deposition are the velocity of the gas, the size of the particles, and the size of the object on which the high-inertia particles are collected. The relevant particle size for inertial techniques is their *aerodynamic equivalent diameter* D_a ,

defined as the diameter of a standard-density (1 g cm^{-3}) sphere with the same terminal velocity as the particle of interest. The ratio of the particle's stopping distance to the size of the collecting body determines whether the particle strikes the body or not. This ratio—a dimensionless parameter—is called the *Stokes number* Stk [19.90, 91]. For typical impactors that accelerate the sample air through a nozzle perpendicularly towards an impaction plate (in conventional impactors, see Fig. 19.2a) or a collecting probe (in virtual impactors), Stk is defined as

$$Stk = \frac{\rho_p D_a^2 C_c U}{9\eta D_{\text{nozzle}}}, \quad (19.6)$$

with

$$U = \frac{Q}{\pi \left(\frac{D_{\text{nozzle}}}{2}\right)^2}, \quad (19.7)$$

where ρ_p is the particle density, C_c is the Cunningham slip correction factor (which accounts for noncontinuum effects that become significant when the value of D_a is comparable to the mean free path λ of the gas molecules), U is the relative velocity of the gas with respect to the body (which, in the present case, is the average air velocity at the nozzle exit), D_{nozzle} is the diameter of the circular nozzle, and Q is the volumetric flow rate through the nozzle.

The relationship of the collection efficiency to D_a is of central importance to the design and characterization of all inertia-based samplers. As an example, the efficiency curve in Fig. 19.2b illustrates the characteristic *cutoff* diameter D_{50} at which 50% of the particles

strike the sampling plate. D_{50} is directly related to Stk_{50} , which depends on the impactor design considered, via

$$D_{50} \sqrt{C_c} = \left(\frac{9\pi D_{\text{nozzle}}^3 Stk_{50}}{4\rho_p Q} \right)^{1/2}. \quad (19.8)$$

As an example, $Stk_{50} = 0.24$, or $(Stk_{50})^{1/2} = 0.49$, is recommended for the design of a circular jet impactor [19.28, 92]. Equation (19.8) indicates that D_{50} can be further decreased by increasing Q , reducing D_{nozzle} (utilized in micro-orifice impactors [19.93, 94]), or enhancing C_c (utilized in low-pressure impactors [19.95, 96]). More detailed information on impactation theory and impactor design can be found elsewhere [19.28, 89, 92, 97, 98]. Other inertia-based sampling devices such as cascade impactors, virtual impactors, cyclones, and aerodynamic lenses are based on the same physical principles [19.99–103]. It should also be noted that inertial particle losses occur in aerosol inlets and tubes when the sample air stream passes through bends or constrictions [19.104]. This effect is particularly pronounced at high gas flow velocities, such as those present in turbulent sampling conditions (Sect. 19.6.3).

Particle Transport Through Brownian Motion and Diffusion Across Gradients

William Hinds [19.28] concisely summarized that

Brownian motion is the irregular wiggling motion of an aerosol particle in still air caused by random variations in the relentless bombardment of gas molecules against the particle. *Diffusion* of aerosol particles is the *net* transport of these particles in a concentration gradient [...] from a region of higher concentration to a region of lower concentration.

The diffusion of aerosol particles and their deposition on surfaces are relevant in various aspects of aerosol sampling. A key parameter is the diffusion coefficient D , which relates the aerosol particle flux J to the particle concentration gradient dn/dx according to Fick's first diffusion law

$$J = -D \frac{dn}{dx}, \quad (19.9)$$

with

$$D = \frac{kTC_c}{3\pi\eta D_p}, \quad (19.10)$$

where k is Boltzmann's constant and T is the absolute temperature.

Fig. 19.3 The aerosol diffusion coefficient in air at 20 °C as a function of diameter (after [19.3] with permission from John Wiley & Sons, Inc.)

The parameter D , as a measure of the intensity of Brownian motion and the rate of gradient-driven particle transport, is strongly dependent on size (Fig. 19.3). For larger particles, C_c is approximately unity (meaning that D_p exceeds the mean free path λ of the gas molecules), and (19.10) yields an (approximately) linear relationship: $D \approx D_p^{-1}$. For smaller particles, $C_c = 1 + 1.657(2\lambda/D_p)$, and particle size and diffusivity are related via $D \approx D_p^{-2}$ [19.3]. It is therefore clear that diffusive separation and deposition can be used most effectively for ultrafine particles (those $< 0.1 \mu\text{m}$ in size), which are associated with the largest D values. Net diffusive transport of particles requires a particle concentration gradient and occurs over comparatively short distances. Note that the distances traveled by particles through Brownian motion are negligibly small compared to aerosol transport via atmospheric convection (i.e., wind and large eddies).

Upon colliding with a wall, aerosol particles adhere to it, meaning that the wall acts as a sink and creates a particle concentration gradient that drops to zero (Fig. 19.4). This gradient causes continuous particle diffusion and deposition at the wall and thus a gradual decrease in the overall concentration. This effect can be used in dedicated aerosol sampling strategies. Moreover, diffusional losses are of fundamental importance in the design and operation of aerosol inlets and tubes (Sect. 19.6.3). In particular, when sampling aerosol particles $< 0.1 \mu\text{m}$ in size, measures must be taken to minimize diffusion losses to the walls of the inlet and tubes [19.104].

Fig. 19.4 Concentration profile for a stagnant aerosol of $0.05 \mu\text{m}$ particles near a wall in the idealized case of particle deposition at a plane wall from an infinite aerosol particle reservoir. The parameter t is the time since initial mixing. The plot illustrates the formation of a particle concentration gradient and its evolution over time (after [19.28] with permission from John Wiley & Sons, Inc.)

Brownian motion and a gradient-driven net transport of aerosol particles require relatively high particle mobilities in the gas phase. Related weak forces, such as *thermophoresis*, similarly rely on high particle mobilities and have a certain relevance in sampling applications. Thermophoresis is the movement of particles in the gas phase in the direction of decreasing temperature. Mechanistically, this can be explained by the higher velocities of gas molecules in a hotter region than in a cooler region: the faster gas molecules impart more momentum (via collisions) to the particles than the slower gas molecules do. Below $\approx 0.1 \mu\text{m}$, the thermophoretic velocity is independent of particle size, whereas this velocity decreases with increasing particle diameter above a size of $\approx 0.1 \mu\text{m}$ [19.28]. A more detailed description of these processes can be found elsewhere [19.105–107]. In principle, thermophoresis could also cause particle losses upon aerosol sampling, but temperature gradients are typically comparatively small, so thermophoretic losses are negligible [19.104].

Particle Migration and Deposition in Gravitational and Electric Fields

External forces such as gravity and electrostatic attraction cause particle migration and are therefore relevant to aerosol sampling applications. The gravitational force F_G that acts on the particles is

$$F_G = \frac{\pi D_p^3 \rho_p g}{6}, \quad (19.11)$$

where g is the gravitational acceleration.

Fig. 19.5 Settling velocity of unit-density spheres in air at 298 K as a function of diameter (after [19.3] with permission from John Wiley & Sons, Inc.)

In the gravitational field, particles instantaneously reach their terminal settling velocity v_G when F_G and the opposing aerodynamic drag force reach equilibrium, i.e.,

$$v_G = \frac{\rho_p D_p^2 g C_c}{18\eta} \quad \text{for } \text{Re}_p < 1. \quad (19.12)$$

Since the gravitational settling velocity increases strongly with size ($v_G \propto D_p^2$), it plays a major role for particles with $D_p > 1 \mu\text{m}$, cannot be neglected for particles with $0.1 \mu\text{m} < D_p < 1 \mu\text{m}$, and is rather insignificant for particles with $D_p < 0.1 \mu\text{m}$ (Fig. 19.5). Gravitational settling is used in dedicated sampling strategies [19.108, 109]. It also plays a critical role in aerosol sampling and transport lines, particularly when supermicrometer aerosols are the focus of the analysis [19.104, 110]. When centrifugal force is used for particle separation and sampling [19.111, 112], the gravitational acceleration g in (19.11) and (19.12) is replaced with the centrifugal acceleration a_c [19.28].

In an electric field, the electrostatic force F_E that acts on a particle is

$$F_E = neE, \quad (19.13)$$

where n is the number of elementary charges e on the particle (i.e., ne is the overall charge on the particle) and E is the intensity of the electric field.

In the electric field, the particles reach their terminal electrical migration velocity v_E when F_E and the opposing aerodynamic drag force reach equilibrium, i.e.,

$$v_E = \frac{neEC_c}{3\pi\eta D_d}. \quad (19.14)$$

The electric migration velocity depends on the overall charge per particle and particle size as ne/D_p . More detailed information on electrostatic sampling strategies can be found elsewhere [19.113]. It should also be noted that the electrostatic charge and the associated electric fields in aerosol inlets and tubes can cause substantial particle losses [19.104]. Accordingly, inlets and tubes are typically made of electrically conductive materials [19.19].

Filtration

Filtration is widely used in aerosol analysis, as it allows simple, flexible, and low-cost aerosol sampling. Because of its popularity and wide range of applications, extended filtration theories for porous membrane, pore membrane, and fibrous filters have been developed [19.114, 115]. These complex filtration theories provide predictive equations that allow the filtration efficiency E (i.e., the fraction of particles retained in the filter) to be quantitatively related to the filter characteristics, air flow velocity, and particle size [19.28, 116]. Generally, filtration involves several particle deposition mechanisms, in particular diffusion, impaction, and interception. Under certain conditions, electrostatic and gravitational settling may also be relevant, but they are not considered in the following theoretical summary. For fibrous filters, the penetration P can be calculated as

$$P = 1 - E = \exp\left(-\frac{4\alpha E_F t}{\pi D_f}\right), \quad (19.15)$$

where α is the filter's packing density (fiber volume/total volume), E_F is the particle deposition efficiency of a single fiber, t is the thickness of the filter, and D_f is the diameter of the fiber.

Equation (19.15) shows that P strongly decreases with increasing filter thickness and also depends on E_F , which can be approximated as the sum of the individual deposition contributions from diffusion (E_D), interception (E_R), and impaction (E_I), i.e.,

$$E_F = E_D + E_R + E_I. \quad (19.16)$$

Especially for small particles, Brownian motion causes the particles to deviate from the air streamlines, increasing the probability that they will strike the fiber (Fig. 19.6a). The efficiency E_D can be calculated as

$$E_D = 2\left(\frac{D_f U_0}{D}\right)^{-2/3}, \quad (19.17)$$

where U_0 is the velocity of the air at the surface of the filter before it enters and D is the diffusion coefficient (19.10).

Fig. 19.6a–c Single-fiber particle collection mechanisms: (a) diffusion, (b) impaction, and (c) interception (after [19.28] with permission from John Wiley & Sons, Inc.)

Impaction on the fibers occurs when inertia causes larger particles to deviate from the air streamlines (Fig. 19.6b). The efficiency E_I can be calculated as

$$E_I = \frac{\text{Stk}}{2\text{Ku}^2} [(29.6 - 28\alpha^{0.62})R^2 - 27.5R^{2.8}] \quad (19.18)$$

with

$$\text{Stk} = \frac{\rho_p D_a^2 C_c U_0}{18\eta D_f} \quad (19.19)$$

and

$$\text{Ku} = -\frac{\ln \alpha}{2} - \frac{3}{4} + \alpha - \frac{\alpha^2}{4}, \quad (19.20)$$

where Ku is the Kuwabara hydrodynamic factor [19.117].

Fig. 19.7 Total filter efficiency versus particle diameter calculated from single-fiber efficiency theory for a fibrous filter that has a uniform fiber diameter of $4\ \mu\text{m}$ and a solidity of 0.1 and is operated at an air flow velocity of $0.15\ \text{m s}^{-1}$. The particle density is $1\ \text{g cm}^{-3}$. The diffusion and impaction/interception filtration regimes are indicated in the figure (after [19.116] with permission from John Wiley & Sons, Inc.) ►

Interception occurs when a particle follows the air streamlines and strikes a fiber because of its finite size (Fig. 19.6c). The efficiency E_R can be calculated as

$$E_R = \frac{(1 - \alpha)R^2}{Ku(1 + R)}, \quad (19.21)$$

where

$$R = \frac{D_p}{D_f}. \quad (19.22)$$

Note that all of the equations shown above have been simplified and are only valid for the following typical conditions: $0.005 < \alpha < 0.2$; $0.001\ \text{m s}^{-1} < U_0 < 2\ \text{m s}^{-1}$; $0.1\ \mu\text{m} < D_f < 50\ \mu\text{m}$, and $\text{Re}_p < 1$. Super-

posing all of the aforementioned processes results in a characteristic efficiency curve for the filter. An example is shown in Fig. 19.7; note that the shape of the efficiency curve changes substantially upon increasing or decreasing the air flow rate [19.28].

19.4 Devices and Systems

This section describes applications of sampler configurations (for trace gases and semivolatile compounds) that are currently employed in various monitoring networks to measure specific compounds around the world. In most cases, the selection of a particular sampler is motivated by the specific objectives and purposes of the respective network. In all applications, the choice of sampler involves a compromise where the advantages outweigh the disadvantages, since no sampler is perfect. These imperfections are illustrated in the following examples. Since a large number of devices and systems have been developed for aerosol particle sampling, it is not possible to cover all of these devices and systems fully here, so only selected examples representing the main sampling principles specified in Sect. 19.3.3 are highlighted.

19.4.1 Sampling of Trace Gases

Four different geometries are used for the passive sampling of inorganic gases: badge [19.118], tube [19.34], radial [19.119], and cartridge [19.13]. These geometries determine the specific sampling rate, an important sampler criterion along with the concentration range

and saturation capacity, which are equally important parameters to consider when selecting a sampler. Due to their relatively short diffusion paths, radial and badge samplers have high uptake rates and are preferred in short-term (daily to weekly) sampling or when low analyte concentrations are expected. Tube samplers with longer diffusion paths tend to be chosen for long-term (weekly to monthly) sampling or when there is a high ambient air concentration. Prevailing environmental factors including wind exposure, temperature, and relative humidity also influence sampler selection.

Table 19.2 summarizes the most common passive sampling methods for the time-integrated collection of atmospheric trace gases, focusing on two of the most frequently targeted gases: ammonia (NH_3) and nitric acid (HNO_3). Both of these trace gases play a critical role in atmosphere–biosphere exchange processes, so their concentrations significantly influence air quality and ecological production. While passive NH_3 samplers have been widely developed and used, the passive sampling of HNO_3 has proven to be more difficult. It was first performed successfully in museums [19.136], where a modified sampler with an open-tube design utilized an appropriately impregnated filter to trap the pollutant. Held

Table 19.2 Overview of passive sampling methods for NH₃ and HNO₃; adapted from [19.131]

Type	Dimensions		Inlet	Collection surface	Collection medium	NH ₃ sam- pling rate (mL min ⁻¹)	HNO ₃ Sam- pling rate (mL min ⁻¹)	Comment, Reference
	L (cm)	A (cm ²)						
Ogawa badge	0.6 × 0.79 (25 holes/0.2 cm in diameter)		Open	Glass fiber or cellulose filter on a stainless steel grid	Citric acid	31.2–32.8	–	Protective cover used outdoors [19.79, 120, 121]

in position by a stainless steel ring, the filter was placed at the bottom of an inverted glass vial. A fine stainless steel screen protected the open end and suppressed turbulent diffusion inside the vial. Although this sampler was conceptualized for indoor use, outdoor applications of it were also successful as long as the exposure times were short and controlled. The development of designs suitable for long-term outdoor sampling was more difficult. A much improved design employed an aqueous reagent solution of NaCl and glycerin as the impregnating agent on a cellulose filter to collect atmospheric HNO₃ during monthly exposure periods [19.123].

Most of the passive samplers described in the literature and listed in Table 19.2 are planar or axial in shape and have limited sampling rates and sampling capacities. A radial coaxial design, as utilized in the Radiello type employed for NH₃ [19.78], provides an improved geometry that helps to circumvent limitations in sensitivity during short-term sampling (due to improved sampling rates) and long-term sampling (analyte loss due to back diffusion is eliminated due to the high capacity of this technique). This design is superior to planar and axial designs because the NH₃ uptake rate is proportional to the height of the diffusive cylinder and inversely proportional to the logarithm of the ratio of the diffusive to the adsorbing cylinder radii. The radius of the diffusive cylindrical surface can only be determined empirically via exposure experiments, which are yet to be performed successfully for HNO₃ due to difficulties associated with the physical and chemical properties of the microporous layer of the tubular diffusive membrane (distributed via Sigma-Aldrich; more detailed specifications are available from <https://www.sigmaaldrich.com/catalog/product/supelco/rad120?lang=en®ion=US>), Accessed 07 July 2021.

Table 19.3 gives an overview of the most common active sampling methods for the time-integrated collection of HNO₃ and other inorganic gas and aerosol species, along with selected references. The filter-pack method, which usually utilizes Teflon, nylon, or im-

pregnated filters in series, is the least accurate but also the simplest and most commonly used sampling procedure. This technique is labor intensive and suffers from possible interference due to the oxidation of nitrites collected on nylon filters, which positively biases HNO₃ collection. This positive bias was found to be caused by the retention of nitrite (from HNO₂ or NO₂ adsorption) on nylon and the subsequent oxidation of this nitrite to nitrate at almost 100% conversion efficiency during photochemically active sampling periods [19.174]. NO₂ adsorption on nylon involves a heterogeneous surface reaction with H₂O,

This has a removal constant of about $1 \times 10^{-4} \text{ ms}^{-1}$ at a H₂O concentration of 2 vol.%. The Teflon-nylon sampling configuration also suffers from the evaporation of aerosol nitrate from the Teflon front filter [19.137].

Several subsequent studies found that impregnating the surface with sodium carbonate led to similar artifact reactions to those for nylon, albeit with significantly lower reaction rates. This implies that N-containing species (such as NO_x and peroxyacetyl nitrate, PAN) are interfering agents that produce small amounts of nitrite and nitrate on sodium carbonate [19.175, 176]. They also found that the heterogeneous artifact reaction of NO₂ with water vapor contributed to the measured nitrite and nitrate levels, but this contribution was much lower than for nylon. However, based on the penetration efficiency and measured interference from NO₂⁻, NO₂ artifacts occur on both nylon surfaces and Na₂CO₃ coatings and are exacerbated during photochemical smog events, during which up to 100% of the ambient NO₂ may be converted to NO₃ [19.175]. As a consequence, all of the species that are retained on the denuder coating and yield nitrite should be considered potential indirect interferents with the measurement of HNO₃.

In the atmosphere, HNO₃ is mainly formed through the reaction of NO₂ with the hydroxyl radical. Hydrol-

Table 19.3 Overview of active sampling methods for NH₃ and HNO₃; adapted from [19.173]

Method	Measured species	References
Impregnated, Teflon, and nylon filters in series	NH ₃ , HNO ₃ , PM: NH ₄ ⁺ , NO ₃ ⁻ , Cl ⁻ , SO ₄ ²⁻	[19.137–143]
Denuder–filter pack	NH ₃ , HNO ₃ , HONO, HCl, SO ₂ , PM: NH ₄ ⁺ , NO ₃ ⁻ , Cl ⁻ , SO ₄ ²⁻	[19.144–147]
Dry-coated denuder	NH ₃ , HNO ₃ , HONO, HCl, SO ₂	[19.148–150]
Wet effluent denuder	NH ₃ , HNO ₃ , HONO, HCl, SO ₂	[19.151–155]
Parallel-plate denuder	NH ₃ , HNO ₃ , HONO, HCl, SO ₂	[19.156–158]
Thermodenuder	NH ₃ , HNO ₃	[19.159, 160]
Wet annular denuder	NH ₃ , HNO ₃ , HONO, HCl, SO ₂	[19.161–166]
Diffusion scrubber and mist chamber	NH ₃ , HNO ₃ , HONO, HCl, SO ₂	[19.167–172]

ysis reactions involving N_2O_5 and NO_3 radicals also yield HNO_3 , as do NO_2 and NO_3 reactions with O_3 and certain non-methane hydrocarbons (NMHC). All of these reactions may also take place heterogeneously on reactive surfaces such as nylon or surfaces impregnated with sodium carbonate.

Various intercomparison experiments [19.177–179] have revealed significant discrepancies between different HNO_3 measurement techniques, emphasizing the need for artifact-free measurement methods to accurately determine HNO_3 and particulate nitrate in the atmosphere. The approach most widely used to sample a gas in the presence of corresponding aerosol particles is the denuder technique. Dry-coated denuders are reliable but labor intensive and provide only long-term average concentrations (for periods on the order of 24 h) [19.180]. These drawbacks have been overcome by various other developments. Four different designs of systems in which wet effluent diffusion denuders with continuously renewed collection surfaces are coupled to ion chromatography (IC) were developed [19.151]. Efficient retention of trace gases and measurements with high time resolution may be achieved by coupling parallel-plate denuders to online analysis. Another development yielded an automated thermodenuder system for the determination of NH_3 in ambient air [19.159]. A device that enjoys some popularity is the wet annular denuder (WAD), in which near-quantitative collection efficiencies are achieved at high sampling rates in a compact design [19.180]. The continuously rotating WAD is an improvement of the original WAD design [19.162]. Diffusion scrubber and mist chamber techniques also provide measurements with high time resolutions and low artifact sensitivities.

In 2007, the mist chamber technique was employed for the first time to measure water-soluble organic gases (WSOGs) and the impact of particle-bound liquid water on the partitioning of water-soluble organic carbon (WSOC) during the summer in Atlanta, Georgia [19.181]. Their results indicated that partitioning to liquid water may significantly contribute to the formation of secondary organic aerosol and fine PM observed in urban regions with high biogenic emissions (such as Atlanta in the summer). WSOGs were measured with a mist chamber [19.182] that collected organic gases with an effective Henry's law constant $K_H \gtrsim 10^3 \text{ M atm}^{-1}$ [19.183], where M is moles per liter (mol L^{-1}). Filtered sample air entered a glass mist chamber at a flow rate of ≈ 20 LPM. The chamber was initially filled with 10 mL deionized water (DIW) and fitted with a hydrophobic Teflon filter at the chamber exit to enable the DIW to be refluxed. The same technique was employed in a 2012 field study performed in the River Po valley in Italy to measure water-soluble

products from the gas-phase oxidation of VOCs that can partition into atmospheric waters, where they are further oxidized to form low-volatility products [19.184]. These products can remain in the particle phase after water evaporation, forming what is termed aqueous secondary organic aerosol (aqSOA). Duncan et al. [19.185] found that WSOG concentrations in indoor environments were significantly (15 times) higher than those outdoors, implying that surface chemistry significantly affects indoor exposure, although little is known about individual WSOG compounds, their kinetics, and the fate of aqueous products.

During the last two decades, filter-based methods have been replaced with continuous denuder devices and optical measurement techniques that are limited to measuring just one compound or species in a particular physical state (i.e., either a gas or a particulate/droplets). These techniques have evolved into samplers that combine aqueous-phase aerosol collectors with the denuder technique for the simultaneous collection of gas and particulate species. During the USEPA-sponsored Atlanta Super Site Experiment in 1999 [19.186], a breakthrough was made in the development of new semicontinuous aerosol measurement techniques with online IC analysis of the resulting aqueous solution.

19.4.2 Sampling of Semivolatile Substances

While the particulate fraction is collected on a filter, the gaseous mass fraction of the semivolatile trace substance may be collected through irreversible sorption to a filter, a coated wall (denuder), or a polyurethane foam plug.

Filter Packs Used With or Without Denuders

The N(III) species ammonia and ammonium (a cation) as well as the N(V) species nitric acid and nitrate (an anion) can be sampled differentially using denuders in combination with a filter pack, with the latter positioned downstream. While the gaseous mass fraction can be accessed using the denuders (with a selective coating), the particulate mass fraction is derived by subtracting the gaseous fraction from the total [19.187, 188] (Fig. 19.8). The use of denuders in combination with filters is uncommon for organics but has been found to be suitable for semivolatile PAHs with high vapor pressures (up to four-ring PAHs [19.189, 190]). The blow-off from quartz and Teflon filters can be collected on a second (backup) quartz filter [19.191].

Sampling Trains with a Filter and Adsorbent

The differential sampling of organics is commonly achieved using a filter in combination with a down-

Fig. 19.8 Schematic design of sampling trains including denuders and downstream front and backup filters (p.a. phosphoric acid coating, s.c. sodium carbonate coating, XAD – XAD-4, a porous, macroreticular, nonpolar, polystyrene-divinylbenzene resin with a high specific surface area of $725 \text{ m}^2 \text{ g}^{-1}$). Adapted from [19.192] with permission from John Wiley & Sons, Inc. T(XRF) Teflon filter for x-ray fluorescence analysis upstream of P(p.a.), a p.a.-coated paper filter, in channel 1, T(IC) Teflon filter for ion chromatographic analysis upstream of GF (s.c.), two stacked glass fiber filters coated with s.c., in channel 2, and a quartz fiber filter Q upstream of a XAD-coated quartz fiber filter XAD-Q

stream adsorbent in a glass cartridge (Fig. 19.9). Glass and quartz fiber filters are most common. An oxidant denuder may be employed upstream to prevent oxidative loss during sampling (Fig. 19.9). Polyurethane foam (PUF) is most suitable for apolar and lipophilic organic gases. The specific surface area of PUF is $\approx 0.005 \text{ m}^2 \text{ g}^{-1}$, and its density is $20\text{--}30 \text{ g L}^{-1}$ [19.83]. The PUF material utilizes both adsorption (which depends on the vapor pressure) and

Fig. 19.9 Schematic design of sampling trains that include a filter and adsorbent. High-volume (Hi-vol) sampling occurs typically at flow rates between 200 and 1000 LPM, whereas Denuder sampling is realized at 10 to 200 LPM. (after [19.83] with permission from the American Chemical Society)

absorption (which depends on the PUF–air partitioning coefficient) mechanisms for retention [19.193]. Eventual breakthrough can be controlled by installing a series of plugs [19.194].

Organics that are more polar can be sorbed to XAD. A combination of PUF with XAD-2 or XAD-4 has also been successfully used for pesticides and other more polar target substances [19.51, 195–197]. The specific surface area of XAD is very large: $300\text{--}600 \text{ m}^2 \text{ g}^{-1}$. XAD-2 is a finely ground, porous, macroreticular, nonpolar polystyrene-divinylbenzene resin. To probe a wide spectrum of SVOC classes, mixed sorbent cartridges (e.g., PUF-XAD-2) are used for active sampling and sorbent-impregnated (SIP) PUF disks are employed for passive sampling [19.52, 194].

19.4.3 Sampling of Aerosol Particles

The sampling of aerosol particles requires an inlet setup that draws in the particle-laden air from the environment of interest (e.g., the atmosphere or indoor air) and transports it to the sampling device(s) through a tubing system. Typical components of an ambient aerosol inlet are the *aerosol inlet head* (which often has an impactor or cyclone to define an upper size cutoff or *cut-point*), smooth transport *tubes* made of conductive material (typically stainless steel with smooth inner surfaces), a *dryer* to control the humidity of the sample air (e.g., via diffusion, dilution, or heating), and an (isokinetic) *flow splitter* to distribute the sample air among several

Fig. 19.10a–d Schematics showing the designs of the main types of inertial classifiers: (a) body impactor, (b) conventional impactor, (c) virtual impactor, and (d) cyclone (after [19.89] with permission from John Wiley & Sons, Inc.)

samplers and/or instruments running in parallel [19.19]. Careful design and validation of the inlet system is as crucial to ensuring representative aerosol sampling as the choice of sampling device. The design and construction of inlets for some applications can be challenging (e.g., in tall tower observatories [19.198]) and technically complex (e.g., for aircraft sampling [19.199, 200]). In addition to the design of the setup, the operational settings for the sampling need to be adapted to the targeted size spectrum and the environmental conditions. For example, sampling in fast-moving air should be *isokinetic* (i.e., there should be the same air velocity inside and outside the inlet tube) and *isoaxial* (i.e., the inlet tube should point into the wind) to ensure representative coverage of larger particles, which are prone to inertia-related artifacts. Isokinetic aerosol sampling is particularly challenging on aircraft due to the very high and variable air velocities involved [19.201, 202]. Moreover, *laminar flow* conditions are used in the inlet tubes in most sampling applications, although *turbulent* sampling may also be suitable in certain contexts (see also Sect. 19.6.3). Detailed overviews of inlet construction, validation, and operational settings can be found elsewhere [19.19, 104, 203].

The following section summarizes key aspects of the design and operation of aerosol sampling devices and systems. These aspects are grouped into the following categories:

1. inertia-based particle size separation and sampling,
2. diffusion-based and thermophoretic sampling,
3. particle migration and deposition in gravitational and electric fields, and
4. filter sampling.

Fig. 19.11 Schematic of a cascade impactor. Moving downstream from stage to stage, the velocity of the accelerated sample air increases and the diameters of the collected particles decrease (after [19.89] with permission from John Wiley & Sons, Inc.)

Fig. 19.12 Particle collection efficiency for a micro-orifice uniform deposit impactor (MOUDI) that includes nano-MOUDI stages (after [19.89] with permission from John Wiley & Sons, Inc.)

Inertia-Based Particle Size Separation and Sampling

Inertia-based aerosol samplers have become widely used and almost indispensable tools in atmospheric science. The main types of inertial classifiers are body impactors, conventional impactors, virtual impactors, and cyclones (Fig. 19.10) [19.61, 89].

Body impactors, which are comparatively simple inertial classifiers, either swirl an impaction surface through the air or draw the air past the impaction surface [19.89, 204, 205]. As a result, large particles (typically $\gg 1 \mu\text{m}$ in size) cross the air streamlines around the obstacle in the fluid and strike the impaction surface (e.g., cylinders, ribbons, or slides). The collection efficiency and size cut-point depend on the sizes of the obstacle and particles and the relative velocity of the particles with respect to the obstacle. The main advantages of body impactors are relatively simple handling and the ability to operate them without sample air transport through inlets (thus circumventing the associated aspiration and tube transmission losses of large particles). One example is a rotating arm impactor called the Rotorod[®] (manufactured by IQVIA[™]), which has a rapidly rotating sampling head (2400 rpm) and two plastic rods (1.5 mm by 23 mm) that act as impaction surfaces and are coated with a sticky grease [19.206]. The Rotorod probes $\approx 120 \text{ L min}^{-1}$, and the particles collected on the rods are analyzed via microscopic identification and quantification [19.206]. Rotorod impactors and samplers with comparable designs are routinely used in bioaerosol sampling and aeroallergen monitoring (i.e., pollen and spores) [19.206–208].

Conventional or jet impactors accelerate the sample air through a nozzle perpendicularly towards a flat

impactor surface, which redirects the particle-laden air flow while collecting particles above a certain inertia threshold. Conventional impactors are widely used in aerosol sampling, and there are numerous impactor designs [19.61, 89]. The designs can differ in terms of the geometry of the nozzles (i.e., circular, rectangular, or slit), the number of nozzles (single vs. multiple), single-stage vs. cascade configuration, low-pressure designs, and low- vs. high-volume operation [19.96, 210–212]. The simplest design is a single-nozzle, single-stage impactor that classifies particles into two size fractions. Impaction theory has established design guidelines that allow the prediction and attainment of a sharp particle cut-point (D_{50}) at a precisely known aerodynamic diameter (D_a) [19.90, 210]. For instance, Fig. 19.11 shows the scheme of a cascade impactor with several classification stages. Every stage is characterized by a specific nozzle-to-impaction plate configuration, which defines its collection efficiency and D_{50} . At each stage, particles with $D_a > D_{50}$ are collected, whereas particles with $D_a < D_{50}$ follow the air streamlines and are passed on to the subsequent stage(s). A widely used cascade impactor for which different models are commercially available is the micro-orifice uniform deposit impactor (MOUDI, MSP Corp., Shoreview, USA) [19.89]. The characteristic collection efficiency curves of the 13 MOUDI classification stages are shown in Fig. 19.12. Its wide accessible particle size range and sharp cut-point characteristics make the MOUDI a valuable tool for highly size-resolved aerosol sampling. The particles, which are deposited on dedicated substrates (e.g., filters, aluminum foil, or glass slides) placed on the impaction plates, are then available for subsequent analysis using a variety of methods [19.7,

Fig. 19.13 (a) Schematic of a virtual impactor and (b) its particle collection efficiency curve. The overall performance of a virtual impactor (i.e., minimal losses of small particles to the major flow and large particles to the minor flow) is defined by several design parameters, such as the nozzle diameter D_{nozzle} , the dimensionless jet-to-collection probe distance S/D_{nozzle} , the dimensionless nozzle throat length T/D_{nozzle} , the collection probe diameter D_1 , and the collection probe design and symmetry (see (a)) [19.101, 209] (after [19.89] with permission from John Wiley & Sons, Inc.)

213–215]. Note that the relationship between particle rebound at the impaction stages and particle phase state is a major issue in impactor operation, as it can cause substantial size classification biases [19.216]. Particle rebound minimization is addressed in more detail in Sect. 19.6.3. A special form of impaction after air acceleration through a jet is realized in liquid impingers, which collect aerosol particles (mostly bioaerosols) in a liquid (e.g., a buffer) via inertia [19.217].

Virtual impactors are closely related to conventional impactors except that a collecting probe (i.e., a tube that receives the particle-laden air) is employed instead of an impaction plate [19.89, 101, 218]. The scheme in Fig. 19.13a illustrates a typical virtual impactor design. A *minor flow* penetrates into the collecting probe and then follows relatively straight air streamlines in the direction of acceleration of the air through the nozzle, whereas a *major flow* is deflected sideways along a curvilinear flow pattern, typically due to vacuum pumping. Large particles with $D_a > D_{50}$ cross the streamlines due to their high inertia and continue their straight motion into the collecting probe. Smaller particles with $D_a < D_{50}$ tend to follow the air streamlines and thus the major flow perpendicular to the receiving tube. The collection efficiency curves of virtual impactors can be as sharp as those of conventional impactors. However, in a virtual impactor, some particles with $D_a < D_{50}$ remain in the minor flow, so the efficiency curve converges to a finite value that is larger than zero (Fig. 19.13b). The fraction of small particles in the minor flow corresponds to the ratio of the minor flow rate to the major flow rate ($Q_{\text{minor}}/Q_{\text{major}}$). In contrast to body and conventional impactors, the particles in both size fractions remain airborne. As an example, a high-volume (500 L min^{-1}) dichotomous virtual impactor with a single accelerating jet classifies the particles into a coarse size fraction with $D_a \gtrsim 2.5 \mu\text{m}$ and a fine size fraction with $D_a \lesssim 2.5 \mu\text{m}$ [19.219]. After classification, the airborne particles in the major flow and/or minor flow can be analyzed online using instrumentation, directed into further classification devices, or collected on filters [19.220–222]. Virtual impactors can also be used to concentrate airborne particle fractions for subsequent analysis [19.223].

Marple and Olson [19.89] concisely summarized that

in a cyclone, a jet of air impinges tangentially on the inner surface of a cylinder and then swirls downward in a cyclonic fashion inside the cylinder, and into a conical section. In the conical section the air reverses direction and spirals upward [...] to the centrally located exit tube [...]

(see Fig. 19.14a). Particles with D_a above the cyclone cut-point cross the streamlines of the swirling air motion and tangentially strike the inner cyclone walls (Fig. 19.14b). Cyclones are available in a wide range of designs (e.g., cascade configurations), and have been used in a broad spectrum of applications [19.226–228]. Theoretical treatments of air and particle motions inside a cyclone are more demanding than for impactors [19.103, 224, 229]. In aerosol sampling, a cyclone is routinely used as a preclassifier to collect a specific particle size range (e.g., the respirable fraction)

Fig. 19.14a,b Particle trajectories inside a cyclone. **(a)** A particle with $D_a < D_{50}$ follows a swirling trajectory and exits the cyclone. **(b)** A particle with $D_a > D_{50}$ crosses the swirling air streamlines and strikes the cyclone wall (after [19.224] with permission from Elsevier)

before a filter sampler [19.230]. In such applications, it is the particle fraction with $D_a < D_{50}$ that remains airborne and is used for subsequent collection and analysis. There are also cyclone designs that collect the large particle fraction with $D_a > D_{50}$ for subsequent analysis. Such wetted wall cyclones that drive the particles into a liquid film are known as tangential impingers, and are widely used in bioaerosol sampling [19.111, 225, 231]. As an example, the BioSampler (SKC Inc., Eighty Four, USA) has become a widely used tangential impinger (Fig. 19.15). Its design utilizes three nozzles to swirl the collection fluid (e.g., a saline solution or buffer) in the collection vessel and propel bioaerosol particles larger than the cut-point at the wetted walls [19.225]. The resulting particle suspension in the collection fluid is available for subsequent analysis [19.232, 233].

Diffusion-Based and Thermophoretic Sampling

Devices that rely on particle separation based on diffusion mobility (i.e., particle diffusion and deposition on surfaces) are used routinely in aerosol sampling. *Diffusion batteries* and *diffusion denuders* are relevant sampling devices in this context. Diffusion denuders—

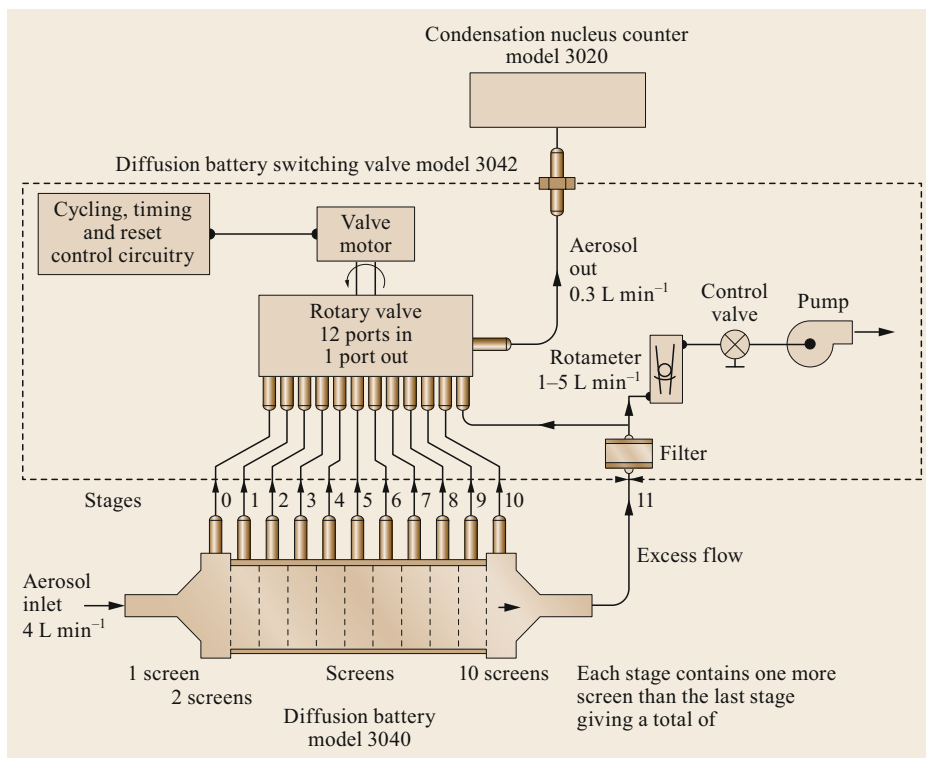

Fig. 19.16 Scheme of a typical ten-stage diffusion battery for the determination of the aerosol particle size distributions in the fine and ultrafine size ranges (after [19.29] with permission from John Wiley & Sons, Ltd.)

Fig. 19.17a,b Examples of thermal precipitator design. (a) Cross-sectional schematic of a heated wire thermal precipitator (after [19.28] with permission from John Wiley & Sons, Inc.) (b) A more modern thermal precipitator design with heating and cooling of the opposite surfaces to enhance the thermal gradient and the precipitation efficiency (after [19.234] with permission from Taylor and Francis)

which remove specific gases from the sample air without affecting the particle phase (see also Sect. 19.4.1)—are applied, for instance, to account for semivolatiles

that are in aerosol particles but evaporate during the sampling process (see also Sect. 19.6.3) [19.18]. Various designs of diffusion batteries (i.e., tube bundles,

Fig. 19.18a,b Electrostatic precipitator designs. **(a)** Scheme of a point-to-plate electrostatic precipitator for depositing aerosol particles onto electron microscope substrates (a TEM grid here) (after [19.235] with permission from Taylor and Francis). **(b)** Example of a specialized application of an electrostatic precipitator in the analysis of exhaled-breath aerosol, which is enriched via electrostatic deposition at an air–liquid interface on a lab-on-chip cartridge (after [19.236] with permission from Elsevier)

parallel plates, screens, or meshes) can be used to determine the size distribution of aerosol particles that are $\lesssim 0.1 \mu\text{m}$ in size [19.28, 237]. In practice, measurement of the penetration P (i.e., the fraction of the particles that enter the diffusion battery that also exit it) allows the diffusion coefficients and corresponding sizes of the analyzed aerosol population to be determined. By operating multiple units in parallel, as illustrated in Fig. 19.16, the particle size distribution can be obtained through complex data inversions [19.238, 239]. However, there are significant limitations on the quality of the data obtained [19.18]. Detailed information on the design, operation, and performance of diffusion batteries can be found elsewhere [19.238, 240]. Diffusion batteries were widely used prior to the development of online instrumentation for ultrafine particle detection (i.e., electrostatic classification), when aerosol particle sizing $< 100 \text{ nm}$ was particularly challenging [19.238]. However, advanced diffusion battery designs are currently being applied in specific applications as they provide operational advantages over other analytical approaches (e.g., high time resolution, robust operation, and a compact design) [19.241–243].

The instruments based on thermophoresis, *thermal precipitators*, are well-established samplers for collecting rather small amounts of particles in the fine and ultrafine size ranges on dedicated substrates (e.g., glass slides or electron microscope grids), mostly for subsequent light or electron microscopic analysis [19.244, 245]. In a typical design, large temperature gradients (typically 10^4 – 10^5 K m^{-1}) are created within small distances between the heat source and the deposition surface [19.234, 246]. The particles are deposited on the colder surface in the periphery of the heat source, such as a heated wire (Fig. 19.17a). In aerosol sampling, thermal precipitators show several operational advantages, such as robust and inexpensive designs, high collection efficiencies, and low flow rates. They have been widely used as personal samplers in occupational monitoring [19.65, 247]. As an example, a recent design for collecting particles $< 100 \text{ nm}$ in size is shown in Fig. 19.17b [19.234].

Particle Migration and Deposition in Gravitational and Electric Fields

The controlled deflection of aerosol particles in electric fields, which is particularly efficient for the ultrafine size range, is a fundamental principle in aerosol science as it provides the basis for widely used online instruments such as differential mobility analyzers and electrostatic precipitators for particle collection [19.113]. Electrostatic precipitators utilize two main processes: first, charging/ionization beyond the natural charge state of the particles; second, the deposition of the particles on a substrate in a strong electric field. In the design

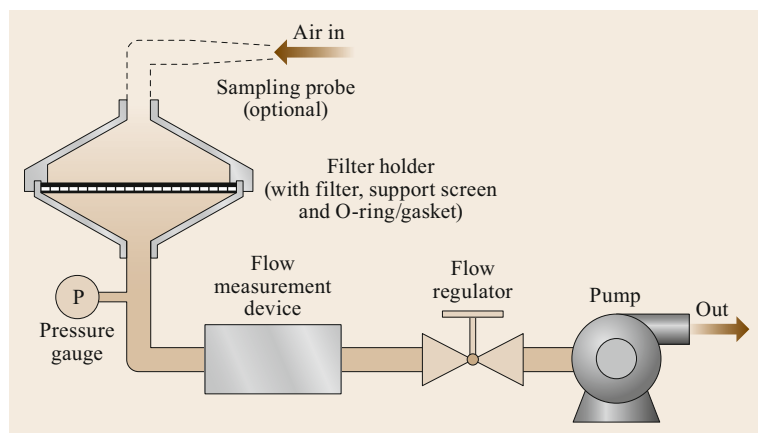

Fig. 19.19 Schematic of a filter collection system typically used for aerosol measurement, comprising a filter holder with a filter medium, a gas flow measurement and control system (e.g., a gas flow meter and a needle valve or gas flow controller), and a pump (after [19.116] with permission from John Wiley & Sons, Inc.)

of so-called point-to-plate precipitators (Fig. 19.18), both processes occur in the same step in a strong electric field (several kV) with corona discharges between a corona needle and the substrate [19.235, 248]. In different designs, the charging and precipitation regions are separated [19.249–251]. Since electrostatic precipitator samples are often used in microscopic analyses (e.g., to retrieve particle size distribution), spatially uniform and representative deposition without a strong size bias is a particularly important performance characteristic [19.252]. Various mobile versions of electrostatic samplers are available [19.235, 250]. Furthermore, dedicated electrostatic precipitators have been used to collect bioaerosols on agar plates, which has the major advantage that the deposition is comparatively gentle, so it conserves organism viability [19.253, 254].

Gravitational deposition has been used for the passive sampling of supermicrometer particles. Most applications of this technique have been from the field of bioaerosol sampling [19.54, 255]; however, coarse-mode mineral dust and sea spray aerosols have also been collected via sedimentation [19.256]. Gravitational sampling is simple and cheap but suffers from several drawbacks, as it is very sensitive to particle size and aerodynamic properties as well as to wind speed and turbulence. Hence, it is prone to sampling bias and a lack of reproducibility. One such device is the so-called Wagner–Leith passive sampler, which is used to collect samples for electron microscopy [19.108, 109]. In this technique, gravitational deposition can be used as an approximation for the overall deposition velocity, although inertial and diffusional processes also provide certain contributions.

Filter Sampling

Filter sampling is the most widely applied method to collect aerosol particles for the subsequent analysis of particle properties such as mass (via gravimetry [19.257]), chemical or isotopic composition (e.g., via spectroscopy, chromatography, mass spectrometry, etc. [19.258, 259]),

taxonomic diversity of bioaerosols (e.g., genome sequencing [19.260]), and for multiple further types of analysis. Filter sampling has the advantages that it is simple, inexpensive, and can be flexibly adapted to the specific requirements of the laboratory analysis (e.g., by adjusting flow rates and sampling times, choosing appropriate filter sizes and materials, and combining it with virtual impactors or cyclones for size fractionation). A scheme of a typical filter sampling setup is shown in Fig. 19.19, and details about the wide range of frequently used systems can be found elsewhere [19.116, 261]. Of central importance is the choice of filter type and material, which has to be adjusted to the intended laboratory analysis. An overview of filter materials, their physical and chemical properties, and their compatibilities with laboratory analysis methods is provided elsewhere [19.261]. Filter characteristics that should be considered when choosing appropriate filters are

1. the particle sampling efficiency,
2. the mechanical, chemical, and temperature stabilities,
3. the blank concentrations of the species of interest,
4. flow resistance and loading capacity, and
5. cost and availability [19.261].

19.4.4 Comparison of the Methods

The major advantages and disadvantages of the various sampling devices and systems highlighted in Sects. 19.4.1–19.4.3 are summarized in Table 19.4. Note that this overview is rather generalized and, in places (i.e., for aerosol particle sampling), simplified, as the advantages and disadvantages strongly depend on the specific requirements of the laboratory analysis of the samples after collection. In fact, some cases may even be ambivalent, since certain aspects of a sampling method may be advantageous in one application and disadvantageous in another.

Table 19.4 Advantages and disadvantages of the different sampling devices and systems

Devices	Advantages	Disadvantages
Sampling of trace gases		
Active	Control over sample volume Artifact correction	Needs electricity Potentially large artifacts under polluted conditions
Passive	Simple, economical, small footprint No electricity required	Uncertain sample volume Prone to artifacts
Sampling of semivolatile substances		
Filter and denuder	Laborious wet chemical technique	Limited mass flow, no high-volume sampling For many substance classes there is no suitable denuder coating available Ultrafine particles (with nonzero sampling efficiencies) are partly misattributed to the gaseous fraction
Filter stack	Simple	Limited mass flow, no high-volume sampling Gas-phase collection limited to acids and bases
Filter and cartridge with sorbent foam plug or sorbent resin	High-volume sampling possible	Limited to hydrophobic and moderately polar trace gases
Sampling of aerosol particles		
Body impactors	Simple operation Collection of coarse particles without inlet lines and associated losses	Low collection efficiencies for fine particles Limited applications
Conventional impactors	Flexible design for many applications Well-defined and sharp size cut-points	Biases from particle rebound Harsh deposition may alter particle morphology and bioaerosol viability
Cascade impactors	Flexible design for many applications Well-defined and sharp size cut-points Coverage of (almost) entire particle size distribution	Biases from particle rebound Harsh deposition may alter particle morphology and bioaerosol viability
Virtual impactors	Flexible design that can be used in combination with many other devices/instruments Particle fractions above and below the cut-point remain airborne for subsequent analysis Application as aerosol concentrator	Some of the particles below the cut-point remain in the minor flow
Cyclones	Flexible design can be used in combination with many other devices/instruments Wetted wall cyclones allow soft bioaerosol collection	Theory of air and particle motions is more demanding than for impactors
Diffusion batteries	Simple and compact design, robust operation Collects ultrafine particles Allows size distribution to be retrieved	Complex data inversions Large uncertainties in results Decreasing collection efficiencies with increasing particle size
Thermal precipitators	Simple, small, robust, and inexpensive design High collection efficiencies for ultrafine particles Low flow rates	Decreasing collection efficiencies with increasing particle size
Electrostatic precipitators	Simple and small High collection efficiencies for ultrafine particles Allows soft bioaerosol collection	Collection efficiency decreases with increasing particle size Deposition is often nonuniform Size distribution is potentially biased
Gravitational samplers	Simple passive sampling No electricity required	Low collection efficiencies for fine and ultrafine particles Prone to sampling biases and a lack of reproducibility
Filter samplers	Simple, flexible, and applicable in various settings Inexpensive and efficient collection over the entire particle size range	Filtration theory is complex

19.5 Specifications

Table 19.5 summarizes the specifications and selected technical details of the trace gas, semivolatile substance, and aerosol particle sampling methods presented above. Since the set of sampling methods presented is very diverse, specifications that are of broad interest (e.g., collected species, sampling times, and flow rates) are summarized. Also note that the experimental uncertainties and errors largely depend on the laboratory analysis of the samples after collection, so

they vary from case to case. To illustrate this case-specific uncertainty, note that cell viability and integrity are important aspects of bioaerosol analysis, but these two parameters may be altered substantially by various sampling methods, such as impaction on solid surfaces with strong desiccation during filter sampling. Accordingly, harsh sampling conditions can lead to major uncertainties in bioaerosol studies, but they are much less significant when sampling nonbiological materials.

Table 19.5 Specifications of and selected technical details for different air sampling methods

Method	Sampling principle and collected species	Operational details (e.g., sampling time/time resolution and flow rates)	Experimental uncertainties and errors
Sampling of trace gases			
Passive	Mostly NH ₃ , HNO ₃ ; less often O ₃ , SO ₂ , CO	Weeks to months Flow rates assumed from diffusional properties	Uncertain sample volume Biased by unquantifiable artifacts
Active	NH ₃ , HNO ₃ , HONO, HCl, SO ₂	Hours to days Controlled flow rate Artifact correction possible	Limited denuder capacity causes breakthrough under certain environmental conditions
Sampling of semivolatile substances			
Filter and denuder	Active Filtration and molecular diffusion followed by an irreversible chemical reaction or sorption	Sampling times: min to h Flow rates: L min ⁻¹	Due to a nonzero sampling efficiency for ultrafine particles, some of these particles are misattributed to the gaseous fraction
Filter stack	Active Filtration, irreversible adsorption	Sampling times: min to h Flow rates: L min ⁻¹	
Filter and cartridge with sorbent foam plug or sorbent resin	Active Filtration, irreversible adsorption	Sampling times: min to h Flow rates: L min ⁻¹ to m ³ min ⁻¹	Sampling artifacts are unavoidable for several substance classes (blow-on, blow-off)
Sampling of aerosol particles			
Inertia-based	Active Deflection of particle-laden air with inertia-driven deviation of particle motion from air streamlines Particle size range: mostly (but not exclusively) $D > 0.5 \mu\text{m}$	Sampling times: min to h Flow rates: L min ⁻¹ to m ³ min ⁻¹ Impactor deposition on 1 to > 10 stages Diverse substrates: e.g., metal foil, glass slides, Si wafers	Particle rebound For microscopy: high substrate loadings create coincidental internal particle mixtures For microscopy: particle morphology altered For bioaerosol analysis: decreased cell viability and altered cell integrity
Diffusion-based	Active Molecular diffusion followed by irreversible adsorption Particle size range: mostly $D < 0.1 \mu\text{m}$	Sampling times: min to h Flow rates: L min ⁻¹ Substrates: tube bundles, parallel plates, screens or meshes	For size distribution retrieval: uncertainties from data inversion
Thermophoretic	Active Diffusion along temperature gradient (10^4 – 10^5 K m^{-1}) followed by irreversible adsorption Particle size range: mostly $D < 1 \mu\text{m}$	Sampling times: min to h Flow rates: L min ⁻¹ Substrates: e.g., glass slides	For microscopy: size biases
Gravitational	Passive Gravitational settling on substrate Particle size range: $D > 1 \mu\text{m}$	Sampling times: h to d Substrates: e.g., glass slides, Si wafers, also agar plates	Large uncertainties due to high dependence on wind speed, particle properties, etc. Sample aging during long sampling runs (days)

Table 19.5 (Continued)

Method	Sampling principle and collected species	Operational details (e.g., sampling time/time resolution and flow rates)	Experimental uncertainties and errors
Sampling of aerosol particles			
Electrostatic	Active Migration in electric field (kV) and deposition on substrate Particle size range: most efficient for $D < 0.1 \mu\text{m}$	Sampling times: min to h Flow rates: L min^{-1} Substrates: e.g., TEM grids	For microscopy: size biases
Filtration	Active Filtration (a combination of diffusional and inertial deposition and interception) Entire particle size range	Sampling times: min to d Flow rates: L min^{-1} to $\text{m}^3 \text{min}^{-1}$ Substrates: porous membrane, pore membrane, and fibrous filters	Blank concentrations of species of interest Sample aging during long sampling runs (days)

19.6 Quality Control

Quality assurance and quality control (QA/QC) are key to ensuring high-quality, reliable sampling and measurement results. The following sections emphasize specific QA/QC aspects of sampling procedures for trace gases, semivolatile substances, and aerosol particles. A detailed overview of QA/QC practices in atmospheric science can be found in Chap. 5.

19.6.1 Sampling of Trace Gases

A valuable QA/QC approach when using passive gas samplers is to collocate two or three samplers at the same site to achieve precise estimates. For active gas samplers, flow control using a critical orifice or temperature-compensated mass flow control ensures accurate measurement of the sample volume. The use of dry gas meters also increases the reliability of the determined sample volume. The treatment of field blanks—samples that accompany the actual sample media (passive sorbents or active denuders) from the lab into the field and back—can be used to determine the overall detection limit of the method employed for passive or active sampling. The capacity of the denuder for the sampled analyte can be estimated from the surface area and the amount of sorbent dissolved in the coating solution, and the maximum operating time of the denuder (i.e., the amount of time that the denuder can operate before the active surface sites on its walls become exhausted and species breakthrough occurs) can be gauged from the flow rate through the denuder and the expected ambient concentrations of the target species.

The Atlanta Super Site Experiment [19.186] provided a quantitative assessment of the performance of a combined denuder-filter technique for time-integrated aerosol measurement. Given the semivolatile character

of HNO_3 , it was recommended that denuders impregnated with sodium carbonate should be used to effectively remove HNO_3 upstream from the Teflon filter that collects fine PM, and that a backup filter impregnated with nylon or sodium carbonate should be employed to collect the volatile fraction of the nitrate aerosol from the front filter in order to accurately measure the nitrate content in $\text{PM}_{2.5}$. However, using the extracts from a tandem denuder setup to quantitatively determine HNO_3 and HONO can cause the HNO_3 to be underestimated and the HONO concentration to be overestimated if the nitrate measured on the second denuder is interpreted as resulting from a secondary heterogeneous reaction of O_3 with nitrite to give nitrate on the denuder walls [19.192].

19.6.2 Sampling of Semivolatile Substances

Absorbent breakthrough can be controlled by using larger cartridges (i.e., a series of sorbent foam plugs) [19.262]. The suitability of PUF can be assessed based on the PUF–air partitioning coefficient $K_{\text{PUF-air}}$ [19.193]. Sampled particulate material can desorb (such material is known as *blow-off*), leading to a positive sampling artifact that is attributed to the gas-phase species. This has been shown to happen for PCBs (polychlorinated biphenyls) [19.263]. Gas molecules may sorb to the filter or sampled particulate material (these sorbed gas molecules are known as *blow-on*), causing a positive sampling artifact that is attributed to the particulate-phase species. This has been observed for polar gas molecules, namely perfluoroalkyl carboxylic acids [19.197]. Organics may be degraded in samplers [19.264]. To prevent the oxidation of particulate PAHs collected on filters, an oxidant denuder is needed upstream during sampling, particularly in the

Fig. 19.20 Mechanisms that occur during aerosol sampling and transport in a sampling probe and a transport tube (after [19.104] with permission under CC 3.0)

presence of high oxidant (O_3 , NO_2) concentrations and when using long sampling times [19.265]. This oxidation yields positive sampling artifacts that presumably relate to oxy-PAHs (as-yet unstudied products) and several nitro-PAHs [19.266].

19.6.3 Sampling of Aerosol Particles

Every aerosol sampling protocol and subsequent sample analysis requires dedicated QA/QC practices that cover all relevant working steps in order to ensure that meaningful analytical results are obtained. General guidelines and recommendations for standardized aerosol measurements have been compiled and published for global and long-term measurement programs [19.19, 267, 268]. Moreover, standardized QA/QC protocols have been established for some aerosol analyses [19.19, 269–272]. However, standardized and widely established QA/QC guidelines are not available for most sampling settings. In the following, selected and general QA/QC practices for sampling preparation, the actual sampling process, postsampling sample treatment, sample analysis, and data validation are summarized.

The preparation of a sampling experiment for laboratory analysis (e.g., x-ray microscopy, ion chromatography, or genome sequencing) involves the careful selection of the most appropriate sampling method (see the advantages and disadvantages of each method in Table 19.4) and sampling substrate. Moreover, an appropriate sampling system consisting of an inlet system and sampling device must be set up. Access to recommendations for the design and operation of aerosol inlets and sampling setups is crucial to most (stationary) aerosol sampling efforts, as the recommendations provide a useful reference when attempting to minimize particle losses from imperfect sample air aspiration and/or sample air transport through the tubing system [19.104, 203]. In particular, the particles at both ends of the aerosol size distribution are those that are

most likely to be lost due to diffusional deposition in the ultrafine fraction or sedimentation and impaction losses in the coarse fraction (Fig. 19.20). Accumulation-mode particles are [19.19]

the most long-lived with respect to atmospheric deposition, and they are also the most inert fraction during particle sampling.

The recommendations for representative (stationary) aerosol sampling of reproducible quality according to the second Global Atmosphere Watch (GAW) report [19.267] and Wiedensohler *et al.* [19.19] can be summarized as follows:

- The *overall inlet design* should resemble a vertical stack on the measurement container that shelters the instrumentation. The stack should be high enough to reduce the influences of local effects (e.g., vegetation and buildings). Ideally, the entire setup (inlet, dryer, flow split, and sampler) is aligned vertically to reduce sedimentation losses, but slight bends in the tube are acceptable, and the data obtained can be corrected afterwards [19.104].
- The *aerosol inlet head* excludes precipitation from the sampled aerosols. It should be an omnidirectional inlet head with high transmission efficiency regardless of the wind direction and speed. The inlet head can have a defined particle cutoff (e.g., PM_{10} , $PM_{2.5}$, or PM_1) due to the use of an impactor or cyclone. Total suspended matter (TSP) inlet heads are used for some applications. It may be necessary to heat the inlet head if the site experiences frequent clouds, fog, or freezing.
- The *tubes* of the inlet setup should be as short as possible. They should also be electrically conductive (e.g., longer sections should be made of stainless steel and, if needed, shorter sections should be conductive silicone/polymer tubes) and grounded to avoid electrostatic particle losses. In most sam-

pling applications, laminar flow conditions with Re_f values of up to ≈ 2000 are recommended (Sect. 19.3.3). The flow is turbulent for $Re_f > 4000$, whereas the regime $2000 < Re_f < 4000$ is called the transition regime. Other sources of (local) turbulence such as bends, connectors, and rough inner surfaces should be avoided, as turbulence strongly enhances diffusional losses. Note that turbulent sampling can be acceptable under certain conditions [19.19].

- The sample air must be *dried* if high ambient RH (relative humidity) levels could lead to hygroscopic particle growth and thus biased sizing or even a risk of water condensation in the sampling setup. If drying is performed, the RH is recommended to be $< 40\%$. Note, however, that drying may encourage the volatilization of semivolatile compounds in the particles.
- If the particle-laden air is distributed to several samplers/instruments, an *isokinetic flow splitter* is needed to ensure that the core of the laminar flow profile is sampled and that the velocities of the sample and main flow are comparable. Both measures promote representativeness in the ultrafine and coarse size ranges.

When sampling is performed on moving platforms (i.e., aircraft) or at locations with high wind speeds, isokinetic and isoaxial sample air aspiration are crucial requirements, but they are often difficult to realize (Fig. 19.20). In general, the specifications for the sampling setup have to be adapted to the probed aerosol population as well as the specific environmental conditions of the sampling application. Aside from optimizing the sampling setup, it is necessary to carefully

characterize and document the inlet system in order to correct the data for unavoidable particle losses [19.104].

During sampling, important operational components such as mass flow meters require frequent calibration and validation. Frequent cleaning of parts of the sampler that are in contact with substrates and/or the sample air may be required. Furthermore, sampling blanks are essential (e.g., to assess filter background levels) in most sampling and analysis procedures. After sampling, quality management should specify the treatment of the filters (such as cooling or storage under inert gas) to minimize/avoid sample aging (e.g., oxidation) or alteration (e.g., growth of microorganisms) [19.260].

Sample analysis involves applying the QA/QC practices of the specific analytical technique(s) utilized, such as gravimetry [19.272], x-ray spectroscopy [19.273], or organic and elemental carbon analysis [19.271]. During sample analysis, sampling-related artifacts must be evaluated. Examples are inhomogeneous particle deposition [19.274] and potential volatilization of certain components (e.g., NH_4NO_3 or organics) due to shifts in partitioning between the gas and particle phases upon changes in temperature or pressure in the sampler [19.18, 275, 276]. For impactor sampling, the rebound of solid particles in inertial aerosol sampling (e.g., in cascade impactors) is a major issue that can significantly alter sampling results [19.216]. Performing dedicated rebound experiments and coating the impactor stages can help to assess and minimize this effect [19.277, 278]. Ultimately, a key aspect of the quality management of aerosol sampling results is the comparison with aerosol online data recorded during the sampling period (if available). Consistency of the results from online and offline aerosol techniques is typically a robust indication of high data quality.

19.7 Maintenance

While passive samplers used for the collection of trace gases or semivolatile substances need almost no maintenance, active samplers require frequent flow checks

and maintenance of components of the actively operating flow system, such as the pump and tubing. The more complex the sampling system (e.g., a continuously op-

Table 19.6 Typical maintenance tasks for (active) air sampling devices, particularly when they are continuously operated. Due to the wide range of sampling methods available, only generalized tasks that do not necessarily apply to all methods are shown

Maintenance interval	Maintenance tasks
At every sample change	Visually inspect the sampler for obvious damage or malfunction Check key operational parameters (e.g., the sample air flow rate displayed)
Weekly to monthly	For sensitive samplings: clean (e.g., sterilize) sample holders and critical parts of the sampler Check the electronic and mechanical functions of key components such as the vacuum and flow control systems (e.g., pumps and mass flow controllers) Check that tube connections are tight (leak tests) and check for free passage of the sample air
Annually	Clean or replace components if necessary (e.g., if the tubes become too restrictive or fail flow checks) Calibration of sampler (if applicable)

erated system with automatic sample switching), the more extensive the maintenance needed. The specific maintenance tasks that must be performed depend on

the sampling system utilized and the frequency of sample collection. A generalized overview of typical maintenance tasks is provided in Table 19.6.

19.8 Application

The field of applications of trace substance sampling in the atmosphere is very broad. It ranges, for instance, from the standardized and continuous monitoring of important pollutants within international measurement networks on the one hand to the case-specific sampling of certain substances within dedicated field experiments on the other. Therefore, this section on the applications of trace substance sampling in the atmosphere cannot provide a systematic or even comprehensive overview of all such applications; instead, it presents selected examples to illustrate the broad spectrum of applications.

19.8.1 Sampling of Trace Gases

As part of the International Global Atmospheric Chemistry (IGAC) project, and supported by the GAW program of the World Meteorological Organization (WMO), the international Deposition of Biogeochemically Important Trace Species (DEBITS) program adopted passive sampling to monitor inorganic gaseous species in tropical regions around the world [19.279–281]. The samplers and analytical procedures used in DEBITS were also adopted by other national and international monitoring programs and applied in other continental-scale air quality studies, including the National Atmospheric Deposition Program's Ammonia Monitoring Network (NADP/AMoN) [19.282]. The samplers are based on the Ferm design [19.9], and expose a specifically impregnated paper disk (sorber) that sits 10 mm behind a 1 μ m PTFE filter disk supported by a circular stainless steel mesh. The circular mesh rests on a polypropylene ring with a 21 mm, downward-facing opening through which ambient sample air diffuses. The 10 mm distance between the sorber filter and the PTFE filter is maintained using a plastic ring. The PTFE filter prevents convective air flow and particles from impacting on the impregnated filter above. The type of gas that is trapped depends on the chemical used as the sorber. In DEBITS, NO₂, SO₂, O₃, and NH₃ are captured using absorbing solutions of potassium iodide (KI), potassium carbonate (K₂CO₃), sodium nitrate (NaNO₃), and citric acid (C₆H₈O₇), respectively. *Pienaar et al.* [19.283] gives an excellent overview of the sampling of inorganic and organic gases by passive diffusion in the DEBITS program.

Persistent organic pollutants (POPs) are monitored by passive sampling networks under the auspices of the

Global Monitoring Plan of the Stockholm Convention on POPs [19.284, 285] (Fig. 19.20). Polyurethane foam disk passive air samplers are used [19.286, 287]. As of 2017, the convention lists 24 substances (substance groups) encompassing obsolete pesticides and flame retardants (such as PBDEs (polybrominated diphenyl ethers)), industrial chemicals (such as PCBs), and combustion by-products (such as PCDDs (polychlorinated dibenzodioxins) and PCDFs (polychlorinated dibenzofurans)). The typical sampling (exposure) time is 3 months. Apart from long-term monitoring, passive sampling networks are also used to determine snapshot distributions (exposure times of a few weeks to months) for whole regions or smaller areas (Africa [19.288], Europe [19.289], and the Aegean [19.290]).

As the effective sampling volume of passive samplers is influenced by the wind velocity and temperature, it is usually only estimated, and results are given in units of mass of substance per sample [19.52, 291]. This method is also only semiquantitative for substances that partition to a significant extent into the particulate phase (semivolatiles; see Sects. 19.1.2 and 19.2.2). As most of the samplers used for POPs are not equipped with a diffusion barrier for particles, ultrafine particles are included (albeit with a low sampling efficiency) [19.292]. Given that the diffusion of particles depends strongly on particle size, this sampling efficiency of particles is dependent on the substance's mass size distribution, which varies both temporally and spatially, so it cannot be calibrated. Passive air samplers with a particle diffusion barrier are also used (adsorbent: XAD-2) to monitor levels of POPs and currently used pesticides [19.293], but the time resolution of these samplers is very low (typically 1 year).

In a more recent 17-month study in the Athabasca Oil Sands region of Alberta, Canada, the comparability of passive and active (denuder) systems for monthly integrated measurements of ambient NH₃ and HNO₃ was evaluated [19.294]. The study took place between June 2011 and October 2012 at two urban ambient air monitoring sites (Fort McMurray and Fort McKay) in the network managed by the Wood Buffalo Environmental Association (WBEA). Passive and active (denuder) surfaces coated with citric acid and phosphorous acid were compared for the collection of NH₃, while sodium chloride (NaCl) and nylon were compared for the collection of HNO₃. The passive samplers tested were the Ogawa

PS-100 [19.79] and Radiello RAD-168 (Radiello, 2006; [19.78], www.radiello.com), while 242 mm long annular diffusion tubes (University Research Glassware, Chapel Hill, NC) served as active samplers. This approach allowed the quantitative assessment of differences in performance, especially in the case of HNO_3 , where the difference between the effective stoichiometric, specific chemical absorption of HNO_3 onto NaCl was compared to the nonspecific physical adsorption of HNO_3 onto nylon, which occurs at an unknown rate.

For NH_3 , using citric acid on both the denuder and passive collection surfaces yielded the best agreement with the lowest bias (between 8 and 25%). Using phosphorous acid on the passive sampling media caused NH_3 to be underestimated relative to citric acid by between -13 and -54% . For HNO_3 , using NaCl on passive surfaces yielded HNO_3 concentrations that were highly biased (by 80–92%) relative to when it was used on active denuder surfaces. However, using nylon instead of NaCl as the passive collection surface caused a consistent and very high bias at both sites (a factor of ≈ 7 –8). Using nylon as the passive collection surface yields exceedingly high HNO_3 values relative to all other passive and active collection surfaces, suggesting artifact reactions that are specific to this surface material. Comparison with long-term HNO_3 data collected elsewhere corroborates the finding that the exposed nylon material causes a significant positive artifact. However, the reactions that drive this specific artifact are currently unclear. Simultaneously measured NO_2 , O_3 , and water vapor data indicate that the nylon surface is susceptible to heterogeneous hydrolysis reactions involving NO_2 , N_2O_5 , and NO_3 radicals.

The average HNO_3 results obtained from NaCl surfaces ($0.23 \mu\text{g m}^{-3}$ from active samplers and $0.44 \mu\text{g m}^{-3}$ from passive samplers) compare well with other long-term measurements in the United States and overseas. For example, SEARCH network measurements made in the southeastern US [19.295] during the same period show overall HNO_3 averages ranging from $0.53 \mu\text{g m}^{-3}$ in rural areas to $1.09 \mu\text{g m}^{-3}$ in urban environs. A similar urban–rural gradient in HNO_3 was reported for various locations in Europe, tropical Africa, and tropical Asia [19.296]. Interestingly, a gradient was also observed at much greater spatial scales; that is, tropical low latitudes exhibited an average annual HNO_3 level of about $1.4 \mu\text{g m}^{-3}$ versus roughly $0.3 \mu\text{g m}^{-3}$ at high European latitudes [19.296], similar to the WBEA domain. They also report an increasing urban–rural gradient in the molar HNO_3/NO_2 ratio (from 2.7% urban up to 18% rural), which they attribute to the slow formation of HNO_3 during transport away from its precursor sources. All of these levels are well below the values of almost $3.0 \mu\text{g m}^{-3}$ obtained from the

Ogawa nylon sampler. In other words, not only do nylon surfaces yield HNO_3 concentrations that are higher than those from collocated samplers, they also yield HNO_3 concentrations that are much higher than observed in urban centers in the US and Europe. Taken together, these results indicate there is a significant but as-yet unexplained positive bias when nylon is used for the passive sampling of HNO_3 .

The denuder difference technique has been successfully employed in the SEARCH network for the semi-continuous measurement of atmospheric HNO_3 and NH_3 , as described in detail by Saylor *et al.* [19.297]. For NH_3 , this approach employs a dual-channel nitric oxide-ozone (NO-O_3) chemiluminescence detector (CLD). Ambient air in both channels flows through sodium carbonate (Na_2CO_3)-coated annular denuders (URG Inc., Chapel Hill, USA) at a flow rate of 1.25 L min^{-1} . NH_3 quantitatively passes through the denuders, whereas HNO_3 is removed. The flow in channel 2 passes directly into a 600°C platinum (Pt) mesh converter followed by a 350°C molybdenum (Mo) converter. The Pt converter oxidizes NH_3 and particulate NH_4^+ to NO and nitrogen dioxide (NO_2). The Mo backup converter reduces all NO_x components to NO. The flow in channel 1 is directed through an annular denuder coated with citric acid that removes NH_3 prior to sequential oxidation (Pt) and reduction (Mo) conversion steps. The difference between the channels is therefore operationally defined as NH_3 . Other reduced nitrogen gases that are removed by a citric acid denuder may be included in this operational definition, thus causing a potential positive bias.

Omitting the oxidizing Pt converter, a simpler dual-channel CLD is used for HNO_3 , whereby channel 2 passes ambient air directly into a 350°C Mo converter while channel 1 quantitatively removes HNO_3 via a Na_2CO_3 -coated annular denuder upstream of the Mo converter. Hence, the difference between the channels in this case is operationally defined as HNO_3 . Annular denuder inlets for each channel are exposed directly to the atmosphere and converters are attached to denuder outlets with short (5 cm) lengths of (1/4)" o.d. Teflon® PFA tubing to minimize the potential adsorption of NH_3 on interior instrument surfaces. The residence time upstream of the converters is kept to $< 2 \text{ s}$ to minimize line losses and the decomposition of NH_4NO_3 . Inlet denuders are replaced once per month. Measurements are performed atop the equipment shelter at a height of $\approx 5 \text{ m AGL}$. The CLD is calibrated with NO every other day and zeroed with dry zero air once a day. One-minute averages are acquired from the CLD and used to calculate and report 5-min average, standard deviation, minimum, maximum, and median statistics. The 5-min data can then be used to generate hourly averages and associated statistics.

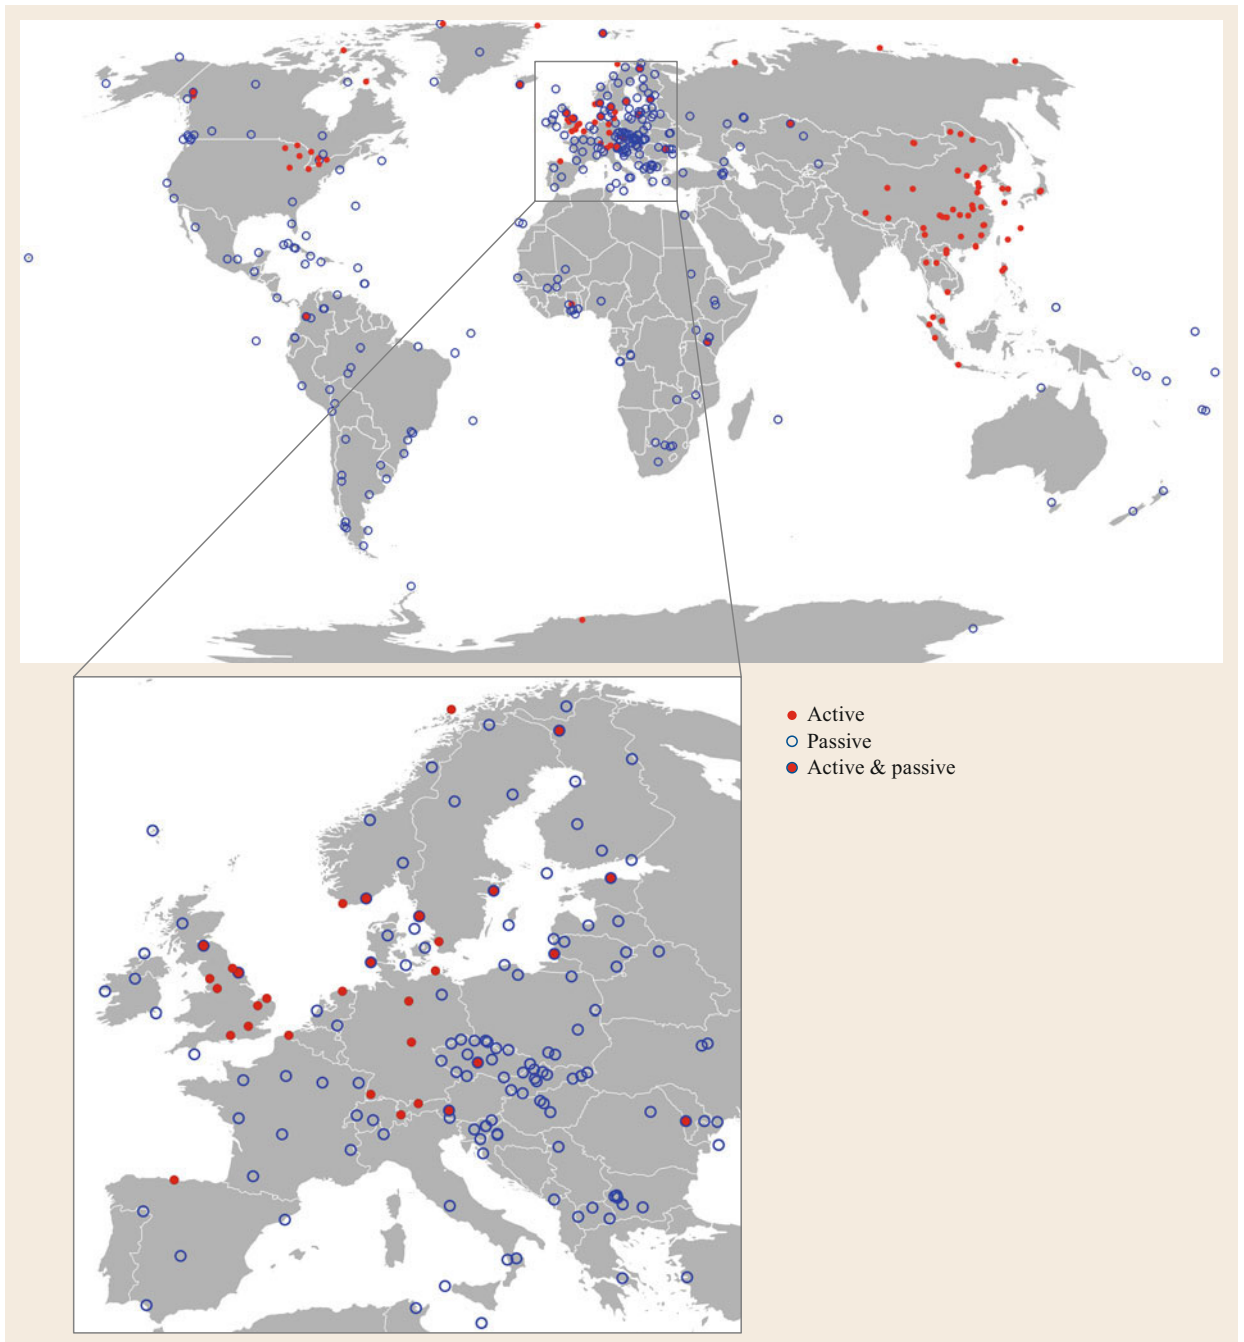

Fig. 19.21 Passive and active air sampling sites for POPs in monitoring networks worldwide [19.298]

19.8.2 Sampling of Semivolatile Substances

Numerous studies on halogenated organic substances and PAHs and their derivatives in continental and ma-

rine atmospheric environments have utilized the separate and simultaneous collection of gases and particles on filters and gases in a downstream adsorbent trap [19.86, 88, 189, 190, 195, 196, 206, 263, 265]. Per-

sistent organic pollutants are monitored by several active sampling networks in Europe, North America [19.299], and the Arctic [19.300] (Fig. 19.21b) using filters and downstream adsorbent traps. The NADP (see also Sect. 19.8.1), EMEP, and AMAP networks are under the auspices of regional conventions on acid deposition (NADP), transboundary air pollution (CLRTAP [19.301]), and the Arctic Council [19.302], respectively.

19.9 Future Developments

Regarding the sampling of trace gases, passive samplers have thus far suffered from undefined sample volumes. However, novel passive samplers for which the relationship of sampling flow to wind speed is known will become available, which will make it possible to calculate the sample volume based on the recorded wind speed.

More chemically specific sampling techniques are desirable for the sampling of semivolatile substances, but such techniques are difficult to implement practi-

19.8.3 Sampling of Aerosol Particles

The range of applications of aerosol sampling is broad, and sampling strategies and setups are diverse. For systematic and comprehensive overviews, we refer the reader to several textbooks as well as review articles that provide detailed information on the broad spectrum of sampling strategies and applications [19.22, 27, 29, 54, 303, 304].

cally due to their generally low reactivities and the huge physicochemical diversity of semivolatile organics. For instance, even substances from the same class show a wide range of polarities (from apolar to highly polar).

The field of aerosol particle sampling and the development of sampling techniques has strongly diversified since its beginnings. Rapid development continues in this field: existing techniques are being modified and optimized further while rather sophisticated novel sampling approaches are being invented.

19.10 Further Reading

Christopher Pöhlker

Multiphase Chemistry Department
Max Planck Institute for Chemistry
Mainz, Germany
c.pohlker@mpic.de

Christopher Pöhlker leads the aerosol analysis and microspectroscopy group at the Max Planck Institute for Chemistry (Mainz, Germany). He has a PhD in atmospheric science. His research focuses on atmospheric chemistry and physics in the Amazon rainforest, physicochemical analysis of atmospheric aerosol particles in relation to land-use changes, climate change, and public health, as well as the development and application of advanced microscopic and spectroscopic techniques in environmental research.

Karsten Baumann

Environmental Sciences and Engineering
University of North Carolina at Chapel Hill
Chapel Hill, USA
kbaumann@unc.edu

Karsten Baumann is Assistant Professor at the Department of Environmental Sciences and Engineering of the Gillings School for Global Public Health (UNC Chapel Hill, NC, USA). He has a PhD in energy technology and air pollution control. Most recently, his research has focused on multiphase chemical processes of persistent organic pollutants as well as the toxicity of biomass burning pollutants in fresh and photochemically aged emissions.

Gerhard Lammel

Multiphase Chemistry Department
Max Planck Institute for Chemistry
Mainz, Germany
g.lammel@mpic.de,
gerhard.lammel@recetox.muni.cz

Gerhard Lammel is head of the research group Organic Pollutants and Exposure at the Max Planck Institute for Chemistry (Mainz), a professor of environmental chemistry at Masaryk University (Brno), a lecturer at the University of Mainz, and editor of the journal *Environmental Science and Pollution Research*. His research focuses on field and laboratory studies of atmospheric and aerosol chemistry as well as modeling and field studies of multicompartamental chemistry.

20. Optical Fiber–Based Distributed Sensing Methods

Christoph K. Thomas , John Selker 

Optical-fiber-based distributed sensing (OFDS) methods have the potential to bridge the observational gap between single-point-based or networks of in-situ sensors and remote-sensing techniques. By providing thousands of measurements at high spatial resolution at centimeter to decimeter scales at sampling rates of currently up to 1 Hz over distances of several kilometers, they enable a wide range of exciting applications in surface and boundary-layer meteorology, including vertical and horizontal profiling, investigating the spatial structure of the near-surface turbulent flow and scalar fields, evaluating spatially explicit atmospheric modeling techniques, and resolving the response of airflow to land-surface heterogeneity, to name but a few. Since the basic OFDS system measures the temperature inside a fiber-optic cable, the technique is often referred to as distributed temperature sensing (DTS). However, since the current portfolio of applications includes many variables other than temperature, we prefer the more universal terminology OFDS. In contrast to most other in-situ or remote-sensing techniques described in this handbook, a single optical fiber can be used for observations across different media such as air, water, ice, snow, mineral soil, or plant tissue, thus the OFDS technique lends itself to interdisciplinary geosciences research. The field of fiber-optic-based distributed sensing is rapidly evolving, and the combination of fiber-optic cables and existing meteorological sensing approaches has led to an expansion in the range of observable variables beyond the temperature in air, soil, snow, and ice to include also soil moisture, wind speed, air humidity, and solar radiation. This chapter describes the fundamental operating principles and the accuracy, precision, and resolution of such measurements, provides an introduction to calibration routines, and gives an overview over deployed optical fibers. It also provides examples for field and laboratory applications, with a focus on surface-energy balance and turbulent airflow studies.

Aerial deployments of optical-fiber-based distributed sensing methods are relevant to all observational applications in meteorology whenever spatial information is useful to resolve a phenomenon or a process, such as when quantifying vertical or horizontal gradients or resolving individual turbulent motions. Unlike any other in-situ meteorological technique, the scales of continuous observations can range from millimeters to thousands of meters in space, and seconds to months in time, thereby enabling the user to determine such quantities at the desired resolution.

Traditional point observations in meteorology assume the validity of Taylor's hypothesis, which states that temporal and spatial scales are related by the mean advective wind speed. This assumption is an important vehicle to translate single-point measurements over time into spatial scales, which forms the basis for similarity theories and weather predictions. In addition, traditional meteorology also requires the spatial ho-

mogeneity of the observational location to fulfill the assumption of ergodicity of the airflow, which states that temporal and spatial averages converge, and therefore observations are representative.

Distributed sensing methods do not a priori require these assumptions due to their simultaneous observations in space and time, and thus can be used to evaluate their validity (e.g., [20.1]). While the user needs to invest substantial experimental effort in constructing a network of fiber-optic cables tailored to the specific measurement task, including a support structure to keep the fiber aloft in the air, continuous referencing of the fiber-optic measurements against traditional thermometers, and careful post-field calibration routines to convert the raw optical signals into environmentally meaningful observations, the rewards of the wealth of observations in space and time at high accuracy are substantial. For these reasons, the range of aerial deployments has grown significantly for meteorological and hydrological applications.

20.1 Measurement Principles and Parameters

Here we briefly introduce optical-fiber-based distributed sensing (OFDS) methods by describing their utility in atmospheric and hydrological applications and their fundamental operating principles. The intention is to provide the reader who is new to these methods with some overview.

20.1.1 Bridging the Gap between In-Situ and Remote-Sensing Techniques

Most studies investigating processes at the interface between air, land, or water surfaces, plants, and the built environment, e.g., addressing questions of air quality, quantifying the urban heat island effect, computing budgets of the surface exchange of energy and matter including carbon, water, and other trace gases, investigating the effects of drought, assessing the impact of cold-air drainage and pooling on agricultural productivity, and forecasting traffic-impairing ground fog, require time-dependent and spatially explicit fields of surface winds and temperatures, humidity, concentrations, etc. as input variables.

While traditional meteorological sensors can provide very accurate and precise point information at high temporal resolution, their time-averaged observations represent spatially averaged information in the proximity of the sensor location described by the scalar concentration or flux footprint. Spatially explicit information on time scales much longer than the averaging

interval can only be derived by relating the point measurements to wind direction, atmospheric stability, sensor height, wind speed, and turbulence strength. These parameters impact the observations' footprint. A sufficient number of time-averaged readings can then be used to assemble a climatological footprint, which can be used to interpret the parameter of interest in a topographic and thus spatially explicit context.

However, even when measurements from several such traditional point sensors are combined into micro- or ecosystem scale using regional or larger networks (e.g., [20.2–5]), the information on vector and scalar quantities can still be considered sparse as the instantaneous footprints of readings from all sensors at the averaging time scale hardly overlap. This lack of time-dependent information on, e.g., air temperature or wind speed, can lead to the masking of passing thermal microfronts, blurring of internal boundary layers defined by changes of surface conditions, or an inability to quantify the momentum and energy contribution of transient boundary-layer-scale eddies. Very dense surface networks, which have the potential to overcome some of these challenges, suffer from increasing observer effects, are cost-prohibitive, or are impractical because of interference from existing surface structures such as trees, lakes, or built infrastructure. Obtaining spatially explicit surface meteorology via satellite or airborne remote-sensing techniques from a variety of platforms (see Chap. 6) may be an elegant and cost-

saving alternative. However, these observations do not only offer benefits, but may also suffer from several challenges: While spatial coverage can be excellent and resolution can be up to the meter scale from, e.g., drone-borne sensors, such measurements are rarely observed simultaneously at all cells within a volume and the reading for each volume element is an implicit spatial average. Hence, only the assembly of spatially explicit information averaged over time will allow an assessment of the process of interest over the desired domain, which sacrifices information on either spatial and temporal variability. Particularly for studies of atmospheric transport by turbulence or under nonstationary conditions, such as process studies during the morning or evening transition, the passage of microfronts, thunderstorms, or other severe weather, these limitations are prohibitive.

Combining measurements from surface sensor networks with those from remote-sensing techniques to synergistically observe vector and scalar fields as input variables raises the unsolved question of whether the explicit time and implicit spatial averages and their variability converge. Hence, there exists an observational gap for many surface meteorological applications, which cannot be filled by either classical technique. In this case, the spatially explicit and very dense readings at high temporal resolution available from distributed sensing methods using arrays of fiber-optic cables can offer a viable alternative to fill this gap with acceptable accuracy and precision if state-of-the-art procedures for quality control are observed. Relatively thin (one to several millimeters in diameter) fiber-optic cables serving as environmental sensors can be installed continuously across air, water, soil, plant, and building material boundaries and thus may provide complete three-dimensional information about the en-

vironment. To date, observations from OFDS systems can be obtained at time scales of up to 1 s, which is sufficient to capture even the most energy-containing and short-lived turbulent eddies for heights outside the dynamic sublayer (approximately 1 m above ground level).

20.1.2 Passive and Active Systems

The basic OFDS system is of passive design, measuring the temperature inside the light-conducting and scattering medium, i.e., in the fiber-optic cable. Hence, these systems are often collectively referred to as distributed temperature sensing (DTS) methods. The reader is referred to Table 20.1 for key references describing the mentioned passive and active sensing applications. The exact procedure to derive temperature from the scattered light depends on the measurement principle of the sensor, which will be described below (Sect. 20.1.4). Even though light is actively injected into the optical fiber by means of discharging a laser diode, which subsequently excites the optical glass core of the fiber-optic cable, these systems are commonly referred to as *passive* as the fiber-optic cable is not actively modified in any other fashion. In contrast, active distributed sensing methods apply time-dependent modifications to the fiber-optic cable to sense environmental state variables other than temperature. The currently available active sensing methods include actively heated and actively wetted systems. The former apply heating to the outer metal jacket of a fiber-optic cable by means of electric resistance with the goal of measuring its heat loss to the surrounding medium, which in combination with a paired passive fiber-optic cable can be used to compute wind speed or soil moisture. The latter apply a thin water film onto the outer jacket of a fiber-optic cable by

Table 20.1 Environmental parameters measured by optical-fiber-based distributed sensing (OFDS) methods using fiber-optic (FO) cables

Quantity	Medium	Type	Basic principle	Reference
Temperature	Water	passive	FO cable in medium	[20.6]
	Ice, snow			[20.7, 8]
	Air			[20.9, 10]
	Soil			[20.11, 12]
	Plant			
Moisture/humidity	Soil	active	Paired passive and actively heated FO cables Paired passive and actively wetted FO cables	[20.11]
	Air			[20.13, 14]
Speed	Air	active	Paired passive and actively heated FO cables	[20.12, 15]
Shortwave radiation	Air	passive	Paired passive FO cables with different albedos (white, black)	[20.16]
	Water			[20.17]
Turbulence – temperature – wind speed – dynamic stability	Air	active	Thin paired passive and actively heated FO cables	[20.10, 12, 15, 18–20]

continuously spraying fine water droplets onto the surface in order to quantify the wet-bulb depression and thus compute air humidity as in classical psychrometry (see Chap. 8). As mentioned above, such distributed sensing methods are currently developing rapidly and their range of application is expanding. The most recent developments include methods that modify the external three-dimensional shape of the outer jacket of a passive or actively heated fiber-optic cable to cause a directionally sensitive heat loss [20.21], which can then be considered as hybrid systems lying somewhere between passive and active distributed sensing systems. The modifications currently under development are discussed in Sect. 20.8.

20.1.3 Measured Parameters

The list of observed environmental parameters derived from passive and active OFDS methods includes the basic temperature measurement in a variety of media as well as other quantities such as wind speed, air humidity, light intensity, soil moisture, and thermal conductivity and capacity (Table 20.1). In this chapter, we distinguish between common hydrometeorological applications requiring time- and space-averaged quan-

ties and geophysical applications studying turbulence by measuring spatiotemporal perturbations of rapidly varying quantities. Even though the basic measurement principles are identical, investigating turbulent geophysical flows using OFDS methods requires a very different design. Such systems are characterized by much finer sampling resolution and greater time response of both the fiber-optic cable and the recording laser of the OFDS system to detect the fingerprint of individual turbulent eddies passing the fiber-optic cable. As mentioned above, this list is expected to expand rapidly as new applications of this novel sensing technique are developed and become available to the user.

20.1.4 Measurement Principles

OFDS measurements can be divided into two categories: those that require light to be drawn from the fiber, which is called *extractive sensing*, and those that report measurements of the properties of the glass itself, referred to as *intrinsic sensing*. In the most extreme form of extractive sensing, a fiber-optic sensor can be made by coating the end of a fiber with an optically responsive paint. Here the light from the fiber acti-

Table 20.2 Principles of optical-fiber-based sensing methods

Name of fundamental principle	Brief explanation	Advantages/limitations	Application examples
Raman backscatter	Observe backscattering of photons at higher and lower energy than those of a narrow injected pulse of light based on Stokes and anti-Stokes (highly temperature dependent) Raman photons	High accuracy possible (0.02 K) Requires detailed calibration Range limited to about 10 km	Ubiquitous in environmental sensing (soil, wells, streams, oceans, aerial) due to excellent accuracy
Brillouin backscatter	Phonons (sound waves) in glass cause a Doppler shift in the backscattered light. The phonon velocity is proportional to the density of the glass and its elasticity, thus being temperature sensitive	Since the Doppler shift has a broad spectrum of values, determining the exact change in shift is difficult, leading to limited accuracy (about 0.1 K) Uses single-mode cable, thus can be employed to about 30 km distances	Can be used to measure physical strain on fiber, and so is commonly employed in mechanical evaluations (e.g., bridges, aircraft wings, etc.)
Rayleigh backscatter	Also known as <i>elastic scattering</i> , Rayleigh backscatter is scattered at the same wavelength as the injected light, and has much higher intensity than the Raman and Brillouin sidebands	Recently shown to be useful for acoustic sensing as well as thermal sensing Can go to very long range (> 30 km) on single-mode fiber High reported accuracy (better than 0.01 K) Equipment tends to be about five times more expensive	Recent products can detect strain, temperature, and acoustic signals with very high spatial resolution (to a few cm)
Bragg gratings	The cladding of the fiber is etched with a series of closely spaced lines which reflect back light of exactly this wavelength. Changes in the fiber density due to strain or temperature change this spacing, which can be used to monitor these factors	Only reports data where the fiber has been etched Loses light at each etching, and each etching must be unique in wavelength, limiting the number of etched points < 200	Mostly used for strain measurements in civil infrastructure

vates/interrogates the paint, and the resulting emitted/reflected light indicates the chemical/physical state of the paint, e.g., its oxygen content, or temperature. In this case, the fiber-optic sensor reports the state of exactly one location. Still considering the extractive approach, if the treatment is applied on the cladding rather than the end of the fiber (see Sect. 20.4.3 for explanation of the terminology), a small fraction of the photons can interact with the treated section, but with most of the photons being retained in the fiber. In such a way, the extractive approach can perhaps interrogate up to on the order of 100 locations along the fiber, making it a *nearly distributed* measurement. The fiber Bragg grating falls into this category, allowing for temperature or strain measurements at up to about 100 locations along a single fiber (Table 20.2). Note that the fiber must be modified at each measurement location.

In contrast, intrinsic OFDS methods employ a fiber that is uniform in its construction and often employ standard telecommunications fibers, so the price of these cables can be much more economical. Intrinsic methods typically employ a single pulse, or a recognizable train of pulses, where location on the fiber is inferred from the time that has passed since the moment the light was injected, assuming that the pulse and response travel at the speed of light after being adjusted for the refractive index of the glass. Note that the optical interaction between the injected light and the glass of the fiber is assumed to be instantaneous, which is generally valid. The modification of the backscattered light indicates the temperature, stress, or local velocity of the glass where the backscatter occurred (cf. methods listed in Table 20.2). The spatial resolution ranging from cen-

timeters to meters depends on either the pulse width of the injected light (for Raman and Brillouin methods, where current instruments have spatial resolution from 0.3 m to 4 m), or the distribution of scattering sites in the glass (for Rayleigh backscatter, with instruments on the market having resolution from 0.03 to 2 m).

Two basic kinds of optical cores are used in fiber-optic cables: single-mode (SM) with a typical core diameter of 9 μm and multimode (MM) typically with a core of 50 μm diameter, but with some cores much larger than this value. Raman and Brillouin scattering produce very faint signals, so having a larger core as provided by MM can provide greater intensity of the backscattered light without moving the process into the nonlinear regime, which occurs at extreme light intensities. On the other hand, since the light can travel along many paths in the fiber, the light disperses into longer pulses as it travels. This typically leads to dispersion on the order of 0.1 m times the square root of the distance from the device, e.g., 0.1 m at 1 km, and 0.2 m dispersion at 4 km. This is a fundamental limitation on the spatial resolution of measurements using MM fibers. SM fibers essentially do not suffer from optical dispersion.

The temporal resolution τ of these methods is purely a function of the measurement precision required, with the precision being equal to $C/\sqrt{\tau}$. In the case of Raman-scattering OFDS, the value of C is about 0.3 K for high-performance instruments set to a spatial resolution of 0.5 m with $\tau = 1$ s (Sect. 20.4.1). Lower-performance instruments have a temporal resolution that is 100 times lower than this value, thus the selection of adequate instruments is very important if high temporal resolution is needed.

20.2 History

OFDS methods were originally developed in parallel in the USA and the UK, as the National Aeronautics and Space Administration (NASA) aimed to understand the temperature dynamics of the Space Shuttle, while in the UK the goal was to provide service to the oil industry for better understanding of the distribution of oil production in wells. Applications in water resources began in the early 2000s with efforts to detect seepage and changes in moisture content in dams. Soon thereafter, applications in environmental monitoring emerged and have since blossomed into a significant portion of the global application of OFDS technology. Use of OFDS in atmospheric measurements has been a more recent domain of activity, led by work such as [20.9] and [20.10] and providing new applica-

tions for actively heated methods [20.15] and humidity measurements [20.13]. The technological requirements of geoscience applications are often much more demanding than those of industrial uses; for example, to identify the flow of groundwater into a stream requires precision of at least 0.02 K, compared with the needs of the petroleum industry, which were satisfied by 1 K resolution. With the move to atmospheric measurements, the demands on OFDS have increased, pushing hard for temporal resolution of < 1 s to allow the resolution of meter-scale turbulent processes. Manufacturers of OFDS instruments have steadily improved their temporal and spatial resolution in response to these needs, though in the past 5 years the rate of improvement has slowed as the technology has encountered fundamen-

tal limits to the fiber light-carrying capacity, the photon efficiency of detectors, and the stability of high-speed amplifiers. While advances in Raman and Brillouin methods have slowed, the interpretation of Rayleigh

scattering for temperature, strain, and acoustic sensing continues to advance rapidly. Tests indicate that, with Rayleigh-scattering OFDS, heretofore unattained levels of spatial and temporal resolution may soon be possible.

20.3 Theory

Here we provide a more detailed quantitative review of the fundamental operating principle of the Raman backscattering OFDS technique for the informed reader, since most commercially available sensors employ this principle for obtaining temperature measurements. Subsequent sections describe the fundamentals of various atmospheric and soil moisture OFDS applications derived from temperature sensing.

20.3.1 Temperature Measurement with OFDS Technique

A good introduction to the theory of OFDS based upon Raman backscatter distributed temperature sensing (DTS) can be found in [20.22] and [20.23]. Here, we review only the basic equations needed to understand and operate such systems. Temperature measurements across individual, but continuously distributed sections along the fiber-optic cable are the fundamental quantity computed from OFDS methods. To a first approximation, the temperature T of a single section of fiber-optic cable located at a mean distance x from the beginning of the measurement section at time step t is proportional to the inverse natural logarithm of the ratio of the power of the Stokes (P_S) to anti-Stokes (P_{AS}) signals resulting from the inelastic Raman scattering of light:

$$T(x, t) \propto \ln \left(\frac{P_{AS}(x, t)}{P_S(x, t)} \right). \quad (20.1)$$

It must be noted that measurements of P_S and P_{AS} for each section represent a spatial average over a cable section of the length given by the sampling resolution Δx of the instrument. The physical resolution of the temperature measurements along the fiber, however, is approximately equal to $3.5\Delta x$ using the *10-90 definition*, as P_S and P_{AS} from directly neighboring sections are statistically not independent (Fig. 20.3). Since the number of Raman photons returned from a single laser pulse is too small to determine its power with sufficient accuracy, OFDS instruments operate at high internal sampling rates between 20 and 50 kHz to compute a temporal average at time step t over the minimum instrument-specific averaging period determining the instrument's temporal resolution τ (for device speci-

cations see Sect. 20.4.1). Hence, each record of $P_{S/AS}$ already represents a statistical quantity that is highly aggregated in both space and time. More precisely, three other quantities are needed to translate the Raman backscatter signals into the desired temperature $T(x, t)$, which results in the following full calibration equation [20.24]:

$$T(x, t) = \frac{\gamma}{\ln \left(\frac{P_S(x, t)}{P_{AS}(x, t)} \right) + C(t) - \int_0^x \Delta\alpha(x') dx'}, \quad (20.2)$$

with γ [K] being considered a constant for each OFDS system, representing the shift in energy between a photon at the incident laser wavelength and the scattered Raman photon; $C(t)$ is a dimensionless specific calibration parameter dependent upon the incident laser and the OFDS instrument. The integral expression in the denominator is a dimensionless quantity representing the differential attenuation of the anti-Stokes and Stokes signals in the optical fiber. The extinction of anti-Stokes and Stokes signals is not identical since they occur at different wavelengths. The effect of such differential attenuation on the temperature measurement is cumulative, which means that this term needs to be integrated over the entire cable length between its start ($x' = 0$) and the measurement location ($x' = x$). If the differential attenuation is constant along the fiber optic cable, then the integral expression simplifies to a single value equal to $\Delta\alpha x$. Since only the quantities $P_S(x, t)$ and $P_{AS}(x, t)$ are directly measured by the instrument, the remaining three quantities need to be obtained indirectly through a matrix inversion using measurements from a physical calibration setup. There now exist open-source software packages including all post-field calibration routines, e.g. [20.25].

The design of the physical calibration setup depends upon the fiber configuration chosen by the user. The four possible configurations include (Fig. 20.1):

- Simple single-ended (Fig. 20.1a)
- Duplexed single-ended (Fig. 20.1b)
- Simple double-ended (not shown)
- Duplexed double-ended (Fig. 20.1c).

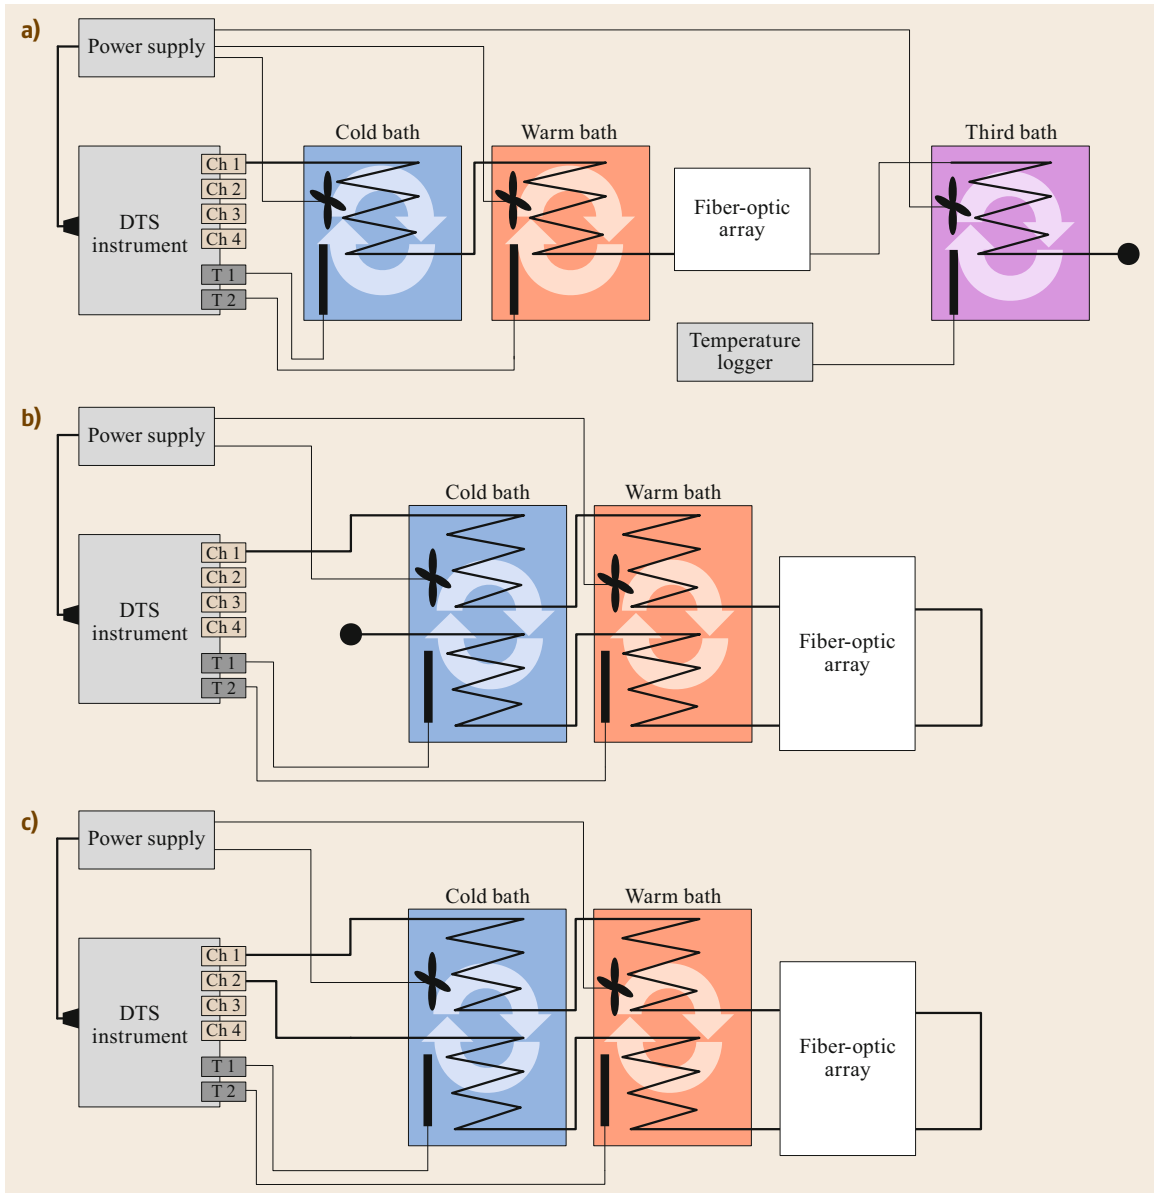

Fig. 20.1a–c Schematic fiber configurations for OFDS technique: (a) simple single-ended, (b) duplexed single-ended, and (c) duplexed double-ended. See text for explanation and limitations and advantages

The terminology of simple or duplexed describes whether each measurement location contains one or two (or more) physically different optical fiber sections. Duplexed configurations allow one to compute a spatial average for each measurement location from either a single fiber-optic cable containing multiple optical SM or MM glass cores or multiple fiber-optic cables with a single glass core. Duplexing may reduce the random and systematic uncertainties of T in certain applications. The terminology of *single- or double-ended*

refers to how the cable is attached to the instrument: either one or both ends of a fiber-optic cable can be attached to the instrument and be used to inject light and receive the backscatter. The latter allows the user to invert the direction in which the light pulse travels and thus reduce the measurement uncertainty in some applications. The advantages and limitations of each configuration are briefly discussed in Sect. 20.6. The simple double-ended fiber configuration differs from its duplexed counterpart only by not routing the fiber

through the fiber-optic array before reconnecting to another optical port of the instrument.

A comprehensive description of how to obtain all the quantities in the calibration equation (20.2) for the single-ended OFDS configuration can be found in [20.26], while [20.27] reviewed this procedure for double-ended configurations. Irrespective of the experimental fiber configuration, a physical calibration setup generally consists of several fiber sections routed through reference environments of known and uniform, but different temperatures. The reference temperatures must be measured independently of OFDS and are commonly obtained using high-grade resistance thermometers (e.g., platinum wire resistance thermometers, see Chap. 7). To date, most OFDS applications use water baths of different temperatures, which are mechanically stirred or mixed by aquarium bubblers to ensure uniform temperatures (see Sect. 20.7 for maintenance recommendations). Due to the requirement of having different temperatures in these reference environments, these baths are often referred to as cold and warm baths. Section 20.6 discusses and recommends practical approaches for how to design and operate reference baths for field and laboratory applications to ensure high-quality temperature measurements.

The theory of using OFDS to measure environmental temperatures in soil, air, water, ice and snow, or plant tissues and across their interfaces is identical and solely depends upon the medium in which the fiber-optic cable is installed. However, for applications in media transmitting solar radiation such as air or clear water, note that temperatures will suffer from radiation errors resulting from the short- and long-wave radiative transfer between the cable and its environment. From simple theoretical considerations, it follows that the error is maximum for peak solar radiation irradiance in still air. Similar to the radiation error for classical single-point thermometers in radiation shields, the radiation error for aerial OFDS deployments is largest for high short-wave radiation loads and low wind speeds and can amount to several degrees kelvin, depending on the cable diameter and its radiative properties [20.28]. An additional source of uncertainty in air temperature measurements by OFDS are errors resulting from conductive heat transport of support structures such as fabrics, pipes, and blocks applied to keep the fiber array in the user-intended configuration aloft in the air. [20.16] reviewed the theory of and quantified both types of errors for aerial OFDS deployments using a coiled fiber-optic cable to obtain air and water temperatures across a vertical pro-

file. They found that, for a thin, 0.9 mm-outer-diameter fiber-optic cable mounted on reinforcement fabric as a mechanical support, the radiation error amounted to between 0.5 and 0.8 K for wind speeds ranging between 2 and 4 ms⁻¹ and short-wave radiation irradiance of $\leq 800 \text{ W m}^{-2}$ above grass. For calm winds and solar irradiances $> 1000 \text{ W m}^{-2}$, the error exceeded 2 K. The effects of solar radiation on fiber-optic cables of different colors and therefore albedos of the outer cable jacket for aquatic installations were investigated quantitatively by [20.10]. They showed that the solar heating error was less than 0.3 K for shallow installation depths of several tens of centimeters below the water surface for clear and very slowly moving streams. With increasing depth or turbidity, the solar heating was less than the measurement resolution of the OFDS even when averaging over longer time periods. In this case, conductive heat transfer from the streambed surface had a much larger impact than solar radiation errors.

20.3.2 Solar Radiation Measurement with OFDS Technique

Theoretically, comparisons of temperature measurements by OFDS techniques using fiber-optic cables with different radiative properties of the outer cable jacket including albedo and emissivity may allow for indirect estimation of short-wave irradiance. This measurement approach would then be identical to that employed in pyranometers using temperature differences between black and white painted surfaces (see Chap. 11). In practice, however, the usefulness of this approach for OFDS methods is limited as the temperature difference between a pair of fiber-optic cables exposed to air is modulated by wind speed and angle of attack, turbulence intensity, and ratio of diffuse to direct-beam solar radiation. These quantities impact the three-dimensional surface radiation of the fiber-optic cable and the turbulent heat transfer coefficient and can be used to compute wind speed and soil moisture (discussed in Sect. 20.3.4). To date, no studies have isolated the effect of solar heating from other confounding processes in order to quantify spatiotemporal variations in solar radiation, while this approach has significant appeal for environmental studies. However, this measurement approach was used qualitatively by [20.29] to estimate shading in streams with varying degrees of vegetation cover. The temperature difference between a pair of helically twisted fiber-optic cables with a white and black outer jacket compared well to independently measured short-wave radiation intensities along the river.

20.3.3 Air Humidity Measurement with OFDS Technique

Since OFDS techniques can precisely measure temperature differences over great extents at high spatial resolution with satisfactory accuracy, they can be used to estimate the air humidity by employing the principle of wet-bulb depression between dry and wetted fiber-optic cable sections as in classic psychrometry (see Chap. 8). [20.13] introduced this measurement approach over a short-statured crop canopy with the intention of using the air temperature and humidity observations from an actively wetted OFDS system at multiple heights to compute sensible and latent heat fluxes based upon Bowen-ratio similarity theory. Their setup consisted of coiled fiber-optic cables in a vertical profile over 6 m in height. One of the cables was wrapped in a cotton cloth and continuously wetted using an irrigation pump at a fixed rate of approximately 41 h^{-1} . The cables were unshielded from solar radiation, which caused a significant increase in cable temperatures by solar heating. [20.14] refined this approach by minimizing the solar heating through shielding the dry and wet cables from direct-beam short-wave radiation with a gauze facing south, while leaving the north face unshielded to allow for sufficient ventilation and evaporation. The sections of the fiber-optic cable to which the water is supplied was excluded from analysis, as their wet-bulb temperature is dominated by the additional heat supplied by the water supply mechanism resulting in an inaccurate determination of the wet-bulb depression and hence air humidity.

20.3.4 Wind Speed Measurement with OFDS Technique

An actively heated OFDS system can be used to measure the wind speed by employing the principle of wind speed-dependent convective heat loss. The underlying basic measurement principle is therefore similar to that used in hot-wire anemometry. [20.15] was the first to propose this measurement approach based upon the temperature difference between two closely co-located fiber-optic cables, one of which is actively heated through electrical resistance while the one is unheated. The unheated fiber-optic cable is expected to be in thermal equilibrium with the surrounding air and thus to report dry-bulb air temperature, assuming that radiative heating errors are negligible. Since the temperature of the actively heated cable will be greater than air temperature, the passing turbulent eddies in-

duce a convective cooling effect proportional to their speed, leading to a response in the cable temperature as sensed by the OFDS device. A small angular dependence of the cooling results from the variation of the efficiency of the energy transfer between the heated cable and the passing eddy with the angle of attack between the cable and the eddy's trajectory [20.19]. The efficiency is largest for airflows orthogonal to the direction of the fiber-optic cable. Hence, this actively heated OFDS technique is most sensitive to the wind component normal to the fiber-optic cable, which needs to be considered by the user when designing the fiber configuration.

A quantitative expression for wind speed can be derived starting from the general energy balance for a section of the fiber-optic cable at distance x , which can be formulated as [20.15]

$$\begin{aligned} Q(x) &= Q_{\text{in}}^{\text{P}}(x) + Q_{\text{in}}^{\text{S}}(x) + Q_{\text{in}}^{\text{L}}(x) + Q_{\text{out}}^{\text{L}}(x) + Q_{\text{out}}^{\text{conv}}(x) \\ &= c_p \rho V \frac{\partial T_s(x)}{\partial t}, \\ \text{I} &= \text{II} + \text{III} + \text{IV} + \text{V} + \text{VI} \end{aligned} \quad (20.3)$$

where Q_{in}^{P} is the energy input from active electric heating, Q_{in}^{S} is the net energy gain from short-wave solar radiative heating, Q_{in}^{L} is the energy gain from long-wave radiative sources (such as the air and surface ground), $Q_{\text{out}}^{\text{L}}$ is the long-wave radiative loss from the cable's surface, $Q_{\text{out}}^{\text{conv}}$ is the convective cooling, c_p is the specific heat at constant pressure, ρ is the mean material density, and T_s is the surface temperature of the fiber section; note that $[Q] = \text{J s}^{-1}$ since all terms are related to the surface area of a fiber section of volume V at measurement resolution Δx . Equation (20.3) is valid under the assumption that energy changes due to mechanical work and conductive heat transfer in both radial and longitudinal directions can be neglected. By convention the sign for energy gain is positive. The expression simplifies when fiber-optic cables with identical properties are used for the heated and unheated sections, which eliminates terms III and IV. Term VI is the key quantity of interest as

$$Q_{\text{out}}^{\text{conv}} \propto h \Delta T \propto \text{Nu} \Delta T \propto \text{Pr}^m \left(\frac{\text{Pr}_a}{\text{Pr}_s} \right)^{\frac{1}{4}} U_N, \quad (20.4)$$

with h being the heat transfer coefficient, Nu the dimensionless Nusselt number, Pr_a and Pr_s the dimensionless Prandtl number evaluated at air $T_a(x)$ and fiber surface temperatures $T_s(x)$, $\Delta T(x) = T_s(x) - T_a(x)$, and U_N the

wind speed component normal to the fiber-optic cable. The exponent $n \approx 0.36$. For the unheated cable, $Q_{\text{out}}^{\text{conv}} = 0 \text{ J s}^{-1}$ since the fiber is assumed to be at air temperature. Applying (20.3) for both fiber-optic cables and solving for wind speed $U_N(x)$ yields a quantitative expression as a function of $\Delta T(x)$

$$U_N(x) = \left(\frac{Q_{\text{in}}^{\text{P}} + Q_{\text{in}}^{\text{S}} + Q_{\text{in}}^{\text{L}} + Q_{\text{out}}^{\text{L}} + \frac{1}{2} c_p \rho r \frac{\partial T_s(x)}{\partial r}}{-C(2r)^{m-1} \text{Pr}^n \left(\frac{\text{Pr}_a}{\text{Pr}_s} \right)^{\frac{1}{4}} K_A \nu^{-m} \Delta T(x)} \right)^{\frac{1}{m}}, \tag{20.5}$$

with r being the radius of the fiber-optic cable, C and m constants with $C = 0.75$ to 0.26 and $m = 0.4$ to 0.6 for $\text{Re} < 20000$, and K_A the thermal conductivity and ν the kinematic viscosity of air. For details of the derivation see [20.15] and the supporting online infor-

mation. Despite the unique spatial information about wind speeds at high resolutions measured continuously along the pair of fiber-optic cables, this measurement approach suffers from two significant shortcomings which limit its utility for observing three-dimensional turbulence and heat fluxes: First, the approach is most sensitive to the wind speed component orthogonal to the fiber-optic cable, as the heat transfer has an angular dependence, but the angle may be poorly defined for stochastic three-dimensional turbulent flows. Secondly, the method cannot determine the direction of the passing eddies and thus the wind direction, which is critical for computing turbulent fluxes as well as properties of the mean airflow. Here, recent research outlined in [20.21] and Sect. 20.8 may overcome these limitations with the goal of constructing a true spatially resolving eddy covariance system able to measure momentum and sensible heat fluxes.

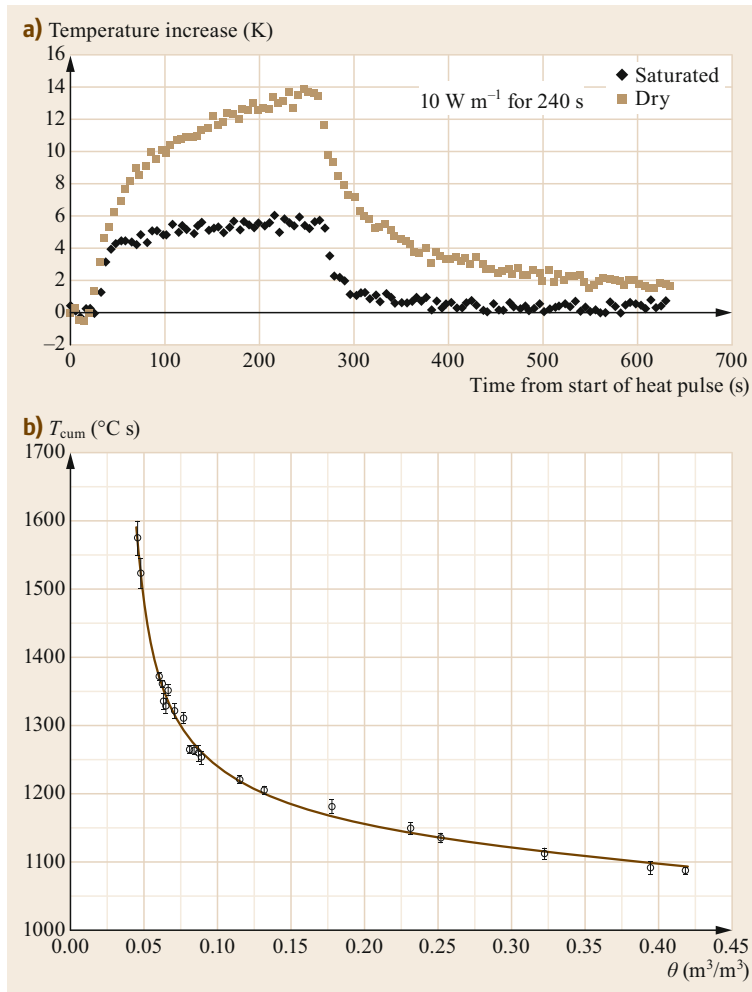

Fig. 20.2 (a) Temperature response of cable embedded in wet and dry sand with a heating rate of 10 W m^{-1} . (b) Cumulative temperature T_{cum} versus soil moisture content θ (after [20.11] with permission from John Wiley and Sons)

20.3.5 Soil Moisture Measurement with OFDS Technique

Soil moisture characterization was the initial application for active OFDS, applying heat to fiber-optic cables to reveal features of the local environment. [20.30] was the first to test this concept, but because of the high noise levels of his instrument and due to the approach taken in data analysis, it was concluded that the technology was not capable of accurate quantification of soil moisture, although it was found to be adequate for determining abrupt changes in the presence or absence of water in soil. [20.11] pointed out that, since wetter soil has both higher thermal heat capacity and higher thermal conductivity, the change in temperature per amount of energy applied is inversely related to the soil moisture content. This gave rise to the so-called T_{cum} -approach to soil moisture measurement, where the total integrated area under a time-temperature plot following the application of a heat pulse can be correlated to moisture content (Fig. 20.2). This approach dramatically improved the signal-to-noise ratio of the heat

pulse signal, and provided accurate and precise soil moisture measurements. The key outstanding issue is how to calibrate this method for each soil, which is an active area of development.

The natural cycles of temperature in the environment can also be used to estimate soil moisture without the need for active heating systems. In this case one may bury one or many fiber-optic cables in the soil, and observe their diurnal and longer-period fluctuations. If one knows the air temperature and net radiation above the site, the dynamics of temperature reveal the thermal properties of the soil, which are in turn a function of the soil moisture content. If one then models not only the energy but also water dynamics of the soil, long-term observations can be used to constrain the hydraulic properties of the soil (permeability and water retention). [20.31] demonstrated the ability to capture both the soil moisture dynamics and the soil characteristics through passive observation of soil temperatures using data assimilation methods. These results are very encouraging for large-scale implementation of this approach.

20.4 Devices

This section summarizes the most important specifications of OFDS instruments, active heating systems, and fiber-optic cables, and relates them to the user's measurement needs and data quality. For active OFDS, we give basic, but important recommendations to maintain safety for humans and machines in close proximity to or in direct contact with the heated fiber-optic array to avoid electric shocks. We also review power recommendations for remote off-grid applications.

20.4.1 Raman-Backscatter Devices

The current commercially available OFDS (DTS) instruments using inelastic Raman backscatter of light in fiber-optic cables can be subdivided into two main categories: standard-performance and high-performance devices.

Standard-performance devices feature a greater minimum spatial sampling resolution and temporal signal integration time, resulting in a lower spatiotemporal resolution of the measurements (Table 20.3). Hence, these devices are best used when the application targets averaged temperature, humidity, and wind speed signals. However, the use of larger and thus more slowly discharging laser diodes allows for higher optical signal intensities, offering an acceptable signal-to-noise ratio of the Raman backscatter photons over a significantly

enhanced maximum cable length exceeding 10 to 20 km per optical port of the device. Since the spatiotemporal aggregation of the temperature measurements in this device category is greater, fewer raw signal computations need to be executed and recorded per unit time, which lessens the need for high-performance central processing units (CPUs) and high-volume onboard data storage. The latter significantly lowers the power needs and makes these units ideally suited for remote and off-grid deployments using batteries in combination with solar panels as a power source. Because of the less resource-demanding components, some devices in the standard-performance category offer ruggedized outdoor enclosures suitable even for an extended environmental temperature range (-40 to $+80^\circ\text{C}$), featuring relatively small outer dimensions and built-in cellphone or radio modems for data transfer to remote servers. These units are well suited for field campaigns even in extreme environments.

High-performance devices use smaller, faster discharging laser diodes, allowing for greater internal sampling rates and a reduced minimum measurement resolution ΔX and integration time Δt , both resulting in observations with much higher spatiotemporal resolution. As a result, these devices are ideal for measuring the fast perturbations of quantities in turbulent flows (see references in Table 20.1). However, the

Table 20.3 Categories of optical-fiber-based distributed sensing devices and their typical characteristics

Characteristic	Category	
	Standard-performance devices	High-performance devices
Minimum spatial sampling resolution Δx (m)	1	0.125
Minimum temporal integration time Δt (s)	30	1
Maximum cable length (km)	10, 20, 50	≤ 5
Typical uncertainty in OFDS temperature measurements at maximum resolution and optimal signal-to-noise ratio (K)	0.2	0.6
Recommended applications	Mean quantities in profiles and transects in air; applications in soil, water, snow, and ice Off-grid applications	Turbulence observations in air and water
Costs per unit (k€) in year 2018	≤ 40	≥ 60

maximum cable length over which physically meaningful measurements can be obtained is reduced compared with the standard-performance devices and is typically < 5 km. Due to the reduced spatiotemporal aggregation, the measurement uncertainty for each $T(x, t)$ is greater since the relative error is proportional to the inverse square root of the number of measurements. These devices require high-performance components, resulting in increased costs and significantly enhanced power requirements that are more suitable for laboratory applications and field deployments with access to line power when sampling over longer periods.

Most standard- and high-performance devices offer multiple optical ports (in most instruments up to four) to which fiber-optic cables can be attached depending on the fiber configuration (Sect. 20.3.1). One device can sample these ports only sequentially at the minimum sampling integration time Δt , while simultaneous observations of multiple cables requires either splicing the individual sections into one long cable whose length is bound by the maximum sampling distance or multiple synchronized OFDS devices. The advantages and disadvantages are briefly discussed in Sect. 20.6. All commercial OFDS devices uses standardized industrial-grade optical connectors of type E2000 for connecting the fiber-optic cables to the optical ports.

20.4.2 Active Heating Systems

Active heating of fiber-optic cables has been shown to be useful in applications in soils, rivers, wells, and atmospheric installations. Active heating of fiber-optic cables is based on converting electrical power into thermal energy via electrical resistance. Heating can be achieved by applying current to metallic armoring concentrically around the fiber, or electrical conductors can be wound around the cable. Required heating rates depend on the application and are typically about 3 W m^{-1} for wind speed measurements [20.12, 15], 5 W m^{-1} for

long-pulse soil water flux, and 10 W m^{-1} for short-pulse soil moisture owing to the differences in heat conductivity and capacity of the medium surrounding the fiber-optic cable. For example, to obtain a heating rate of 1 W m^{-1} along a 1 km cable with a resistance of $10 \Omega \text{ km}^{-1}$ would require 31 V; 10 W m^{-1} would require 100 V, recalling that $P = U^2 R^{-1}$, where P is electric power, U is voltage, and R resistance. Clearly as the heating rate and length of cable increase, so does the voltage required to achieve the goals, and also the risk to safety. Care must be taken to ensure that the insulation provided is adequate to provide for human safety. The safety precautions also apply to the reference baths needed for accurate calibration of the OFDS measurements: one must isolate the actively heated fiber-optic cable sections in the environmental fiber-optic array from those contained in the water baths by mechanically severing the electricity-conducting armoring or wound conductors. Power systems with dedicated device-specific ground fault protection of the heating unit are highly recommended. In case of using heated cables in aerial applications, added electric insulation, e.g., by thin polyethylene (PE) plastic coating of the fiber-optic cable, can greatly slow the thermal response of the cable. The heating approach can be implemented with uninsulated fiber, but we strongly advise against it because of the risk of electrical shock. If used at all, such a system should be implemented so that nonlethal voltages are employed, requiring the use of shorter spans between electrical connections and the use of a floating-ground transformer. This setup ensures that anyone in contact with the heated cable simply establishes a ground for the system, but imposes no current. Any site with actively heated cable needs to have extensive signage to let visitors know to avoid contact between the heated cable and people/machines while the system is active.

The electrical energy delivered to the cable needs to be actively managed to ensure delivery of constant power. Since the electrical resistance of conductors is

a function of temperature, we recommend the use of a data-logging dynamic power controller, where the pulse width of the applied current can be continuously adjusted to obtain the specified power level. Designs for such a system are available from the Center for Transformative Environmental Monitoring Programs [20.32], and some commercial systems are now on the market.

20.4.3 Fiber-Optic Cables

The selection of fiber-optic cables involves balancing many design considerations. Starting from the inside of the cable, the selection of the correct optical core is essential to success. The first requirement is that the fiber matches the requirements of the interrogator, i.e., the OFDS instrument being used. As mentioned above, the device may require 9 μm -core single-mode (SM) fiber, or if multimode (MM) fiber is needed, may employ 50 or 62.5 μm cores. Further, the glass of the fiber can be treated to be *bend insensitive*, wherein the light will stay in the core even if the fiber experiences a significant bend. Generally speaking, bend-insensitive fiber is preferred, since in many applications the cable might be subject to bending, and there is no loss of performance otherwise. Generally, OFDS instruments are designed to be compatible with what is known as Cat 2-fiber, which refers to the bandwidth of the fiber for data communication.

All optical fibers must be protected from degradation by applying an external *buffer* layer to the bare glass. There is a range of materials that may be used to form this buffer, with the most important feature being the range of temperature over which they remain stable. Generally, the buffers are tinted with different colors of coating to help identify each fiber in the cable. Standard telecommunications fibers are coated with material that is stable to long-term exposure to 85 °C, and short-term exposure to slightly over 100 °C. If higher temperatures are expected, a specialized buffer must be employed. Plastic buffering can be obtained with temperature resistance to about 250 °C, with exotic gold- and carbon-coated fibers capable of measurements to over 800 °C. The cost of these fibers is strongly affected by the buffer material choice, starting at around 0.1 € m^{-1} for standard fiber to well above 10 € m^{-1} for high-temperature materials. Further, the operations needed to remove the buffer as required for joining fibers by employing a fusion splicer become very challenging with high-temperature buffers.

Beyond temperature, the glass must be protected from water and hydrogen gas, which if in long-term contact will eliminate the refractive index contrast between the core and jacket glass (referred to as *cladding*), thus leading to light loss from the fiber. Optical fibers

are therefore typically encased in waterproof protection, which can be injection molded directly onto the buffered fiber known as *tight buffering*, or can be placed into a tube known as *loose-tube buffering*. If loose-tube is employed, there is the option of having the fiber embedded in hydrogen-scavenging gel, which eliminates degradation by exposure to this otherwise highly diffusive gas. The loose-tube can be made of many materials, with cables to be exposed to high pressures or other aggressive environments typically employing stainless steel for the tube. Stainless-steel loose-tubes can be constructed with external diameters as small as 0.8 mm for a single fiber, or of several millimeters in diameter if multiple fibers are to be included in the cable. In the oil industry, the stainless tube is often further encased in an aluminum tube, which has much lower gas permeability and further stabilizes the cable against hydrogen ingress.

Generally, further protection is needed outside the buffering to protect the fiber from tensile stress. Tensile elements made of aramid or steel are often employed for this purpose. In the case of actively heated cables, it is sometimes useful to have copper among the metal elements to reduce the electrical resistance of the cable. One must keep in mind that the working tension on a fiber-optic cable is not dictated by the breaking strength of the cable, but rather the tension at which the cable stretch might give rise to tensile stress on the fiber. Should the fiber experience such stresses, this can modify the optical properties of the fiber, which can be problematic if temperature is the target of the measurement. Local stresses from excess tensile load will lead to time-varying local changes in the calibration between backscatter and temperature (see (20.2)), leading to experiments where the temperature is impossible to determine. To avoid this stress, fibers are generally placed in loose-tube buffers with *overstuff* of about 0.1–0.5%, meaning that, for each meter of cable, there is actually 1.001–1.005 m of fiber. In this way a cable can experience 0.1–0.5% change in length without passing stress onto the fiber itself. If the manufacturer puts too much overstuff on the fiber, it can lead to stresses due to the helical bending of the fiber within the loose tube. This problem can sometimes show up only after the cable has been unloaded from the reel, so it is a good idea to obtain optical test reports for the cable both on and off the reel. Most OFDS instruments set an apparent refractive index of the cable to correctly define the relationship between photon timing and location along the cable. This parameter is adjusted until the location of a particular thermal defect matches with the cable markings at that distance. Clearly such an approach intrinsically accounts for the cable overstuff as part of the refractive index. If no such adjustment is

made, the accumulated error in apparent location compared with the actual location can be considerable, e.g., on the order of 5 m error per 1 km of cable.

Many times, a plastic jacketing material will be applied outside the elements that provide crush and tensile protection to give the cable greater environmental resistance, easier handling, and allow for selection of color and markings. This material should be selected with great care to ensure it meets the installation's thermal and mechanical requirements. A common problem in environmental sensing is that the cable markings imprinted by the manufacturer, also known as *meter-marks*, rub off when the cable is guided into the installation. The loss of distance markers can be problematic when it comes to associating specific points along the cable with the data that was obtained from that location. The outer jacket also influences the thermal response time of the system (see discussion in [20.10]). Specifically, if the core of the cable is made up of high-thermal-mass materials while the jacket has low thermal conductivity, the response time of the cable can be on the order of minutes. For many experiments this is not an issue, but especially for actively heated and aerial installations, thermal insulation of the jacket can be essential to resolving the process of interest. If active heating is employed, the jacket must also be mechanically and electrically protective against the possibility of contact between the energized elements and the external environment to prevent electrical shock.

For long-term installations, it is important to consider the stability of the cable components. For example, it is often tempting to use white-jacketed cable to reduce solar heating. While some white plastics are stable, many lack the ultraviolet (UV) stability that darker colored jackets have. Unsuitable cables may deteriorate in a matter of weeks to months, and few plastics that are not specifically designed for outdoor use will be stable in long-term environmental deployments.

In summary, the construction of the nonglass components of cables used for environmental sensing is pivotal to the success of an OFDS deployment. Whether it be exposure to solar radiation, chewing animals, excessive tension, or tight bends, all of these factors must be considered as one selects the cable appropriate to a particular experiment.

20.4.4 Off-Grid Installations

Power is often a key parameter driving the selection of instrumentation for distributed environmental sensing. OFDS instruments have power consumption that generally falls between 5 and 500 W. The ultralow-power systems achieve these efficiencies by powering down the laser and internal data systems for most of

the time, taking data only at prescribed times. Since the signal-to-noise ratio of OFDS measurements is typically inversely related to the square root of the active measurement period, shutting down the instrument has a cost of increasing the noise. For instance, if one were to record for 15 min every 4 h, this would provide an energy savings of 16-fold, but would result in an error four times greater than had the instrument been recording data continuously. Depending on the instrument and length of cable interrogated, the noise could well be acceptable under these conditions, and the energy savings could be pivotal in experimental logistics.

Many installations in remote locations are operated based on solar battery charging. In this case, one must take care to provide ample battery power to sustain operation in the worst weather conditions you expect to see. Many high-quality OFDS instruments are available with a power consumption of 30 to 40 W, which is under 1 kWh d⁻¹. A single 100 Ah 12 V battery with 1.2 kWh can power such an instrument for one day, but such deep discharges dramatically shorten the battery life and do not provide for poor weather conditions. Three such batteries would generally be sufficient, since the batteries should receive some charge each day, which should be able to sustain a week of low-recharge conditions. The power input from the solar panels should be selected to be at least three times the charging capacity so that, on cloudy days, one will obtain a good fraction of the power needed to operate the system, and so one day with good weather will recover a full charge of the batteries. Again, these *rule-of-thumb* values are just listed to give an impression of the trade-offs and considerations at play: budgets, security, feasibility of transporting heavy batteries, and other considerations may dramatically change the design. A small gasoline-powered generator can be a very useful emergency energy source. Beyond pure energy, one should also be mindful of the quality of power. It is preferred to use instruments that can run natively on DC power as this saves the loss of energy in inversion, and generally can be more fully isolated from lightning and other power quality issues. If using an inverter, it is important to verify that the quality of the power is adequate. Some OFDS instruments have large start-up power demands, which can overwhelm systems that would otherwise appear adequate. Also, some inverters have square-wave rather than sine-wave voltages, which can be incompatible with OFDS power supplies. Finally, the reliability of power is not only a matter of convenience, but also potentially important in protecting your instrument: some lasers can be damaged by spontaneous loss of power. In this sense, we recommend inclusion of an uninterruptable power supply for all OFDS installations. Further, we highly recommend

that remote installations be fit with cellphone connection so that the operation of the OFDS system and the status of the power system can be verified regularly without site visits.

20.4.5 Comparison of Methods

The choice between devices of different performance categories, different cable measurement configurations, the use of passive and active systems in combination

with the variety of choices for fiber-optic cables including buffering and power supply makes OFDS an extraordinarily versatile measurement technique. This versatility is reflected in the rapidly expanding range of applications. One cannot say that a high-performance device yields improved measurements compared with a standard-performance device. The opposite may apply. The user needs to select the device which offers optimal performance for a specific observational task (see next section).

20.5 Specifications

Selection of appropriate OFDS instruments for one's application requires quantitative understanding of the spatial and temporal resolution, precision, and accuracy required to achieve the scientific goals. Here, we review the basic issues in instrument specification so that the user can make an informed decision.

We first consider the resolution of changes in temperature in distance along the fiber. The spatial resolution Δx is computed by observing the reported response from a step change in temperature, e.g., the signal generated along a fiber going from warm air into cold water. The distance between where the instrument reports 10 and 90% of this temperature change is taken to be the spatial resolution of the device, which corresponds to approximately 3.5 units (Fig. 20.3). In unpublished data, we have found that the weighting function supporting the reported value is Gaussian, incorporating temperature from a span about the point. It is important to note that many OFDS instruments in their specifications boast sampling at spacings far less than the

reported spatial resolution. As long as the Nyquist requirement of sampling is no more than half the true spatial resolution, sampling at closer spacing provides no advantage.

The effects of the choice of spatial and temporal resolution can be combined into a simple *instrument quality* equation. Taking the temporal resolution to be τ (s) and the spatial resolution to be λ (m), the precision of the measurement will be equal to $C/\sqrt{\tau\lambda}$, where C is the instrument constant. By averaging over longer times and longer distances, the precision is improved. Generally, high-performance instruments have smaller values of C , though this is not universally the case. C is a primary criterion for the identification of the suitability of an instrument for a particular experiment. Manufacturers do not generally state the value of C , but it is easily obtained from their published performance curves.

Suitability for a particular experiment is also a function of the severity of the environmental conditions to which the instrument will be exposed. There are several

Fig. 20.3 Illustration of 10-90 definition of OFDS spatial resolution and underlying weighting function for photons from a section of cable. The position along the fiber is given in arbitrary units of length with step temperature change at 0. The *thin red line* represents the actual temperature change, the *thick black line* is the reported OFDS temperatures, the *light black line* the Gaussian weighting function over which the OFDS averages in its reported temperature at position 0, and the *dashed lines* indicate the locations along the cable of the 10% and 90% quantiles of change in reported temperature

instruments on the market that are completely sealed, making them more capable of long-term employment in high-dust environments. Different OFDS instruments have very different operating temperature ranges. Indoor-rated machines are generally constrained to use in the +5 to +40°C range, while ruggedized instruments can operate from -40 to +60°C. Low-power instruments with power demands < 40 W can further be sealed into waterproof enclosures, which extends the range of sites where OFDS can be easily deployed.

20.6 Quality Control

As mentioned in Sect. 20.3.1, OFDS requires the use of reference sections with known temperatures to solve for all terms of the full calibration equation (20.2) during post-field data processing. To solve for the three unknown terms, i.e., γ , $C(t)$, and the differential attenuation, a minimum of three reference sections with known $T(x, t)$ is required which vary in at least one dimension: either the position from the start of the fiber x or the temperature T , or both. As a result, all four potential fiber configurations (Fig. 20.1) need to accommodate this requirement by either using three separate water baths (Fig. 20.1a) or routing the fiber-optic cable through at least two baths twice (Fig. 20.1b, c). In practice, each reference section shall contain at least 40 to 50 individual fiber section units at the selected sampling resolution Δx to reduce the calibration uncertainty without using up too much fiber. This full experimental setup is recommended to significantly reduce measurement uncertainty, particularly for applications in which high trueness and accuracy are required. However, all commercially available OFDS instruments also offer simplified calibration setups in which either no external reference sections or only one or two reference sections in form of cold and warm baths are used. This simplified setup works because all instruments have an internal reference coil of fiber-optic cable of approximately 80 m length in combination with a classic internal temperature sensor to perform a crude single-point calibration, and require the user to enter a spatiotemporally fixed value for the differential attenuation into the control software. The ad hoc temperatures obtained from these simplified calibration setups are helpful to obtain a first glance of the environmental temperatures during the experiment and check for potential flaws in the fiber geometry, routing, and support. These flaws commonly lead to unphysical and sudden temperature changes caused by, e.g., applying excessive pressures by pinching the fiber-optic cable and deforming the optical core, using bends with too small radii leading to

We see that OFDS instrument performance has many metrics, including spatial and temporal precision, power consumption, dust resistance, and the range of temperature at which the instrument can operate. Success in using OFDS depends on matching the instrument to the goals and conditions of the experiment, where there is no generally *best* instrument, rather requiring matching of the qualities of the instrument to the characteristics of the application.

excessive light losses, or bad fiber splices resulting in enhanced light reflection and attenuation. Hence, we recommend choosing a calibration setup which combines the advantages of the simplified setup during the experiment with those from the full calibration setup during postprocessing to achieve maximum data quality. Since multiple individual single-core cables with identical or different properties or multiple optical cores of a multicore cable can be combined into one longer optical path by means of an optical fusion splicer, the user needs to ensure that each cable section can be properly calibrated by using the minimum number of reference sections for evaluating the full calibration equation. In particular, the differential attenuation of optical fibers varies across batches, manufacturers, age, and usage history of the fiber-optic cable and leads to skewed temperature signals when incorrectly determined or unknown. Here, we provide some guidance on which fiber configuration to choose depending on the measurement task and resources.

20.6.1 Single-Ended Configurations

These configurations use a smaller amount of fiber-optic cable and offer the remaining optical ports of the OFDS instrument to be used for additional cables. If only a single optical port is used for sampling, these configurations maximize repetition rates and the collected data have the greatest temporal resolution. In case of a simple single-ended configuration (Fig. 20.1a), light is injected in only one direction through the fiber-optic cable, which is routed through two reference baths of different temperatures before the cable enters the experimental fiber-optic array, and a third bath after it. For duplexed single-ended configurations (Fig. 20.1b), a third physical bath is unnecessary as the cable is routed back to the initial set of baths, yielding a total of four reference sections. Having four reference sections allows for independent

verification of the calibration routine by comparing its computed temperature with the independently measured value from the reference sensor as only three baths are used for the matrix inversion. The shortcomings of single-ended configurations are the inability to overcome measurement artifacts resulting from directional light losses, and a heteroscedastic distribution of random measurement error as the signal-to-noise ratio for the Raman backscatter peaks diminishes nonlinearly toward the end of the measurements. In other words, the random error for $T(x, t)$ toward the end of the cable is systematically larger, which is of particular concern for fiber-optic installations using the maximum cable length and duplexed configurations. For duplexed configurations, the cable sections closest to the start of the cable having the smallest random error are combined with those from the far end of the cable suffering from the largest random error. While duplexing reduces the overall uncertainty by a factor of $\sqrt{2}$ through sampling each measurement location twice, it *contaminates* the sections offering the smallest random uncertainty near the beginning of the array. Whether the resulting spatial random error is acceptable or can be partly compensated by greater temporal aggregation depends upon the application.

20.7 Maintenance

While the key to successful application of OFDS is proper design and installation of the system, some maintenance should be expected as well. Particular attention should be paid to the performance of the reference baths and reference thermometers upon which interpretation of the final data collected depends, but breaks in cables, deterioration of power systems, and contamination of connectors are also frequent sources of failure in the field. We review these issues here.

Because the sensitivity of photodetectors, amplifiers, and mechanical connections between fibers depends on their temperature as well as their age, it should immediately be clear that the parameters found in (20.2) should be recalculated frequently. As described above, it is advisable to maintain at least three reference baths along any cable, of which at least one should be at a different temperature from the other two. This means that continuous maintenance of precise reference baths, monitored by high-precision thermometers, will be an ongoing and essential aspect of any installation. All liquid-filled baths must be subject to continuous circulation to avoid stratification, and the cables should be held in the bath without contacting the vessel holding the

20.6.2 Double-Ended Configuration

These configurations use larger amounts of fiber-optic cables and require the use of two optical sampling ports per cable, as the light is sequentially injected from both ends of the cable. The fiber-optic cable is typically routed through two reference baths of different temperatures located close to the start and end of the optical path, yielding a total of four reference sections, which offers the advantage of independent verification of the calibration routine as described in the previous subsections. While double-ended configurations reduce the temporal sampling resolution through sequential sampling of the optical ports of the OFDS instrument, they allow for compensation of directional artifacts by selecting data from the *best* travel direction of the light. As in case of the single-ended configurations, duplexing reduces the overall measurement uncertainty but may introduce a spatially skewed random measurement error. For some applications requiring the highest measurement quality at maximum temporal and spatial resolution, including atmospheric turbulence observations using OFDS, combining the first two halves of the fiber-optic array sampled from each direction of a simple double-ended configuration is the optimum choice.

liquid. For short-term installations, two of the baths might be held at ambient conditions, and the third as an ice bath. For longer-term installations, where power is available, we recommend use of a mechanically cooled chest freezer to act as the cold bath. This must be controlled to avoid fully freezing or fully thawing, which requires active regulation to account for the changing external heat load. For very long-term installations we recommend the use of solid-state references, where the cable is wound around a series of thoroughly isolated thermal masses that provide stable and distinct temperatures.

If any dust is present on the face of a fiber-optic connector, the high-energy light from the laser will likely vaporize this dust, resulting in contamination on both surfaces of the fiber optics being joined. For this reason, whenever fibers are removed or reinserted into an OFDS instrument, the connectors must be cleaned meticulously to ensure that they are completely free of contamination. All outer surfaces of the connectors should be cleaned using an alcohol-wet lint-free towel, while the optical face of the fiber should be cleaned only with a dry-cleaning system designed specifically for this task.

Cables exposed to the insults of natural environments are frequently damaged, either fully eliminating the light path, or causing loss of light that will interfere with calibration. Power systems, many of which depend on batteries and solar charging, are also sub-

ject to deterioration and failure. Hence, we recommend having a schedule for frequent reinspection of the data from an OFDS system to ensure that the system is operating and that the cables remain in-tact.

20.8 Applications

The current range of OFDS applications is already broad and growing rapidly. Here, we focus on providing examples relevant to the scope of this handbook, including atmospheric turbulence, meteorological observations, surface energy balance, and some surface hydrological applications. However, we acknowledge that many other applications exist, including studies of groundwater flows, river discharge, sewerage systems, and slope stability and landslides. The reader is referred to the frequently updated list of OFDS studies found on [20.32] for a broader scope.

20.8.1 Atmospheric Profiling

The vertical distribution of temperature across the air–water interface is of interest to investigate and quantify the process of evaporation and sensible heat exchange to study the formation of surface fog and the impact of water bodies on the microclimate of lake shores. OFDS using fiber-optic cable coiled around a support material can measure these temperature profiles at high spatial resolution on the centimeter scale, resolving the very steep gradient of temperature at the interfacial boundary

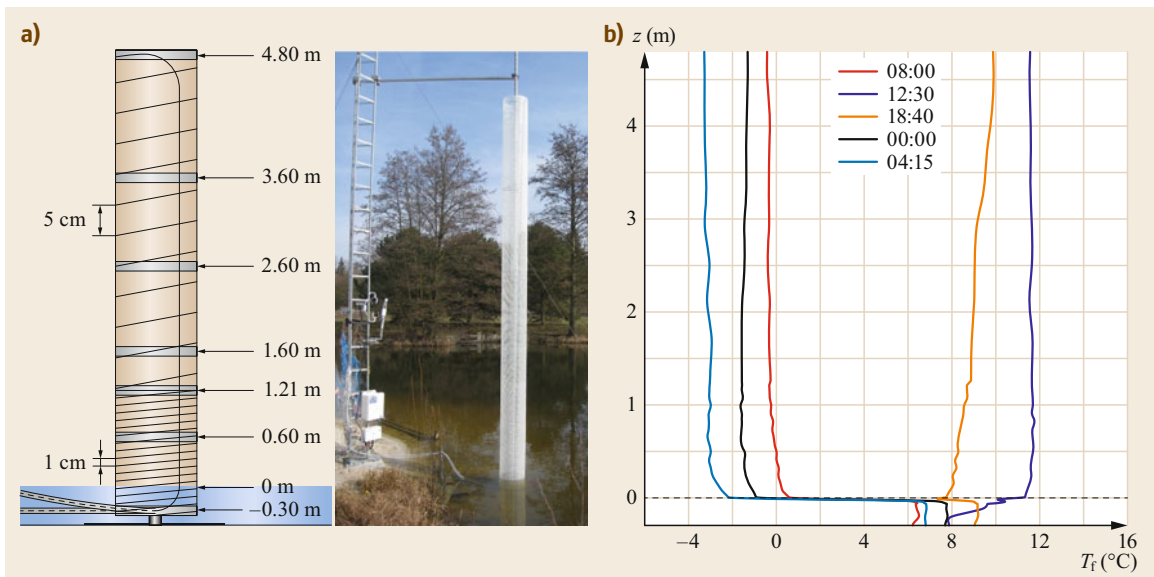

Fig. 20.4a,b Obtaining vertical profiles of temperature at the air–water interface above a lake: The coiled fiber-optic OFDS configuration allowed spatially continuous sampling with up to 0.01 m vertical resolution across 5 m in height using reinforcement fabric as mechanical support material (a). The radiation and conductive errors of the fiber-optic cable and between the support material and the fiber-optic cable were carefully evaluated. OFDS enabled quantification of the very steep temperature gradient near the interfacial boundary, which is greatest in the early morning hours. Temperatures are shown as deviations from the temporal average at the top of the column for a calm night with clear skies and a net radiative forcing of 64 W m^{-2} (b) (after [20.16] © A. Sigmund et al., licensed under CC-BY 3.0)

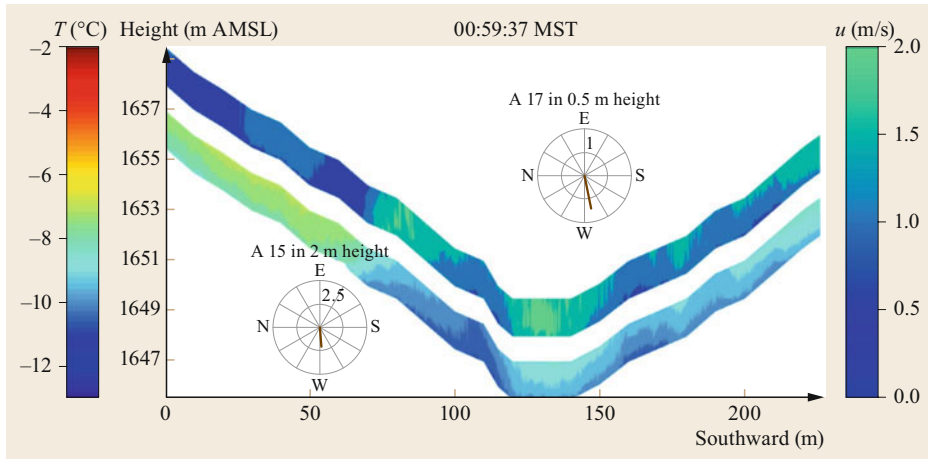

Fig. 20.5 Observing the effects of gentle topography on atmospheric turbulence: Space series of instantaneous wind speeds u (*upper V-shaped graph*) and air temperatures T (*lower V-shaped graph*) across a shallow gully observed at three heights (0.5, 1.0, and 2.0 m above ground, spatially interpolated during postprocessing) sampled by actively heated OFDS during the Shallow Cold Pool experiment. The turbulent temperature perturbations are smallest at the bottom of the gully, but largest on the south-facing slope (*left half* in image) because of lee-turbulence mixing down warm air in this weak-wind boundary layer for northerly flows (from *left to right* in the image). No other experimental technique can map turbulent perturbations at such fine resolutions in the surface layer

(Fig. 20.4). A standard-performance OFDS instrument was used with a minimum temporal aggregation time of $\Delta t = 30$ s at a sampling resolution of $\Delta x = 1$ m. The radius of the column made from the support fabric was chosen such that its circumference was equal to the sampling resolution.

20.8.2 Turbulent Airflows

High-resolution actively heated OFDS allows for observations of the small-scale and short-lived perturbations of atmospheric turbulence in air temperature and wind speed, which may be of interest to investigate the topographic impacts on the formation and behavior of cold-air drainage and pools. A fiber-optic array constructed from a pair of fiber-optic cables consisting of a passive, unheated PVC-jacketed white cable in combination with a resistively heated cable with stainless-steel outer jacket was used to measure air temperature and wind speed at three heights across a 220 m-wide shallow gully during the Shallow Cold Pool experiment [20.12, 19, 20.33] (Fig. 20.5). A high performance-type OFDS instrument was used with a temporal aggregation time of $\Delta t = 1$ s at a sampling resolution of $\Delta x = 0.125$ m using a simple single-ended configuration with three reference baths sampling the passive and heated ca-

bles sequentially, which resulted in records of 0.5 Hz for air temperature and of 0.25 Hz for wind speed. The space series reveal superimposed eddies of varying size for nighttime conditions dominated by cold-air drainage perpendicular to the transect and into the view plane.

20.8.3 Hydrological Applications

Applications of OFDS to environmental sensing were first applied to hydrological processes [20.6, 22, 30]. In this application, temperature is employed as a signature for parcels of water and to identify the structure of turbulence and mixing. The use of actively heated methods in combination with measuring the response time provides an indication of any changes in local heat capacity and thermal diffusivity. Placed in rivers and wells, OFDS was shown to be able to identify the location and intensity of groundwater entry. In lakes and seas, OFDS can identify stratification and thus the presence and magnitude of internal waves (Fig. 20.6; [20.34–36]). In soils, OFDS has allowed for observation of water content and flow of water with unprecedented spatial resolution (e.g., using active heating in [20.11] and using passive observation of profiles of soil temperature by [20.31]).

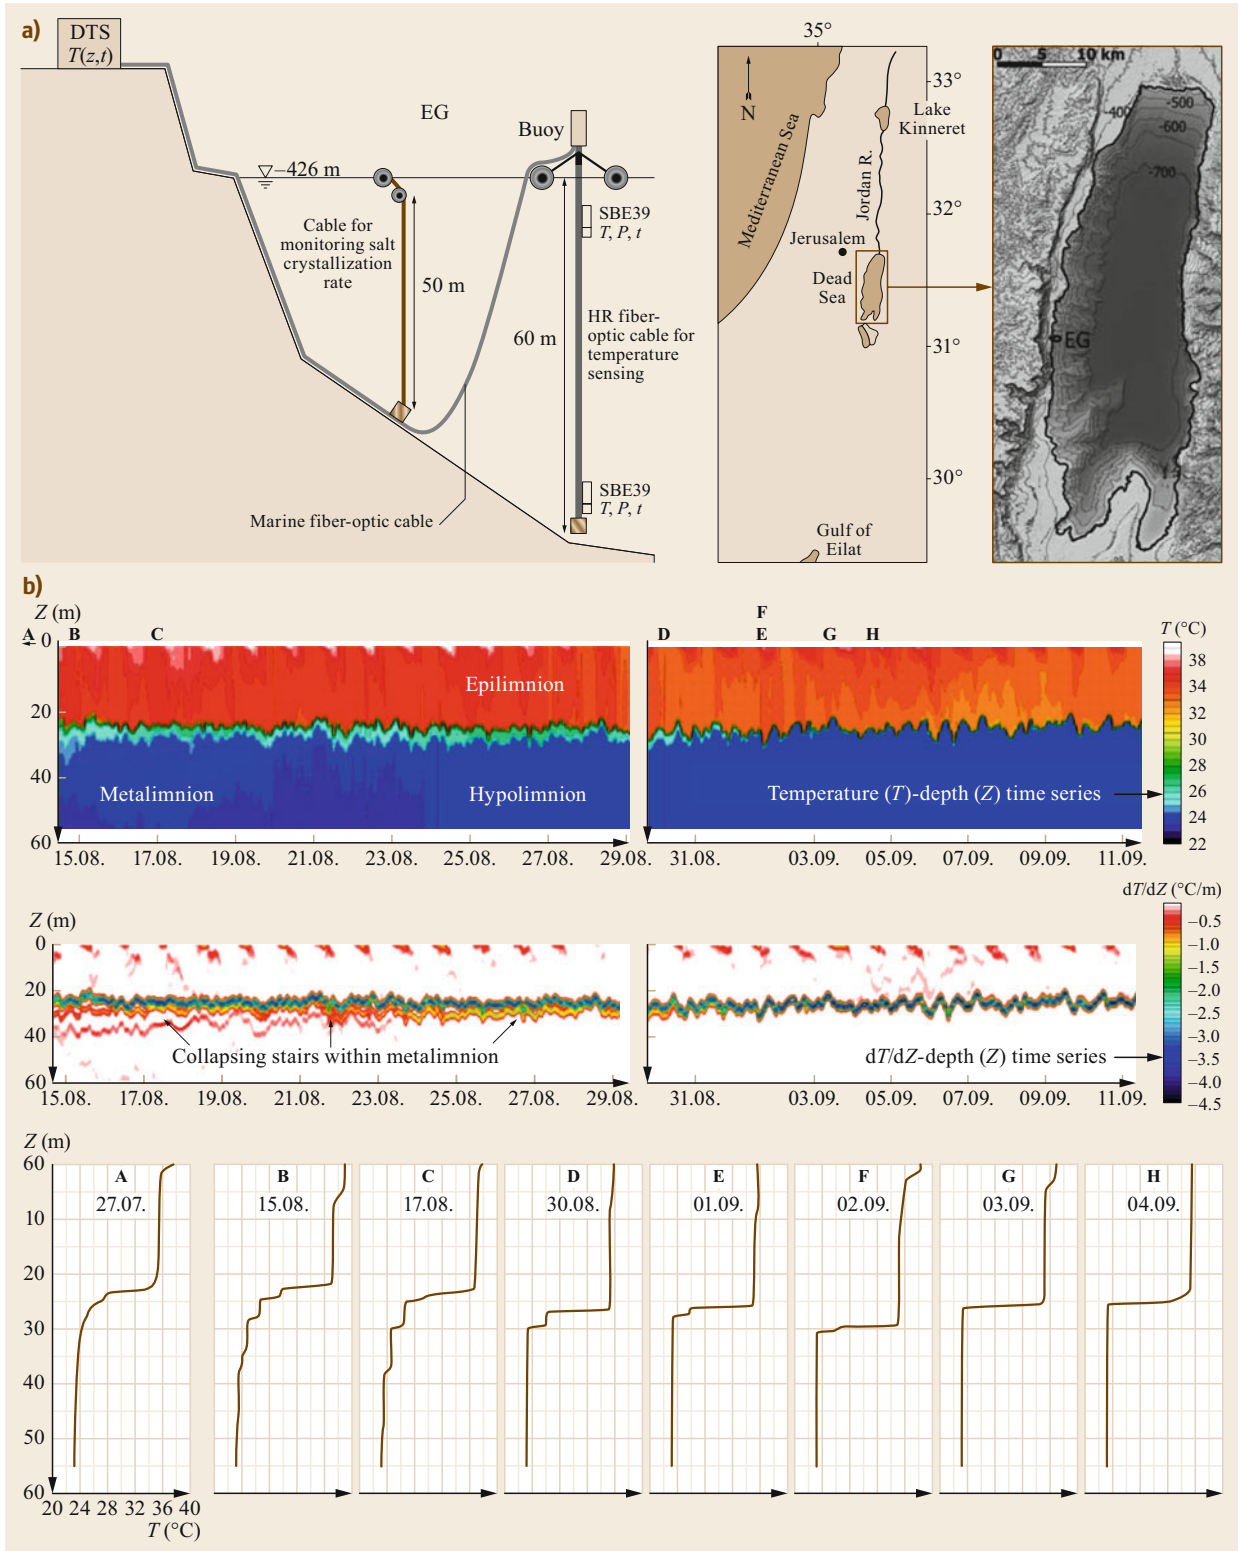

Fig. 20.6 Data from a 55 m vertical profile of high-resolution fiber-optic cable installed in the Dead Sea. The 26 mm-diameter cable had two helically wrapped loose-tube fiber optics which had fiber length of 11 m for each 1 m of cable. The time series of temperature shown illustrate the sharpening of the thermal stratification of the upper 50 m of the Dead Sea from late July to September 2012, overlaid by approximately 5 m excursions of the thermal interface driven by internal waves (after [20.34] with permission from John Wiley and Sons9 ◀

20.9 Future Developments

Here, we briefly present some directions in which OFDS methods are currently evolving. If successful, the resulting applications will greatly enhance the utility of OFDS in cross-disciplinary geosciences research.

Current development of OFDS for atmospheric applications aims at adding wind direction to the parameters which can be obtained at high spatiotemporal resolution. An observational system capable of measuring air temperature, and three-dimensional wind speed and direction at submeter and second resolutions over scales of hundreds and thousands of meters could be used to estimate spatially resolved fluxes of sensible heat and momentum using the spatial eddy covariance method. Such flux estimates would represent true spatial averages without the assumption of ergodicity and avoid the need for spatial homogeneity of the sampling

location and stationarity. The technical approach for adding wind direction to the list of parameters obtained from OFDS is built around the differential directional heat loss from heated fiber-optic cable from small flow obstacles imprinted onto the fiber. First tests of this approach have yielded promising results in controlled laboratory environments [20.21], and first methodological studies are being published at the time of writing.

Other efforts to enhance the sensing capabilities of OFDS aim at extending the wind speed range of the actively heated technique by applying a dynamic heating rate proportional to the wind speed. Such a system would have an optimal signal-to-noise ratio for determining $\Delta T(x, t)$ (see (20.5)) independent of wind speed and would allow for sampling high mean advective velocities during storms and increased gust speeds.

John Selker, OSU Distinguished Professor of Biological and Ecological Engineering at Oregon State University (28 years) and co-Director of both CTEMPs.org and TAHMO.org, and PI of the OPEnS Lab (OpenSensing.org) has worked in more than 20 countries across 5 continents. His focus areas include environmental instrumentation, groundwater processes, and ecohydrology. He served as editor of *Water Resources Research*. Selker has published over 200 peer-reviewed articles. In 2013 he was elected Fellow of the American Geophysical Union, and 2013 received the John Hem Award for Science and Technology from the American Groundwater Association.

Odor Measurements

Ralf Petrich , Axel Delan 

Odor measurements in the atmosphere are carried out using human noses or instruments as sensors. Only human noses are currently able to record an odor impression. To measure odor intensity, distinguish between the presence or absence of odors, or classify odors, instruments can also be used.

From the perspective of typical applications, there are two basic approaches. On one hand, high odor concentrations in the air (several orders of magnitude above the human perception threshold) are measured using olfactometry. This method combines a device for dilution and the evaluation of the diluted odors, usually by human noses. Applications of this method are the determination of odor emitter concentrations in industry or agriculture and, beyond the scope of atmospheric measurements, the characterization of scents. On the other hand, the measurement of low odor concentrations (around or slightly above the human perception threshold) are obtained by means of field inspections. In this case, human assessors breathe the air to be tested and record their odor perception.

Odor concentration, perception frequency, and hedonic impression are typical parameters determined within the scope of odor measurement. Statistical methods play an important role during the evaluation of the raw data obtained from the assessors to finally get representative measurement values.

Measurements of odors in the atmosphere have become more and more important in the last 20 years. In contrast to indoor odor measurements and scent characterization of consumer products, atmospheric odor measurement is usually connected to the assessment of odor nuisances around facilities with odor emissions, such as industrial plants, agricultural operations (livestock), waste and wastewater treatment plants, or composting facilities. There are methods of direct odor

measurement, such as field inspections by panel members who visit the locations where odor measurements are required. Moreover, the concept of odor units was developed to measure the amount of an odor within a unit volume. Thus, it is possible to mathematically describe processes like odor emission, dilution, mixture, or dispersion. Also, direct odor concentration measurements can be carried out using olfactometry.

21.1 Measurement Principles and Parameters

Odor measurements can be carried out for several reasons. For instance, odor annoyances reported by people living near odor emitting facilities are quantified based on odor measurements. Furthermore, if the scents of certain consumer products like perfumes, cars, or food must be characterized, odor measurements (outside the scope of atmospheric measurements) are used.

21.1.1 Measured Parameters

Different kinds of parameters can be obtained from an odor measurement. Odor concentration plays a central role. This concentration describes the amount of odor within a given volume of air. In this context, odor is mathematically treated as an extensive magnitude like, for instance, mass or energy. To accomplish this, the concept of an *odor unit* must first be introduced. An odor unit (OU) is defined as exactly the amount of an odorant (a substance that stimulates the human olfactory sense) within one cubic meter of gas, which constitutes the average human odor perception threshold. Thus, the concentration of one odor unit per cubic meter is the concentration at which the average (regarding her or his odor perception) human starts to perceive the odor. A more detailed representation of the theory behind this concept is given in Sect. 21.3.1.

Once the odor unit and its concentration are defined as quantities, they can be used for calculations and to derive other quantities. For instance, if a gas with an odor concentration of 100 ou m^{-3} is diluted by the factor 20, the resulting concentration is 5 ou m^{-3} . Furthermore, if the amount of time is determined during which a concentration in ambient air, for instance 1 ou m^{-3} , is exceeded, the perception frequency of a specific odor is obtained as another measured parameter.

Other parameters like the hedonic impression of a specific odor, for instance *pleasant* or *unpleasant*, can usually not be treated within the concept of a numerical quantity, but as verbal descriptions. The most relevant measured parameters are summarized in Table 21.1.

21.1.2 Principles of Measurement

As usual, *to measure* means comparing a quantity to a standard. To measure odors is complicated for two reasons. On one hand, the only standard to compare to is the human olfactory perception, which to be precise means the human olfactory perception threshold.

On the other hand, the method to compare a sample of gas to this standard can also be difficult if dilution or a special sample treatment is involved. To accomplish the task of comparison, two basic approaches can be used. The conventional method uses human noses as detectors. Recently, technical instruments have also been used to characterize odors.

Another way to structure measurement principles is based on the odor concentration of the gas under study. On one hand, high odor concentrations in the air (several orders of magnitude above the human perception threshold) are measured using olfactometry. This method combines a device for dilution and the evaluation of the diluted odors, usually by human noses. Applications of this method are the determination of odor concentration of odor emitters in industry or agriculture and, beyond the scope of atmospheric measurements, the characterization of scents. On the other hand, the measurement of low odor concentrations (around or slightly above the human perception threshold) is obtained by means of field inspections. In this case, human assessors (panel members) breathe the air under investigation and record their odor perception. Field inspections can be carried out as grid inspections or plume inspections.

For grid inspections, panel members visit a spatial grid of fixed measurement points over a representative time span (typically one year) and record their odor perceptions, usually every ten seconds over a period of ten minutes at each measurement point. Thus, a spatial distribution of the perception frequency is obtained for the assessment area.

Plume inspections are used to determine the shape and size of the area where an odor plume originating from a given point can be perceived and recognized, with respect to the specific meteorological and odor source conditions. For that, the panel members record the presence or absence of the odor under investigation at different points downwind of a source. They can stay at a fixed measurement point in the assessment area over a certain time (stationary method) or they can move around and follow a plume in the assessment area and record their perception as a function of location and time (dynamic method).

More detailed background information on the measurement principles is given in Sect. 21.3. Table 21.2 shows the sensor types and their respective measurement principles and parameters.

Table 21.1 Measured parameters

Parameter	Description	Unit	Symbol
Odor concentration	Mathematical equivalent to mass concentration, describing the amount of odor within a given volume of air	ou m ⁻³	<i>c</i>
Perception frequency	Percentage of time during which a specific odor is perceived	%	<i>P</i>
Hedonic impression	Verbal description of the type of odor (pleasant, unpleasant, etc.)	–	–

Table 21.2 Principles of odor measurements and applications

Type of sensor	Measurement principle			Parameter		
	Olfactometry	Grid inspection	Plume inspection	Odor concentration	Perception frequency	Hedonic impression
Human nose	×	×	×	×	×	×
Instrument	×	×	×		×	

21.2 History

Olfaction is phylogenetically the oldest sense and man's interest in scents or odors can be traced back into ancient history [21.1]. But only in the nineteenth century were efforts to assess olfaction solidified by *Gabriel Valentin* (1810–1883) in 1842 and *J. Passy* in 1892 [21.2]. Around 1888, *Hendrik Zwaardemaker* developed a device for obtaining olfactory perception thresholds. This device can be regarded as the predecessor for the olfactometers since developed and produced.

The last 20 years of the twentieth century saw development in olfactometry, when interest in the quantification of olfactory perception was promoted by applications in pollution management, environmentalism, and scent management for consumer products. Many test procedures were developed for the human olfactory sense from a medical perspective. Also, studies on the olfactory sense and its statistical parameters (for instance odor perception threshold) were carried out in North America and Europe.

At the end of the twentieth century, a lot of knowledge was available regarding the measurement of the parameters mentioned above.

Sophisticated devices (olfactometers) were developed and built to accurately dilute samples. At first, these olfactometers had simple dilution mechanisms controlled manually; later, computer-controlled dilution mechanisms were introduced. The first olfactometers were able to serve only one panel member; recent devices can serve up to ten panel members at once. Elaborate statistical methods were also developed to accomplish quality management.

With this knowledge and the availability of devices, it was finally possible to handle odor measurements at the same scientific level as the measurements of other atmospheric parameters.

Finally, a set of regulations was developed in Europe and North America to regulate the procedures of olfactometry and field inspections as the most common odor measurement principles [21.3–5].

21.3 Theory

In the following section the concept of odor units is described. Based on this concept, several measurement principles are introduced later in the section.

21.3.1 Derivation of the Odor Unit Concept

As mentioned in Sect. 21.1.2, the basic odor measurement concept is the odor unit. An odor unit is defined as the amount of an odorant within one cubic meter of gas, which constitutes the average human odor perception threshold.

Regarding this definition, several important aspects must be considered. The actual amount of an odorant expressed as its mass in a given volume of air is proportional to the number of odor units within this volume with respect to the specific odorant. The mass concentration of an odorant that corresponds to 1 ou m⁻³ is the specific odor threshold of this odorant. For ammonia, for instance, this value lies between 1 mg m⁻³ and 5 mg m⁻³.

Another aspect in the definition is the term *average human odor perception threshold*. Everyone has

their own (personal) threshold (mass concentration of an odorant within ambient air), above which an odorant becomes perceptible. Below this threshold, the odorant is not perceived, though its mass concentration within the ambient air is not zero. To work with a value averaged over a statistically representative set of people (average threshold), the variation in personal thresholds must be investigated. It was found that even for a mixed population (both genders and ages within the adult range), the personal thresholds do not vary by orders of magnitude. The value can therefore be regarded as stable enough to be used in the definition of odor units. Finally, the *average threshold* can be regarded as the amount of an odorant within ambient air at which half of a statistically representative set of people perceives the odor and the other half does not [21.5]. Thus, *averaging* the perception threshold mathematically corresponds to finding the median value.

In practice, the representative set of people mentioned above is constituted by a panel of assessors. To ensure typical odor perception, the panel members are checked on a regular basis to determine whether their odor perception threshold for certain substances (for instance, *n*-butanol) is within a predefined range. Such a panel of assessors is used for all the measurement principles described below.

Finally, one more aspect must be kept in mind. The amount of odor units within a given volume is always coupled to the one odorant under study. Though odor units offer a convenient way to mathematically handle dilutions, it is not possible to describe the processes if odorants are mixed this way. If an air sample with a certain odor concentration (odor units per volume) is mixed with a sample with another odorant, the odor concentration of the resulting mixture cannot be expressed as a weighted average of the original concentrations. This is because different odors can cover, amplify, or attenuate each other on mixing. The only way to obtain the odor concentration of the mixture is to characterize it with an independent measurement.

21.3.2 Conventional Measurement Principles

As summarized in Table 21.1, different measurement principles are available to determine different measurement parameters. The central measurement principle is olfactometry, which can measure the odor concentration and the hedonic impression of a sample. Other measurement principles like field inspections can yield measurement parameters such as the absence or presence of odors, perception frequency, and the hedonic impression. Instrument-aided measurement principles must be calibrated with measurements based on the

human nose and can then be used to determine odor concentration, the absence or presence of odors, the classification of odors, and perception frequency. However, while nose-based measurements are usually used to study arbitrary odors, instrument-based measurements can only be used to study exactly the odors they were calibrated for, but no other odors.

Olfactometry

Olfactometry as a measurement principle can be used to investigate odor samples with odor concentrations well above the perception threshold of the odor under study. This is caused by the central principle of olfactometry, the sample dilution. For instance, an air sample is diluted and presented to a panel of human assessors until half of the panel members perceives the odor and the other half does not. At this dilution, the air presented to the panel has an odor unit concentration of 1 ou m⁻³ per definition. The dilution factor is recorded and used to derive the odor concentration of the original, undiluted sample. If, for instance, a dilution of 6000 is necessary to reach the panel's odor threshold, the original sample has an odor concentration of 6000 ou m⁻³.

To implement this procedure, a measurement device called an olfactometer is used. An olfactometer usually has two sections. One section consists of the dilution instrument; the other section presents the diluted sample to a panel of assessors and records their odor perception at different dilution levels.

The dilution instrument is the most sophisticated part of an olfactometer. On one hand, it must allow for calibrated dilution in a typical range from 10 to 5000. Even higher dilutions might be reached using predilution. On the other hand, the instrument components must not emit their own odors or modify the odors under study. Thus, typically only materials like glass, stainless steel, or polytetrafluorethylene (Teflon, PTFE) can be used.

Twentieth-century olfactometers were manually controlled to adjust the dilution factor. Current devices usually use automatic control units to adjust the dilution as part of a computerized measurement procedure. Panel sizes to test the diluted sample range from one to ten for common olfactometers.

Usually, the measurement procedure starts with a very high dilution so that the diluted sample presented to the panel is well below the perception threshold of all panel members. Then, the dilution is decreased step by step (for instance, a factor of two at each step) and the odor concentration presented to the panel increases. When the perception threshold of all panel members is reached (perceptions from all members have been recorded), the procedure is finished and will be evaluated. To decrease statistical uncertainty, this procedure

is repeated with the same sample a number of times, for instance three times.

Two common procedures for presenting the diluted sample to the panel members are known [21.5]. In the *yes/no mode*, the assessor is asked to evaluate the presented gas and to indicate if an odor is perceived (yes/no). The assessor is aware that in some cases blanks (only neutral gas) are presented. An additional outlet that always presents neutral gas may be made available to the assessor to provide a reference. Also, neutral reference gas might be presented between the stimulus cycles.

In the *forced choice mode*, the assessor is presented with two or more outlets, of which one presents the stimulus and the other(s) neutral air. The location of the stimulus in consecutive presentations is randomly changed among the two or more outlets. The assessor is asked to indicate which of the outlets presented the stimulus.

By evaluation of the panel member responses over the decreasing dilution factor, it is possible to find the panel's average odor perception threshold. If this threshold is reached, the respective dilution factor is used to determine the sample's odor concentration. Detailed information on olfactometry can be found in [21.5].

Field Inspection – Grid Mode

Grid mode is one of the field inspection methods mentioned in Sect. 21.1.2. Because olfactometry, with its practical lower detection limit of approximately 10 ou m^{-3} , cannot be applied to directly determine odor exposure in the field (faint odors at the concentration where they can just be recognized), grid inspection is not based on the dilution of sample air but brings the panel members to the field for in-place assessment [21.3].

The grid inspection is a statistical survey method carried out over a sufficiently long period of time (typically one year) to provide a representative map of the exposure to recognizable odor, spatially distributed over the assessment area. These measurements are used to determine the distribution of the perception frequency for recognizable odors in ambient air in an assessment area under meteorological conditions that are assumed to be representative for the local meteorology [21.3].

The odor perception frequency can, for instance, be used as an exposure indicator to assess the odor annoyance originating from one or many specific odorant source(s) emitting in a particular area under study.

For grid inspections, the panel members visit a spatial grid of fixed measurement points many times and record their odor perceptions. Usually, the perception is recorded every ten seconds over a total period of ten minutes (60 records) at each measurement point. From these records, a value for the perception frequency can be derived at the respective measurement point.

Typically, the assessment area is inspected with a frequency of approximately twice per week, while the actual time of day for the measurement changes stochastically. Also, the panel member carrying out the measurement is selected stochastically from a pool of at least ten assessors.

Inherently, each inspection represents only a snapshot of the real situation. For that reason, extensive statistical evaluation must be carried out to determine the relevance of the results. The perception frequency usually uses an hour as the time basis (odor hour frequency). By taking two snapshots per week, only 104 samples are available after a typical assessment time of one year. A perception frequency value with respect to the 8760 h of one year derived from only 104 snapshots bears a high statistical uncertainty. This aspect is one of the major disadvantages of grid inspection, besides the immense expense of visiting the assessment area 104 times.

Field Inspection – Plume Mode

Plume inspections are used to determine the shape and size of the area where an odor plume originating from a given point can be perceived and recognized with respect to the specific meteorological and odor source conditions. In contrast to the grid mode, the assessment area is not visited sequentially over a long span of time by the panel members; instead, a snapshot at a specific time is taken by a group of panel members visiting the assessment area simultaneously. The panel members record the presence or absence of the odor under investigation at different points downwind of a source. They can stay at a fixed measurement point in the assessment area over a certain time (stationary method) or they can move around and follow a plume in the assessment area and record their perception as a function of location and time (dynamic method).

The primary parameter measured with this method is the presence or absence of recognizable odors at a specific location downwind of a source, which is recorded by a number of panel members. From these results, the extent of the plume can be assessed as the transition from absence to presence of recognizable odor.

On one hand, the results are typically used to determine a plausible extent of potential exposure to recognizable odors. On the other hand, it is possible to estimate the total emission rate based on the plume extent, using reverse dispersion modelling [21.4].

21.3.3 Instrument Odor Measurement Systems

For instrument odor measurement systems (IOMSs), the human nose as a sensor is replaced by a technical system that can detect odorants in the air. For

a while, these devices were also called *electronic noses*, however all known IOMSs are far from being able to perform similar measurement tasks as the human nose. In particular, the physiological hedonic impression of an odor cannot be measured by an IOMS, but only by the human nose.

Thus, IOMSs are presently restricted to the following measurement tasks:

- Distinguish between the absence and presence of a single specific odor under study
- Classify multiple specific odors under study
- Estimate the odor concentration for a single specific odor under study

Nearly all presently known IOMS rely on a multidimensional sensor system that is sensitive to as many odorants as possible. During measurement, a multidimensional pattern is recorded, where each dimension can be regarded as an indicator for a single odorant concentration. Apparently, most of these sensor systems are not only stimulated by odorants, but also by odorless substances in the air, which leads to adverse cross-sensitivity effects. Conversely, not all odorants that stimulate the human olfactory perception also stimulate the various sensor systems, which leads to the effect that not all the odors perceptible by humans can be detected by the different kinds of IOMSs.

In practice, several kinds of IOMSs are used. For instance, gas chromatography (GC), ion-mobility spectroscopy (IMS), or electrochemical sensor arrays.

While the electrochemical sensor arrays are relatively cheap, they usually suffer from cross-sensitivity, drift effects after some time of exposure to the atmosphere, and the lack of enough independent dimensions to reliably characterize an odor. GC and IMS are well-established measurement principles for gas analysis and thus can also be used as IOMSs. For GC, the resulting chromatogram holds the multidimensional information on as many as possible odorants; for IMS it is the drift-time spectrum. Both GC and IMS are much more expensive than arrays of electrochemical sensors, but also much more effective in odor characterization.

Usually, methods of multivariate data analysis or pattern recognition techniques are applied to evaluate the multidimensional information obtained from the measurement systems.

In general, each IOMS must be calibrated using data obtained from measurements with the human nose, usually with measurement principles involving panel members as explained above. At present, there is no known system that is able to measure odors without a calibration based on human olfactory perception.

IOMS are able or will be able to measure specific odors depending on their training. However, the human nose is much more sensitive than any sensor technique currently available. With human noses, not only can odor concentration or the absence/presence of odors be measured, but the hedonic impression or nuisance level can also be determined. Especially for the determination of hedonic impression and nuisance level, an IOMS will not be usable in the near future.

21.4 Devices and Systems

As explained in the previous sections, the most important sensor system for measuring odors is the human nose. It is either used for direct measurement parameter recording or for calibration of IOMSs.

As technical devices used for odor measurement, the olfactometer plays a central role. IOMSs have recently been used for restricted measurement tasks as stated above. The basic operation principles of the devices were explained in Sect. 21.3.

Table 21.3 summarizes the devices introduced so far. Since IOMSs can only be regarded as supplemental sources of measurement data besides the conventional measurement principles described in Sect. 21.3.2, they are regarded here in general as IOMSs, without respect to the possible measurement principles realized within them. Also, the different kinds of olfactometers are regarded as a device class, without distinguishing between the models of different manufacturers.

Table 21.3 Advantages and disadvantages of the different device classes

Devices	Advantages	Disadvantages
Olfactometer	Direct measurement of any odor concentration using the human nose as sensor	Only batch investigations with relatively high expenditures due to necessary laboratory, device, and human resources
IOMSs	Fast measurement even under field conditions with the possibility of real-time applications	Indirect measurement of a specific odor concentration after calibration with olfactometer measurements

Fig. 21.1 Example for an olfactometer with panel members during a measurement (photo courtesy Olfasense)

Last but not least, it must be kept in mind that the device classes of olfactometers and IOMSs cannot be compared with each aspect of their application scope. IOMSs, for instance, are often used to distinguish between the absence and presence of a specific odor under study or to classify odors at reception level near the human perception threshold. Olfactometers, however,

Fig. 21.2 Example for an IOMS based on ion mobility spectroscopy

are used to investigate samples with much higher odor concentration by dilution to determine the odor concentration in odor units per volume.

Figure 21.1 shows an olfactometer along with the panel members during a measurement and Fig. 21.2 shows an ion-mobility spectrometer as an example of an IOMS.

21.5 Specifications

The measurement principles explained above have different application domains and are used to determine different measurement parameters. Therefore, a comparison of the specifications cannot be easily accomplished, as is possible for other measurement devices described in this book that use tables containing concrete numerical parameters. Here, it is rather useful to discuss the specifications of each measurement principle separately.

For IOMSs, no specifications can be given since the application of these devices is not yet investigated within the usual scope of a measurement principle.

21.5.1 Olfactometry Specifications

Olfactometry is primarily used to determine the odor concentration, though it is also possible to determine the hedonic impression. When describing specifications, it only makes sense for the odor concentration measurement, since the hedonic impression cannot be quantified.

For insight on specifications, especially measurement accuracy, it is important to review the measurement procedure. Starting at a very high dilution well below the perception threshold of the panel members, the concentration of the diluted sample is increased step-wise by a factor of two at each step until the aver-

age perception threshold of the panel is reached. Thus, the inherent resolution of the measurement principle is coupled to this increase step. If only one measurement is carried out, the uncertainty of the measurement result lies between half the result value and double the result value (a factor of two up and down). To reduce this quite large uncertainty, repeated measurements of the same sample are carried out (usually a total of three measurements). From a statistical view, each repetition reduces the statistical uncertainty by the factor 1.41 (square root of 2). In practice, the determination of the total uncertainty must consider the statistical uncertainty of the finite number of panel members (infinity would mean to have the average threshold value without uncertainty) and the systematic errors, for instance due to the precision of the dilution apparatus. A detailed description on handling the different uncertainties during olfactometry is given in [21.5].

The initial inherent uncertainty is of a factor two up and down and seems to be very high compared to the measurement of other atmospheric parameters. However, since according to Weber–Fechner’s law the physiological stimulus perceived by humans is proportional to the logarithm of the physical quantity (odor concentration, in this case), the measurement uncertainty can be expressed as approximately three decibels (correlates to a factor of two) on the logarithmic stim-

ulus scale. While the odor concentration can cover a range of several orders of magnitude between the perceptions *none* and *extremely strong* on the stimulus scale, the uncertainty of a factor of two up and down can be accepted, especially if it is further reduced by repeated measurements.

21.5.2 Field Inspection Specifications

Field inspection measurements are principally based on observations of the absence and presence of an odor under study by the panel members. Though, in special cases, the intensity of the stimulus is also recorded, the numerically useful information remains the panel member's decision between absence and presence. Thus, the resolution of a measurement consisting of these yes/no decisions basically depends on the number of independent single measurements. If just a single perception is recorded, the statistical uncertainty of this measurement is 50% if the panel member is presented with a stimulus near the perception threshold. It is to be expected that the panel member might err on the perception, so the single observation is either right or wrong with a probability of 50% each. To overcome this, repeated measurements are carried out over a certain period of time, typically for ten minutes with one observation every ten seconds (60 in total). If all the observations were independent of each other, the statistical uncertainty would be reduced by a factor of 1.41 (square root of 2) for each observation. So, a total number of 60 observations would significantly reduce the statistical uncertainty if all the observations were independent of each other, which of course they are not, since the conditions causing the absence or presence of an odor are not independent within a time span of ten minutes. So, since the dependency of the single observations from each other is very difficult to express and is different for each measurement, a specific uncertainty value cannot be given.

21.6 Quality Control

For odor measurements, quality control must be implemented in terms of the technical devices, laboratory operations, and panel members involved in the measurements. Detailed information on quality control is given in [21.3–5].

The olfactometer as primary device to measure odor concentration must be continuously checked, with a focus especially on the dilution apparatus. At least once every year the dilution apparatus must be checked or calibrated. This is a special challenge, since the range of the dilution factor covers several orders of magnitude and must be precise over the whole range.

To estimate the measurement uncertainty, an extended approach can be followed. It makes use of the odor hour concept, which by convention declares that an odor hour (time span of one hour, during which a human being has perceived the odor at least once) happens if during the ten-minute measurement period at least six of the 60 single observations stated an odor presence. This concept was introduced to quantify odor nuisance, which was found to be determined primarily by the percentage of odor hours with respect to the number hours in a whole year (perception frequency). If this perception frequency exceeds a certain value, for instance 10%, the overall odor nuisance can be regarded as substantial.

To measure the perception frequency, grid inspections are typically carried out with a total of 104 measurements over one year (two measurements each week). Once again, it can be accepted that the uncertainty of one single measurement is due to the yes/no decision if an odor hour was found or not, especially if the odor concentration in the field is close to the perception threshold. If the panel member doing the measurement is allowed to err in one measurement of the total 104, the overall error due to that single wrong measurement will be almost 1%. If errors happen more often, the yearly error percentage will increase accordingly.

One way to reduce statistical uncertainties is to make sure that the 104 single measurements are equally distributed over as many boundary conditions as possible: over the time of day, days of week, and the four seasons. Also, there should be no correlation between the mentioned boundary conditions and the panel members, meaning that each panel member should cover as much of the other boundary variances as possible. Then, even with the unfamiliar high statistical uncertainties, the results of a field inspection can be used to assess the perception frequency.

A detailed description of uncertainty handling for field inspections can be found in [21.3, 4].

Also, panel members must be checked in certain intervals, for instance every six months, to determine if their odor perception threshold is still within a certain range around the expected average. Since the minimum number of panel members usually is ten, it must be guaranteed that this comparatively (within the statistical context) low number of individuals does not contain members with extraordinary low or high odor perception threshold. The check is usually done by letting the members take part in ordinary olfactometry measurement with samples of known odor concentrations. To eliminate the need for calibrating this procedure, sam-

ples are prepared from neutral air mixed with a suitable amount of a substance with known odor threshold, for instance *n*-butanol.

Quality control on the level of overall laboratory operation includes full documentation of the regular check and maintenance activities and, if possible, the implementation of a recognized quality management system. Another way to ensure quality is to implement collaborative studies, where a uniform set of samples is investigated by different laboratories with the goal of obtaining comparable results.

Quality control for field inspections (grid and plume mode) are implemented on a general level through the

21.7 Maintenance

Maintenance, like quality control, includes activities pertaining to the devices, especially the olfactometer. Besides the activities to calibrate and check the dilution apparatus, cleaning procedures are especially necessary to prevent unwanted odors being emitted from parts of the measurement system itself. This applies not only

21.8 Application

As discussed in the first sections of this chapter, applications of odor measurements are different for the individual measurement parameters.

One of the most common applications of atmospheric odor measurements is the assessment of odor nuisances around facilities with odor emissions, such as industrial plants, agricultural operations (livestock), waste and wastewater treatment plants, or composting facilities. For this purpose, the measurement of perception frequency delivers a parameter to assess the degree of odor nuisance. Even if the expenditures for carrying out a full grid inspection over one year are quite high, this is the only way to obtain an assessment if modelling the odor perception frequency with dispersion models does not lead to reliable results.

Odor concentration measurement is the standard measurement to characterize the odor emission of the facilities mentioned above. If the amount of odor units emitted per unit time is known, this value can be used to assess the processes within the facilities or to act as input parameters for dispersion modeling. Figure 21.3 shows an example of simulated odor hour frequencies in the vicinity of several buildings.

Finally, though not actually within the context of atmospheric measurements, the odor characterization of consumer products (e.g., perfume scents and car smells) can be accomplished by determination of the hedonic impression.

procedures for the panel members described above. Furthermore, quality control on a situation-based level is carried out through plausibility considerations. Thus, for a field inspection, wind direction, for instance, is recorded to be able to decide if an odor source might contribute to an odor stimulus measured during a field inspection. Through these plausibility considerations, erroneous measurements can be sorted out.

Quality control for IOMSs is not currently an issue, however there are activities within the European Committee for Standardization (CEN) to develop standards for quality management for these devices as well.

to the olfactometer, but to all the components for sampling, diluting, and storing samples.

The panel members should not be regarded as being *maintained*, however regularly checking each member's odor threshold can be regarded as a maintenance activity pertaining to the panel as a whole.

Fig. 21.3 Example of simulated odor hour frequencies obtained from dispersion modeling

21.9 Future Developments

Olfactometry and field inspections are well-established measurement procedures. They deliver reliable results for odor concentration or perception frequency.

Current and future developments should pursue the goals of reducing the expenditures of measurements (field inspections), eliminating the human nose and instead using other sensors to objectify measurements, and obtaining online source monitoring (with odor concentration well above the perception threshold) to obtain an indicator for odor nuisance. For these goals, the development of IOMs plays an important role. As mentioned before, IOMs will become available for special measurement tasks, such as detecting the absence or presence of an odor or to classify odors, for instance to do source apportionment.

Odor concentration measurement with IOMs is still not broadly available and probably will not be in the near future, since changes in odor composition influence the device output the same way or even more than changes to the odor concentration itself.

IMS is currently one of the most promising techniques used for IOMs, since it combines a very sensitive sensor system with long-term stability and very short measurement cycles within the range of seconds.

Especially for IMS, the data handling is very complicated, since complex and nonlinear relationships between raw data (drift time spectra) and measurement parameters (odor concentration) must be evaluated. However, a lot of progress is expected within this field.

21.10 Further Readings

Ralf Petrich

IFU GmbH Privates Institut für Analytik
Frankenberg, Germany
ralf.petrich@ifu-analytik.de

Physicist Ralf Petrich received his PhD in the numerical evaluation of optical spectra. He has worked for NASA, Daimler-Benz, and the environmental office of the state of Saxony in Germany. Currently, he heads the development department at IFU GmbH, a private institute for analytics in Frankenberg, Germany. His primary fields of work are numerical modelling of pollution dispersion in ambient air and the development of technical approaches for odor measurement.

Axel Delan

IFU GmbH Privates Institut für Analytik
Frankenberg, Germany
axel.delan@ifu-analytik.de

Axel Delan is a physicist and managing director of IFU GmbH, a private institute for analytics in Frankenberg, Germany, that performs research and development on technical solutions for olfactometry. He has 25 years of experience managing an accredited and notified monitoring company for emissions and immissions of odors. Due to his wide experience, he works on international olfactometry standardization and is a publicly appointed and sworn authorized expert.

Visual Observations

Thomas Foken , Raymond Rülke

Visual observations of the state of the weather have been made for hundreds and thousands of years. Observers have always been impressed by natural phenomena. Since the beginning of measurements nearly 500 years ago, visual observations have become a relevant part of meteorological observations – even when they only represent empirical relationships. Although electronic sensors and automatization now significantly reduce the importance of visual observations made by direct measurements or the combination of measurements, some observations are still in use and are reported in this chapter. These include the Beaufort wind force scale, the cloud classification scheme, and the atmospheric visibility observation. These observations remain relevant because they cannot be easily replaced, as in the case of cloud classification, or they provide a fast overview of the meteorological situation in the absence of measurements.

Visual observations of the state of the weather and of weather phenomena have been made since ancient times and continue to be part of international and national observation programs [22.1]. With the ongoing automation of meteorological observations, visual observations have been or will be replaced by combinations of dif-

ferent measuring techniques. Nevertheless, visual observations are important when describing the present state of the weather and can also be used for very short-term weather forecasting (nowcasting). This chapter describes different observations and their classification according to international recommendations [22.2].

22.1 Principles of Visual Observations

Visual observations are rarely given in physical units, however the state of the atmosphere can be estimated or approximated in intervals of relevant parameters. Because a description of the state of the atmosphere is often dependent on an individual observer, a classification is made using the international weather code [22.3],

often in units from 0 to 9. Only for wind strength is a special unit employed, the Beaufort, which has been in use for about 200 years and is related to the appearance of the ocean surface, special states of trees, or damage to structures. The most important observed parameters are given in Table 22.1.

Table 22.1 Observed Parameters

Parameter	Description	Unit	Symbol
Weather conditions	Classification of the state of the weather		
Wind speed	Classification of the strength of the wind dependent on the conditions of the sea surface (e.g., waves) or on land (e.g., trees and buildings)	Bft	u
Wind direction	Derived from the movement of plants, etc.	°	
Cloud genera	Application of cloud atlases		
Cloud cover	Visual observation	Octa	C_H, C_M, C_L
Height of clouds	Height of the cloud base and vertical extension	km	
Precipitation	Classification of the amount, duration, and frequency Type of precipitation: rain, snow, hail, etc.	mm, h	R_N
Visibility	Visibility/distance of landmarks	km	
State of surface	Classification of the state of the soil surface or soil		

22.2 History

The beginnings of the visual observations discussed in this section are related to the first classifications of weather phenomena and the use of this information in observation diaries together with measured data. Diaries with visual observations have been kept since ancient times and their information is still apparent in many weather proverbs, like the weather records for Oxford and Driby for 1337–1344 by the cleric *William Merle* (†1347) [22.4]. Since the beginning of aircraft-based measurements, pilots also made visual observations, and until the middle of the twentieth century so-called *weather flights* were carried out. Even today, pilot reports contribute to upper-air monitoring.

22.2.1 Classification of Visual Observations

The classification of visual observations is closely connected with the implementation of the weather code used in telegraphy. However, for clouds and wind speed, useful classifications were developed long before.

Classification of Clouds

Surprisingly, a classification for clouds only dates back to the beginning of nineteenth century based on the early ideas of *Robert Hooke* (1635–1703) [22.5]. The first comprehensive classification was made by the French naturalist *Jean-Baptist Lamarck* (1744–1829) [22.6], who classified five main cloud types with 12 species. But this classification was not successful due to the complicated French descriptions. For a long time, the classification system presented in 1802 by the English chemist and businessman *Luke Howard* (1772–1864) was widely distributed [22.7–9] and used by scientists and even artists and poets (*Alexander von Humboldt*, 1769–1859, *Johann Wolfgang von Goethe*,

1749–1832 [22.10]). Howard used Latin for his classification system, separating the clouds into families (categories), genera (forms), and species, after the classification of plants from *Carl Linnaeus* (1707–1778). He defined four main categories of clouds: cumulus, stratus, cirrus, and nimbus. This system has remained nearly unchanged up to the present day. Howard found that there are forms in between these categories: cumulus-stratus, cirrocumulus, and cirrostratus. Stratocumulus, another cloud type, was described by *Ludwig Friedrich Kämtz* (1801–1867) in 1840 [22.11]. The distinction between cirrostratus and cirrocumulus as well as altostratus and altocumulus was explained by *Émilien Renou* (1815–1902) [22.12] in 1855 and cumulonimbus was described by *Philippe Weilbach* in 1880 [22.13]. Finally, nimbostratus was defined by the International Commission for the Study of Clouds in 1930.

Several classifications that were developed in the nineteenth century are listed in [22.14], but significant progress was made when cloud photographs became available. *Albert Riegenbach* (1854–1921) [22.15] and *Ralph Abercromby* (1842–1897) were pioneers in cloud photography and a selection of their photos was published in [22.14]. Based on this work, Abercromby [22.16] and *Hugo Hildebrand Hildebrands-son* (1838–1920) [22.17] updated Howard's classification and published a classification that was similar to the classification adopted in 1894 by the International Meteorological Conference (see Chap. 1). Two years later, the first International Cloud Atlas was published [22.18]. The first weather satellite of the Television Infrared Observation Satellite (TIROS) program began a new chapter of cloud photography from space in 1960. Of course, the first TIROS pictures [22.14] cannot compare with the high-resolution images from modern satellites.

Scaling of the Wind Speed

In the eighteenth century, wind speed observations were mostly unsatisfactory for sailing ships and windmills. The engineer *John Smeaton* (1724–1792) was probably one of the first to define terms for different classes of wind speeds for wind mill applications. The first hydrographer of the British Admiralty, *Alexander Dalrymple* (1737–1808), combined these terms with those of sea-faring [22.19]. *Francis Beaufort* (1774–1857) included this list of terms in his weather diaries [22.20] in 1806 and used it for his own observations. From 1807 he developed his own scale and first used it on the cruises of the *Beagle* in 1831. Two years prior, in 1829, the Royal Navy had appointed Beaufort as hydrographer. In 1838 the British Admiralty adopted his scale for all ships, as did the International Meteorological Congress in Brussels in 1853 [22.21, 22]. In an instruction of the Smithsonian Institute from 1870, the Beaufort scale was first applied to wind observations on land [22.19].

22.2.2 Diaries and Codes of Visual Observations

In the first manuals for weather observations provided by *Robert Hooke* (1635–1703) [22.5], the coverage and genera of clouds were recommended weather observations in addition to measurements. These observations have been part of weather diaries since that time, together with instrumental observations (see Chap. 1, Sect. 1.2.2). The description of these visual observations was presented in accordance with the experience of the

observer and recordings were still not performed in the standardized manner that became available one to two centuries later. Within the first meteorological network of the *Societas Meteorologica Palatina* [22.23], written descriptions of weather phenomena were replaced by symbols in 1780 to unify the observations. This classification was further enhanced and, in 1873/74, the International Meteorological Conference (see Chap. 1, Sect. 1.2.3) proposed a selection of symbols that has remained valid to the present day (see Sect. 22.4.1).

Karl Kreil (1798–1862), who was Director of the Zentralanstalt für Meteorologie und Erdmagnetismus in Vienna between 1851 and 1862, proposed the use of the electric telegraph, developed between 1833 and 1835 in Göttingen, for the transmission of weather data. About 20 years later during the Crimean War, a heavy storm on 14 November 1854 resulted in the loss of many vessels. Following this, in 1856, the French weather service established the transmission of weather observations by telegraphy to enable the preparation of weather maps [22.4]. From this time it became necessary to make use of numerical codes for visual observations as well. A revised system of these codes was presented at the Conference of Directors of the International Meteorological Organization in Copenhagen in 1929. After the Second World War, the Conference of Directors in Washington D.C., in 1947, and especially a follow-up conference in London, proposed a modified weather code similar to the present form [22.24]. The first edition of the Manual of Codes was issued in 1971 and has been updated regularly until today [22.3].

22.3 Theory

There is no theory behind visual observations, but each observation follows certain international [22.2, 3] or national [22.25] regulations. This makes visual ob-

servations comparable and minimizes the subjective influence of individual evaluations.

22.4 Observed Parameters

Several meteorological elements and phenomena can be observed visually and are described in this section. To make visual observations comparable, code figures are used that are identical to the weather codes listed in the Handbook of Codes [22.3]. The use of code figures facilitates storage and application in digital databases. In the tables of this section the relevant code figures are shown for comparison with the World Meteorological Organization (WMO) regulations. However, the listed tables of code figures contain only a selection of the most common; for more details see the Handbook of Codes [22.3].

22.4.1 Weather Phenomena

The most important visual observations describe the status of present or past weather. The Handbook of Codes [22.3] lists 100 different phenomena and uses the code symbol *ww* representing the numbers 00 to 99. An overview of when one of these numbers applies, is given in Table 22.2; for details see [22.3]. Furthermore, a one-digit code *W* characterizes the weather of the last hour; see Table 22.3. The most important symbols related to *ww* codes are shown in Table 22.4 and

Table 22.2 Present weather phenomena according to the code figure ww [22.3]

Code figure (ww)	Present weather phenomena
00–49	No precipitation at the station at the time of observation
00–19	Fog, ice fog, duststorm, sandstorm, or drifting or blowing snow at the station at the time of observation or during the preceding hour
20–29	Precipitation, fog, ice fog, or thunderstorm at the station during the preceding hour but not at the time of observation
30–39	Duststorm, sandstorm, or drifting or blowing snow
40–49	Fog or ice fog
50–59	Drizzle
60–69	Rain
70–79	Solid precipitation not in showers
80–99	Showery precipitation or precipitation with current or recent thunderstorm

Table 22.3 Weather during past hour according to the code figure W [22.3]

Code figure (W)	Past weather
0	Cloud covering 1/2 or less of the sky throughout the appropriate period
1	Cloud covering more than 1/2 of the sky during part of the appropriate period and covering 1/2 or less during part of the period
2	Cloud covering more than 1/2 of the sky throughout the appropriate period
3	Sandstorm, duststorm, or blowing snow
4	Fog, ice fog, or thick haze
5	Drizzle
6	Rain
7	Snow or mixed rain and snow
8	Shower(s)
9	Thunderstorm(s) with or without rain

the intensities of falling hydrometeors are given in Table 22.5.

The various weather phenomena can be described in the following way [22.25]:

Haze: Relative humidity < 80%. The air contains very fine, solid, or liquid particles (dust, aerosol) that considerably reduce the transparency of air, however the visibility is at least 1 km.

Mist: Relative humidity \geq 80%. Tiny water particles suspended in the atmosphere reduce visibility. Visibility is between 1 and \approx 8 km.

Fog: Very small water droplets are suspended in the air near the Earth's surface, which reduce the horizontal visibility to values < 1000 m. The sky may still be visible above.

Table 22.4 Some selected symbols for ww code figure. The combination of a symbol with] is used for phenomena in the last hour. Symbols after [22.25] with permission from VDI e. V. Düsseldorf, Germany

ww code figure	Symbol	Weather phenomena
05		Haze
10		Mist
13		Lightning visible, no thunder heard
17		Thunderstorm, but no precipitation at the time of observation
31		Slight or moderate duststorm or sandstorm
45		Fog or ice fog, sky invisible
50		Drizzle, not freezing, intermittent, slight at time of observation ^a
53		Drizzle, not freezing, continuous, moderate at time of observation ^a
57		Drizzle, freezing, moderate or heavy (dense)
60		Rain, not freezing, intermittent, slight at time of observation ^a
70		Intermittent fall of snowflakes, slight at time of observation ^a
80		Rain shower(s), slight ^a
89		Shower(s) of hail, with or without rain or rain and snow mixed, not associated with thunder, slight ^a
95		Thunderstorm, slight or moderate, without hail, but with rain and/or snow at time of observation ^a

^a For intensities, see Table 22.5

Dust and sand: Lithometeors can be raised by strong, turbulent wind and reduce visibility. During a duststorm or sandstorm, an extensive area is affected with dust-filled air and visibility < 1 km.

Drizzle: Precipitation consisting of very fine water droplets < 0.3 mm in diameter. Supercooled droplets with a temperature < 0°C may turn into a thin layer of ice or black ice immediately on impact with the ground or other objects.

Rain: Precipitation of falling and clearly visible drops > 0.3 mm in diameter. Supercooled droplets with a temperature < 0°C may turn into a thin layer of ice or black ice immediately on impact with the ground or other objects.

Snow: Precipitation in the form of ice crystals, mainly of intricately branched, hexagonal form and of-

Table 22.5 Intensity of falling hydrometeors (drizzle, rain, snow) [22.2]

Variable	Range (mm h ⁻¹)	Intensity ^a
Drizzle	< 0.1	Light
	0.1 to < 0.5	Moderate
	≥ 0.5	Heavy
Rain (also showers)	< 2.5	Light
	2.5 to < 10.0	Moderate
	10.0 to < 50.0	Heavy
	≥ 50.0	Violent (intense, extreme)
Snow (also showers)	< 1.0 (water equivalent)	Light
	1.0 to < 5.0 (water equivalent)	Moderate
	≥ 5.0 (water equivalent)	Heavy

^a Intensity values based on a 3-min recording period

ten agglomerated into snowflakes, formed directly from the freezing of water vapor in the air. A mixture of snow and rain is called *rain and snow mixed*.

Hail: Showery precipitation consisting of irregular pellets or balls of ice, more or less solid, round to oval, and diameters mostly ranging between 5 and 50 mm. Larger hailstones may also occur.

Showers: Precipitation events characterized by the suddenness with which they start and stop, and by rapid changes of intensity.

Lightning: Visible electrical discharge in association with a thunderstorm. Lightning may occur between clouds (intracloud) or between a cloud and the ground.

Thunderstorm: A local storm produced by a cumulonimbus cloud and accompanied by lightning and thunder. The time gap between lightning discharge and audible thunder is ≤ 10 s (≈ 3 km) for very close thunderstorms.

Table 22.6 Wind force according to the Beaufort scale (Bft) for open sea and 10 m ASL [22.2]

Number (Bft)	Description term	Wind speed range		Maximal wave height (m)	Specification
		(kn)	(m s ⁻¹)		
0	Calm	< 1	0–0.2		Sea like a mirror
1	Light air	1–3	0.3–1.5	0.1	Ripples with the appearance of scales are formed, but without foam crests
2	Light breeze	4–6	1.6–3.3	0.3	Small wavelets; still short but more pronounced; crests have a glassy appearance and do not break
3	Gentle breeze	7–10	3.4–5.4	1.0	Large wavelets; crests begin to break; foam of glassy appearance; perhaps scattered white horses
4	Moderate breeze	11–16	5.5–7.9	1.5	Small waves, becoming longer; fairly frequent white horses
5	Fresh breeze	17–21	8.0–10.7	2.5	Moderate waves, taking a more pronounced long form; many white horses are formed (chance of some spray)
6	Strong breeze	22–27	10.8–13.8	4.0	Large waves begin to form; the white foam crests are more extensive everywhere (probably some spray)
7	Near gale	28–33	13.9–17.1	5.5	Sea heaps up and white foam from breaking waves begins to be blown in streaks along the direction of the wind
8	Gale	34–40	17.2–20.7	7.5	Moderately high waves of greater length; edges of crests begin to break into the spindrift; the foam is blown in well marked streaks along the direction of the wind
9	Strong gale	41–47	20.8–24.4	10.0	High waves; dense streaks of foam along the direction of the wind; crests of waves begin to topple, tumble and roll over; spray may affect visibility
10	Storm	48–55	24.5–28.4	12.5	Very high waves with long overhanging crests; the resulting foam, in great patches, is blown in dense white streaks along the direction of the wind; on the whole, the surface of the sea takes a white appearance; the <i>tumbling</i> of the sea becomes heavy and shock-like; visibility affected
11	Violent storm	56–63	28.5–32.6	16.0	Exceptionally high waves (small and medium-sized ships might be lost to view behind the waves); the sea is completely covered with long white patches of foam lying along the direction of the wind; everywhere, the edges of the wave crests are blown into froth; visibility affected
12	Hurricane	≥ 64	≥ 32.7	–	The air is filled with foam and spray; sea completely white with driving spray; visibility very seriously affected

Table 22.7 Wind force according to the Beaufort scale over land for the standard measurement height of 10 m [22.2]

Number (Bft)	Description term	Wind speed range		Specification	
		(m s ⁻¹)	(km h ⁻¹)	With plants as an indicator	Other indicators
0	Calm	0–0.2	< 1		Calm; smoke rises vertically
1	Light air	0.3–1.5	1–5		Direction of wind shown by smoke drift but not by wind vanes; no noticeable wind; smoke rises nearly vertically
2	Light breeze	1.6–3.3	6–11	Leaves rustle	Ordinary vanes moved by wind; wind felt on face
3	Gentle breeze	3.4–5.4	12–19	Leaves and small twigs in constant motion	Wind extends light flag; hair is disturbed
4	Moderate breeze	5.5–7.9	20–28	Small branches are moved	Dust and loose paper raised, hair disarranged
5	Fresh breeze	8.0–10.7	29–38	Small trees in leaf begin to sway	Crested wavelets form on inland waters; force of wind felt on body
6	Strong breeze	10.8–13.8	39–49	Large branches in motion	Some inconvenience in walking; whistling heard in telegraph wires; umbrellas used with difficulty
7	Near gale	13.9–17.1	50–61	Whole trees in motion	Inconvenience felt when walking against the wind
8	Gale	17.2–20.7	62–74	Breaks twigs off trees	Generally impedes progress; difficulty with balance in walking
9	Strong gale	20.8–24.4	75–88		Slight structural damage occurs (chimney pots and slates removed)
10	Storm	24.5–28.4	89–102	Trees uprooted	Considerable structural damage occurs
11	Violent storm	28.5–32.6	103–117	Very rarely experienced	Widespread damage
12	Hurricane force	≥ 32.7	≥ 118	Devastation	Devastation

22.4.2 Wind Speed and Direction

Wind speed and wind direction can be easily observed by detection of its influence on water surfaces, plants, and obstacles in the surroundings of the observer.

Wind Speed

The wind speed can be observed as wind force according to the *Beaufort* scale (Bft), which is a method that converts the effects of the wind into a scale. The wind forces are still in use in the weather forecast, even when they are not observed, but calculated from the wind speed (Tables 22.6 and 22.7). The scale was developed for effects on the sea surface but was adapted to the effects of wind on land (Table 22.7).

Wind Direction

For observing wind direction, the exact knowledge of the north direction or another direction is essential. In the case of high wind speeds, the observation of the wind direction is relatively easy. The direction should be estimated by observing the drift of smoke, movement of leaves, or the like. At an airport, a wind drogue may be used. Due to the friction in the atmospheric boundary layer (see Chap. 1) the wind direction changes with height, such that the surface wind (usu-

ally measured at a height of 10 m AGL, see Chap. 9), is different from the direction of the geostrophic wind above the atmospheric boundary layer. Therefore the movement of clouds cannot be applied [22.2]. The description of wind directions and their coding is given in Table 22.8.

22.4.3 Clouds

Cloud observation is fascinating with respect to the variety and mutability of cloud appearance and formation. Cloud measurement needs an enormous technical effort and is described in Chaps. 24, 25, 27, 30, 31. For the visual observation of clouds, cloud atlases should be applied as they provide not only descriptions of clouds but also numerous pictures and diagrams. Recently published atlases are [22.26, 27].

Three cloud parameters should be observed: the genera (type) of clouds, the cloud cover of the sky, and the height of cloud base and vertical extension. Furthermore, besides the genera, species and varieties can also be observed, with cloud atlases supplying details. Exact visual determination of the cloud base height in accordance with the present code numbers – up to 3 km in 30 m increments and > 3 km in 100 m increments – is hardly possible.

Table 22.8 Observation of the wind direction (after [22.25] with permission from VDI e. V. Düsseldorf, Germany)

Name of direction	Direction code	Wind rose with direction code and code number
North	N	
Northeast	NE	
East	E	
Southeast	SE	
South	S	
Southwest	SW	
West	W	
Northwest	NW	
Calm	C	C or 00, always combined with wind force 0 Bft

Cloud Genera (Type)

Clouds are grouped into three main categories: high-level, mid-level, and low-level clouds, depending on the height of the respective cloud bases. There are ten main cloud types (genera), which are assigned to these three altitude levels. Clouds with a large vertical extent belong to the low-level cloud section while the nimbostratus becomes part of the mid-level for synoptic reasons. This classification is described in Table 22.9, while Fig. 22.1 shows images of typical clouds for the genera.

The following definitions of the cloud genera are presented according to the WMO [22.26]:

Cirrus (Ci): Detached clouds in the form of white, delicate filaments or white or mostly white patches or narrow bands. These clouds have a fibrous (hair-like) appearance, a silky sheen, or both.

Cirrocumulus (Cc): Thin, white patch, sheet, or layer of cloud without shading; composed of very small elements in the form of grains, ripples, etc., merged or

separate, and more or less regularly arranged; most of the elements have an apparent width of $< 1^\circ$.

Cirrostratus (Cs): Transparent, whitish cloud veil of fibrous (hair-like) or smooth appearance; totally or partly covering the sky; generally produce a halo phenomena.

Alto cumulus (Ac): White or grey, or both white and grey, patch, sheet, or layer of cloud; generally with shading, composed of laminae (a layer or layers), rounded masses, rolls, etc., which are sometimes partly fibrous or diffuse and which may or may not be merged; most of the regularly arranged small elements usually have an apparent width of between 1° and 5° .

Altostratus (As): Greyish or bluish cloud sheet or layer of striated (grooves or channels in cloud formations, arranged parallel to the flow of the air), fibrous, or uniform appearance, totally or partly covering the sky, and having parts thin enough to reveal the Sun at least vaguely, as through ground glass or frosted glass. Altostratus does not show halo phenomena.

Table 22.9 Cloud base height of genera above ground level in temperate regions [22.2]

Code figure	Level	Genera (type)	Genera code	Usual range of height (wider range) (km)	Remarks
0	High (C_H)	Cirrus	Ci	6–12	Ci from dissipating Cb may occur below 6.0
1		Cirrocumulus	Cc	6–12	
2	Middle (C_M)	Cirrostratus	Cs	6–12	Cs may develop in As
3		Alto cumulus	Ac	2–6	
4		Altostratus	As	2–6	As may thicken with progressive lowering of the base to become Ns
5		Nimbostratus	Ns	Surface – 3	Ns is considered a mid-level cloud for synoptic purposes, although it can extend to other levels
6	Low (C_L)	Stratus	St	Surface – 0.6 (1.2)	
7		Stratocumulus	Sc	0.3–1.35 (2.0)	For stations over 150 m ASL the base of low-level clouds will often be less than indicated
8		Cumulus	Cu	0.3–1.5 (2.0)	
9		Cumulonimbus	Cb	0.6–1.5 (2.0)	

Fig. 22.1 Cloud genera (types) according to Table 22.9. Photos © B. Mühr

Nimbostratus (Ns): Grey cloud layer, often dark, the appearance of which is made diffuse by more or less continuously falling rain or snow, which in most cases reaches the ground. It is thick enough throughout to blot out the Sun. Low, ragged clouds frequently occur below the layer, with which they may or may not merge.

Stratocumulus (Sc): Grey or whitish, or both grey and whitish, patch, sheet, or layer of cloud that almost always has dark parts; composed of tessellations, rounded masses, rolls, etc., which are nonfibrous (except for virga) and which may or may not be merged; most of the regularly arranged small elements have an apparent width of $> 5^\circ$.

Stratus (St): Generally grey cloud layer with a fairly uniform base, which may give drizzle, snow, or snow grains. When the Sun is visible through the cloud, its outline is clearly discernible. Stratus does not produce halo phenomena except, possibly, at very low temperatures. Sometimes stratus appears in the form of ragged patches.

Cumulus (Cu): Detached clouds, generally dense with sharp outlines, and developing vertically in the form of rising mounds, domes, or towers, of which the bulging upper part often resembles cauliflower. The sunlit parts of these clouds are mostly brilliant white; their bases are relatively dark and nearly horizontal. Sometimes cumulus is ragged.

Cumulonimbus (Cb): Heavy, dense cloud with a considerable vertical extent in the form of a mountain or huge towers. At least part of its upper portion is usually smooth, fibrous, or striated, and nearly always flattened; this part often spreads out in the shape of an anvil or vast plume. Under the base of this cloud, which is often very dark, there are frequently low ragged clouds either merged with it or not, and precipitation sometimes in the form of virga.

Besides these genera, further classifications are possible such as *species* that characterize special forms of the clouds or *varieties* that characterize, for example, the transparency of a cloud. Furthermore, *supplementary features* or *accessory clouds* and a few *special clouds* are classified [22.26].

Cloud Cover

The coverage of the sky by clouds is measured in oktas, where 0/8 is only given for a totally cloud free sky and 8/8 only if no blue sky is visible at all. Clouds that are present within an elevation angle between the horizon and 5° – 8° are not considered. The scheme is documented in Table 22.10. The value of cloud cover can also be separated for high-level (C_H), mid-level (C_M), and low-level (C_L) clouds.

Table 22.10 Cloud cover observation [22.2]

Code figure (N)	Okta	Meaning in tenths
0	0	0
1	1 okta or less, but not zero	1/10 or less, but not zero
2	2 oktas	2/10–3/10
3	3 oktas	4/10
4	4 oktas	5/10
6	6 oktas	7/10–8/10
7	7 oktas or more, but not 8 oktas	9/10 or more, but not 10/10
8	8 oktas	10/10
9	Sky obscured by fog and/or other meteorological phenomena	
/	Cloud cover is indiscernible for reasons other than fog or other meteorological phenomena, or observation is not made	

Cameras are specifically designed to measure cloud cover. For example, they scan the entire sky using curved mirrors. The image from the sky is analyzed to calculate the proportion of cloud cover [22.2].

22.4.4 Visibility

Visibility was first defined for meteorological purposes as a quantity to be estimated by a human observer, and observations made in that way are widely used [22.2]. This is, of course, a very subjective factor. More objective is the measurement of the transparency of the atmosphere represented by the meteorological optical range (MOR) (see Chap. 13). Visibility observations by a human observer depend on the photometric and dimensional characteristics of the object and the individual contrast threshold of the observer. At night, the intensity of light sources, the sensitivity of the observer's eyes to darkness, and the observer's illuminance threshold are of great importance for the observation of visibility.

Table 22.11 Horizontal visibility [22.3]

Code figure (w_e)	Visibility (m)
0	< 50
1	50–199
2	200–499
3	500–999
4	1000–1999
5	2000–3999
6	4000–9999
7	10 000–19 999
8	20 000–49 999
9	$\geq 50 000$

Table 22.12 State of the ground without snow or measurable ice cover. Numbers 0–2 and 4 apply to representative bare ground and numbers 3 and 5–9 to an open representative area [22.3]

Code figure (E)	State of the ground
0	Surface of ground dry (without cracks and no appreciable amount of dust or loose sand)
1	Surface of ground moist
2	Surface of ground wet (standing water in small or large pools on surface)
3	Flooded
4	Surface of ground frozen
5	Glaze on ground
6	Loose dry dust or sand not covering ground completely
7	Thin cover of loose, dry dust or sand covering ground completely
8	Moderate or thick cover of loose, dry dust, or sand covering ground completely
9	Extremely dry with cracks

For observations, landmarks are necessary for daytime and lamps for nighttime visibility. The following are example landmarks that can be selected:

- For distances up to 1 km: utility poles, traffic signs, trees, bushes, or houses
- For distances up to 5 km: houses, poles, or towers
- For larger distances: mountain ridges, mountain peaks, or towers

The visibility ranges together with the code figure are given in Table 22.11.

22.4.5 State of the Ground

The observation of the conditions near or on the Earth's surface gives information about its state, for example, whether it is wet or dry, or covered by snow or ice. It is an indicator of the recent weather or the weather in the past,

Table 22.13 State of the ground with snow or measurable ice cover for an open representative area [22.3]

Code figure (E')	State of the ground
0	Ground predominantly covered by ice
1	Compact or wet snow (with or without ice) covering less than one half of the ground
2	Compact or wet snow (with or without ice) covering at least one half of the ground but ground not completely covered
3	Even layer of compact or wet snow covering ground completely
4	Uneven layer of compact or wet snow covering ground completely
5	Loose, dry snow covering less than one half of the ground
6	Loose, dry snow covering at least one half of the ground but ground not completely covered
7	Even layer of loose, dry snow covering ground completely
8	Uneven layer of loose, dry snow covering ground completely
9	Snow covering ground completely; deep drifts (50 cm or more above the general snow surface)

and can indicate dangerous situations for agriculture, air travel, ground traffic, etc. Tables 22.12 and 22.13 give an overview of states of the ground and code figures for situations with and without ice and snow cover.

22.4.6 Comparison of Visual and Instrumental Observations

Visual observations have the disadvantage that their results cannot be given in exact numbers and the code figures [22.3] only provide the means to compare and to use these observations for weather prediction or nowcasting. Nevertheless, visual observations can give many details of the state of the weather and weather phenomena that cannot easily be measured with instruments. Table 22.14 is an attempt to show the advantages and disadvantages of visual observations.

Table 22.14 Advantages and disadvantages of visual observations in comparison to direct measurements

Visual observations	Advantages	Disadvantages
Weather phenomena	Very many details on intensities, etc., can be detected	Exact numbers, e.g., for intensities, amounts, or duration, cannot be given
Wind speed (Beaufort scale)	Evaluation of the wind speed and possible damage	Only estimation of possible wind speeds
Wind direction		Might not be very precise
Cloud genera (type)	Cloud genera as well as species and varieties can be observed in great detail (dependent on the observer)	Different observers might not have the same results
Cloud cover	Observation of the whole sky	Accuracy depends on the observer's skills
Cloud base height		Not exact, only rough estimation
Visibility	Visibility information even for sectors possible	Accuracy depends on the observer
State of ground	Very many details possible	

22.5 Quality Control

The quality of visual observations is highly dependent on the experience and abilities of the observer. Observers should therefore compare and discuss their ob-

servations to enable uniform data quality. Where possible, such as for cloud height or wind speed, the observations should also be compared with measured data.

22.6 Application

The reduction in the number of manned meteorological stations, due mainly to their high cost, has resulted in a reduction in the density of visual observations. The amount of data decreases as well as the possibility for the application of these data. Nevertheless, mainly for nowcasting, these observations are still helpful.

Because time series of visual observations are much longer than those of instrumental measurements, it is strongly recommended that these observations, at least at selected meteorological stations, should be continued.

At some very exposed locations like mountain crests or summits, technical equipment and instruments are subjected to very harsh environmental conditions.

At least at certain times, precise measurements cannot be performed or guaranteed at these locations. Particularly at these locations, visual observations are of great importance for obtaining any information about the state of the weather.

In the past, visual observations were used, for example by farmers, for short-term weather forecasts with high precision for a time period of up to 24 h and sometimes even longer under special synoptic situations. Unfortunately, observers with appropriate experience are rarely available. Nevertheless, the general interest in weather phenomena and their documentation still persists. Additionally, continuous and high-quality manual observation is costly.

22.7 Future Developments

Due to the reduction of manned meteorological stations for mainly financial reasons and their replacement by automatic weather stations, there is an urgent need to replace visual observations with instrumental methods. For some meteorological elements this can be easily done (e.g., cloud height), while other parameters re-

quire complex combinations of different sensors (e.g., cloud cover), otherwise valuable and detailed information will no longer be available (e.g., cloud genera). The process of replacing the observations is ongoing and different meteorological services will probably develop their own systems (Table 22.15).

Table 22.15 Meteorological elements that are typically derived from visual observations and possible replacement techniques according to information from the German Meteorological Service

Meteorological element	Visual observation	Replacement technique	Chap.
State of weather	Estimation	Present weather sensor and other techniques	12, 13
Visibility	Estimation with distance marks	Visibility sensors	13
		Lidar	26
Cloud height	Estimation	Ceilometer	24
Cloud coverage	Estimation	Ceilometer	24
		Weather radar	30
		Radar in mm range	32
		Cloud camera	
Cloud genera	Estimation with cloud atlas	Cloud camera	
		Satellite image	42, [22.28]
Snow height	Snow level	Snow height sensor	
Snow water content	Snow scale	Snow and ice accumulation sensor	
Precipitation intensity and type	Estimation	Present weather sensor	12
		Radar in mm range	32
Thunderstorm	Estimation	Lightning and other sensors	14
Soil conditions	Estimation	Imaging techniques	42, [22.28]

Another solution is the implementation of additional available stations (commercial and private) in the meteorological network (see Chap. 43) or even the crowdsourcing of simple measurements (see Chap. 44).

Hopefully, the variability, beauty, and spectacular impression of weather phenomena will still be of interest to enthusiasts even when these observations are not part of the standard meteorological observations.

Sodar and RASS

Stefan Emeis 

Vertical profiles of the wind speed, turbulence components, and the temperature in the lower regions of the atmospheric boundary layer can be determined by performing active acoustic and radioacoustic sounding with ground-based devices. This chapter introduces two types of instruments—sound detection and ranging (sodar) devices and radioacoustic sounding systems (RASS)—that can be used to carry out such measurements. While sodars can provide quantitative vertical wind and turbulence profiles and qualitative mixed-layer height and inversion height data, RASS can provide that as well as quantitative temperature profiles. Both types of instruments have a typical height range of several hundreds of meters, and their vertical resolution is on the order of 20 m.

Ground-based sonic/sound detection and ranging (sodar) devices and radioacoustic sounding systems (RASS) are active remote-sensing devices that are used to observe boundary-layer wind, turbulence, and—in the case of RASS—temperature profiles (see [23.1] for an overview of all ground-based remote-sensing techniques that are used to investigate and monitor the atmospheric boundary layer). A sodar evaluates the Doppler shifts of sound waves backscattered due to

refraction index fluctuations caused by the small temperature and humidity gradients present in atmospheric turbulence, whereas a RASS emits electromagnetic and acoustic waves and uses one of them (either electromagnetic or acoustic waves) to follow the propagation of the other (acoustic or electromagnetic waves, respectively), which permits the determination of the speed of sound and thus the temperature of the atmosphere.

23.1 Measurement Principles and Parameters

Sodar and RASS devices are used to obtain boundary layer profiles of wind, turbulence, and temperature. Note that, just like many well-established and commonly used abbreviations (such as *radar*), *sodar* and *lidar* are often written in lowercase letters—as they are throughout this chapter. However, the acronym RASS is still generally written in uppercase letters.

23.1.1 Relevance of Wind, Turbulence, and Temperature Measurements of the Atmospheric Boundary Layer

Temperature, humidity, and wind are the main parameters that determine the vertical structure of the atmospheric boundary layer. While the vertical profiles of temperature and humidity are mainly responsible for the static stability of this layer, wind and turbulence dominate the dynamics of the boundary layer.

The static and dynamic states of the boundary layer dictate the strengths and the directions of fluxes of energy, momentum, and other atmospheric constituents (humidity and pollutants) between the Earth's surface and the atmosphere. The strengths of these fluxes correlate with shear and turbulence intensity. The direction is given by the gradient of the mean of the transported property.

The horizontal and vertical dispersions of pollutants correlate with the turbulence intensity. Pollutants that have been dispersed upward by turbulence and are transported upward by thermal convection during the day can undergo considerable horizontal displacement during the night due to stronger winds or even low-level jets [23.2] above the stable near-surface layer.

Wind turbines have become much larger in recent years. Hub heights of between 100 and 150 m are common for modern onshore turbines [23.3]. These turbines operate in the Ekman layer. Remote sensing is the only meaningful way to detect and monitor winds and turbulence at these heights (see Chap. 51 for further details).

23.1.2 Measured Parameters

In contrast to other meteorological variables, the wind is a vector, i.e., it is characterized by a magnitude (the wind speed) and a direction (the wind direction). Generally (except in small-scale and convective processes), the vertical wind component is much smaller than the horizontal wind components, so often only horizontal wind speeds are measured. Furthermore, wind is a highly variable atmospheric parameter; its speed and direction fluctuate strongly. This phenomenon is called the gustiness of the wind.

In the following, x and y are the two horizontal directions (positive towards the east and the north, respectively), z is the vertical direction (positive upward), and $u(t)$, $v(t)$, and $w(t)$ are the three instantaneous time-dependent wind components in the three directions x , y , and z . The following wind speeds can be defined (see Tables 23.1 and 23.2):

- The mean wind speed

$$\bar{u} = \frac{1}{T} \int_0^T \sqrt{u^2(t) + v^2(t) + w^2(t)} dt, \quad (23.1)$$

- The mean horizontal wind speed

$$\bar{u}_h = \frac{1}{T} \int_0^T \sqrt{u^2(t) + v^2(t)} dt, \quad (23.2)$$

- And the mean vertical velocity

$$\bar{w} = \frac{1}{T} \int_0^T w(t) dt, \quad (23.3)$$

where the integral in the following equations is always taken from time $t = 0$ to the end of the time period T over which the speeds are averaged.

Furthermore, sodars and RASS are able to observe the variance of the vertical wind component (see Tables 23.1 and 23.2)

$$\sigma_w = \sqrt{\frac{1}{T} \int_0^T (\bar{w} - w(t))^2 dt}. \quad (23.4)$$

The only turbulence parameter obtained using sodar and RASS is the variance of the vertical velocity component σ_w .

The acoustic temperature T_s (Table 23.2) can be obtained using a RASS. The exact definition of this temperature, which is very similar to the virtual temperature, is given in (23.10) in Sect. 23.3.1 below.

23.1.3 Siting Considerations

Sodars and RASS are sensitive to noise but they also produce noise. This is also true of electromagnetic radiation for RASS. This limits the selection of possible sodar or RASS measurement sites and implies that sodars and RASS cannot be operated close together

Table 23.1 Parameters derived from sodar measurements

Parameter	Description	Unit	Symbol
Radial wind components	Doppler analysis only permits the derivation of radial velocities; sodar detects radial velocities sequentially in at least three different directions using the Doppler beam swinging (DBS) technique	m s^{-1}	u_1, u_2, \dots, u_n
Cartesian wind components	Computed from the radial wind components using trigonometric relations	m s^{-1}	u, v, w
Radial turbulence component	Only the vertical component of the turbulence can be determined using vertical sounding; it is derived from either the broadening of the frequency of the backscattered signal or the temporal fluctuations in the vertical velocity component	m s^{-1}	σ_w
Mixed-layer depth	Determined from the backscatter intensity (mainly the decrease in backscatter intensity with height) using an algorithm	m	MLH
Inversion height	Height of inversion is determined from the secondary maximum in the backscatter intensity	m	

Table 23.2 Parameters that are derived from RASS measurements

Parameter	Description	Unit	Symbol
Acoustic temperature	Vertical profile is determined from a vertically propagating sound pulse	K	T_s
Radial wind components (Doppler RASS only)	Doppler analysis only allows the evaluation of radial velocities; sodar detects radial velocities sequentially in at least three different directions via the Doppler beam swinging (DBS) technique	m s^{-1}	u_1, u_2, \dots, u_n
Cartesian wind components (Doppler RASS only)	Computed from the radial wind components using trigonometric relations	m s^{-1}	u, v, w
Radial turbulence component (Doppler RASS only)	Only the vertical component of turbulence can be determined using vertical sounding; it is derived from either the broadening of the frequency of the backscattered signal or the temporal fluctuation of the vertical velocity component	m s^{-1}	σ_w
Mixed-layer depth (Doppler RASS only)	Determined from the acoustic backscatter intensity (mainly the decrease in the backscatter intensity with height) using an algorithm	m	MLH

(within a few hundreds of meters of each other) because they would interfere with each other. Since these instruments sound mainly in the vertical direction, the chosen measurement site must provide a free sky view. Public access to operational instruments of this type should be prohibited for two reasons. On the one hand, vandalism must be discouraged. On the other hand, the acoustic and electromagnetic radiation emitted from the instruments can be harmful to humans. The noise pressure within the antennae of a three-antenna sodar or the enclosure of a phased-array sodar can damage ear drums. Spending an extended period at distances of up to ≈ 4 m from the sending electromagnetic antenna of a RASS can also be harmful.

Both types of instruments need a steady power supply, which can be provided by either the grid or a system of solar panels connected to an energy storage unit. The transportation of such heavy instrumentation to the intended site requires access roads that are suitable for use by heavy-duty vehicles (this includes sufficient vertical clearance all the way to the measurement site!). Sections 23.3.1 (on fixed echoes), 23.5.2, and 23.5.3 give additional information on the requirements for sites at which these instruments can be operated.

23.1.4 Measurement Principles of Sodars

A sodar consists of a pulsed sound emitter and a receiver [23.4]. Sound waves are scattered by turbulent temperature fluctuations in the atmosphere, since the refractive index for sound waves changes at the boundaries of these fluctuations. The fluctuations that reflect the sound pulses emitted from the sodar are assumed to move with the mean wind. Therefore, acoustic waves that are backscattered in the atmosphere are Doppler shifted in frequency if the air is in motion. Sodars that analyze the Doppler shift of the backscattered sound pulses in order to determine the vertical wind profile are called *Doppler sodars* (see Table 23.3 and Fig. 23.2 for instrument terminology). The Doppler shift is proportional to the radial velocity v_r (see Tables 23.1 and 23.2 and Sect. 23.3.2). The range is dictated by the travel time of the pulse and the backscattered wave. An overview of the basic principle of sounding with a sodar and the history of sodar development are described in [23.5]; a summary of acoustic remote-sensing techniques and their theoretical background was recently provided by Bradley [23.6].

Table 23.3 Measurement principles for wind, turbulence, and temperature, and applications of such measurements

Parameter	Measurement principle			Application	
	Doppler	Backscatter intensity	Sound speed	Mean	Turbulent
Wind	×			×	
Turbulence	×	×			×
Temperature gradient		×			×
Temperature			×	×	

Sodar measurements depend on the state of the atmosphere. If the atmosphere is extremely well mixed (i.e., temperature fluctuations are very small), almost no sound is reflected from the atmosphere, and the signal-to-noise ratio for sodar can be so low that it is not possible to accurately determine the wind speed (via the Doppler shift). Such a scenario tends to occur during the afternoon on days with low mean wind speeds and strong vertical mixing due to thermal heating.

For optimal backscatter, the spatial size of temperature gradients in the atmosphere should be about half the acoustic wavelength (Bragg condition) [23.7]. This condition can be fulfilled by the temperature gradients within turbulence elements as well as those across inversion layers. It is necessary to differentiate between these two possibilities when deducing information on the atmospheric state from the backscattered signal. This can be done by either assessing the general weather conditions or, if a Doppler sodar is used, by analyzing the variance of the simultaneously recorded vertical velocity. High variances indicate thermal forcing, where the backscatter intensity is proportional to the turbulence intensity, whereas low variances indicate stable layering, where the backscatter intensity should be proportional to the mean vertical temperature gradient (i.e., inversion).

For a sodar (just as for radar), the backscattered signal is representative of a certain atmospheric volume. If the duration of the sound pulse is 100 ms, the sodar detects simultaneous backscatter from a volume 33 m deep. If this volume is 500 m AGL, it has a radius of 44 m (assuming that the opening angle of a single emitted sound beam is 5°). Additionally, the three-dimensional wind information must be integrated from a full measurement cycle comprising one vertical and two to four tilted beams (see the description of the Doppler beam swinging technique in Sect. 23.4.1). This implies that the radius of the detected atmospheric

volume at a height of 500 m AGL is about 150–200 m. This means that a sodar performs volume- and time-averaged measurements.

23.1.5 Measurement Principles of RASS

A radioacoustic sounding system (RASS) performs acoustic and electromagnetic sounding simultaneously [23.8, 9]. Two different types of RASS have been developed: the Bragg RASS and the Doppler RASS [23.10].

The *Bragg RASS* (sometimes called a wind-temperature radar) is a wind profiler (see Chap. 31 and [23.11]) with an additional acoustic emitter. When the Bragg condition is fulfilled [23.7] (i.e., the wavelength of the sound waves λ_a is half the wavelength of the electromagnetic waves λ_e , see Tables 23.4 and 23.5), there is optimal backscatter of the electromagnetic waves from the acoustic waves. The electromagnetic signal is emitted at a fixed frequency, but the emitted sound has a continuously varying frequency f_a . The propagation speed of the acoustic signal can be determined from the acoustic wavelength $\lambda_{a,B}$ at which optimal backscatter occurs via the dispersion relation

$$c = \frac{\lambda_{a,B}}{2} f_a. \quad (23.5)$$

A sound frequency of about 100 Hz is used for a VHF wind profiler operating at 50 MHz, while a sound frequency of ≈ 2 kHz optimally fulfills the Bragg condition for an UHF wind profiler operating at 1 GHz. Because the attenuation of sound waves in the atmosphere depends strongly on frequency [23.12], an UHF RASS can detect the temperature profile up to a height of ≈ 1.5 km, whereas a VHF RASS can determine the temperature profile throughout the troposphere.

Table 23.4 Parameters that are measured using sodar

Parameter	Description	Unit	Symbol
Frequency	The mean frequency and the width of the frequency spectrum of the backscattered signal are recorded as functions of propagation time	s^{-1}	f_a
Acoustic backscatter intensity	Parameter is recorded as a function of propagation time	dB	P_R

Table 23.5 Parameters that are measured using a RASS

Parameter	Description	Unit	Symbol
Acoustic frequency (Doppler RASS only)	Mean frequency and width of the frequency spectrum of the backscattered signal are recorded as functions of the propagation time	s^{-1}	f_a
Acoustic backscatter intensity	Parameter is recorded as a function of propagation time	dB	P_R
Electromagnetic frequency	Mean frequency and width of the frequency spectrum of the backscattered signal are recorded as functions of the propagation time	s^{-1}	f_e

Table 23.6 Additional parameters that are required to interpret sodar measurements

Parameter	Description	Unit	Symbol
Atmospheric temperature	Needed to determine the speed of sound, which is then used to derive the distance from the scattering volume	K	T
Orientation, alignment	Orientation with respect to north is needed to convert radial wind velocities into Cartesian wind components; instrument should be aligned horizontally	degrees	
Distance to scattering objects	The distance to possible scattering objects (trees, buildings, electricity cables, ...) must be known in order to identify fixed echoes	m	

A *Doppler RASS* is a sodar with an additional electromagnetic emitter and receiver operating at a frequency of $f_{e,0}$. This instrument is able to detect the acoustic shock fronts of the acoustic pulses and determine their propagation speed from the backscattered electromagnetic waves. This propagation speed is equal to the speed of sound, which is in turn a known function of the air temperature (see also Tables 23.6) and humidity. Using the Doppler shift Δf_e (see Sect. 23.3.3) of the electromagnetic radiation backscattered at the density fluctuations caused by the sound waves, the propagation speed c of the sound waves can be determined as

$$c = 0.5c_1 \frac{\Delta f_e}{f_{e,0}}, \quad (23.6)$$

where c_1 denotes the speed of light. Just like a Bragg RASS, a Doppler RASS emits a *chirp* (a sound signal) to check that the Bragg condition is optimally met, considering that the temperature varies significantly across the entire height interval considered.

The propagation speed c_g is the sum of the speed of sound c and the vertical movement of the air w in which the sound waves propagate, i.e.,

$$c_g = c + w. \quad (23.7)$$

The vertical air speed component w can be determined separately from the Doppler shift of the backscattered electromagnetic clear-air signal when operating a Bragg RASS, or from the Doppler shift of the backscattered acoustic signal when operating a Doppler RASS. The height profile of c can then be converted into a height profile for the acoustic temperature T_s (see Sect. 23.3.1). This acoustic temperature is a sufficiently accurate approximation of the virtual air temperature for many applications.

A Bragg RASS has a greater maximum range than a Doppler RASS but a coarser height resolution. A Doppler RASS is also much easier to implement than a Bragg RASS, meaning that a Doppler RASS is less expensive.

23.2 History

The development of ground-based remote-sensing devices started during World War II with the construction of the first weather radars [23.13]. The first acoustic wind profilers (sodars) were invented shortly after World War II. The idea for a RASS device originated in the early 1970s.

23.2.1 History of Sodar Measurements

Acoustic sounding technology was developed shortly after World War II [23.14]. Most of the theoretical foundations for this field were laid by *Valerian*

Iljitsch Tatarskij [23.15], with the initial development of acoustic sounding technology occurring in the Soviet Union [23.16, 17] and (a decade later) in the United States [23.18]. Analyzing the backscatter intensity was the main focus in the beginning. More recently, the emergence of wind energy applications in the last decade of the twentieth century has fostered renewed interest in this wind measurement technology. The use of Doppler analysis to derive wind speed is now the main application of acoustic sounding technology. However, the rapid development of optical Doppler wind lidars between 2005 and 2010 heavily suppressed

further development in the field of sodar devices. Although optical techniques are much more expensive than acoustic techniques, optical techniques have become more popular because they do not suffer as much from environmental interference and because they have higher data availability during a given time period (see Chap. 27 for further discussion of Doppler wind lidars).

23.2.2 History of RASS Measurements

The acoustic backscatter intensity gives only a very crude estimate of the vertical temperature gradient. This

23.3 Theory

The following sections provide the theoretical background for both sodars and RASS. The theory behind the propagation of acoustic waves in the atmosphere is utilized for both types of instruments, while the theory behind the propagation of radio waves is only employed for RASS.

23.3.1 Sound Propagation in the Atmosphere

Sound waves are elastic vibrations that propagate as longitudinal waves (i.e., the material vibrates in the same direction as the direction of propagation of the sound wave). For ideal gases, the speed of sound c is given by

$$c = (\gamma RT)^{0.5}, \quad (23.8)$$

where γ is the ratio of the specific heats (c_p/c_v), R is the specific gas constant of an ideal gas in $\text{J kg}^{-1} \text{K}^{-1}$, and T is the absolute temperature in K.

The speed of sound in air is mainly a function of the temperature. Nevertheless, changes in the humidity of the air affect both R and γ , so the speed of sound also depends on the humidity. If the humidity is given in terms of the partial pressure e or the specific humidity q , the speed of sound in humid air can be expressed as

$$c = (\gamma_{\text{tr}} R_{\text{tr}} T_s)^{0.5} = 20.048(T_s)^{0.5}, \quad (23.9)$$

where γ_{tr} is the ratio of the specific heats for dry air, R_{tr} is the gas constant of dry air in $\text{J kg}^{-1} \text{K}^{-1}$, and T_s is the acoustic temperature in K, as given by

$$T_s \approx T \left(1 + 0.329 \frac{e}{p} \right) \approx T(1 + 0.531q), \quad (23.10)$$

where p is the air pressure in the same units as e .

led to the development of the RASS nearly 50 years ago [23.8]. RASS were constructed by either adding a radar component to a sodar (Doppler RASS) or by adding a sound component to a wind profiler (Bragg RASS). Although RASS suffer from the same environmental interference as sodar devices, they have not been superseded by optical techniques so far. Passive radiometers (Chap. 29) have come onto the market, but they do not offer the same high vertical resolution as RASS. Raman lidars (Chap. 25) are much more expensive and have poor signal-to-noise ratios during the daytime due to interference from scattered sunlight.

T_s is very similar to the virtual temperature T_v that is commonly used for humid air in meteorology, although it differs from it slightly, as described by

$$T_s = T_v - 0.0489 \frac{eT}{p} \quad (23.11a)$$

or

$$T_s = T_v - 0.079q, \quad (23.11b)$$

where T , T_s , and T_v are in K, e and p are in hPa, and q is in kg kg^{-1} .

Attenuation of Sound Waves in the Atmosphere

The attenuation of sound waves in the atmosphere depends on the frequency, temperature, and humidity. The attenuation-dependent transmittance follows the Bouguer–Lambert–Beer law

$$\tau(x, f) = \exp \left(- \int_0^x \alpha(x', f) dx' \right), \quad (23.12)$$

where the absorption coefficient $\alpha(x, f)$ is in m^{-1} and

$$\alpha = f^2 \left[1.84 \times 10^{-11} \frac{p_r}{p} \left(\frac{T}{T_{20}} \right)^{1/2} + \left(\frac{T}{T_{20}} \right)^{5/2} \times \left(\frac{f_{\text{O}_2} \times 0.01275 \times \exp(-2239.1/T)}{f_{\text{O}_2}^2 + f^2} + \frac{f_{\text{N}_2} \times 0.1068 \times \exp(-3352/T)}{f_{\text{N}_2}^2 + f^2} \right) \right], \quad (23.13)$$

where p_r is a constant pressure (1013.25 hPa), p is the surface pressure at the observation site in hPa, T is the

absolute surface temperature in K, and T_{20} is a constant temperature (293.15 K).

Equation (23.13) requires two relaxation frequencies: f_{O_2} for oxygen, as given by

$$f_{O_2} = \frac{p}{p_r} \left[24 + 4.04 \times 10^4 h \left(\frac{0.02 + h}{0.391 + h} \right) \right], \quad (23.14a)$$

and f_{N_2} for nitrogen, evaluated using

$$f_{N_2} = \frac{p}{p_r} \left(\frac{T}{T_{20}} \right)^{1/2} \left[9 + 280h \times \exp \left(-4.170 \left(\left(\frac{T}{T_{20}} \right)^{-1/3} - 1 \right) \right) \right]. \quad (23.14b)$$

Both of these relaxation frequencies also depend on the relative humidity

$$h = 100 \frac{e}{p}, \quad (23.14c)$$

where h is in %. Further details can be found in [23.12, 19, 20].

Apart from shock waves (described in Sect. 23.3.3), the propagation of electromagnetic waves is only marginally influenced by atmospheric properties, so they can be neglected here.

Backscattering of Sound Pulses in the Atmosphere

Turbulent inhomogeneities of the temperature, humidity, and wind velocity lead to local changes in the speed of sound and thus to the scattering of some of the sound energy. This process is referred to as clear air scattering or Bragg scattering. In backscattering (scattering angle = 180°), only temperature and humidity inhomogeneities (not wind velocity fluctuations) contribute to the scattered signal. Backscattering is most effective when it occurs at turbulent structures with sizes that are half the wavelength of the sound wave (the Bragg condition). Scattering also occurs at precipitation particles.

When an emitting power of ≈ 1 kW is used, a backscattered signal with a power of $\approx 10^{-15}$ W is obtained. This is below the hearing threshold of the human ear (10^{-12} W) but well above the noise produced by the Brownian motion of atmospheric molecules (6×10^{-19} W). The sound frequencies used (1500–4500 Hz) are well within the sensitivity range of the human ear.

The ratio of the emitted to the received power is given by the sodar equation

$$P_R = r^{-2} \left(\frac{c\tau_d A \varepsilon}{2} \right) P_0 \beta_s \exp(-2\alpha r) + P_{bg}, \quad (23.15)$$

where P_R is the received power, P_0 is the emitted power, r is the distance between the sodar and the scattering element, ε is the antenna efficiency, A is the effective antenna area, τ_d is the pulse duration (typically between 20 and 100 ms), β_s is the backscattering cross-section (typically on the order of $10^{-11} \text{ m}^{-1} \text{ sr}^{-1}$), and P_{bg} is the background noise.

The speed of sound c and the absorption coefficient α are defined in (23.8) and (23.13) above. The background noise also includes contributions from ambient noise with the same sound frequency, e.g., traffic noise. The ratio of the two terms on the right-hand side of the sodar equation is called the signal-to-noise ratio (usually abbreviated to SNR). The backscattering cross-section β_s is a function of the temperature structure function C_T^2 [23.15]. When using the wavenumber $k = 2\pi/\lambda$ for a monostatic sodar, we find that

$$\beta_s(180^\circ) = 0.00408 k^{1/3} \frac{C_T^2}{T^2}. \quad (23.16)$$

This equation gives an average over all scattering elements within the atmospheric volume that is hit by the cone-shaped beam [23.21].

Fixed Echoes

Sodar beams also have side lobes. If these side lobes hit highly reflective obstacles, sound energy with a strength that is similar to or even much stronger than the atmospheric return is scattered back towards the instrument. The backscattered signals from these objects are called fixed echoes. Fixed echoes can strongly influence and disturb sodar measurements. Since fixed echoes are reflected from fixed (i.e., stationary) objects, they cause the deduced wind speed to be much lower than it really is. Avoiding fixed echoes requires good measurement site selection for sodar instruments in order to guarantee unbiased wind speed measurements. Sodar must therefore be sited away from obstacles such as buildings, trees, and—most importantly—electric transmission cables. If the sodar has to be sited near such objects, it should be situated such that the distance to the highly reflecting objects does not conflict with the range of the atmospheric layers that are to be investigated. This often means positioning the sodar closer to such objects than the lowest range gate of the instrument (usually ≈ 40 m).

23.3.2 Doppler Analysis

Wind and turbulence are measured with a sodar by analyzing the Doppler shift of the backscattered acoustic pulse that was originally emitted with a frequency f_0 . Assuming that the scattering volume for the sound waves is moving with the wind, the Doppler-shifted sound frequency f_D is given by

$$f_D = f_0 \frac{c - v_r}{c + v_r}, \quad (23.17)$$

where v_r is the radial velocity along the path of the emitted sound beam (positive away from the sodar) and f_0 the emitted acoustic frequency. Solving for the radial velocity v_r gives

$$v_r = c \frac{f_0 - f_D}{f_0 + f_D}. \quad (23.18)$$

23.3.3 Principle of Radioacoustic Sounding

Measurements are achieved using a RASS by modifying the propagation conditions for electromagnetic waves in a controlled manner using sound waves. The scattering of electromagnetic waves from refractive-index modifications generated by acoustic waves differs from scattering due to atmospheric turbulence (such as that used for wind profiler radar measurements) in several respects [23.9]:

1. Modifications of the atmospheric refractive index propagate as spherical waves at the speed of sound, whereas moving refractive-index variations caused by natural turbulence do not show any systematic behavior.
2. The spherical wavefronts focus the scattered electromagnetic waves. Therefore, to obtain a sufficiently high receiver signal, the antenna needs to be located near the focus (*acoustic spot*) formed by the sound waves.
3. Horizontal wind carries sound waves away and causes the focus of the backscatter signal to drift, limiting the maximum range. In a turbulent atmosphere, sound-wave scattering extends the focal area beyond that of the electromagnetic transmitter antenna, reducing the adverse effect of drift on the maximum range.
4. Atmospheric absorption also decreases the sound intensity, leading to a reduction in the maximum range of the RASS, similar to that for a sodar.
5. The backscatter signal is maximized when the ratio of the electromagnetic to the acoustic wavelengths is 2 : 1 ($\lambda_e = 2\lambda_a$, known as the Bragg condition; see Fig. 23.1).

When the Bragg condition is met, the power $P_s(z)$ received at the RASS is described by the RASS equation

$$P_s(z) = 0.588 \times 10^{-14} c_g \frac{\Delta z}{(\lambda_e z)^2} \frac{P_a P_e}{B_a} g \tau I P_{N,N_0}, \quad (23.19)$$

where P_{N,N_0} is the normalized backscatter power for $N = N_0$, N is the number of acoustic waves within the scattering volume Δz (the backscatter power is proportional to N^2), P_a is the transmitted acoustic power, P_e is the transmitted electromagnetic power, B_a is the acoustic bandwidth, g is a gain parameter ($g = g_a$ if $g_e \geq g_a$; otherwise, $g = g_e^2/g_a$), g_a is the gain of the acoustic antenna, g_e is the gain of the electromagnetic antenna, τ is the acoustic transmission due to atmospheric absorption, I is an inhomogeneity parameter that accounts for atmospheric turbulence ($I < 1$ describes a turbulent, agitated, layered atmosphere whereas $I = 1$ is indicative of a stationary, quiet, homogeneous atmosphere), and Δz is the radial extent of the scattering volume.

The equation used to determination c_g depends on the type of RASS employed. For a Doppler RASS, we have

$$c_g = -\frac{\lambda_e}{2} \Delta f_e \approx -\lambda_a \Delta f_e. \quad (23.20)$$

For a Bragg RASS, we have

$$c_g = -\lambda_a f_B. \quad (23.21a)$$

As both Δf_e and f_B are actually equal to the acoustic frequency f_a , we find that

$$c_g = -\lambda_a f_a \quad (23.21b)$$

for both types of RASS.

Finally, the speed of sound and the radial wind component due to atmospheric motion must be separated (see (23.7)). If the effect of a nonzero radial velocity v_r is neglected when deriving the temperature T from the sound velocity c_g , the resulting error is 1.7 K per m s^{-1} of the unknown radial wind v_r . The simplest method of suppressing the effect of the vertical wind consists of pointing the RASS vertically and averaging the speed of sound c_g over a long period of time, as the long-term vertical wind over horizontal terrain tends to zero. This method is usually applied in routine measurements. In a convective atmosphere, however, usual averaging times of between 10 and 30 min may not be sufficient, resulting in a considerable error in the temperature measurement due to the vertical wind. If the terrain is tilted, the average vertical wind may be nonzero, so averaging over long periods of time is not a solution. In these

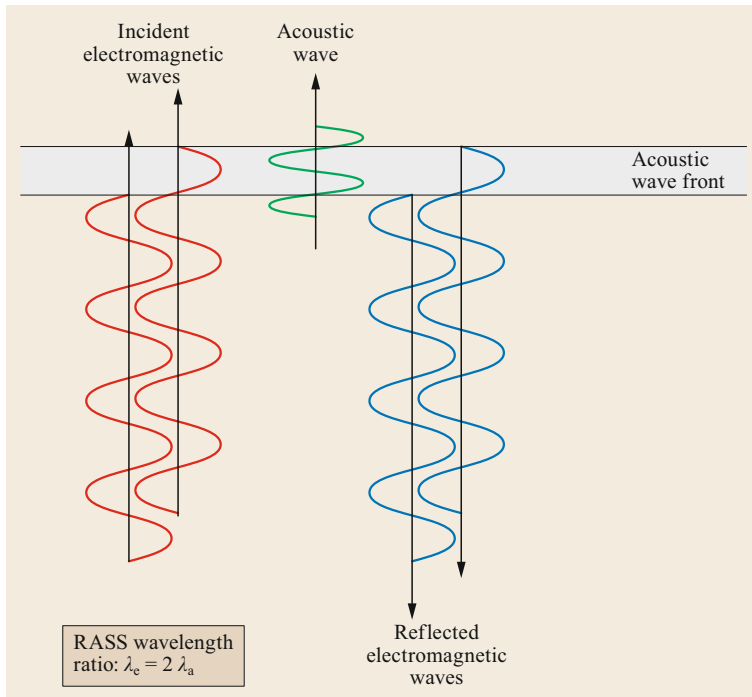

Fig. 23.1 Illustration of the Bragg condition for Doppler RASS instruments. Here, acoustic waves are shown in *green*, whereas emitted and reflected electromagnetic waves are shown in *red* and *blue*, respectively. The electromagnetic waves are reflected at the leading and trailing edges of the sound pulse. For all of the reflected electromagnetic waves to be in phase, the wavelength of the emitted electromagnetic waves must be twice the wavelength of the moving sound pulse

cases, the vertical wind component measured with the sodar (when using a Doppler RASS) or with the wind profile radar (when using a Bragg RASS) can be used for correction. The vertical temperature profile is assessed with a RASS by determining the thermodynamic speed of sound c in each altitude interval.

23.3.4 Vertical Range

The vertical range of the wind and temperature data obtained from a sodar and a Doppler RASS is determined from the travel time of the sound pulses. For a Bragg RASS, the vertical range is determined from the travel time of the electromagnetic waves. The maximum vertical range is influenced by the attenuation of sound waves in the atmosphere (see Sect. 23.3.1).

23.3.5 Vertical and Temporal Resolution

The pulse duration τ_d determines the height resolution of the instrument via the relation

$$\Delta z = 0.5c\tau_d. \quad (23.22)$$

The sodar equation (23.15) shows that the backscatter power is also proportional to the pulse duration. Therefore, the choice of pulse duration is made from a trade-off between height resolution (preferably short pulse durations) and maximum range (preferably long

durations). Equation (23.19) is valid for a perfect rectangular pulse but can also be used as a good first approximation for real pulses.

To avoid unwanted interference, a new pulse cannot be emitted before the backscatter from the previously emitted beam has been received, so a measurement cycle of a sodar lasts six to ten times as long as the time needed for a sound pulse to travel to the maximum vertical range of the instrument. For a sodar or Doppler RASS operating at 1500 Hz, this implies that the duration of a measurement cycle is ≈ 20 s when the range is 1000 m.

23.3.6 Determination of the Mixed-Layer Height and Inversions

The layering of the atmospheric boundary layer due to the vertical temperature and moisture distribution and the existence of inversions within this layer or on top of it strongly influence the development of atmospheric motions and high pollutant concentrations in the air. Well-mixed layers of the atmospheric boundary layer are characterized by enhanced turbulence compared to the stably stratified free troposphere above. For a convective boundary layer (CBL), the mixed-layer height (MLH) is usually identical to the temperature inversion height.

Beyrich [23.22] has listed possible analyses of the MLH and inversions based mainly on acous-

tic backscatter intensities measured by a sodar. Asimakopoulos et al. [23.23] analyzed these methods further and grouped them into three approaches to deriving the MLH from sodar data: the horizontal wind speed (HWS) method, the acoustic received echo (ARE) method, and the vertical wind variance (VWV) method.

The ARE method is the simplest method of determining the MLH from acoustic remote sensing. Most of the methods listed in [23.22] are variants of this type. This method does not require an analysis of the Doppler shift of the backscattered signals. The MLH is derived from either the most negative slope, the change in curvature of the vertical profile of the acoustic backscatter intensity, or the height at which the backscatter intensity decreases below a certain prespecified threshold value. Inversions are found by searching for secondary maxima in the vertical profile of the backscatter intensity.

The ARE method can be enhanced in two ways. The first way is to include further variables for which data are provided by Doppler sodars in the MLH algorithm. For instance, the utilization of the variance of the vertical velocity component is demonstrated in [23.24]. The second way to enhance the ARE method is to determine not only the MLH from sodar measurements but also the heights of lifted inversions. Especially above orographically complex terrain, the vertical structure of the atmospheric boundary layer (ABL) can be very com-

plicated [23.25]. Enhanced ARE methods (and optical methods that use ceilometers and wind lidars) are described in more detail in [23.26].

The HWS method requires an analysis of the Doppler shift of the backscattered signals. It involves analyzing the shape of hourly-averaged vertical wind-speed profiles under the assumption that wind speed and wind direction are almost constant within the mixing layer but the wind speed increases gradually towards the geostrophic value at the top of the mixing layer. Given the underlying assumptions, the applicability of this method is probably limited to well-developed CBLs. Such CBLs are often higher than the maximum range of a sodar. Even if the CBL height is within the range of the sodar, the algorithm used to analyze the Doppler shift often fails above the inversion atop the CBL due to poor signal-to-noise ratios. Therefore, this method is not recommended.

The VWV method also only works for CBLs. It focuses on the vertical profile of the variance of the vertical velocity profile σ_w . In a CBL, σ_w is usually greatest at a height that is between 0.35 and 0.4 times the inversion height. Thus, in principle, this is an extrapolation method. It has been attempted for sodar measurements because it permits MLH detection up to heights that are 2.5 times above the highest that can be probed (usually between 500 and 1000 m) with a sodar. *Beyrich* [23.22] classified this method as unreliable.

23.4 Devices and Systems

This section describes typical configurations of current sodar and RASS systems (see Fig. 23.2 for an overview of different techniques and instruments).

23.4.1 Sodars and Minisodars

The Doppler beam swinging (DBS) technique [23.27] is the standard technique used by sodars. It is different from the usual technique employed by Doppler wind lidars (see Chap. 27), which uses conical scanning to get wind information from different directions. With DBS, at least three—but often five—beams are subsequently emitted in different directions. Two (or four) beams at right angles to each other are emitted at zenith angles of $\approx 15^\circ$; the third (or fifth) beam is emitted vertically. The angle between the slanted beams should be as low as possible to receive the three (or five) different sets of information, which are later used to compute the three orthogonal wind components from air volumes that are close together. If the angle becomes too small, the computation of horizontal wind components

from near-vertical radial velocity components along the beams becomes too uncertain. There is a trade-off between getting information from air volumes that are close together and the certainty with which the horizontal wind components can be computed.

The radial wind component along a beam with a zenith angle δ and an azimuth angle ϕ is composed of all three Cartesian wind components u (towards the east), v (towards north), and w (upwards), i.e.,

$$v_r(\delta, \phi) = u \sin \delta \sin \phi + v \sin \delta \cos \phi + w \cos \delta. \quad (23.23)$$

Inversely, all three Cartesian components can be computed from (at least) three radial velocities in different noncoplanar directions.

Equations (23.12) and (23.13) show that sound attenuation in the atmosphere is strongly frequency dependent. Higher frequencies are attenuated much faster than lower frequencies. Therefore, sodars that are designed to have larger ranges operate at

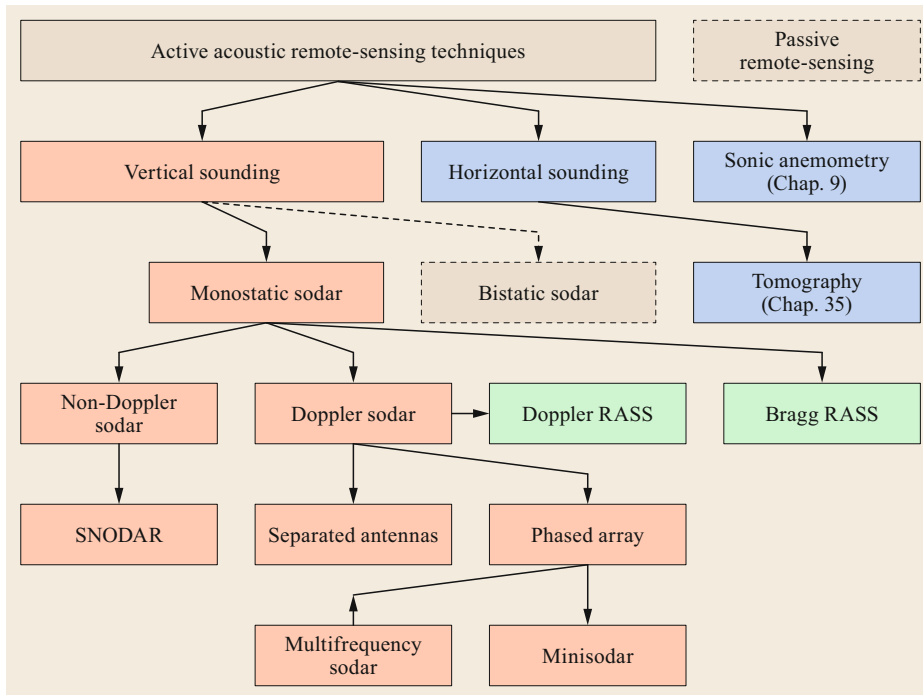

Fig. 23.2 Organigram of acoustic sounding techniques. Techniques in *brown boxes* and *green boxes* are presented in this section. Techniques in *blue boxes* are introduced in other sections. Techniques in *dashed boxes* are not relevant to this chapter

≈ 1500 Hz. However, a second class of sodars has been developed—*minisodars* [23.28]—that are optimized for short-range measurements (up to ≈ 200 m AGL). This shorter range permits more measurement cycles because the time that the sodar must wait to receive the reflected pulse is also shorter. Furthermore, environmental noise is reduced somewhat compared to standard sodars. Minisodars are usually designed for use as phased-array sodars (see Sect. 23.4.1).

Sodars with Antennas

The first Doppler sodars utilized three parabolically shaped antennas (horns) that could be aligned in three different directions (Fig. 23.3). In such systems, the bottom of each antenna has one or a few sound transducers that are operated simultaneously. The transducers first act as loudspeakers and are then switched electronically to act as microphones. The shape of the antenna helps to focus the sound beam. In addition, the antennas at least partially prevent noise interference from reaching the sound transducers and shield the region close to the instrument from excessive sound pulses, which could damage unprotected ear drums. The most suitable and common alignment used in these systems is one where two antennas are inclined by a zenith angle of $\approx 15^\circ$ and have an azimuth angle of 90° between them, while the third antenna is adjusted to be precisely vertical. The sound transducers in the three antennas are oper-

Fig. 23.3 Sodar with three antennas (horns) (photo © Stefan Emeis)

ated sequentially in order to prevent interference from the other antennas. The waiting time between two sound emissions from different antennas must at least be twice the travel time of the sound pulse to the maximum range of the instrument.

Phased-Array Sodars

Phased-array sodars were first constructed in 1989 [23.29]. They are systems in which a field (array) of acoustic transducers is responsible for forming and directing beams (Fig. 23.4). Between 16 and 64 acoustic transducers are usually arranged in a planar array and adjusted to create a defined phase relationship between them. The array of transducers is operated such that sound beams are formed due to interference

Fig. 23.4 Phased-array sodar with 64 sound transducers and no enclosure (photo © Helmut Mayer)

between the sound waves from the individual loudspeakers (Fig. 23.5). These beams are comparable to the beams described above for the systems with antennas. The whole system requires an enclosure that protects the system from environmental noise and ensures that operators and people passing by do not experience dangerous sound levels.

Monostatic and Bistatic Sodars

In a monostatic sodar, the receiver is close to the emitter. The intensity of the backscattered signal depends only on temperature fluctuations in the atmospheric boundary layer. Monostatic sodars have the advantage of compactness, and the instruments are more readily deployed in the field because the instrument package is self-contained. This is the standard configuration of presently available sodars.

In a bistatic sodar, the receiver is deployed away from the emitter. In this case, velocity fluctuations in the atmosphere also contribute to the intensity of the backscattered signal. The Doppler shift and scattering cross-section for bistatic sodars were analyzed by *Thomson and Coulter* [23.30] and *Wesely* [23.31]. Early experiments with bistatic sodars are described in [23.32, 33]. While bistatic sodars have been constructed and used in experiments, there are no commercially available bistatic sodars. Recent studies utilizing these sodars can be found in [23.34, 35].

Other sodar designs [23.36] in which several receivers are arranged around one central sound source (multistatic sodars) have also been proposed. This should allow all three components of the wind to be detected for the same atmospheric volume. Such instruments could be operated in complex terrain without the need to correct for curved streamlines (see Sect. 23.6.3).

Mono- and Multifrequency Sodars

In addition to monofrequency sodars, multifrequency sodars are available. These emit a series of pulses with different frequencies within one shot. Field tests have proven that the multifrequency technique has significant advantages. The use of, say, eight different frequencies halves the minimum acceptable signal-to-noise ratio compared to single-frequency sounding. Moreover, the multifrequency mode improves the accuracy of the instantaneous values of measured parameters and significantly increases the ability to reliably recognize noisy echo signals. Further details regarding multifrequency sodars are given in [23.37].

The principles of pulse code methods that are used to enhance the range and data availability are reviewed and investigated in [23.38]. In particular, detailed simulations are performed using weather-like targets, a comb of frequencies, a chirp, and a phase-encoding method. Three Doppler-adaptive matched filters are described, and two of these are evaluated against the simulated noisy atmosphere. It is found that the comb of frequencies produces the least variance in the estimated Doppler wind speed. A filter based on a single evaluation of a Fast Fourier Transform of the received signal provides Doppler wind measurements to an accuracy of about 1%. The Doppler-adaptive filters add little computational or hardware overhead, and produce a simple output consisting of the best estimate for the wind speed component.

Non-Doppler Sodars

The first sodars were non-Doppler sodars. Later, Doppler sodars became the standard, and now nearly all commercially available sodars are Doppler sodars. Nevertheless, a few non-Doppler sodars do exist. An example is a special sodar developed for use in extremely cold environments. This SNODAR (surface layer non-

Fig. 23.5a–c Measurement principle of phased-array sodars. (a) Loudspeaker 6 fires first and loudspeaker 1 last, (c) loudspeaker 1 fires first and loudspeaker 6 last, and (b) all loudspeakers operate simultaneously

Fig. 23.6a,b Doppler RASS with the acoustic (sodar) instrument at the center and radio antennas to the left and right: (a) 475 MHz system (photo © Stefan Emeis); (b) 1290 MHz system (photo © METEK GmbH, Elmshorn)

Doppler acoustic radar) is designed to measure the height and turbulence intensity of the atmospheric boundary layer above the Antarctic plateau. This is, for example, useful to astronomers who are planning to install future optical telescopes there. SNODAR works by sending an intense acoustic pulse into the atmosphere and listening for backscatter from inhomogeneities resulting from temperature gradients and wind shear. Its operating principle is very similar to that of a well-known underwater sounding technique: SONAR. SNODARs are monostatic sodars with a minimum sampling height of 5 m, a range of at least 200 m, and a vertical resolution of 1 m. They operate at frequencies of between 4 and 15 kHz. Sound waves with such high frequencies propagate relatively well in the low temperatures of the Antarctic atmosphere [23.39].

23.4.2 RASS

There are two types of RASS. One (known as a *Doppler RASS*) is a combination of a sodar with a continuous-wave electromagnetic transmitter and receiver; the other (known as a *Bragg RASS*) is a wind profiler radar (see Chap. 31 and [23.11]) combined with a continuous sound transmitter. The latter combination is sometimes also called a wind-temperature radar (WTR).

Sodar RASS (Doppler RASS)

In today's terminology, the first RASS, which was first designed and built by *Marshall et al.* [23.8], was a Doppler RASS in which acoustic pulses were pursued by continuous electromagnetic radiation emitted from a transmitter (Fig. 23.6). Altitude assignment is achieved for a RASS by measuring the propagation time of the acoustic pulses, much as in a sodar; the time taken for the electromagnetic pulses to return is

negligible. The observed frequency shift of the electromagnetic backscatter signal is interpreted as a Doppler shift. The emitted acoustic pulse is a chirp over a selected sound frequency range that is centered on the Bragg resonance frequency to guarantee that the Bragg condition is met for all temperatures.

Wind Profiler RASS (Bragg RASS)

Adding a sound source to a radar wind profiler yields a Bragg RASS or wind-temperature radar (Fig. 23.7). The first attempts to use such combinations were confronted with the problem that a Stokes shift rather than a Doppler shift was observed [23.40]. *Peters et al.* [23.41] showed that instead of measuring the Doppler frequency, the desired information can be extracted from the Bragg resonance curve. The Bragg resonance is obtained by varying the acoustic frequency and monitoring the backscatter maximum. Whereas the Doppler shift of the backscattered electromagnetic radiation provides information on the speed of sound when using a Doppler RASS, the Bragg resonance provides the acoustic wavelength when using a Bragg RASS (i.e., the acoustic wavelength is measured instead of the speed of sound). To achieve this, a Bragg RASS continuously transmits an acoustic frequency spectrum which is centered on the Bragg resonance frequency. This is in marked contrast to the single pulses transmitted by a Doppler RASS.

23.4.3 Comparison of the Methods

Different types of sodars and RASS have been developed for different measurement purposes, although the presence of various types also reflects the historical development of these instruments. Table 23.7 gives a concise overview of the advantages and disadvantages

Table 23.7 Advantages and disadvantages of the different types of sodars and RASS

Device	Advantages	Disadvantages
Sodar with antennas	Higher vertical range	Heavier instrument—a lorry is needed for deployment
Phased-array sodar	Smaller and lighter instrument—can be transported by a sport utility vehicle (SUV)	Reduced vertical range
Minisodar ($f_a \gtrsim 4000$ Hz)	Higher vertical resolution	Limited vertical range (200–300 m)
Bistatic/multistatic sodar	Velocity fluctuations also produce backscatter when using a multistatic sodar, all three wind components can be measured in the same atmospheric volume	More complicated deployment—all receivers must be connected to the grid and to data transfer, still very experimental
Multifrequency sodar	Higher signal-to-noise ratio, higher range	Enhanced electronics, noise interference
Non-Doppler sodar	Simpler technique and data evaluation	No wind velocity can be obtained
Doppler RASS	Higher vertical resolution, relatively portable, simpler technology, less expensive	Lower range
Wind profiler RASS	Lower vertical resolution	Higher range, not usually portable, more complicated technology, expensive

Fig. 23.7 A Bragg RASS with the radar instrumentation (wind profiler radar) at the center and additional acoustic sources (orange cylinders) next to it. The whole system is surrounded by a fence to prevent interference from other manmade sources of electromagnetic waves (e.g., radar and television emitters) (photo © Stefan Emeis)

of the different types of sodars and RASS. The first six rows refer to sodars, and the last two rows to RASS. Note that the first four rows refer to instruments with

different layouts. The advantages and disadvantages presented in rows 5 and 6 could—at least in principle—apply to any of the sodars referred to in rows 1–4.

23.5 Specifications

This section summarizes information on the measured parameter accuracies and ranges that can be obtained with sodar and RASS measurements. Noise protection rules and electromagnetic permit procedures are also discussed.

23.5.1 Measured Parameter Accuracies and Ranges

The measured parameter accuracies and ranges for sodars and RASS are summarized in Table 23.8. The range of wind speed values is limited by the accu-

racy at the lower end and by environmental noise and noise generated at the edges of the instrument at the upper end. The range of temperature values is only limited by the selected frequency range of the acoustic chirp (Doppler RASS) or the continuous acoustic signal (Bragg RASS).

23.5.2 Permits Required for RASS Operation

RASS devices emit radio waves that can interfere with other telecommunication services. National regulations on the allocation of operating frequencies must

Table 23.8 The accuracies and ranges of wind, turbulence, and temperature measurements obtained using sodars and RASS (based on [23.4, 9])

Parameter	Accuracy	Range
Wind speed (radial wind component)	0.3 m s ⁻¹ for a single measurement; 0.05 m s ⁻¹ for the average of 40 measurements	0.05 to ≈ 20 m s ⁻¹
Wind speed (computed from the radial wind components)	0.3–0.5 m s ⁻¹ for the average of 10 min of measurements	0.3 to ≈ 20 m s ⁻¹
Standard deviation of the vertical wind component	0.16 m s ⁻¹ based on 40 measurements	0.16 to several m s ⁻¹ (no real upper limit)
Temperature	0.5 K; error of 1.7 K per 1 m s ⁻¹ of the unknown vertical wind component (averaging reduces this error; see (23.7))	No principal limit for the temperature range; it depends on the width of the frequency spectrum of the acoustic signal. Doppler RASS: no temperature data for wind speeds ≈ 12–15 m s ⁻¹ because the wind drifts the sound pulse away from the focus of the receiving electromagnetic antenna

therefore be observed when using such systems. In Germany, the standard RegTP 321 ZV 044 [23.42], which references certain international regulations, applies in this context. An application for a permit to operate a RASS must be filed with the Bundesnetzagentur für Elektrizität, Gas, Telekommunikation, Post und Eisenbahnen (RegTP; the Federal Agency for Electricity, Gas, Telecommunication, Post and Railroad Grids).

23.5.3 Compliance with Noise Regulations

In Germany, the operator of a sodar or a RASS must comply with standards and statutory regulations that are relevant to noise, such as the EU's Noise Directive 2003/10/EC [23.43], the German Federal Immission Protection Law (BImSchG [23.44]), or the guideline VDI 2058 Part 2 [23.45]. An a priori application for a permit is not required in Germany.

23.6 Quality Control

General quality assurance and quality control procedures are described in Chap. 3. In this section we focus on quality assurance and quality control procedures that are specific to sodar and RASS devices.

The quality of wind and temperature data from sodar and RASS devices depends mainly on the signal-to-noise ratio (i.e., the intensity ratio of the backscattered signal to the background noise) and the quality of the data evaluation algorithm used. Sodar and RASS devices are usually shipped with built-in data evaluation algorithms. The manufacturers of these devices should

indicate the minimum signal-to-noise ratio that must be attained in order to extract meaningful data from the built-in data evaluation algorithms. The temporal and vertical consistency of the final wind and temperature data provides valuable insight into the reliability of the retrieved data. Table 23.9 gives an overview of common instrument errors.

The signal-to-noise ratio usually decreases with increasing range because the backscattered sound intensity decreases with the square of the range (Sect. 23.3.1). The maximum range is frequency de-

Table 23.9 Typical measurement errors with sodars or RASS

Instrument	Error(s)	Reason(s)
Sodar	No wind data	Antenna is covered with snow, technical failure of instrument
Sodar	Low vertical range, spatially and temporally inconsistent data	Signal-to-noise ratio is too low due to ambient noise (could be caused by rain or very high wind speeds), intensity of atmospheric turbulence is too low to cause sufficient acoustic backscatter
Sodar	Low vertical range in wind data during morning or afternoon	Atmosphere nearly adiabatic
Sodar	Wind speed minima in vertical profiles always occur at the same height (and backscatter intensity is enhanced)	Fixed echo, azimuth angle of antenna must be adjusted or a better measurement site is needed
RASS	No temperature data	Technical failure of instrument
RASS	Missing temperature data for certain heights and for a limited period	Excessive wind speeds (often due to nocturnal low-level jets) have blown the signal away from the focus of the receiving electromagnetic antenna

pendent (Sect. 23.3.1). The signal-to-noise ratio can be strongly influenced by environmental noise at the measurement site. Noise with the same frequency as the emitted sound pulses is especially problematic. Measurement sites in noisy industrial areas or close to motorways or railway lines should be avoided. The signal-to-noise ratio is also degraded by strong winds, as such winds can generate noise in the vicinity of the instrument or even at the edges of the instrument itself.

Some manufacturers also supply data processing software with their instruments. Such software often include visualization tools (e.g., to display time–height cross-sections of the retrieved data), printing options, and data export options. Key parameters that can be entered into the software include temporal and vertical averaging intervals and the start and end dates of the data to be processed.

Some manufacturers provide access to the raw data obtained by the instruments. The analysis of such raw data requires special skills. The processing of raw data may be helpful when attempting to detect and explain inconsistencies in the data sets or to calculate nonstandard output variables.

23.6.1 Wind Speed Calibration

Wind speeds from sodar and RASS devices do not require calibration as long as signal-to-noise ratios are high enough to permit the accurate measurement of the Doppler-induced frequency shift using the built-in data evaluation algorithm. Wind speed data are obtained from Doppler shift analysis using a basic physical principle that does not require any calibration. Nevertheless, it is useful to check the resulting data against the corresponding data provided by a cup anemometer or a sonic anemometer on a mast. Note that it is important to take differences in measurement principles (volume measurements with a sodar or RASS and almost point measurements with a cup or sonic anemometer) into account when comparing data from remote-sensing instruments with in-situ data.

23.6.2 Temperature Calibration

Temperature data from a RASS device do not require calibration as they are derived using a basic physical phenomenon: the detection of the speed of sound in air. This speed is a function of temperature and humidity only (see Sect. 23.3.1). Nevertheless, it may be useful to check the data against that afforded by a thermometer. Again, differences in measurement principles (volume measurements with a RASS and almost point measure-

ments with a cup anemometer) should be taken into account when comparing data from remote-sensing instruments with in-situ data.

23.6.3 Specific Quality Control Methods

The calculation of wind speeds using monostatic remote-sensing devices such as sodars and RASS is based on the assumption that the streamlines are straight (no curvature in any direction) within the measurement volume defined by the separate beams in the Doppler beam swinging technique (see Sect. 23.4.1) or by the walls of the cone in conical scanning. The presence of streamlines that are curved towards the instrument causes the wind speed to be underestimated, whereas the presence of streamlines that are bent away from the instrument leads to an overestimated wind speed [23.46]. Thus, wind data from ground-based remote sensing on a hilltop are lower than the true wind speeds above the instrument, whereas wind data obtained in a valley are higher than the true wind speeds. Some manufacturers claim that they have built-in corrections for streamline curvature in their evaluation algorithms. These corrections cannot be rated here, because the manufacturers do not disclose how their algorithms calculate such corrections. The best way to determine the necessary corrections to the measurements is to run a flow model in conjunction with the instrument. This curvature problem occurs with sodars as well as with wind lidars (Chap. 27).

Measured wind speeds and turbulence data (i.e., the variance of the vertical wind component) must be checked for the impact of fixed echoes (Sect. 23.3.1). Fixed echoes lead to wind speeds that are lower than they should be because reflections from immobile objects are included in the data. Fixed echoes usually occur at a certain height above the ground that corresponds to the direct (diagonal) distance between the remote-sensing device and the object that is generating the fixed echoes. Thus, wind speeds that are consistently lower than expected at a particular height may be indicative of fixed echoes. Another clue that fixed echoes are occurring is the presence of very high backscatter intensities, because most solid objects reflect sound waves much better than the atmosphere does. It is not possible to correct for fixed echoes a posteriori. The best way to deal with them is to discard the flawed wind and turbulence data.

Temperature data are not influenced by curved streamlines because temperature is derived using vertical sound emission only. Temperature sounding also does not suffer from fixed echoes. Thus, for a Doppler

Table 23.10 Maintenance of sodars and RASS

Maximum interval	Sodar (all types)	Doppler RASS	Bragg RASS
Daily	Check incoming data for consistency		
Daily	Perform a visual check of the instrument (unless the site is within a well-guarded and supervised area)		
Every 3 months	Check that all loudspeakers are functioning properly	Check that all loudspeakers and antennas are functioning properly	
Every 2 years	Check all electrical cables and devices		

RASS, the maximum range of the temperature data is usually considerably higher than the maximum range of the wind data.

Temperature determination can be hampered by high wind speeds. In this case, the sound waves emitted from the Doppler RASS are blown outside the

focus of the receiving radio antenna. Thus, it is sometimes impossible to detect the temperature in areas with high wind speeds caused by nocturnal low-level jets. Depending on the size of the instrument, temperature determination can be problematic when wind speeds are $> 10\text{--}15\text{ m s}^{-1}$.

23.7 Maintenance

Just like any device that is connected to the electrical grid and operated outdoors, sodars and RASS devices require technical and electrical maintenance. No additional substances such as gases or liquids have to be supplied during the measurements. The overall amount of maintenance required for such instruments is low (see Table 23.10). Manufacturers' instructions should be followed, and software updates should be uploaded as soon as possible.

A direct connection to the instrument's computer via the internet or mobile telecommunications services is advisable. Error messages issued by the software can give hints about malfunctions. Daily data transfer from the instrument to the operator's institution is recommended. Regular checks of the consistency of the incoming data can provide further insight into potential malfunctions.

23.8 Applications

The most informative data products obtained from ground-based remote-sensing instruments such as sodars and RASS devices are time–height cross-sections of wind speed, wind direction, the vertical component of turbulence, and temperature. The vertical profiles of these parameters can be extracted from time–height cross-sections. Time series of selected parameters (e.g., mixed-layer height) can also be extracted.

An example of real-world data obtained using a sodar is presented in Fig. 23.8, which shows the daily variation in the horizontal wind in an alpine valley during a clear-sky day. Steady southerly to southwesterly winds representing the down-valley flow are seen to occur from 10 p.m. to 8 a.m. (GMT+1), whereas turbulent northerly to northeasterly winds representing the up-valley flow are observed between 10 a.m. and 8 p.m.

Another real-world dataset provided by a sodar is depicted in Fig. 23.9, which shows a perfect example of the measurement of wind speeds in a nocturnal low-level jet. The maximum wind speed along the axis of the jet is $\approx 12\text{ m s}^{-1}$, whereas the wind speed underneath

and above the jet is $\approx 5\text{ m s}^{-1}$. The measurements were performed in a very quiet environment, which made it possible to observe the upper part of the low-level jet, where the wind speed decreases with height (very often, a sodar can only measure wind speeds below the jet axis, not those above it).

A final example (Fig. 23.10) shows the diurnal temperature variation in the lower atmospheric boundary layer on a clear-sky day, as measured with a Doppler RASS. Potential temperature data are presented. In the early morning (between 2 a.m. and 10 a.m. GMT+1), cold air (blue) occurs near the surface. Warmer air (green) occurs above the cold air. At ≈ 10 a.m., vertical mixing starts, and soon afterwards the air is well mixed vertically until ≈ 6 p.m. Then cooling sets in again near the surface while the air remains warm above. The white area in the upper right corner corresponds to missing data. Data are missing from this region because high wind speeds caused by a low-level jet drifted the sound pulse from the Doppler RASS out of the focus of the receiving electromagnetic antenna.

Fig. 23.8 Time–height cross-section of horizontal wind vectors measured over the course of one day (x -axis) for heights of 50–800 m AGL using a three-antenna sodar. Time resolution: 30 min; height resolution: 30 m. Arrow length is proportional to wind speed (see the legend in the *upper right corner*). Arrow direction indicates the wind direction (upward: wind from the south; to the right: wind from the west; etc.). Measurements were performed in an almost north–south-oriented valley on the northern side of the Alps at Oberau (Germany) on 8 May 1998

Fig. 23.9 Nocturnal vertical wind-speed profiles obtained with a three-antenna sodar; the profiles show the presence of a low-level jet at ≈ 300 m AGL. Six wind speed profiles (each averaged over 30 min) obtained for heights ranging from 40 to 600 m AGL (vertical resolution: 20 m) are plotted. The measurements were performed at the Charles-de-Gaulle Airport in Paris (France) during the first three hours of 26 June 2005

Fig. 23.10 Time–height cross-section of potential temperatures on a clear-sky day measured over a period of 24 h (local time) for heights of 40–420 m (vertical resolution: 20 m) using a Doppler RASS. Colors (see the color bar at the *lower right*) indicate potential temperatures ranging from 5 °C (*dark blue*) to 25 °C (*purple*). The measurements were performed at the northern outskirts of Augsburg (Germany) on 6 April 2009

23.9 Future Developments

Although they are relatively old techniques, there is still a need for these vertical sounding devices that actively emit sound waves. While wind profile measurements are increasingly being performed with wind lidars rather than sodars (because wind lidars offer enhanced data availability and do not suffer from environmental interference), RASS are still the best available devices for measuring the temperature profiles of the lower regions of the atmospheric boundary layer. Passive radiometers have much poorer vertical resolution, meaning that they are generally not well suited to boundary layer studies. Raman lidars also have deficiencies, especially during the daytime, when the intense short-wave solar radiation causes interference.

Apart from classical scientific boundary layer studies, new fields of application for ground-based remote sensing have developed in recent decades, which has reinvigorated the development of acoustic sounders. One of the most important of these new fields of application is wind energy (see Chap. 51 and [23.3]). Wind energy requires highly vertically and temporally resolved wind, turbulence, and temperature profile

data for site assessments, yield forecasts, and load assessments. While site and load assessments are especially valuable for the manufacturers of wind turbines, yield forecasts are mandatory for electrical grid operators and for successful trade actions at energy exchanges.

Another field in which sodars and RASS have been deployed in the last few decades is urban studies. However, in this case, the active emission of sound waves is a disadvantage of these instruments, as it is becoming increasingly difficult to find acceptable measurement sites for sodars and RASS in densely populated areas. Therefore, researchers are attempting to develop measurement configurations that shield urban populations from the emitted sound waves. One such configuration is the bistatic sodar (see Sect. 23.4.1), in which the vertical emission of sound pulses is well shielded and the receiver is located away from the instrument.

Methods of correcting wind profile data from sodars (and wind lidars) located in complex terrain (see Sect. 23.6.3) are still being developed. Some manufacturers offer built-in correction algorithms, although they do not explain how they work. Others suggest running

simple flow models in parallel with the measurements to obtain the necessary corrections. Attempts to produce feasible correction algorithms for ground-based monostatic wind profilers operating in complex terrain will

continue even if sodars start to disappear, because wind lidars have the same problem.

In the long run, the importance of acoustic sounding techniques will decrease.

23.10 Further Reading

A general overview of acoustics can be found in

- Rossing, T.D. (ed.): Springer Handbook of Acoustics, 2nd edn. (Springer, 2014).

The standard resource on sodars is the book by Bradley [23.6]. There is no corresponding book on RASS devices. The bilingual VDI Guideline 3786 Part 18 [23.9] is most probably among the most concise sources of information in this regard.

A general overview of ground-based remote sensing of the atmospheric boundary layer can be found in [23.1].

A short overview of all atmospheric measurement techniques can be found in

- Emeis, S.: Measurement Methods in Atmospheric Sciences. In-situ and remote. (Borntraeger, Stuttgart 2010), XIV + 257 pp.

The 2014 edition of the WMO Guide to Meteorological Instruments and Methods of Observations (WMO No. 8) covers radar in detail but mentions sodars and RASS only briefly (in Chapter 5 of Part II).

Stefan Emeis is an unsalaried Professor of Meteorology at the University of Cologne, group leader at KIT, and editor-in-chief of *Meteorologische Zeitschrift*. His research mainly involves ground-based remote sensing of the atmospheric boundary layer. He has written books on measurement techniques and wind energy, organized conferences (e.g., ISARS 13, METTOOLS VI), and was awarded the Honorary Medal of the VDI and the Reinhard Süring Medal from the German Meteorological Society.

24. Backscatter Lidar for Aerosol and Cloud Profiling

Christoph Ritter , Christoph Münkel 

Backscatter lidars are relatively simple, hence easy to maintain, active remote-sensing instruments, which is why they can be relied upon to continuously detect cloud and aerosol layers and determine the mixing layer height under convective conditions while unattended. In this chapter, the principle of backscatter lidars and their main components are described; this discussion also serves as an introduction to more sophisticated lidar systems. In addition, we examine the extraction of backscatter profiles and basic aerosol properties from lidar data, which normally requires the selection of an appropriate aerosol-type-dependent lidar ratio. Examples of the applications of these instruments are also provided.

The word *lidar* is an acronym of *light detection and ranging*. A lidar is an active remote-sensing instrument that uses a light source, usually a pulsed laser, to sound the atmosphere. Particles in the atmosphere backscatter some of the light produced by the lidar, and this backscattered radiation is recorded by a telescope near the laser. Knowledge of the time difference between the emission of the laser pulse and the arrival of the backscattered photons at the telescope allows the altitude of the backscattering event to be determined. In other words, when the lidar is operating, a *lidar profile*

is obtained in which the number of photons P is recorded as a function of time t , which is related to the altitude z of the backscatter event via

$$z = \frac{c}{2t}, \quad (24.1)$$

where c is the speed of light in the atmosphere. The factor of 2 is included in this equation because the recorded photons have to travel the distance z twice: they travel to the altitude at which they are backscattered before traveling back to the telescope.

While lidars are versatile instruments that can measure various environmental quantities, such as aerosol properties (e.g., the extinction coefficient) using the Raman effect (Chap. 25), the wind via the Doppler effect (Chap. 27), trace gas concentrations using the ratio of the lidar profiles at colors that are sensitive or insensitive to the species of interest, or the temperature via the Raman effect for rotational states of molecules, we only consider simple backscatter lidars in this chapter. These instruments collect elastically backscattered light that provides information on aerosols, clouds, and—under convective conditions—the boundary layer altitude. One simple example of such an instrument is a ceilometer, which continuously—and unattended—records the altitudes of clouds and atmospheric visibility for airports and weather services.

24.1 Measurement Principles and Parameters

In this section, optical parameters that are frequently encountered when using backscatter lidars for atmospheric science are defined and discussed. The most important of these are the volumetric backscatter β (unit: $\text{m}^{-1} \text{sr}^{-1}$) and the extinction coefficient α (units: m^{-1}). Both of these parameters actually consist of multiple contributions. One of these contributions is due to scattering from particles (which may be cloud or aerosol particles); another is due to Rayleigh scattering from gases in the atmosphere, even when it is clear. As light that is scattered or attenuated by one atmospheric constituent cannot then interact with another atmospheric constituent, the total backscatter and extinction coefficients are simply the sums of the contributions of the individual components, i.e.,

$$\begin{aligned}\beta &:= \beta^{\text{total}} = \beta^{\text{aer}} + \beta^{\text{Ray}} \\ \alpha &:= \alpha^{\text{total}} = \alpha^{\text{aer}} + \alpha^{\text{Ray}} + \alpha^{\text{absorp}}.\end{aligned}\quad (24.2)$$

Here, the superscripts aer and Ray denote the contributions due to scattering from particles and Rayleigh scattering, respectively. The superscript absorp denotes the fraction of the molecules that absorb the light, because α^{Ray} is only the contribution of Rayleigh extinction to the scattering. The molecules that absorb at wavelengths relevant to lidar are mainly trace gases such as ozone (the Chappuis band) [24.5], water vapor [24.6], and carbon dioxide [24.7].

β^{Ray} , α^{Ray} , and α^{absorp} are proportional to the number concentration of air N_{air} or the absorbing trace gas N_x . Therefore, the Rayleigh and aerosol components of the backscatter and extinction coefficients can easily be separated through the use of radio sounding data

The extinction coefficient and the asymmetry parameter of the scattering are generally the most important quantities which determine the (generally unclear) radiative forcing of aerosol [24.1]. Nevertheless, even simple backscatter lidars can provide important information on aerosols. For example, backscatter lidars were used to track the volcanic ash plumes that restricted air traffic in Europe in 2010 [24.2]. Moreover, backscatter profiles from lidar data have been used to improve or constrain cloud properties in climate models; for example, data from the spaceborne CALIPSO lidar were employed in [24.3]. The height of a convective boundary layer can also be derived using backscatter lidar data, as demonstrated in [24.4].

obtained at a nearby site or the density profile of an appropriate atmosphere.

Both the backscatter and extinction are extensive quantities, meaning that they do not depend on the size of the physical system (i.e., the aerosol number concentration in our case). For example, an increased value of the backscatter coefficient at a particular altitude simply means that there is additional scattering at this height. It cannot tell us why this is—it may be that a few particles are scattering the light unusually efficiently, or there could be high abundance of weakly scattering aerosol particles.

The backscatter and extinction coefficients are generally also functions of the wavelength λ of the incoming light. The only important exception arises when the scattering or absorption is due to large particles in clouds. In cirrus clouds, for example, the diameters of ice crystals can exceed $100 \mu\text{m}$ [24.8]. These particles are so large that the *gray approximation* holds for electromagnetic waves in the visible spectrum, which simply means that β and α are independent of wavelength. Aerosol particles are, in contrast, much smaller, so the scattering and absorption depend on the wavelength of the light. The coefficients are frequently assumed (or measured) to have a power-law-like wavelength dependence, such as

$$\begin{aligned}\alpha^{\text{aer}}(\lambda) &= C_1 \lambda^{A_a} \\ \beta^{\text{aer}}(\lambda) &= C_2 \lambda^{A_b},\end{aligned}\quad (24.3)$$

where A_a and A_b are the Ångström exponents for the extinction and backscatter [24.9]. The values of these exponents lie in the interval $[-4. . . 0]$, with the Rayleigh limit (i.e., the particles are much smaller than the wave-

length) as the lower bound and the gray approximation as the upper bound.

Instead of determining A_b from multiwavelength lidar data, sometimes the color ratio (CR) is defined as the ratio of the aerosol backscatter for different colors, i.e.,

$$\text{CR}(\lambda_1, \lambda_2) = \frac{\beta^{\text{aer}}(\lambda_1)}{\beta^{\text{aer}}(\lambda_2)}. \quad (24.4)$$

Here $\lambda_1 < \lambda_2$, meaning that $\text{CR} \geq 1$. The color ratio is an intensive quantity, as it is determined by the size of the particles, not their concentration. Hence, the addition of a second color to a lidar system has the advantage that approximate size information can be obtained. According to the definition of A_b , the color ratio goes to 1 when the grey approximation holds, while $\text{CR} \rightarrow (\lambda_2/\lambda_1)^4$ at the Rayleigh limit.

Using the fact that many lasers emit linearly polarized light, the aerosol linear depolarization ratio δ^{aer} can be defined as the ratio of the aerosol backscatter coefficients for the polarization states perpendicular and parallel to the laser; in other words,

$$\delta^{\text{aer}}(\lambda) = \frac{\beta_{\perp}^{\text{aer}}(\lambda)}{\beta_{\parallel}^{\text{aer}}(\lambda)}. \quad (24.5)$$

Note that δ^{aer} may also be defined as the ratio of the perpendicular polarized backscatter to the sum of the backscatter polarized in the parallel and perpendicular directions [24.10]. Using Mie theory, it can be shown that backscattering by spherical particles does not change the polarization of the light, whereas backscattering from nonspherical particles usually does. Uniformly spatially oriented symmetric ice crystals for which the vertical dimension is the smallest one (e.g., ice plates) are the only exception to this (i.e., backscattering from such crystals results in a negligible change in polarization), but these crystals can be distinguished from spherical particles by pointing the lidar just a few degrees away from the vertical [24.11]. Hence, by inserting an additional recording branch into the lidar to examine the polarization of the light, the shape and thus the state of aggregation (given that liquid particles are almost spherical due to surface tension) of the scattering particles can be determined. The value of δ^{aer} would be expected to be about zero for a liquid aerosol, up to around 30% for desert dust [24.12], and more than 50% for cirrus clouds [24.13]. The aerosol depolarization ratio has the advantage that it depends solely on the properties of the aerosol, not on the molecular contribution (Rayleigh scattering). However, aside from cirrus clouds and desert dust, aerosols always have $\beta_{\perp}^{\text{aer}} < \beta_{\parallel}^{\text{aer}}$, so δ^{aer} can become quite noisy. For this reason, the volume depolarization or total depolarization

ratio δ^{tot} is sometimes used. This is defined as the ratio of the lidar signals in the two orthogonal polarization states [24.14],

$$\delta^{\text{tot}} = \frac{P_s}{P_p}. \quad (24.6)$$

The attenuated backscatter coefficient B may also be used [24.15]. The attenuated backscatter is defined via the simple elastic lidar equation (see Sect. 24.3) as

$$B(z) = \beta(z) \exp\left(-2 \int_{z_0}^z \alpha(\hat{z}) d\hat{z}\right) = \frac{1}{C} P(z) z^2. \quad (24.7)$$

The backscatter coefficient B has units of $\text{m}^{-1} \text{sr}^{-1}$, so it has the advantage of reducing the basic lidar equation to just one unknown, which can be readily derived from the measured signal once the lidar constant C is known. However, the extinction and backscatter coefficients are more useful for constraining the radiative forcing of an aerosol [24.16].

It is also common to denote the product

$$S(z) = P(z) z^2 \quad (24.8)$$

as the range-corrected signal.

A more frequent method of solving the lidar equation is presented in Sect. 24.3. To achieve this, a relation between the backscatter and extinction is required; the *lidar ratio* (LR) is commonly used, which is defined as

$$\text{LR}(\lambda) = \frac{\alpha^{\text{aer}}(\lambda)}{\beta^{\text{aer}}(\lambda)}. \quad (24.9)$$

Values of the the lidar ratio range from < 10 sr for supercooled water droplets [24.17] to ≈ 100 sr for small, highly absorbing aerosols [24.18]. The lidar ratio depends mainly on the refractive index of the aerosol particles, but also on their shape and size (the ratio is higher for smaller and more elongated particles) [24.19, 20]. Due to its importance for evaluating and interpreting lidar data, the LR is discussed further in Sect. 24.3.

The aerosol optical depth τ should also be evaluated to facilitate comparisons with photometers. It is defined via

$$\tau(z) = \int_{z_0}^z \alpha^{\text{aer}}(\hat{z}) d\hat{z}. \quad (24.10)$$

Due to their lack of height resolution, photometers can only measure the integral of the aerosol-induced extinction over the whole atmospheric column, whereas lidars

Table 24.1 Parameters measured using backscatter lidars

Parameter	Description	Unit	Symbol
Attenuated backscatter	A measure of the light that is attenuated and elastically scattered at an angle of 180°	m ⁻¹ sr ⁻¹	<i>B</i>
Backscatter coefficient	A measure of the light that is elastically scattered at an angle of 180°	m ⁻¹ sr ⁻¹	β
Extinction coefficient	A measure of the attenuation of a beam of light	m ⁻¹	α
Range	Distance from the system to the base height (or distance) of interest	m	<i>z</i>

Table 24.2 Intensive properties that can be derived using lidars

Parameter	Description	Unit	Symbol
Lidar ratio	Ratio of the aerosol extinction coefficient to the aerosol backscatter coefficient	sr	LR
Color ratio	Ratio of the aerosol backscatter coefficients for different colors	–	CR
Ångström exponent for backscatter	Spectral dependence of the backscatter coefficient	–	<i>A_B</i>
Ångström exponent for extinction	Spectral dependence of the extinction coefficient	–	<i>A_a</i>
(Linear) depolarization ratio	Ratio of the backscatter coefficients for light that is polarized perpendicular and light that is polarized parallel to the laser	%	δ

provide height-resolved profiles of atmospheric quantities.

Finally, the backscatter ratio *R* is given as

$$R(\lambda) = \frac{\beta(\lambda)}{\beta_{\text{Ray}}(\lambda)} = 1 + \frac{\beta^{\text{aer}}(\lambda)}{\beta_{\text{Ray}}(\lambda)}. \quad (24.11)$$

As can be seen from this definition, the backscatter ratio is dimensionless. An ideal aerosol-free atmosphere would have $R = 1$. Note that the backscatter ratio and backscatter coefficient depend on each other.

Tables 24.1 and 24.2 summarizes the abovementioned parameters.

24.2 History

William E.K. Middleton (1902–1998) and *Athelstan F. Spilhaus* (1911–1998) introduced the acronym *lidar* in 1953 [24.21], 7 years before the invention of the laser. Consequently, the first lidar systems did not resemble those used today. Indeed, the first attempts to measure cloud base heights were made in the 1930s; those experiments involved recording the light scattered from a pulsed or continuous searchlight beam at just one height using an inclined telescope mirror and then applying trigonometry. However, the history of lidar technology is often considered to begin with the invention in 1962 of the *Q*-switched laser, which produces short, high-power laser pulses. A year later, the detection of mesospheric dust using an *optical radar* was reported [24.22]. While a detailed analysis of the lidar signal (see Sect. 24.3) was not yet possible, lidar was soon being utilized to perform ranging measurements, such as tracking the distance to the Moon. The first Apollo missions as well as unmanned Russian spacecraft placed special prisms on the Moon that allowed its distance from the Earth to be tracked with centimeter precision.

Lidar technology rapidly evolved, making it useful for an increasing number of applications, such as digital elevation modeling, the monitoring of agriculture and forest fires, vehicle automation, wind farm optimization, and even biological warfare alarm systems.

Nowadays, almost all analysis of backscatter data is based on the work of *James D. Klett* (1940) [24.23, 24]. However, the first stable analytical inversions of lidar signals were performed in Russia by *Bruno V. Kaul* and *Vladimir E. Zuev* (1925–2003) [24.25, 26]. In the Western world, the *slope method*, a solution of the lidar equation based on simplified assumptions, was used initially (see Sect. 24.3.2) [24.27].

The first spaceborne lidar was flown onboard the space shuttle *Discovery* for almost two weeks in September 1994 [24.28]. This LITE (Lidar In-space Technology Experiment) mission utilized a three-wavelength backscatter lidar and was carried out to demonstrate the feasibility of performing lidar measurements of clouds, aerosols, the planetary boundary height, and stratospheric temperatures from space. In 2006, the CALIPSO satellite was launched. Onboard this satellite is the CALIOP lidar, which delivers valuable information on global aerosol and cloud coverage [24.29]. CALIOP employs a two-wavelength laser that is widely used by the lidar community: a Nd:YAG laser emitting at 1064 and 532 nm (the second harmonic). It also utilizes depolarization separation, allowing some of the intensive quantities defined in Sect. 24.3 to be measured directly. Automatic differentiation between clouds and various types of aerosols has been greatly improved by this mission.

24.3 Theory

In this section, we provide the general solution of the elastic lidar equation. This solution depends on the lidar ratio (24.8), a boundary condition (the value of the backscatter coefficient at a predefined altitude), and of course the lidar profile (along with its noise). Values of the lidar ratio and the aerosol linear depolarization ratio are also given for various types of aerosols.

24.3.1 Concept and Basic Lidar Equation

Here, we denote the range from the lidar system to the point in the atmosphere at which the scattering processes occur by z . However, it is worth remembering that not all backscatter lidars are ground-based; some are used on aircraft and in space (see Chap. 38). Moreover, ground-based backscatter lidars can also be used in horizontal or scanning mode.

The main components of a lidar are a laser with emission optics, a telescope with recording optics, and a signal processing and storage unit, all of which are shown in Fig. 24.1. These components are described in detail in Sect. 24.4.

Typically, a laser is used to emit photons into the atmosphere in short pulses (≥ 10 ns). Some lasers used in lidars emit more than one wavelength simultaneously, which can be achieved by, for example, including additional optical components that double or triple the orig-

inal frequency of the laser. A beam-widening telescope (BWT) is usually employed to decrease the divergence of the laser beam, permitting a smaller, better-defined image of the laser in the sky. Other components such as a plane-parallel mirror may also be necessary to direct the laser beam further into the atmosphere. Particles in the atmosphere can scatter light elastically in the opposite direction to the incoming light; the resulting light is known as *backscatter*. In this section, we use the volumetric backscatter coefficient β , which has units of $\text{m}^{-1} \text{sr}^{-1}$. This backscatter coefficient indicates how well a particular atmospheric layer acts as a mirror, and its value is typically a function of the wavelength λ of the incoming light.

A telescope that collects the backscattered light from the atmosphere is positioned next to the laser or emission mirror. Figure 24.1 depicts this as a Newton-type telescope with a parabolic primary and a plane secondary mirror, but other telescope designs are also used. A field stop that limits the field of view (FOV) of the recording telescope is located in the focal plane of the recording telescope. This field stop increases the signal-to-noise ratio by ensuring that the laser beam is recorded while blocking out as much of the sky background as possible. A collimating lens is employed behind the aperture stop. This lens produces the parallel beam of light needed by optical components as dichroic

Fig. 24.1 The main components of a lidar system (BWT: beam-widening telescope, IF: interference filter, PBS: polarizing beam splitter, PMT: photomultiplier tube)

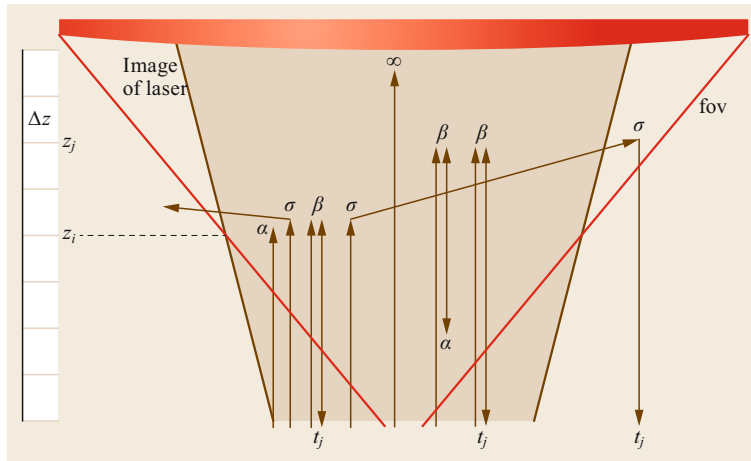

Fig. 24.2 Correct and unwanted events in a lidar system (FOV: field of view of the recording telescope)

mirrors and interference filters (IFs), which utilize multiple beam interference (i.e., the angle of incidence of the beam at the surface is important).

Dichroic beam splitters that reflect or transmit light differentially depending on its wavelength are commonly used in lidars to separate different wavelengths in the laser light or to distinguish between elastically and inelastically scattered light from the atmosphere (see the chapter on the Raman effect). As the number of colors recorded by a lidar is usually small, spectrometers have only rarely been used in lidars. Interference filters are used to eliminate any unwanted stray light before the remaining light is recorded by photomultiplier tubes (PMTs). In some lidars, the light is separated into its polarization states, which are recorded independently because they provide information on the shape of the scattering particles (see below). The light can be separated into its polarization states using polarizing beam splitters (PBSs), which separate the light into components that are polarized parallel (p or \parallel) and perpendicular (s or \perp) to the laser. The measured photocurrent from the PMTs is then counted using transient recorders. Figure 24.1 also shows that the transient recorders (there is normally one for each PMT) require a time stamp to ensure that they are synchronized with the laser flash. Finally, the data are stored in a computer, which can also be used to initially visualize the signal.

Even lidars that are used for meso- and exospheric research [24.30, 31]) will struggle to detect signals > 150 km, meaning that, according to (24.1), the signal must be recorded by a ground-based system within ≈ 1 ms at most. Hence, the lidar profile is recorded such that the flashing of the lidar triggers the transient recorders to start counting the output of the photomultipliers. The sampling frequency is on the order of MHz, which determines the altitude resolution of the lidar. According to (24.1), sampling at 20 MHz yields

an altitude resolution of 7.5 m. A height profile of the measured photocurrent is therefore obtained from each photomultiplier.

Figure 24.1 depicts just one backscatter lidar setup. Some lidars, especially the Raman lidars discussed in Chap. 25, use more colors and photomultipliers. Sometimes the same telescope is used for beam expansion to record the signal.

We will not be discussing continuous-wave (CW) lasers here as they are covered in Chap. 27. White-light femtosecond lidars [24.32, 33] are also omitted from the present discussion because they have only been used in atmospheric research to a very limited extent, even though they are not a new type of lidar [24.34].

Two physical quantities are fundamental to understanding the information content that can be retrieved by a lidar: the previously introduced volumetric backscatter coefficient β (in $\text{m}^{-1} \text{sr}^{-1}$) and the volumetric extinction coefficient α (in m^{-1}). The extinction coefficient describes the energy or the number of photons in the beam that is/are lost as the beam propagates. This loss may due to either scattering σ (in m^{-1}) or absorption a (in m^{-1}); in other words, $\alpha(\lambda, z) = \sigma(\lambda, z) + a(\lambda, z)$.

Figure 24.2 illustrates valid and unwanted events that contribute to the lidar signal. The FOV of the recording telescope is shown in red and the image of the laser beam in light green. The image of the laser is only fully located inside the FOV of the telescope when the altitude z is greater than z_i , which is called the *overlap height*. Evidently, to obtain full overlap, the divergence angle of the laser beam must be smaller than the FOV. Some photons that are scattered or absorbed within the height interval Δz_i are delineated in green in Fig. 24.2. The first photon (i.e., the photon furthest left) is absorbed at this altitude and does not, therefore, yield a signal at the detector. The same is true of the second photon, which is scattered sideways, meaning that

it moves outside of the FOV. However, the third photon is backscattered and is detected by the detector at time t_i , which corresponds to z_i via (24.1). The next photon is scattered to the side; we will come back to this photon later. While most photons are not scattered at all under cloud-free conditions and therefore leave the atmosphere (denoted by the infinity sign in the figure), just as the light from faint stars can be seen at night, some photons are backscattered at z_j . As before, some photons may be absorbed or scattered laterally at this height (not shown in the figure). Among those that are backscattered within the interval Δz_j , only the photons that are not absorbed or scattered laterally on their way down will be recorded at t_j .

So far we have only considered photons in the *single scattering approximation*—in other words, photons that are scattered only once. While this is a justifiable approximation in clear sky conditions and is also widely applied when there are thin clouds, multiple scattering must also be accounted for. This is shown in Fig. 24.2 on the left: one of the photons that is scattered sideways within the interval Δz_i is scattered again within the interval Δz_j and is subsequently recorded by the lidar. This is due to the fact that the final atmospheric scattering event took place within the FOV, even though it occurred outside the image of the laser. Hence, the amount of visible multiple scattering depends on not only the scattering efficiencies below z_j but also the FOV of the recording telescope. Moreover, it is clear from the figure that multiple scattering makes the image of the laser larger (but less defined), similar to the beams from the headlights of an automobile in foggy conditions.

Consider the number of photons per time/height bin $P(z)$ that are received at the detector. This quantity will depend linearly on the number of photons emitted by the laser per pulse P_0 . Moreover, it will depend linearly on the transmission efficiencies of the emission and recording optics: T_{emi} and T_{rec} , respectively. Further, it will depend linearly on the backscatter coefficient $\beta(z)$ at the altitude of interest z as well as the probability that the backscattered photons hit the surface of the recording telescope, A/z^2 . Next, we need to take into account the loss of photons due to extinction α (given by Bouguer–Lambert–Beer’s law) on the way from the lidar (located at z_0) to altitude z and back down to the detector. Hence, we have

$$P(z) = P_0 T_{\text{emi}} T_{\text{rec}} \frac{A}{z^2} \beta(z) \exp\left(-\int_{z_0}^z \alpha(\hat{z}) d\hat{z}\right) \times \exp\left(-\int_z^{z_0} \alpha(\hat{z}) d-\hat{z}\right). \quad (24.12)$$

Combining all of the technical quantities into the lidar constant C and rearranging the terms in the exponentials leads to the normal lidar equation in its simplest form (full overlap, purely single scattering),

$$P(z) = C \frac{1}{z^2} \beta(z) \exp\left(-2 \int_{z_0}^z \alpha(\hat{z}) d\hat{z}\right). \quad (24.13)$$

When using this equation, it is assumed that the height resolution is so high that the variability of the backscatter and extinction coefficients within each altitude step $[z_i, z_{i+1}]$ is negligible and the length of the laser pulse is shorter than the altitude resolution. If these conditions are not fulfilled, a convolution that relates the measured $P(z)$ to the emitted photons that are received from different altitudes should be considered. This is explained in [24.35].

24.3.2 Background Correction and Properties of Lidar Signals

Before solving the elastic lidar equation, we first provide an example of lidar signals in Fig. 24.4. Lidar profiles at 355 and 1064 nm that were obtained simultaneously are shown, with the count rate given in arbitrary units. The raw signals received by the system are shown as dotted functions. These depict an excessive count rate, which occurs for two reasons: first, in the daytime, the signal includes photons from the laser and unwanted photons from the sky. As a whole lidar profile can be obtained in < 1 ms (see (24.1)), it can often be assumed that this background illumination remains constant over this time and can be subtracted from the measured signal. To reduce this background illumination, a small field of view of the recording telescope and interference filters that are as narrow as possible are desirable. Second, the transient recorders can produce an artificial count rate (see Sect. 24.4). Both of these effects need to be corrected for in a process called background correction.

This can be done by subtracting the artificial count rate either at such high altitudes that the laser does not contribute to the signal, or using the count rate before the laser flashes. Hence, we can define a background count rate P_{bg} that is the average of the lidar signal at a background altitude z_{bg} without laser light, i.e.,

$$P_{\text{bg}} = \text{mean}(P_{\text{measured}}(z_{\text{bg}})). \quad (24.14)$$

We can also derive the physical count rate via

$$P(z) = C \frac{1}{z^2} \beta(z) \exp\left(-2 \int_{z_0}^z \alpha(\hat{z}) d\hat{z}\right) = P_{\text{measured}}(z) - P_{\text{bg}}. \quad (24.15)$$

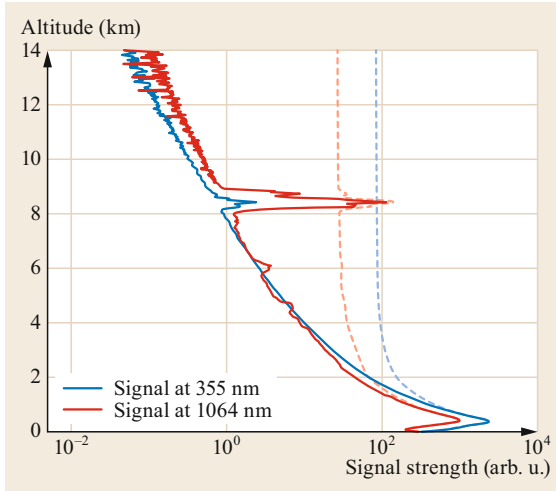

Fig. 24.3 Examples of lidar signals. Note that the molecular contribution from Rayleigh scattering is stronger at shorter wavelengths

These physical count rates at both wavelengths are shown as continuous lines in Fig. 24.3. There are several features of the figure that should be noted. The first noteworthy aspect is the impact of the overlap $\lesssim 500$ m. Below this altitude, the count rate rises with increasing height, as more and more of the laser light contributes to the recorded image. Second, a cloud at ≈ 8 km altitude is much more visible in the IR than in the UV. The reason for this is the Ångström exponent of the backscatter (A_B in (24.3)), which is -4 for Rayleigh scattering but much smaller for particles and especially clouds. Therefore, the molecular contribution is greater in the UV, and the corresponding lidar profile looks *smoother*, and the contrast in count rate between the clouds and the background atmosphere is lower in the UV and higher in the IR. As the contribution from Rayleigh scattering is low in the IR, smaller lidar systems may need some aerosol to be present for a successful evaluation.

Third, it is apparent that the extinction is weaker in the IR and stronger in the UV, as the count rate decays quicker with altitude for the 355 nm channel. This is due to the spectral dependence of A_A in (24.3).

Finally, it can be seen that the count rate decays significantly in the atmosphere. The z^{-2} dependence of the lidar signal is the main reason for this. However, the backscatter coefficient, which is almost proportional to the number density of clear air (scale height: ≈ 8 km), and the exponential term of the extinction also contribute to the deterioration in the count rate with increasing altitude. This imposes some technical constraints on the components in a lidar, as the dynamic range—the difference between the strongest and weakest signals detected by a lidar—may cover more than four orders of magnitude.

24.3.3 Solution of the Elastic Lidar Equation

As already defined above, the elastic lidar equation can be written in the form

$$P(z)z^2 =: S(z) = C\beta(z) \exp\left(-2 \int_{z_0}^z \alpha(\hat{z})d\hat{z}\right), \quad (24.16)$$

where $S(z)$ is the range-corrected lidar signal. The integration is performed from the height of the lidar system z_0 to the altitude of interest z . For a multiwavelength system, (24.16) can be written separately for each color.

This equation links the lidar profile to two physical unknowns: the volume backscatter coefficient β (in $\text{m}^{-1} \text{sr}^{-1}$) and the extinction coefficient α (in m^{-1}). Clearly, a unique solution can only be obtained if we assume a particular relation between α and β . Note that β and α are the total backscatter and extinction coefficients, which contain contributions from the air molecules and aerosol or cloud particles.

The lidar ratio $\text{LR}(z)$, as defined in (24.7), is usually chosen such that (24.16) is transformed into a backscatter equation only. This is achieved by writing

$$\alpha = \alpha^{\text{acr}} + \alpha^{\text{Ray}} = \text{LR}(\beta - \beta^{\text{Ray}}) + \alpha^{\text{Ray}}. \quad (24.17)$$

Hence, we can rewrite (24.15) as

$$\begin{aligned} S(z) \exp\left(2 \int_{z_0}^z (\alpha^{\text{Ray}} - \text{LR}\beta^{\text{Ray}})d\hat{z}\right) \\ = C\beta(z) \exp\left(-2 \int_{z_0}^z \text{LR}(\hat{z})\beta(\hat{z})d\hat{z}\right). \end{aligned} \quad (24.18)$$

If the air density profile and hence α^{Ray} and β^{Ray} are known, all of the terms on the left-hand side are known, leaving one equation for the total backscatter coefficient.

Taking the logarithm and the derivative with respect to height of (24.18), we obtain

$$\begin{aligned} \frac{d}{dz}(\ln S(z)) + 2(\alpha^{\text{Ray}} - \text{LR}\beta^{\text{Ray}}) \\ = \frac{1}{\beta(z)} \frac{d\beta}{dz} - 2\text{LR}(z)\beta(z), \end{aligned} \quad (24.19)$$

from which the nonlinear differential equation

$$\begin{aligned} \frac{d\beta}{dz} = \left[\frac{d}{dz}(\ln S(z)) + 2(\alpha^{\text{Ray}} - \text{LR}\beta^{\text{Ray}}) \right] \beta(z) \\ + 2\text{LR}(z)\beta^2(z) \end{aligned} \quad (24.20)$$

is easily derived.

This is a Bernoulli differential equation of degree 2 (the highest exponent of β), which can be converted into a linear differential equation via the Bernoulli substitution

$$\tilde{\beta} = \beta^{1-n}, \quad (24.21)$$

where n is the degree of the original equation. This substitution yields

$$\frac{d\tilde{\beta}}{dz} = (1-n)\beta^{-n}\frac{d\beta}{dz} \quad (24.22)$$

and

$$\beta^n = \tilde{\beta}^{\frac{n}{1-n}} \quad (24.23)$$

as well as the linear differential equation

$$\begin{aligned} \frac{d\tilde{\beta}}{dz} + \left[\frac{d}{dz}(\ln S(z)) + 2(\alpha^{\text{Ray}} - \text{LR}\beta^{\text{Ray}}) \right] \tilde{\beta}(z) \\ = -2\text{LR}(z). \end{aligned} \quad (24.24)$$

We solve this equation by introducing the integrating factor

$$M(z) := \exp \left[\int \frac{d}{dz}(\ln S(z)) + 2(\alpha^{\text{Ray}} - \text{LR}\beta^{\text{Ray}}) dz \right] \quad (24.25)$$

and by referring to the very important paper written by *James Klett* in 1981 [24.23], which explains that a numerically stable solution can only be found when the integration is performed from the far range back to the system. Hence,

$$\int_{z_{\text{ref}}}^z d\hat{z}, \quad \text{with } z < z_{\text{ref}}, \quad (24.26)$$

so

$$M(z) = \exp \left[\int_{z_{\text{ref}}}^z \frac{d}{dz}(\ln S(z)) + 2(\alpha^{\text{Ray}} - \text{LR}\beta^{\text{Ray}}) d\hat{z} \right] \quad (24.27)$$

$$\begin{aligned} M(z) &= \exp[\ln(S(z_{\text{ref}})) - \ln(S(z))] \\ &\times \exp \left(2 \int_{z_{\text{ref}}}^z \alpha^{\text{Ray}} - \text{LR}\beta^{\text{Ray}} d\hat{z} \right) \end{aligned} \quad (24.28)$$

$$M(z) = \frac{S(z_{\text{ref}})}{S(z)} \exp \left(2 \int_{z_{\text{ref}}}^z \alpha^{\text{Ray}} - \text{LR}\beta^{\text{Ray}} d\hat{z} \right). \quad (24.29)$$

Using this integrating factor and

$$\begin{aligned} N(z) &:= 2 \int_{z_{\text{ref}}}^z M(\hat{z})(-\text{LR}(\hat{z})) d\hat{z} \\ &= 2 \int_z^{z_{\text{ref}}} M(\hat{z})\text{LR}(\hat{z}) d\hat{z}, \end{aligned} \quad (24.30)$$

we can derive

$$\tilde{\beta}(z) = \frac{c + N(z)}{M(z)}, \quad (24.31)$$

and hence

$$\beta(z) = \frac{M(z)}{c + N(z)}. \quad (24.32)$$

To determine the backscatter profile $\beta(z)$ unambiguously, the integrating constant c must be determined. Again, [24.23] suggests that $z = z_{\text{ref}}$ (at the far side of the system) should be selected. The reason for this is simply that $M(z)$ and $N(z)$ are functions that depend on the range-corrected lidar signal and decay with increasing z . If c is chosen to be far away from the lidar and the integration is performed from z_{ref} to z_0 , $M(z)$ and $N(z)$ will become larger, eliminating the influence of an inappropriately chosen integrating constant. In contrast, choosing c to be at z_0 and integrating from z_0 to z would yield unstable results. Therefore, we assume that $\beta(z_{\text{ref}})$ is known for $z < z_{\text{ref}}$. Moreover, we note that

$$\begin{aligned} M(z_{\text{ref}}) &= \frac{S(z_{\text{ref}})}{S(z_{\text{ref}})} \exp \left[2 \int_{z_{\text{ref}}}^{z_{\text{ref}}} (\alpha^{\text{Ray}} - \text{LR}\beta^{\text{Ray}}) d\hat{z} \right] \\ &= 1 \end{aligned} \quad (24.33)$$

and

$$N(z_{\text{ref}}) = 2 \int_{z_{\text{ref}}}^{z_{\text{ref}}} M(\hat{z})\text{LR}(\hat{z}) d\hat{z} = 0, \quad (24.34)$$

from which we derive

$$c = \frac{1}{\beta(z_{\text{ref}})}. \quad (24.35)$$

Thus, the final numerically stable solution for deriving the backscatter profile from the elastic lidar equation

Fig. 24.4a,b Impact of noise in the lidar signal (a) on the retrieval of the backscatter coefficient (b)

(consistently integrating from z to z_{ref} ; note the change of signs!) reads

$$\beta(z) = \frac{\frac{S(z)}{S(z_{\text{ref}})} \text{ST}(z)}{\frac{1}{\beta(z_{\text{ref}})} + \frac{2}{S(z_{\text{ref}})} \int_z^{z_{\text{ref}}} \text{LR}(\tilde{z}) S(\tilde{z}) \text{ST}(\tilde{z}) d\tilde{z}} \quad (24.36)$$

or

$$\beta(z) = \frac{S(z) \text{ST}(z)}{\frac{S(z_{\text{ref}})}{\beta(z_{\text{ref}})} + 2 \int_z^{z_{\text{ref}}} \text{LR}(\tilde{z}) S(\tilde{z}) \text{ST}(\tilde{z}) d\tilde{z}}, \quad (24.37)$$

where

$$\text{ST}(z) = \exp\left(-2 \int_z^{z_{\text{ref}}} (\alpha^{\text{Ray}} - \text{LR} \beta^{\text{Ray}}) d\tilde{z}\right).$$

In honor of James Klett's work in this field, (24.37) is frequently called the *Klett solution*.

In summary, a solution for the elastic lidar equation was pursued by expressing it as a function of the total backscatter coefficient β and introducing the lidar ratio LR. This led to a differential equation that required the backscatter to be calibrated as a boundary value problem. To guarantee the numerical stability of the result, this boundary value had to be applied at the far side of the system, and the integration had to be performed accordingly. Hence, the backscatter profile $\beta(z)$ depends on three quantities:

- The error in the lidar profile $PE(z)$
- The assumed boundary value $\beta(z_{\text{ref}})$
- The chosen profile of $\text{LR}(z)$.

Figure 24.4 shows how the backscatter depends on these quantities.

The dependence of β on the noise in the lidar profile is shown in Fig. 24.4. Figure 24.4b presents an artificial aerosol backscatter profile that shows high and almost height-independent backscatter in the lowest 1.8 km, which could correspond to a well-mixed boundary layer. Above 1.8 km, the backscatter is weaker except for two elevated aerosol layers and some cirrus cloud at an altitude of ≈ 11 km (blue profile in Fig. 24.4b). This aerosol backscatter gives rise to the blue lidar profile shown in Fig. 24.4a. Noise in the lidar signal (green profile in Fig. 24.4a) will produce the backscatter shown in green in Fig. 24.4b. Even with noise present, it is clear that the backscatter can still be retrieved quite reliably.

The dependence of the backscatter profile on the chosen boundary condition is shown in Fig. 24.5. The boundary condition was fixed within the altitude range 11.8–12 km. The green and red functions show the solutions when the boundary condition is lowered or increased by a factor of 1.1, respectively. From Fig. 24.5b, it is apparent that the deviation of the lower/higher solution from the reference solution decreases with altitude. In this respect, the Klett method gives stable results: if the integration is performed from an altitude of 12 km towards the ground, the impact of a wrongly chosen boundary condition slowly decays. This decay becomes stronger as the atmosphere becomes more turbid [24.35]. Nevertheless, the boundary condition does influence the solution, and it is beneficial to have lidar

Fig. 24.5a,b Impact of the boundary condition on the retrieval of the backscatter coefficient. **(a)** Shown are three solutions, which differ in the applied boundary condition by 10%. **(b)** The deviation of a too low (green) or too high (red) chosen boundary condition with respect to the reference (blue in **(a)**). It can be seen that the impact of a wrong chosen boundary conditions decays towards the ground

systems that reach the low stratosphere, as this region is normally only slightly affected by aerosols. In this case, the backscatter coefficient at the fitted altitude is only slightly larger than the Rayleigh backscatter, i.e., $\beta^{\text{Fit}} = (1 + \varepsilon)\beta^{\text{Ray}}$ where ε is an arbitrary small number > 0 . These fitting conditions are called *clear sky conditions*. With a little experience, an incorrectly chosen boundary condition is easily spotted—either a peak occurs in the counting rate with altitude (as shown in Fig. 24.4; this must be avoided), or the resulting backscatter profile gives rather low values across the whole troposphere, which indicates that the chosen β^{Fit} is too low.

In a multiwavelength system, the boundary conditions for all the different wavelengths can be estimated consistently by assuming an Ångström exponent for the backscatter (24.3) and then using this to calculate the boundary conditions based on one guess for the first color, as shown in the example below.

Let $\beta^{\text{Fit}}(532 \text{ nm}) = 1.05\beta^{\text{Ray}}$ and $A_B = -1$. This means that, for 532 nm,

$$\beta^{\text{aer}}(z_{\text{Fit}}) = \frac{1}{20}\beta^{\text{Ray}}(z_{\text{Fit}}). \quad (24.38)$$

Therefore, for the doubled wavelength (1064 nm),

$$\begin{aligned} \beta^{\text{Ray}}(1064 \text{ nm}) &= \left(\frac{1064}{532}\right)^{-4} \beta^{\text{Ray}}(532 \text{ nm}) \\ &= \frac{1}{16}\beta^{\text{Ray}}(532 \text{ nm}) \end{aligned} \quad (24.39)$$

and

$$\begin{aligned} \beta^{\text{aer}}(1064 \text{ nm}) &= \left(\frac{1064}{532}\right)^{A_B} \beta^{\text{aer}}(532 \text{ nm}) \\ &= \frac{1}{2}\beta^{\text{aer}}(532 \text{ nm}). \end{aligned} \quad (24.40)$$

Hence, doubling the wavelength reduces the Rayleigh backscatter by a factor of 16, while the aerosol backscatter decreases by only a factor of 2. This means that the fit condition for 1064 nm is

$$\begin{aligned} \beta^{\text{aer}}(z_{\text{Fit},1064\text{nm}}) &= \frac{1}{20} \times 16 \times \frac{1}{2}\beta^{\text{Ray}}(z_{\text{Fit},1064\text{nm}}) \\ &= 1.4\beta^{\text{Ray}}(z_{\text{Fit},1064\text{nm}}), \end{aligned} \quad (24.41)$$

or, more generally,

$$\beta^{\text{Fit}}(\lambda_2) = \left(\frac{\lambda_2}{\lambda_1}\right)^{4-A_B} \varepsilon(\lambda_1). \quad (24.42)$$

This example also shows that clear sky conditions for near-infrared and longer wavelengths must be handled with care.

The influence of a wrongly chosen lidar ratio is demonstrated in Fig. 24.6. It can be seen that lower lidar ratios always lead to higher backscatter values and vice versa. The higher the backscatter and the longer the integration distance, the more pronounced the difference. The lidar ratio is therefore an important parameter

Fig. 24.6a,b Impact of the lidar ratio on the retrieval of the backscatter coefficient. **(a)** Three solutions are shown for different lidar ratios. **(b)** Impact of a too low chosen (green) or too large chosen (red) lidar ratio on the resulting backscatter

for retrieving the backscatter, and it is discussed further in Sect. 24.3.7. Choosing the lidar ratio poorly results in noticeable errors during the retrieval of the backscatter.

In short, determining the backscatter coefficient to a precision of about 10% requires appropriate selection of the boundary condition and (especially) the lidar ratio. Even so, the backscatter coefficient is still the quantity that is easiest to derive from lidar data.

The situation is even worse for the extinction coefficient, as it enters the normal lidar equation (24.2) via the expression

$$\exp\left(-2 \int_0^z \alpha(\hat{z}) d\hat{z}\right), \quad (24.43)$$

which is *infinite smooth*, meaning that there are infinite continuous derivatives with respect to altitude z , regardless of the real extinction profile in the atmosphere.

An example of this is shown in Fig. 24.7. This shows an arbitrary extinction profile (blue curve in the Fig. 24.7a). Just as for the backscatter profile in Fig. 24.4, different maxima can be distinguished, which are due to the presence of an aerosol in the boundary layer, elevated layers, and thin cloud. Figure 24.7b shows the integral of the extinction profile, which is much smoother and increases monotonically. Figure 24.7c shows the variation in (24.43) with height. A tiny amount of noise (barely visible) has been added

to this plot (green curve). This small amount of noise is still relatively minor in Fig. 24.7b (see the green curve), but it is enough to completely destroy the solution for the extinction profile (green curve in Fig. 24.7a). This points to a problem with deriving the profile of the extinction coefficient from lidar data: it enters the lidar equation in an infinite smooth expression behind which an arbitrary extinction profile is hidden. Calculating the derivative d/dz increases the noise dramatically. Hence, the retrieval of the extinction coefficient from lidar data is an ill-posed problem [24.36]. However, it should be noted that the problem is with the position of the extinction in the lidar equation, not the extinction coefficient itself. Instead of using the Klett method as explained above, some authors solve the basic lidar equation for the extinction coefficient. This works as well, but most of the information on the shape of the solution comes from the first term, not the exponential term, in (24.43).

24.3.4 Simplifications

In turbid conditions, or for cloud measurements, the assumptions $\alpha^{\text{aer}} \gg \alpha^{\text{Ray}}$ and $\beta^{\text{aer}} \gg \beta^{\text{Ray}}$ hold true, such that $\alpha \approx \alpha^{\text{aer}}$ and $\beta \approx \beta^{\text{aer}}$. Therefore, we introduce the *total lidar ratio* $L := \alpha/\beta$ and derive (completely analogously to the section above)

$$S(z) = C\beta(z) \exp\left(-2 \int_{z_0}^z L(\hat{z})\beta(\hat{z})d\hat{z}\right). \quad (24.44)$$

Fig. 24.7a–c Critical impact of noise on the determination of the extinction coefficient. (a) Noise-free (blue) and noisy (green) extinction coefficient, (b) the corresponding profiles of the integral of the extinction coefficient (again blue noise-free and green noisy), (c) the corresponding attenuation term of the lidar equation. It can be seen that only little noise in the lidar profile destroys the solution for the extinction

Hence,

$$\frac{d}{dz} \ln(S) = \frac{1}{\beta} \frac{d\beta}{dz} - 2L\beta. \quad (24.45)$$

As a side note, historically or when using a lidar horizontally in a homogeneous medium, the term $d\beta/dz$ (almost) vanishes and the equation above simplifies accordingly. This is known as the *slope method* [24.23, 27].

Otherwise, using the analog Bernoulli substitution and the guidance supplied by Klett, we obtain the simpler expression

$$\beta(z) = \frac{S(z)}{S(z_{\text{ref}}) / (\beta(z_{\text{ref}}) + 2 \int_z^{z_{\text{ref}}} S(\hat{z})L(\hat{z})d\hat{z})}. \quad (24.46)$$

24.3.5 Extensions to the Lidar Equation

Figure 24.2 illustrates the overlap height—the height above which the field of view (FOV) of the recording telescope contains the full image of the laser beam. This is an important parameter in a lidar system. An overlap occurs even for coaxial lidars in which the outgoing laser beam and the recording telescope share a common optical axis. The reason for this is the field stop in the focal plane of the recording telescope, which is included to reduce the FOV and hence the stray light contamination at daytime operation. This can be seen in Fig. 24.8.

If the laser beam is viewed at a finite distance, its image will form behind the focal plane. While only the rays that pass through the center of the telescope (a) and the ray through the focal point (b) are important when constructing the image in geometrical optics, in reality *all* of the rays that travel from the object through the telescope contribute to the brightness of the image (e.g., the *dashed ray*). Figure 24.8 clearly shows that some of the rays from the edge of the telescope are blocked. Hence, for finite object distances, only part (not the whole) of the telescope contributes to image formation. This reduction in the effective telescope area needs to be accounted for in the lidar equation. The corresponding overlap function, which is often denoted $O(z)$, starts at 0 for $z = z_0$ and approaches a constant value (close to 1) at the altitude z_{overlap} when the overlap is (almost) complete. Hence, the overlap can be included in the lidar equation as

$$\begin{aligned} P(z) &= C \frac{1}{z^2} \beta(z) \exp\left(-2 \int_{z_0}^z \alpha(\hat{z})d\hat{z}\right) O(z) \\ &= C_* \frac{1}{z^2} \beta(z) \exp\left(-2 \int_{z_{\text{Overlap}}}^z \alpha(\hat{z})d\hat{z}\right). \end{aligned} \quad (24.47)$$

In many applications, the lidar data is only evaluated for altitudes $z > z_{\text{overlap}}$. In this case, the lidar has a blind spot close to the system. The overlap problem becomes even more pronounced for larger telescope mirrors that

Fig. 24.8 Image formation and the impact of the field stop

may be required to obtain a sufficient return signal from high altitudes. Therefore, lidars with two recording mirrors, in which the smaller mirror collects the light from the near range, are sometimes constructed.

Some approaches for estimating the overlap function from experimental data have been proposed. For example, the scattering of a pure molecular atmosphere with a known expected count rate can be used. In this case, the overlap for each height bin is the ratio of the measured to the expected count rates [24.37]. However, in the real atmosphere, the overlap depends on the number of scattering particles. Turbid conditions lead to an increased probability of scattering events, some of which end up in the FOV of the telescope. In contrast, the count rate is lower in clear conditions, so $O(z, \text{turbid}) > O(z, \text{clear})$.

As shown in previous sections, the lidar ratio, depolarization ratio, and color ratio (all of which are intensive quantities) are derived from the ratios of different lidar signals. If each optical branch (including its interference filter and photomultiplier) had precisely the same alignment, the overlap would be identical for all signals, so it would cancel out. While this is typically hard to achieve, it is clear that lidar properties derived from ratios of different signals are less affected by the overlap.

Given the small FOVs (typically < 1 mrad) of ground-based lidar systems, the assumption of single scattering largely holds for aerosol layers or thin clouds. However, in turbid conditions, some of the photons recorded by the detector have been scattered several times and have therefore zigzagged through the atmosphere. This phenomenon is called multiple scattering (see the photon on the left in Fig. 24.2), and it results in signal count rates behind a cloud that are higher than would be expected from the single scattering lidar equation. An excessive backscatter value translates into a lidar ratio that is too small in and behind clouds (see (24.9)), as pointed out in [24.38].

To compensate for this, a multiple scattering factor η is usually introduced such that the normal lidar equation for single scattering (SS) is generalized to an equation for total scattering (TS), i.e.,

$$P_{\text{SS}}(z) = C \frac{1}{z^2} \beta(z) \exp \left(-2 \int_{z_0}^z \alpha(\hat{z}) d\hat{z} \right) \quad (24.48)$$

and

$$P_{\text{TS}}(z) = C \frac{1}{z^2} \beta(z) \exp \left(-2 \int_{z_0}^z \eta(\hat{z}) \alpha(\hat{z}) d\hat{z} \right). \quad (24.49)$$

This leads to

$$\eta(z) = 1 + \frac{\ln \left(\frac{P_{\text{SS}}(z)}{P_{\text{TS}}(z)} \right)}{2 \int_{z_0}^z \alpha(\hat{z}) d\hat{z}}. \quad (24.50)$$

Values of 0.5–1 for the multiple scattering factor have been estimated [24.38].

Multiple scattering can be treated in different ways—by performing computationally expensive Monte Carlo simulations (see, for example, [24.39]) or by considering the energy distribution in the image of the laser while it is propagating through the atmosphere [24.40].

Also important is a noticeable shift in depolarization: multiple scattering requires a backscatter angle of slightly less than 180° (left ray in Fig. 24.2). It is shown in [24.41] that the plane of polarization—which is conserved for light that is backscattered at 180° from spherical particles—is significantly altered for other backscatter angles, even 179° . This is why water clouds show significant depolarization once multiple scattering sets in.

The amount of multiple scattering rises as the FOV of the lidar system increases [24.39]. It also depends on the geometrical width of the laser beam and the FOV of the recording telescope, because larger surfaces make it more probable that photons scattered roughly in a forward direction remain in the FOV. Thus, multiple scattering is much more severe for spaceborne than for ground-based lidar systems [24.42].

24.3.6 Transition Method

Under favorable conditions, a layer-integrated extinction coefficient and hence also the lidar ratio can be determined from the elastic lidar equation. One of the ways to achieve this is called the transition method, in which we compare the range-corrected lidar signals obtained directly above (z_{top}) and below (z_{bot}) a layer that may contain a cloud or a dense aerosol. We therefore write

$$S(z_{\text{top}}) = C\beta(z_{\text{top}}) \exp\left(-2 \int_{z_0}^{z_{\text{bot}}} \alpha(\hat{z}) d\hat{z}\right) \times \exp\left(-2 \int_{z_{\text{bot}}}^{z_{\text{top}}} \alpha(\hat{z}) d\hat{z}\right) \quad (24.51)$$

$$\Leftrightarrow S(z_{\text{top}}) = \frac{\beta(z_{\text{top}}) S(z_{\text{bot}})}{\beta(z_{\text{bot}})} \exp\left(-2 \int_{z_{\text{bot}}}^{z_{\text{top}}} \alpha^{\text{Ray}}(\hat{z}) d\hat{z}\right) \times \exp\left(-2 \int_{z_{\text{bot}}}^{z_{\text{top}}} \alpha^{\text{aer}}(\hat{z}) d\hat{z}\right). \quad (24.52)$$

The integral in the last term is simply the aerosol optical depth (AOD) of this layer. Hence,

$$\text{AOD}_{\text{Layer}} = \frac{1}{2} \ln \left(\frac{\beta(z_{\text{top}}) S(z_{\text{bot}})}{\beta(z_{\text{bot}}) S(z_{\text{top}})} \right) - \int_{z_{\text{bot}}}^{z_{\text{top}}} \alpha^{\text{Ray}}(\hat{z}) d\hat{z}. \quad (24.53)$$

This method has its value in cases where $\beta(z_{\text{bot}})$ and $\beta(z_{\text{top}})$ can be assumed; for instance, when multiple lidar observations are made that are close to each other in space or time, or—even simpler—when $\beta(z_{\text{bot}})$ and $\beta(z_{\text{top}})$ are assumed to be equal (i.e., for geometrically thin clouds).

The layer-integrated lidar ratio is then given by

$$\text{LR}_{\text{Layer}} = \frac{\text{AOD}_{\text{Layer}}}{\int_{z_{\text{bot}}}^{z_{\text{top}}} \beta^{\text{aer}}(\hat{z}) d\hat{z}}. \quad (24.54)$$

Alternatively, the Klett solution can be applied in an iterative loop with the lidar ratio varying between z_{bot} and z_{top} until the desired $\beta(z_{\text{bot}})$ is obtained.

24.3.7 Importance of the Lidar Ratio

In contrast to the abovementioned special cases or more complex lidar systems such as Raman lidars or high spectral resolution lidars (HSRLs; see, e.g., [24.43]), a backscatter lidar usually cannot determine the extinction coefficient. For this reason, a lidar ratio (see (24.8)) must be assumed in advance when using the Klett method. This lidar ratio is an intensive quantity that does not depend on the aerosol concentration, only on the intrinsic properties of the aerosol particles: their size, shape, and refractive index.

Therefore, we would expect the same type of aerosol to show different LRs depending on its precise chemical composition and age and the water-uptake and meteorological conditions present, even though this issue is largely overlooked in the literature. Nevertheless, long-term experience with different lidar systems has shown that fairly consistent datasets are obtained, with lower LRs observed for clean conditions and cirrus clouds and higher values for absorbing aerosols. Some relevant values are compiled in Table 24.3. These values can be used for orientation when it is possible to identify the type of aerosol seen by the lidar.

To underline that actual LRs may deviate from the values shown in Table 24.3, we should mention the work of Ackermann [24.51], who used Mie theory and assumed some basic aerosol properties (such as the refractive index and a log-normal size distribution) to analyze the hygroscopic behaviors of different aerosol species. Ackermann found, for example, that the LR of continental aerosol strongly increases with relative humidity. Also, it was reported in [24.52] that the LR of sea salt depends on the wind speed: higher winds decrease the observed LR. Moreover, nonspherical particles typically present a higher LR than spherical particles because the backscatter efficiency decreases with increasing particle elongation [24.53].

Again, it should be noted that the values in Table 24.3 are only rough estimates. As changes in photochemistry, coagulation, and water uptake can alter the scattering-relevant microphysical properties (the size, shape, and refractive-index distributions) of real aerosols within minutes, the real lidar ratio will fluctuate over time.

Because the extinction caused by aerosols decreases with wavelength, it is more important to choose an appropriate lidar ratio for short wavelengths than for those in the infrared. Lessening the extinction due to aerosols decreases the difference between the attenuated backscatter and the backscatter coefficient, mean-

Table 24.3 Lidar ratios for different aerosol types (FT: free troposphere, CALIPSO: Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations)

Type of aerosol	355 nm	532 nm	1064 nm	Reference	Remarks
Clean continental	–	35 sr	30 sr	[24.44]	CALIPSO
Clean marine	–	20 sr	45 sr	[24.44]	CALIPSO
Marine	–	20–37 sr	–	[24.45]	Higher values in the FT
Dust	–	40 sr	55 sr	[24.44]	CALIPSO
Dust	–	57 sr	–	[24.46]	Tenerife (Sahara)
Dust	49–61 sr	50–70 sr	–	[24.45]	Sahara
Dust	33–43 sr	30–43 sr	–	[24.45]	Gobi, Saudi Arabia
Polluted continental	–	70 sr	30 sr	[24.44]	CALIPSO
Polluted continental	43–70 sr	29–64 sr	–	[24.45]	Europe, N. America
Polluted continental	–	45–64 sr (less during monsoon)	–	[24.18]	China
Polluted dust	–	65 sr	30 sr	[24.44]	CALIPSO
Smoke	–	70 sr	40 sr	[24.44]	CALIPSO
Smoke	33–59 sr	42–64 sr	–	[24.45]	Boreal forests
Volcanic ash	55–65 sr	50–60 sr	–	[24.47]	Europe
Arctic aerosol	25–40 sr	30–55 sr	35–50 sr	[24.48]	European Arctic
Arctic aerosol	48–72 sr	48–72 sr	–	[24.45]	Measured over Europe
Cirrus clouds	–	17–41 sr	–	[24.13]	East Asia
Cirrus clouds	–	28–38 sr	–	[24.49]	CALIPSO (over oceans)
Liquid clouds	18.5 sr	18.5 sr	18.5 sr	[24.50]	

ing that the Klett solution (24.41) does not critically depend upon the choice of LR for long wavelengths. On the other hand, in the UV, any flaw in the choice of the lidar ratio will lead to a major error in the backscatter coefficient.

24.3.8 The Color Ratio

As defined above in (24.4), the CR provides a rough estimate of the size of the aerosol. If we recall the definition of the color ratio and consider two arbitrary wavelengths, 532 and 1064 nm, we have

$$\text{CR}(532 \text{ nm}, 1064 \text{ nm}, z) = \frac{\beta_{532 \text{ nm}}^{\text{aer}}(z)}{\beta_{1064 \text{ nm}}^{\text{aer}}(z)}. \quad (24.55)$$

The small particle limit in scattering theory is given by the Rayleigh limit, the cross-section of which is proportional to λ^{-4} . Hence, in the case of pure Rayleigh scattering, the CR for 532 and 1064 nm would be $(1/2)^{-4} = 16$. In contrast, at the large particle limit, values of around 1 would be expected, as the scattering becomes less dependent on the wavelength. However, it is not possible to classify an aerosol in a straightforward manner based on its color ratio. This is because, for typical aerosol particle sizes that are accessible to lidar (i.e., a radius of 0.1–5 μm), the backscatter coefficient depends strongly on the refractive index [24.54]. Hence, one color ratio does not contain enough information to

determine the size of the scattering aerosol particles. The situation is different for cirrus clouds, for which the refractive index is that of ice. Although they consist of large ice crystals with size and shape distributions that depend on the temperature, altitude, the vertical movement of the air, and possibly other parameters, observations and modeling efforts seem to suggest that $\text{CR} < 1$ are common. For example, in [24.55], cirrus clouds over the US were analyzed and an average color ratio of 0.88 was obtained from a year-long observational cycle. Also, simulations reported in [24.56] indicated that $\text{CR} \approx 0.7$ for hexagonal columns and $\text{CR} \approx 0.8$ for hexagonal plates with wavelengths of 532 and 1064 nm. On the other hand, $\text{CR} \approx 2$ were found for large spherical particles.

Values widely distributed around 2 were also derived using the spaceborne lidar in CALIPSO [24.44]. It was found that the color ratio distribution peaked at $\text{CR} \approx 2$ in different cases involving dust and smoke aerosols over the land and ocean. In cases where the coarse mode contribution is negligible (e.g., for anthropogenic pollution [24.12] or at remote sites such as the polar regions), the color ratio is typically larger. Values of around 5 were found for Arctic haze with wavelengths of 532 and 1064 nm [24.48].

The size of an aerosol in the accumulation range can be estimated quite precisely from multiwavelength Raman lidar; for more on this, please refer to the chapter on Raman lidar (Chap. 25).

Table 24.4 Depolarization ratios for different aerosol types

Type of aerosol	355 nm	532 nm	Reference	Remarks
Fresh desert dust	25%	31%	[24.12]	HSRL lidar, Morocco
Desert dust	–	32%	[24.57]	CALIPSO over the Atlantic
Marine aerosol	2%	3–5%	[24.12]	
Marine aerosol		Max. 22%	[24.14]	Crystalline sea salt
Dust	17%	26%	[24.12]	
Anthropogenic		6%	[24.12]	Europe
Boreal biomass burning		7%	[24.12]	Aged aerosol over Europe
Boreal biomass burning		5%	[24.58]	Aged aerosol over Asia
Tropical biomass burning	16%	16%	[24.12]	
Volcanic	35%	37%	[24.12]	Eyjafjalla, Iceland in 2010
Cirrus		10–100%	[24.13]	Asia; 100% for optically thin cloud

24.3.9 Depolarization

The measurement of aerosol depolarization is a mature technique that provides a reliable scheme to classify and distinguish different aerosol types. As stated above, backscatter at spherical particles preserves the polarization of the light. As liquid particles are almost spherical in shape due to the action of surface tension, depolarization also gives a quick indication of the state of aggregation of the particles. However, the polarization of the light backscattered from hexagonal ice crystals—which are common in cirrus clouds—is also unchanged if the laser beam is perpendicular to the plane with hexagonal symmetry. For this reason, it is convenient to incline the beam of the laser just a few degrees away from the vertical to remove the symmetry of the ice crystals [24.11]. It is also worth bearing in mind that the smallest particles do not depolarize the light effectively [24.14], as the shape becomes less important with decreasing radius. Nevertheless, the depolarization induced by air molecules is nonzero and depends on the spectral resolution. Following the guidance given in [24.59], we assign the (roughly) elastic backscattering from air molecules to the *Cabannes line*, for which the vibrational and rotational states of the molecules remain unchanged. This line is surrounded by a spectrum of rotational Raman lines. Together, the Cabannes line and the rotational Raman spectrum are usually called the *Rayleigh spectrum*. In [24.59], it is stated that the depolarization of the Cabannes line for lidar applications (180° backscatter, linear initial polarization) is 0.363%. This depolarization is therefore expected even in completely aerosol-free layers if narrow interference filters with a bandpass of < 0.3 nm are employed. When filters with a wider bandpass are used, more and more of the rotational Raman lines are recorded too, which increases the depolarization of the clear air to 1.43%.

Table 24.4 compiles depolarization measurements for different aerosol types. The depolarization induced by desert dust, the most abundant type of aerosol on

Earth, is significant. So far, only a few lidar instruments have measured the depolarization in the near-infrared as well. However, the inclusion of an additional depolarization channel in the infrared was shown in [24.60] to facilitate the determination of the effective radius of aerosol particles > 1 μm using multiwavelength lidar systems.

Some of the values in the table are also presented in [24.61], which provides an aerosol classification scheme based on the lidar ratio and depolarization. 100% depolarization for thin and subvisible cirrus clouds over Taiwan, regardless of altitude, have been reported [24.13]. In [24.62], observations performed over North America were used to show that depolarization may increase with decreasing temperature; the same may also be true for China [24.63].

24.3.10 Determination of the Boundary Layer Height by Lidar

Assuming that the main source of aerosols is the ground and that convection lifts the aerosols up and mixes them almost homogeneously within the atmospheric boundary layer (ABL), the altitude of the ABL can easily be derived using a backscatter lidar. There are several slightly different methods of achieving this; these methods are explained in [24.64]. The idea behind all of them is that the profile of the backscatter coefficient $\beta(z)$ or that of the attenuated backscatter $B(z)$ shows higher, almost altitude-independent, values within the ABL and lower values above the ABL. Hence, we require the derivative of $\partial B/\partial z$. In fact, the ABL height H_{ABL} can be determined relatively simply via the gradient method (GM),

$$H_{\text{ABL}}^{\text{GM}} = \min \left(\frac{\partial B(z)}{\partial z} \right). \quad (24.56)$$

Slightly lower values for the ABL height are found by using the inflection point method (IPM), which employs

the second derivative

$$H_{\text{ABL}}^{\text{IPM}} = \min \left(\frac{\partial^2 B(z)}{\partial z^2} \right). \quad (24.57)$$

According to [24.65], this inflection point method gave the best agreement with radiosonde data.

Other methods use either the derivative of the logarithmic attenuated backscatter profile or filter the $B(z)$ profiles with wavelets [24.64, 66].

24.4 Devices and Systems

In this section we discuss the main components of a lidar and some basic design considerations. The complexity of lidar systems will be highlighted and the most important technical parameters for understanding the advantages or disadvantages of a given system are introduced.

All lidar systems can be separated into two parts: the emission optics that produce the outgoing light beam, and the recording branch that retrieves the backscattered light and counts the signal.

The backscattered photons produce an image of the laser at each altitude. This is recorded by a telescope. In lidar systems that use different colors or possess polarization sensitivity, the individual wavelengths or polarization states must be separated and guided onto detectors such as photomultipliers.

24.4.1 Components of the Emission Optics

The emission optics can be divided into the laser and the beam-widening telescope (BWT). The laser is the light source for the lidar, implying that it is a key component. Its most important parameters are:

- **Power.** Measured in watts, the power is the number of photons that the laser emits, meaning that it governs the quantity P_0 in the main lidar equation. The power is the product of the pulse energy (in J) and the repetition rate of the laser (in Hz). Note that for lidar operation it is beneficial to distribute the laser energy into a few strong pulses because the background illumination is added to each shot. Hence, strong pulses with low repetition rates lead to a better signal-to-noise ratio (SNR). Lasers frequently require a warm-up period to obtain their full power.
- **Divergence.** This is the angle by which the diameter of the beam widens as it propagates. It is a very important quantity for lidar operations. The FOV of the recording telescope is normally larger than the

The abovementioned conditions of a well-mixed ABL and dominant aerosol sources on the ground are frequently fulfilled during the day in the low and mid-latitudes, so many publications have reported successful determinations of the ABL height using lidar. However, the situation is more complicated under stable conditions: if the aerosol is advected over long ranges and the atmosphere is stably stratified, the methods mentioned above cannot retrieve the correct ABL height. We will give examples of this in Sect. 24.8.

beam divergence, such that the whole laser beam lies within the FOV of the recording telescope (this corresponds to $O(z) = 1$ in the main lidar equation (24.13)). Hence, a laser with a small beam divergence yields a small FOV and decreased sensitivity to background illumination. When choosing an appropriate laser, it should be noted that the divergence can slowly increase during operation due, for example, to the aging of flash lamps in the laser. Moreover, for lidar applications, the appropriate definition of the divergence is the angle within which all of the laser energy is confined, whereas manufacturers sometimes define it as the angle at which the laser energy drops by 50% of its maximum value (i.e., the *full width at half maximum*, FWHM).

- **Beam point stability.** This refers to any drifting of the direction in which the laser beam is emitted over time, and is normally much smaller than the divergence. However, it is sometimes only calculated when the laser has warmed up.
- **Pulse duration.** This quantity becomes important when a high altitude resolution is required, as the basic lidar equation assumes that the length of the laser beam is smaller than the altitude bins.
- **Polarization accuracy.** Due to optical components behind the laser head, the effective polarization accuracy will be $< 100\%$. In particular, reflections that occur behind the laser to guide the beam into the sky have the potential to deteriorate the polarization accuracy.
- **(Spectral) line width.** This parameter, which has units of cm^{-1} , describes the spectral purity of the laser. It can be increased by injection seeding, which is required for wind measurements performed via coherent detection (see the chapter on wind lidar). In injection seeding, a small spectrally pure laser is used to *seed* the cavity of the main laser, meaning that it determines the mode of the main laser that is

Fig. 24.9 Image formation in a beam-widening telescope

amplified. An extremely small spectral width is not required to determine the visibility or aerosol properties.

- *Energy distribution within the laser beam.* This is not normally an important quantity, as the whole laser beam is detected. However, we mention it here because it relates the beam divergence based on the FWHM to the full divergence.

Aside from the abovementioned parameters, other *soft factors* must also be considered in lidar applications. Long-term stability of the beam properties and the laser energy are generally desired. Therefore, maintenance that changes the optical setup should be minimized; e.g., for flash-lamp-pumped lasers, it is desirable for the laser properties to remain unchanged as the lamp ages, and for flash lamp replacement to be possible without the need to realign the optics. Power consumption, cooling solutions, and sensitivity to temperature changes or vibrations also need to be considered when choosing a laser.

Beam-Widening Telescope

The emission optics frequently also contain elements other than the laser and the mirrors that are needed to guide the laser light into the atmosphere. Many systems use a beam-widening telescope, which increases the diameter of the laser beam but reduces the tangent of the beam divergence by the same factor, as can be seen in Fig. 24.9.

Consider two lenses with focal lengths of f_1 and f_2 and a common focal plane, as seen in Fig. 24.9. The two lenses are arranged as in a reversed Keplerian telescope. The angle γ implies that the laser spot radii before (r_1) and after (r_2) beam widening obey the relation

$$\frac{r_2}{r_1} = \frac{f_2}{f_1}. \quad (24.58)$$

To study the laser beam divergence before (α_1) and after (α_2) beam widening, we consider rays through the center of the lenses and the image scale S , which leads to

$$S = \tan(\alpha_1)f_1 = \tan(\alpha_2)f_2 \quad (24.59)$$

and therefore

$$\frac{\tan(\alpha_2)}{\tan(\alpha_1)} = \frac{f_1}{f_2}. \quad (24.60)$$

The sketch shown in the figure uses geometrical optics, which is justified if all dimensions and spot sizes are much larger than the longest wavelength. Figure 24.9 shows an optical design that should actually be avoided, as a real image of the laser will form at S , producing heat and turbulence within the telescope. To avoid this problem, a Galilean telescope with a virtual image is preferable.

24.4.2 Recording Optics

The detection branch is divided into four systems: the recording telescope, the optics for spectral separation, the recording devices, and the counting electronics.

The Telescope

One of the most important parameters of the telescope is its diameter. Larger mirrors collect more light but also produce longer overlap ranges.

The focal length (f) is not very important. Although the focal length determines the image scale, the most important quantity of a lidar is the FOV of the telescope. When an aperture stop is inserted into the focal plane of a telescope with a diameter of d , the FOV is determined (according to Fig. 24.3) via

$$\text{FOV} = 2 \arctan\left(\frac{d}{2f}\right). \quad (24.61)$$

A smaller FOV reduces the amount of stray light collected during daytime observations. However, a smaller FOV also means a higher overlap altitude.

Another consideration regarding the recording optics is the surface smoothness, for which the criterion introduced by Maréchal in 1943 is relevant (see, e.g., [24.67]). This criterion considers the root mean square (RMS) difference between an ideal wavefront and one deformed by a nonideal telescope surface. Any degradation is negligible if the RMS difference between wavefronts is smaller than 1/14 of a wavelength. If the Maréchal criterion is fulfilled, the optics are as good as they can be for their size, and they are said to be *diffraction limited*. Note that:

- The deviation is measured at the wavefront. A mirror with a defect depth of Δ produces an optical path difference of 2Δ , so the surface roughness of the mirror must be smoother than 1/14 of a wavelength.
- The Maréchal criterion considers the whole surface and is thus superior to the Rayleigh criterion. Consider a perfect mirror with a small defect of depth $\Delta > \lambda/8$. This tiny defect will give rise to a wavefront error of $> \lambda/4$, meaning that the Rayleigh criterion is violated, although it will still deliver good images. More realistically, a mirror with a surface roughness $\Delta \approx \lambda/10$ will produce stray light and will not fulfill the Maréchal criterion.
- As lidar systems consist of many optical surfaces, and as the atmosphere by astronomical seeing further degrades the image quality, it is advisable to have a telescope that is better than simply *diffraction limited*. Ideally, the whole optical path should meet the Maréchal criterion.
- As the deviation is evaluated in comparison to the wavelength, the user should bear in mind the shortest wavelength of the lidar. Optical defects are clearly more severe for UV wavelengths than for infrared ones.

On the other hand, the FOVs of lidar systems are generally small (≤ 1 mrad), meaning that off-center optical aberrations such as comas generated by parabolic mirrors can normally be neglected. It is easier for any optical system to produce a good on-axis image than to image large FOVs.

The thermal stability of the mirror and telescope structure should also be considered. As the temperature at which the lidar is operated will change over time, a system that does not require refocusing due to temperature shifts is desirable. Nowadays, mirrors made from quartz or ceramic glass with very small thermal expansion coefficients are available. The same is true of

telescope tubes made from carbon fibers. Alternatively, the system can be designed such that the telescope structure and the mirror have identical thermal expansion coefficients.

Another issue regarding the thermal stability of the optics is the potential for problematic internal strain in a mirror. Such strain will lead to permanent surface changes as the temperature fluctuates, even when the mirror has been polished to high precision in a lab. This can only be avoided by heating the substrate to a specified temperature and then cooling it so slowly that all internal stress dissipates. This process is called *annealing*, and is mandatory for optical mirrors.

Optics for Wavelength Separation

The main parameters for interference filters (IFs) are the central wavelength (of transmission), the bandwidth, the peak transmission, and the angle at which the filter is to be used. Moreover, the out-of-band suppression—the extent to which light of the wrong wavelength is suppressed—is also important, for two reasons. First, sometimes a very weak signal must be recorded next to a strong signal in a lidar (see the chapter on Raman lidar). Second, glass can fluoresce if it is illuminated with UV light such as the third harmonic of the frequently used Nd:YAG laser at 355 nm [24.68]. Hence, due to the optical components within a lidar, leakage is observed from the strong elastic signal observed at shorter wavelengths to the weaker Raman-shifted light at longer wavelengths. Therefore, it is recommended that weak signals should be separated from strong UV signals as quickly as possible along the optical path in order to strongly suppress the elastic signal in the inelastic branch. An example involving a water vapor system is discussed in [24.69]. Systems that utilize a large amount of light transmission through glass, such as those with fiber optics, are prone to fluorescence.

Finally, the effects of temperature and aging on interference filters should also be accounted for. The peak transmission is a function of temperature; however, as different technologies are used to manufacture IFs, this temperature dependence can vary from IF to IF. While modern IFs last several years without degrading, the application of narrow spectral filters in a changing environment necessitates careful monitoring.

The same considerations outlined above are also valid when choosing dichroic mirrors. Additionally, as these mirrors are normally located in the middle of the optical train, far from the photomultipliers, smooth optical surfaces are required so that they do not degrade the overall optical quality. Also, antireflection coatings can strain optical surfaces, potentially degrading the optics or introducing birefringence.

Recording Devices

In lidar applications, it is not normally necessary to record two-dimensional (2-D) images, only the backscattered light from the laser. This is typically done using devices such as photomultiplier tubes (PMTs) or avalanche photodiodes (APDs). In both of these devices, the photoelectric effect and current amplification are used to obtain an output voltage that is within the linear dynamic range of the device, thus ensuring that the output voltage is proportional to the number of incident photons. A large dynamic range is often required in lidar applications due to the $1/z^2$ dependence of the signal strength with range z (24.13). It should be noted that PMTs show hysteresis, meaning that the recorded photocurrent is a function of the previous photocurrent: if the illumination changes quickly (e.g., rapidly rises), the internal voltage of the PMT is altered (reduced) to adapt to this new situation and keep the output signal constant. However, as real devices require time to adapt to a new voltage, the recorded output signal depends on the previous amount of incident radiation to some extent.

PMT photocathodes can be made from various materials, and the photocathode material determines the range of wavelengths that the PMT is sensitive to. Two important parameters for PMTs are the *quantum efficiency* (QE), which is the number of photoelectrons emitted at the photocathode divided by the number of incident photons, and the *radiant sensitivity*, which is the photoelectric current at the cathode divided by the incident radiant flux. The gain and the noise (sometimes called the dark current) are also important. Dark current can arise in different ways: due to thermal emission at the cathode or the dynodes, ohmic leakage between the anode and other electrodes, cosmic rays or radioactivity, or *scintillation* caused by the collisions of stray photoelectrons with the PMT housing or glass body.

Nevertheless, PMTs are robust, long-lasting devices that show very good performance at UV and visible wavelengths. Infrared photons have lower energy, so it is harder for them to generate a voltage (via the photoelectric effect) that is clearly above the noise limit. Therefore, avalanche photodiodes (APDs) are an alternative for longer wavelengths. APDs work in a similar way to PMTs: they consist of a doped semiconductor material to which a voltage is supplied. Incident photons produce additional charge pairs (electrons and holes) in the material that are accelerated by the supplied voltage, generating a current gain through impact ionization. Hence, APDs are even capable of counting single photons.

The sensitivity of the detection surface may not be constant. As objects from finite and infinite distances will be imaged differently (see Fig. 24.8), the light

should not be focused on the PMT, as this could cause the effective efficiency to become a function of altitude, leading to artificial gradients in the lidar profile. A thorough overview of PMTs is given in documentation provided by Hamamatsu, a PMT manufacturer [24.70].

Counting Electronics

The photocurrent produced by the detector in a lidar system is typically counted using transient recorders. One of the most important parameters of a transient recorder is the digitalization frequency f , which determines the vertical resolution of the lidar signal according to

$$\Delta z = \frac{c}{2f}, \quad (24.62)$$

where Δz is the height resolution and c is the speed of light.

Transient recorders can record the photocurrent from the detector in two different ways. In the photocounting mode, single detection events are counted whenever the photocurrent rises above a predefined threshold value. This is normally the preferred mode for weak signals, but there is a maximum count rate beyond which the current spikes produced by different photons merge together, making them difficult to separate. In contrast, recording in analog mode means that an integrated photocurrent is calculated for each height bin Δz . In this mode, the signal quality depends on the digitization depth (units: bits). In the analog mode, strong signals from the near range or clouds can be retrieved well, but electronic noise presents a challenge when this mode is used to detect weak lidar signals.

This is demonstrated in Figs. 24.10 and 24.11. In these figures, the fictitious output (photocurrent) of the PMT current is given in blue. In the photocounting mode, a threshold photocurrent must be selected. Since the current from a detected photon is normally much stronger than the electronic noise of the detector, choosing the value of this threshold is usually a straightforward task. Hence, almost independent of the threshold value, three photocounting events are detected in the case shown in the figures. Note that, in this mode, the unit of the photocounting channel is Hz. In the analog mode, the photocurrent is integrated over the complete altitude bin, so it is measured in ampere. The output depends critically on the background noise. In the example given in the plot, this background is not even flat—it rises over time (i.e., with altitude). Baselines that exhibit this behavior do actually occur in real signals. For this reason, the photocounting mode is preferable under low light conditions. However, high-intensity conditions are depicted in Fig. 24.11. In this case, a count rate of four would strongly underestimate

Fig. 24.10 Detector output (blue) and detection threshold (green) for low light levels

Fig. 24.11 Detector output (blue) for high light levels

the signal: in reality six photons were detected, three of which arrived so close together in time that the detector produced a constant output (i.e., the output becomes saturated) during the interval containing those events. Thus, the analog mode is better suited to retrieving the count rate in this situation.

Some modern transient recorders can record the events from one detector in both photocounting and analog modes simultaneously, meaning that two different lidar profiles (with the same physics) can be retrieved. For some transient recorders, the process of calculating the analog signal introduces a significant time delay, meaning that this signal is shifted in time compared to the photocounting signal (this is particularly apparent for low altitudes).

24.4.3 Design Considerations

Due to the range of environmental monitoring tasks that lidars are used for nowadays, there are various types of backscatter lidars that differ in size, measured quantities, range, ease of use, and eye safety. While small backscatter lidars such as ceilometers have been available commercially for a number of years, meaning that their reliabilities are relatively well known, larger multiwavelength systems are quite new to the market. For this reason, the majority of research instruments are still developed in-house by universities and institutes and therefore vary from type to type. This means that special standards such as algorithm intercomparisons are important for maintaining a reliable standard (see Sect. 24.6).

When choosing a lidar, the first task is obviously to establish the parameters that need to be measured and the altitude to be probed. This influences the selection of the laser and the wavelengths employed. Three designs are possible for the arrangement between the laser and the recording telescope; these are depicted in Fig. 24.12.

In the biaxial configuration, the optical axes of the laser and telescope are different. This design makes it easier to block laser light from low altitudes that could disturb the measurements (e.g., for measurements in the stratosphere or beyond). The other two designs utilize a common optical axis for laser and telescope. In the in-line setup, the same telescope is used to widen and guide the laser beam and record the backscattered signal.

The overlap and hence the starting point for a reliable signal is an important consideration in all designs. Some solutions utilize several telescopes: a smaller one with a wide FOV for the near range and a larger one for longer distances. Given that this requires two telescopes and two recording branches (i.e., filters, multipliers, and transient recorders), adopting this approach will substantially increase the cost, size, and complexity of the lidar.

Another important parameter is the eye safety of the laser. Systems that are not eye safe are subject to regulations such as air traffic or national laws. Lasers are classified into four groups: those in class 1 are not dangerous in normal use, whereas those in class 4 present a high risk to the eyes and skin. The distance from the laser at which the light from it is safe for eyes (skin) is called the *nominal ocular hazard distance* or NOHD (*hazard distance* or HD). These distances depend on various laser parameters: the power, the wavelength, the pulse repetition rate, the beam divergence, and the beam diameter. Widening the laser beam can reduce the NOHD: if the laser diameter becomes larger than a human pupil, the full power of the laser cannot enter the

Fig. 24.12a–c The three possible designs of a lidar system: (a) biaxial, (b) coaxial, and (c) in-line

eye, so the risk is reduced. A radar is used in some lidar systems to monitor for any aircraft approaching the FOV, which triggers the deactivation of the laser. This technology has actually existed for a number of years [24.71].

Yet another fundamental criterion is the ease of use of the lidar system. While some of the big multiwavelength Raman systems require regular maintenance (e.g., flash lamp replacement for the laser, or monitoring the spectral positions of the narrow-band filters) and are therefore mainly used for case studies, simple backscatter lidars such as ceilometers or micro pulse lidars can run continuously for years unattended [24.72]. This is obviously a big advantage for environmental monitoring of any kind.

As lidar systems are sometimes installed remotely, grounding can be a concern. Similarly, transient recorders can be disturbed by radio emissions, leading to oscillatory behavior. According to (24.1), a frequency of 10 MHz corresponds to a wavelength of 15 m. Hence, the electronic parts of a lidar must be shielded properly.

24.4.4 Ceilometers

The main tasks of a ceilometer are to determine the cloud base height and vertical visibility and to investigate aerosol layers in the lower troposphere. Unattended 24/7 operation under all meteorological conditions and an eye-safety class of 1M are mandatory

requirements for such lidar systems. Network deployment ability requires that maintenance costs are low and maintenance intervals are long.

Manufacturers of ceilometers must consider all of these points. Therefore, ceilometer designs usually differ significantly from those of lidar systems used for research. Typical design differences are listed below (see keywords in Sects. 24.4.1 and 24.4.2):

- **Laser.** Typical ceilometer lasers operate in the near-infrared region. The most common light sources are therefore laser diodes and Nd:YAG lasers operated at the first harmonic. Lifetime and cost considerations are the main factors to consider when choosing the laser.
- **Telescope.** Most common optical designs of ceilometers use one or two lenses instead of a complex telescope. Lens diameters of ≤ 15 cm are sufficient for ceilometer tasks. This setup allows for a compact, robust, and cost-effective construction, regardless of whether a biaxial or coaxial design is chosen. Biaxial designs use one lens to collimate the laser beam and another to focus the backscattered light onto the receiver; the optical axes are either parallel or slightly inclined. Coaxial designs require one lens only. To avoid optical crosstalk between the transmitter and receiver, the traditional beam splitter setup is replaced with a novel design that divides the lens into separate transmitting and receiving areas [24.4, 73] (Fig. 24.13).

Fig. 24.13 Optical system designs for ceilometers (after [24.73])

- *Optics used for wavelength separation.* Ceilometer IF passbands are chosen to be wide enough to compensate for laser wavelength tolerances or temperature dependences. Current commercial systems use IFs with passbands ranging from about 2–30 nm.
- *Recording devices.* Most ceilometers use APDs, but there are also systems with PMTs.
- *Counting electronics.* Analog digital converters (ADCs) are commonly used in ceilometer electronic design; more sophisticated devices such as transient recorders are generally not required for ceilometer applications.
- *Bird deterrent.* Reliable automatic operation of ceilometers requires the continuous monitoring of all measurement parameters that can affect the performance of the lidar system. This includes the transmission characteristics of the glass window shielding the lens. Animals, in particular birds, are often the reason for reduced transmission. One way to reduce the likelihood of reduced transmission due to birds is to install a deterrent device that encourages birds to perch in an area away from the window.

24.5 Specifications

As with many other remote-sensing instruments, it is not a trivial task to define the *resolution* of a lidar system. The maximum range at which cloud or aerosol layers can be detected depends on the meteorological situation and is therefore dependent on when and where the observations are made. Generally, the laser beam is attenuated in thick cloud. Thus, measurements of regions above clouds can be invalid, although valid lidar signals may be detected from those altitudes on

clear days. In contrast, very clear conditions with low backscatter will lead to a weak lidar signal with more noise. The presence of an aerosol layer at this altitude increases the count rate and the SNR. Moreover, the signal quality also depends on the solar altitude. The quality is best during the night, and some lidar systems even shut down before the sun enters the field of view.

For this reason, statements are sometimes made that a lidar at a specific site can resolve aerosol lay-

Table 24.5 Typical application-dependent resolution and eye-safety class requirements for lidars

Lidar type	Parameter (Table 24.1)	Application	Typical range resolution	Typical temporal resolution	Eye-safety class	Continuous operation?	Remarks
Ceilometer	Attenuated backscatter	Cloud base detection	5–10 m	2–30 s	1M	Yes	
		Detection of aerosol layer boundaries	10–50 m	1–10 min	1M	Yes	
Single-wavelength particle backscatter lidar	Backscatter coefficient Extinction coefficient Lidar ratio	Investigation of elevated aerosol layers	10–200 m	10 s–10 min	1M, 2, 2M, 3B	Typically not required	Includes ceilometer capabilities
Multi-wavelength lidar systems	Color ratio Ångström exponent of backscatter Ångström exponent of extinction	Aerosol classification, optical properties of clouds	7.5–150 m	0.5 s–10 min	1M, 2, 2M, 3B	Typically not required	Includes single-wavelength system capabilities
Polarization lidar	Depolarization	Aerosol classification	10–200 m	10 s–10 min	1M, 2, 2M, 3B	Typically not required	Includes (at least) ceilometer capabilities

ers with a given backscatter at a certain altitude > 50% of the time. The maximum resolution depends on the sampling speed of the electronics and the number of laser shots that are written in each data file. However, in many applications, some of the lidar profiles are

averaged to obtain a SNR that is best suited to the given application. Table 24.5 summarizes some typical specifications of various lidar systems used for cloud and aerosol research, including the required laser class, ranging from 1M (eye safe) to 3B (highly dangerous).

24.6 Quality Control

As it is an active remote-sensing instrument, a lidar collects light. Pointing such a system in the direction of the sun will increase the background light dramatically, and may even harm the recording devices. For this reason, lidars are frequently switched off when the sun is close to the FOV (e.g., at noon in the tropics).

Similarly, thick clouds will reduce the range of a lidar instrument. An example is given in Fig. 24.14. Here, a cloud at an altitude of 2 km presents a count rate at 1064 nm that is almost two orders of magnitude larger than that at the end of the overlap range (about 500 m high). Above the cloud, the signal even has negative values; in other words, count rates below that produced when only the background illumination and electronic noise are recorded. According to (24.23), this phenomenon is unphysical, as is the rise in count rate with altitude seen in Fig. 24.14. A count rate that rises with altitude would mean a negative backscatter or extinction coefficient. Hence, it is clear that the lidar signals above the cloud in Fig. 24.14 cannot be evaluated.

The fact that thick cloud can completely attenuate the lidar signal presents a major challenge to ground-based systems. Hence, ground-based lidar studies of turbulence and the interactions between aerosol, moisture, and clouds above the top of the cloud are very limited.

24.6.1 Hardware Quality Control

As the laser is a critical component of a lidar, its power is monitored in some systems. This can be done by splitting the laser beam and focusing a fraction (on the order of 1%) of its light onto a photodiode. The transmission through the final optical window that separates the lidar from its surroundings (and may therefore be degraded by precipitation, dust, or even scratches) may also be monitored. Of course, it is also necessary to check that switching cooling systems on and off or devices that are only sporadically activated in the system do not produce electronic artifacts in the lidar signal.

Fig. 24.14 Effects of thick cloud on the lidar signal. Note the negative signal at 2–6 km, and the rising count rate with altitude above the cloud

It is crucial to align the emission and recording optics correctly. Simply recording the altitude corresponding to the maximum lidar signal (i.e., when the full laser beam is recorded by the telescope) is difficult because, as mentioned earlier, environmental variations will affect not only the backscatter coefficient but also the multiple scattering and hence the overlap. Therefore, the altitude at which the signal maximum occurs and the count rate at that maximum will constantly change over time for a backscatter lidar. In systems where the optics are not permanently fixed, it is more convenient to align one branch of the optics (e.g., the emission branch) relative to the other (the recording branch) using a motor and to monitor the measured count rate within a particular height interval as a function of the relative alignment. This is called an overlap scan. As can be seen from Fig. 24.15, the position that gives optimal alignment is easily discerned. Typically, not all of the recording channels share precisely the same optical axis. Nevertheless, as the divergence of the laser beam must be smaller than the FOV of the telescope, there should be a plateau with a constant count rate for different alignment positions. Noise in the data and (especially) variations in the count rate due to changes in the backscatter coefficient within the considered altitude range or in the extinction coefficient below that altitude range lead to an imperfect plateau. For this reason, such an overlap scan can only be performed under cloud-free conditions. Drastic temperature changes that could affect the various optical components or vibrations due to transport may necessitate an overlap

Fig. 24.15 Example of an overlap scan. Height interval: 1000–1500 m

check. Modern systems may track the overlap automatically using a small camera that tracks the image of the laser at the field stop (see Fig. 24.1).

The possible sensitivity of transient recorders to radio emissions or strong and variable electric fields that may originate, for example, from the laser and its power supply has already been mentioned.

When installing a lidar in the field, it is important to include a proper floor, a sufficient electrical supply and appropriate grounding, and effective protection against moisture. Intense sunlight or harsh, cold winds must not shift the system outside its prescribed temperature range, as this could cause the laser to lose power or even fail and the bandpasses of the interference filters to shift. The emission window must be dry and clean all the time.

24.6.2 Error Analysis

The quality of the evaluation process can also be checked, using software. Problems such as that shown in Fig. 24.14 (negative count rates, or, more generally, count rates below that of the background) can be detected by software automatically. In the same way, signals that become saturated or very weak should be identified.

The signal quality is generally gauged via the signal-to-noise ratio (SNR). In its simplest form, this can be written as

$$\text{SNR}(z) = \frac{P(z)}{\sqrt{P_{\text{bg}} + P(z)}}, \quad (24.63)$$

where $P(z)$ is the lidar signal (as above) and P_{bg} is the background count rate. However, this definition is slightly controversial. If we consider that the total measured signal P_{tot} is equal to the sum of the (real) lidar signal and the background count rate [24.74], i.e.,

$$P_{\text{tot}}(z) = P(z) + P_{\text{bg}}, \quad (24.64)$$

and we take P to be in units of photons and assume that the electronic noise can be neglected because it is much smaller than the noise from Poisson statistics, then

$$\Delta P = \sqrt{P_{\text{tot}} + P_{\text{bg}}} = \sqrt{P + 2P_{\text{bg}}}, \quad (24.65)$$

which leads to

$$\text{SNR}(z) = \frac{P(z)}{\sqrt{P(z) + 2P_{\text{bg}}}}. \quad (24.66)$$

Hence, slightly different approaches are found in the literature. In [24.75], the authors start by using (24.63) and then analyze this subject in far more detail. This analysis is not repeated here because it requires detailed knowledge of technical parameters (transmission of the optics, detector characteristics) that an average user of lidar data would not have. On the other hand, a quick check of the quality of raw data can be performed using either (24.63) or (24.66). While the presence of clouds obviously modifies the lidar signal dramatically, the lidar profile should be similar for cloudy and cloud-free conditions, as should the SNR.

Software intercomparisons [24.76] as well as dedicated instrumental intercomparison campaigns [24.77] have been performed for networks of lidar systems, and the results have been reported. Such reports can be useful when selecting a new lidar system.

24.6.3 Depolarization

The importance of having reliable information on the depolarization induced by the scattering particles in order to distinguish ice from water clouds or the main aerosol types was mentioned earlier. Good calibration of the depolarization is therefore also mandatory, including possible crosstalk correction. *Crosstalk* is parallel polarized (with respect to the laser) light that is

erroneously measured in the perpendicular polarized channel, and vice versa. A rather easy method of checking for an alignment error between the emission and receiving branches is to use a half-wave plate [24.78, 79], also called a $\lambda/2$ plate, which consists of birefringent material that introduces a phase shift between perpendicular polarized light. The maximum phase shift is 180° (half a wave). Rotating the $\lambda/2$ plate causes parallel-polarized light to be shifted into perpendicularly polarized light and vice versa. Hence, differential sensitivities and optical misalignment can be determined. Let P_{\perp} and P_{\parallel} be the perpendicular and parallel polarized lidar signals, respectively. If $\delta^{\text{tot}} = \beta_{\perp}/\beta_{\parallel}$ is the total or volume depolarization ratio (as introduced in Sect. 24.3), we can define the gain ratio G of an ideal system as

$$m \equiv \frac{P_{\perp}}{P_{\parallel}} = G\delta^{\text{tot}}. \quad (24.67)$$

Now, if a phase shift angle of Θ occurs due to a phase shift between the emission and receiving optics, we obtain (following [24.79])

$$m = G \left(\frac{\delta + \tan^2(2\Theta)}{1 + \delta \tan^2(2\Theta)} \right). \quad (24.68)$$

If we now rotate the $\lambda/2$ plate by several known angles φ_j , we get

$$m_j(z) = G \left[\frac{\delta(z) + \tan^2(2(\Theta + \varphi_j))}{1 + \delta(z) \tan^2(2(\Theta + \varphi_j))} \right], \quad (24.69)$$

for the altitude of interest z . In (24.69), m_j (the ratio of lidar profiles) and φ_j are known, whereas the gain G , the volume depolarization ratio $\delta(z)$, and the misalignment angle Θ are not known. Hence, if we consider at least three different angles φ_j , the unknowns in (24.69) can be determined, meaning that the system can be calibrated. A detailed work on the calibration of polarization lidars using Mueller matrices [24.80] was recently published. In some lidar systems, this half-wave plate is controlled by a motor so that it can be routinely rotated by different φ_j .

24.7 Maintenance

As lidar systems consist of various rather sophisticated optical and electronic components, care must be taken during either design or operation to assure constant and adequate quality of the system (Table 24.6).

First, the laser requires attention. While some modern diode lasers are robust and easy to operate, even in harsh environmental conditions, other laser types require maintenance (e.g., replacing flash lamps, which

Table 24.6 Maintenance of backscatter lidar systems

Interval	Maintenance activity	Comment
Regularly	Check data flow	
Weekly and after snow or storm events	Check the instrument: is the window clean, is there any visible damage?	
Quarterly	Check that the blower is free from plants and dust	
Yearly (if necessary)	Change dehumidifier	Performed by some manufacturers
3–4 years	Replace laser	Performed by manufacturer
4–8 years	Replace computer	Performed by manufacturer

can necessitate realignment of the emission optics, a cooling system check, and the cleaning of critical optical components, as dust can be burned into glass by intense laser light). This is particularly true of the powerful lasers used in multiwavelength Raman lidars. Generally speaking, however, the weaker lasers used in ceilometers do not require maintenance and last several years in continuous operation.

Some optical components such as laser heads or surfaces that are used in multiple beam interference show a dependence on the temperature. A temperature control system for the whole lidar can therefore be useful. As mentioned earlier, it is also important to check that the (de)activation of cooling systems and the presence of devices that are only active sporadically do not produce electronic artifacts in the lidar signal.

Many other components of a lidar are much sturdier. The transient recorders, dichroic mirrors, interference filters, and photomultipliers are all quite robust and do normally not require special care. Modern IFs age better than older IFs. Old PMTs lose their ability to reliably

record high count rates, so a regular check of the data (see Sect. 24.6.3) is recommended.

As with all instruments installed outside, the lidar should be checked after strong rain or snow events (Is the entrance window clean, and is there any moisture inside the instrument?), frost (Is the window clean, and are the electrical plugs still working?), storms (Is the system firmly anchored?), and lightning (Has the electrical supply been affected?) The window requires the most frequent attention (i.e., cleaning). If the cleaning technique is not specified by the manufacturer, cleaning is typically performed with water and mild soap. Any remnants are removed with distilled water.

Given the cost of a lidar and the fact that smaller units are designed to run unattended even at remote sites for a long time, it may be helpful to install a surveillance camera that monitors the system (including its entrance window) and possibly other parameters such as the cloud cover or visibility. This can also aid the interpretation of the lidar data and help to identify any flaws, especially at new sites.

24.8 Applications

This section presents a few examples of the quantities that can be derived using backscatter lidars.

While this chapter only considers the use of backscatter lidars in atmospheric and environmental research, these lidars are also used for other important applications, including altimetry and remote sensing of vegetation [24.81–83] as well as 3-D distance mapping of autonomous vehicles [24.84–86].

Fig. 24.16 Three ceilometers used during a comparison campaign conducted in 2019 by DWD (Deutscher Wetterdienst) in Hamburg, Germany. The ceilometer *on the left* has a design with a single-lens optical system and a mirror with an aperture (a Vaisala CL31). The ceilometer *in the middle* (behind the power box) is a Lufft CHM 15K double-lens system. The ceilometer *on the right* is another double-lens system, a Vaisala LD-40. Source: DWD ▶

Examples of modern ceilometers are shown in Fig. 24.16. Each instrument weighs ≈ 70 kg and allows continuous, unattended operation.

Fig. 24.17 Profile of the attenuated backscatter observed by a ceilometer on 06.06.2012 at 02:14:40

24.8.1 Using a Ceilometer as an Autonomous Backscatter Lidar

Ceilometers are autonomous working backscatter lidars that were originally only used to measure cloud altitudes. However, modern instruments can also detect aerosol layers or precipitation. This is shown in Fig. 24.17. According to the profile, a geometrically

shallow cloud is present at an altitude of ≈ 2.3 km. Directly below the cloud, in the melting layer, a *dark band* is visible at 2050 m. This is a frequently observed layer of decreased backscatter in the melting region of a cloud (e.g., [24.87]). Above a cloud, the attenuated backscatter naturally becomes noisier due to the extinction within the cloud; however, if there is a second cloud layer above the first one, this second layer may

Fig. 24.18 Attenuated backscatter time–height cross-section plot from 06.06.2012, showing clouds, precipitation, and boundary layer properties. Log colorscale: $0.1 = 100.0 \times 10^{-6} \text{ m}^{-1} \text{ sr}^{-1}$ (pixel size = $16 \text{ s} \times 10 \text{ m}$)

be also detected through a significant rise in the count rate. Attenuated backscatter is seen from the ground to ≈ 1950 m; this attenuation increases with altitude. This is due to precipitation from the cloud: the drops start to evaporate once they enter drier air, which decreases the drop size, affecting the scattering efficiency and the backscatter.

To ensure that the system automatically delivers an accurate value for the cloud base, the potential existence of several cloud layers or precipitation should be considered when analyzing lidar retrievals.

Figure 24.18 shows a typical contour plot obtained from lidar data. It shows the time (x -axis), the altitude (y -axis), and the strength of the (attenuated) backscatter (in different colors). Reddish colors refer to large backscatter values. The changes in cloud height and cover are obvious. Moreover, precipitation (occurring from 02:10 to 03:00 and shortly before 04:00) can be discerned, as can a melting layer (which shows less attenuated backscatter than altitudes below or above it, and occurs at 2100 m during the precipitation events). Information on the boundary layer can also be extracted: a nocturnal layer comprising the lowest 300 m, and the residual layer at around 1200 m.

Figure 24.19 shows an example of the successful determination of the boundary layer altitude. The attenuated backscatter $B(z)$ see (24.7) is shown as a time–height cross-section plot. The boundary layer altitude is derived as the minimum of the gradient of $B(z)$. The yellow and black vertical lines denote sunrise and sunset. Before the convective rise triggered by the warmth from the sun, the plot shows a nocturnal layer and a residual layer. The formation of a new nocturnal layer is visible after 22:00.

Figure 24.20 shows an example of the retrieval of water vapor via the differential absorption lidar DIAL approach (Chap. 26). In the near future, commercially available DIAL lidars will monitor the boundary layer for key meteorological quantities. This figure shows the result of an intercomparison between colocated instruments: data from a DIAL water-vapor lidar is compared to that from a Raman lidar (see the chapter on Raman lidar) and a radiosonde. Two typical features can be seen: first, higher concentrations of the measured quantity will generally yield a better retrieval, as the altitudes with low absolute deviations (in green along the y -axis)

correspond to high concentrations. Second, lidar utilization involves compromising between range and data quality: the DIAL system has a small (almost negligible) overlap range but becomes naturally noisy above the boundary layer, whereas the more powerful Raman lidar detects too little water vapor at the lowest altitude (400 m) but exhibits a much better signal-to-noise ratio > 1.5 km.

24.8.2 Caveats Regarding the Stable Boundary Layer Height

As mentioned in Sect. 24.3.10, ABL determination becomes much more difficult if there is no vertical mixing, as this causes the attenuated backscatter needed to determine the ABL to weaken. A relevant example from the Arctic Ocean is shown in Fig. 24.21. A research aircraft flew south from the ice-covered Arctic Ocean towards Spitzbergen. At the end of the plot (around 13:16 UTC), it reached the open ocean, where clouds formed, leading to high values of the attenuated backscatter coefficient measured at 532 nm. Also depicted in Fig. 24.21 is the altitude of the ABL derived by dropsonde, which is a radiosonde that is dropped from an aircraft and parachutes to the ground. The red crosses in the figure mark the height of the ABL from this dropsonde. The criterion that was applied to derive the altitude of the ABL from sonde data under thermally stable conditions was the critical Richardson number. It is apparent that the ABL height already starts to rise around the edge of the ice, probably because leads (i.e., fractures in the ice that allow heat, moisture, and aerosols to rise into the atmosphere) are more frequent in the ice close to the edge. According to the contour plot of the attenuated backscatter, there are some subtle elevated aerosol layers but there is no clear relation between aerosol and the ABL height. Hence, under stable conditions and when aerosol is advected rather than of local origin, attempts to determine the ABL height by lidar can fail. Between 12:58 and 13:05 UTC, the aircraft flew over a region with many open leads, which produced an aerosol load and local convection. During this interval, the attenuated backscatter coefficient within the ABL shows almost no height dependence. Even so, the lidar-derived ABL height and that derived using the sonde only agree fairly well.

Fig. 24.19 Attenuated backscatter time–height cross-section plot from 30.03.2019, showing layer boundaries derived from gradient minima of nocturnal, residual, and convective layers, as well as the sunrise and sunset (yellow and black vertical lines)

Christoph Ritter

Physics of the Atmosphere
Alfred-Wegener-Institute
Potsdam, Germany
christoph.ritter@awi.de

Christoph Ritter works in the field of atmospheric remote sensing at the Alfred Wegener Institute, the German Institute for Polar and Marine Research, in Potsdam. After studying physics and astronomy, he became interested in the Arctic climate. He has participated in many international aerosol and boundary layer research campaigns in Spitsbergen, and is especially interested in combining remote-sensing and in-situ measurements.

Christoph Münkel

Vaisala GmbH
Hamburg, Germany
cmuenkel@web.de

In 2019, Christoph Münkel retired from his position as senior scientist at Vaisala GmbH, Hamburg. Having attended courses in mathematics, physics, and astronomy, he received a Diplom-Mathematiker (master's degree) from Hamburg University. He develops algorithms for lidar applications, participates in international boundary-layer research campaigns, and participates in standardization bodies for remote sensing. He is a coauthor of the Springer book *Lidar: Range-Resolved Optical Remote Sensing of the Atmosphere*.

Raman Lidar

25. Raman Lidar for Water-Vapor and Temperature Profiling

Volker Wulfmeyer , Andreas Behrendt 

The Raman lidar technique is a refinement of the lidar method and permits, besides the measurement of particle optical properties, the simultaneous profiling of the water-vapor mixing ratio and temperature with high range resolution and accuracy. This technique does not require a laser transmitter with a certain wavelength; it uses standard high-power lasers. Certain portions of the spectrum of the atmospheric backscatter signal are extracted as measurement signals. The noise and systematic errors in each profile can be characterized, which is a fundamental requirement for many applications. Many ground-based Raman lidar instruments that are intended for research have been constructed, some of which are already operational. The first airborne Raman lidar systems are also now in use, and commercial systems have recently become available. This technique has the potential to be used extensively within surface networks for obtaining atmospheric thermodynamic data with regional to global coverage. Spaceborne Raman lidar operation will also be feasible in the near future.

In this chapter, we describe and discuss the use of Raman lidar, a remote-sensing technique for probing the water vapor and temperature distribution in the atmosphere [25.1]. This method is based on the measurement of inelastically backscattered Raman lidar signals. As each type of atmospheric molecules causes a characteristic Raman shift frequency and the intensity of the backscattered radiation is proportional to the number density of the scattering molecules, the cross-sensitivity of this technique to other atmospheric constituents such as aerosol and cloud particles is significantly reduced. Signals that are almost solely dependent on the wa-

ter-vapor mixing ratio or temperature can be obtained by elegant combinations of Raman channels—in other words, by monitoring the Raman scattering of different molecules in different vibrational and rotational energy states. By means of stable calibrations and very robust and efficient receiver setups, water-vapor Raman lidar (WVRL) and temperature Raman lidar (TRL) are currently the only operationally active remote-sensing methods that allow us to probe these fundamental atmospheric variables with high accuracy, resolution, and range.

In the following, after introducing the principle behind the Raman lidar technique, we present the equations that are employed to derive water-vapor and temperature profiles. We explore typical configurations of Raman lidar systems focusing on key elements such as the laser transmitter, the receiver, and the data acquisition system. We consider various applications of the

technique, including atmospheric monitoring, the verification and calibration of models and other observing systems, data assimilation, and process studies. Finally, we discuss the future of water-vapor and temperature Raman lidar systems in terms of their utilization in networks as well as on airborne and spaceborne platforms.

25.1 Measurement Principles and Parameters

A typical Raman scattering spectrum is presented in Fig. 25.1 [25.2]. Either the rotational Raman scattering around the elastic signal (in this case at 354.7 nm) is studied or the vibrational-rotational Raman scattered spectra of water vapor, nitrogen, oxygen, and carbon dioxide are analyzed, or a combination of both.

Observations of water vapor and temperature can be made using a receiver with wavelength-selective elements to extract the different Raman signals from the backscatter signal of a laser pulse transmitted into the atmosphere. Systems that combine WVRL with TRL

are the focus of this chapter; they are termed water-vapor and temperature Raman lidar (WVTRL) systems in the following. An overview of the variables that can be measured directly with WVTRL is presented in Table 25.1.

The performance of a Raman lidar during daytime differs from that during the night due to the significant sensitivity of the signal-to-noise ratios (SNRs) of the water-vapor and temperature signals to the daylight background. However, advanced Raman lidar systems possess resolutions of 1–10 s and 10–100 m for

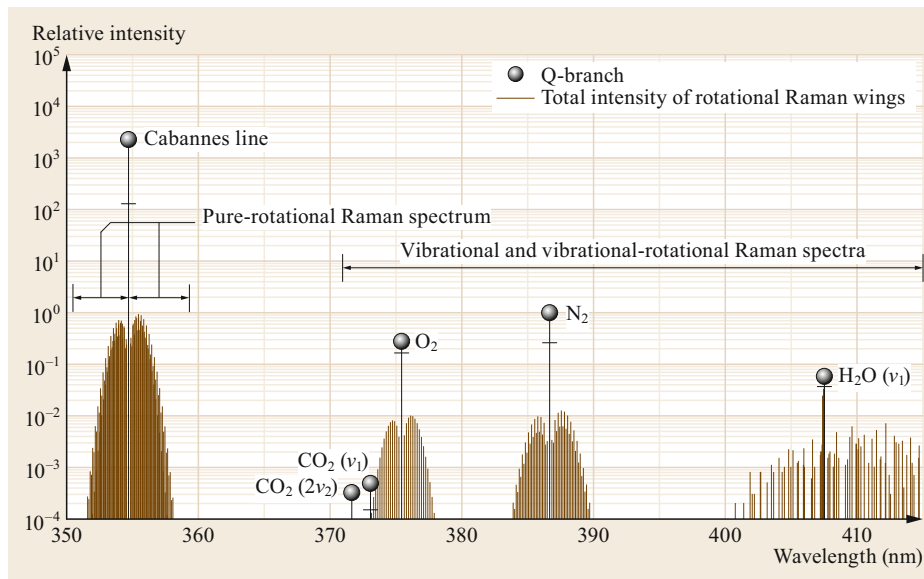

Fig. 25.1 Raman backscatter spectrum (after [25.2]) for a laser wavelength of 354.7 nm. Note that the spectrum is the same for any laser wavelength provided the Raman shifts are calculated in frequency units, as the energies of the transitions are constant

Table 25.1 Atmospheric variables that can be directly measured in dependence of range using WVTRL

Variable	Description	Unit	Symbol
Water-vapor mixing ratio	Ratio of water vapor density to the density of dry air	g kg^{-1}	M
Temperature	Physical air temperature	K	T
Particle backscatter coefficient	Backscattering due to atmospheric aerosols and/or cloud particles	$\text{m}^{-1} \text{sr}^{-1}$	β_{par}
Particle extinction coefficient	Extinction due to aerosol and/or cloud particles	m^{-1}	α_{par}
Lidar ratio	Ratio of the particle extinction coefficient to the particle backscatter coefficient	sr	S

Table 25.2 Further variables that can be derived from combined WVTRL measurements in dependence of range

Variable	Description	Unit	Symbol
Relative humidity	Ratio of the partial pressure of water vapor to the saturation pressure	%	RH
Virtual temperature	Temperature of dry air with the same density as the sampled moist air, assuming both the dry and moist air are at the same pressure (see also Chap. 8)	K	T_V
Buoyancy	Force exerted by a surrounding fluid to an immersed air parcel	N kg^{-1}	B
Convective inhibition	Energy required to overcome lids and stable air levels for deep convection	J kg^{-1}	CIN
Convective available potential energy	Energy available in the atmosphere when deep convection is taking place	J kg^{-1}	CAPE

the lower troposphere and a few hundred meters for the region from the upper troposphere to the lower stratosphere during both the day and night. A detailed overview of system performance is presented in Sect. 25.5.

By combining different Raman channels, it is also possible to determine several derived variables. These variables are summarized in Table 25.2. For water-vapor and temperature measurements, the derived variables include relative humidity, virtual temperature, buoyancy, convective inhibition (CIN), and convective available potential energy (CAPE).

By combining the measured signals in a different way, the scattering and extinction due to particles can be distinguished and measured independently without the need to make any additional assumptions (e.g., [25.2–4]). Therefore, Raman lidar is also a well-established

technique for determining the optical properties of aerosols and cloud particles in dependence of range and relating those properties to aerosol and cloud particle microphysics as well as their interaction.

For a discussion of the principle of backscatter lidar, please refer to Chap. 25. The performance of WVTRL is compared with those of other measurement techniques later in this chapter (Sect. 25.5). WVTRL systems at several sites are currently operational, and their high data qualities demonstrate why WVTRL are extensively used in measurement stations and in proposed ground-based networks (see Chap. 63). WVTRL systems also recently became available commercially. Last but not least, we mention that WVTRL systems are being used on airborne platforms too [25.5, 6], and their inclusion on spaceborne platforms has been proposed [25.7, 8].

25.2 History

The first Raman lidar measurements were performed by *Donald A. Leonard* in 1967 [25.9] using a pulsed nitrogen ultraviolet laser operating at 337.1 nm. The Raman scattered radiations of nitrogen and oxygen were detected in order to demonstrate the use of Raman lidar to observe atmospheric trace gases. In 1968, *John Cooney* [25.10] employed a ruby laser transmitter at 694.3 nm to detect the Raman scattering from nitrogen molecules in order to profile the density of the atmosphere. 1969 saw the first use of a frequency-doubled ruby laser to measure the Raman scattering from both water vapor and nitrogen [25.11], thus enabling the atmospheric profile of the water-vapor mixing ratio M to be derived. The WVRL technique was born. Shortly after, a similar measurement was reported by another group [25.12]. The combination of rotational Raman backscatter signals for atmospheric temperature profiling was pioneered by *John Cooney* in 1972 [25.13]. During the 1980s and 1990s, WVRL measurements were refined through the use of advanced laser transmitters and filter technology, especially for improving the daylight background suppression [25.14–17].

The temperature rotational Raman lidar (TRL) technique was fostered in parallel with work focusing in particular on improving system efficiency and stability and reducing the daylight background, too [25.2, 18–23]. It is noteworthy, that there is another lidar technique using Raman signals for temperature measurements, Raman integration lidar, which must not be confused with the TRL technique which directly measures temperature. The Raman integration technique uses the assumption of hydrostatic equilibrium to estimate the molecular density in the stratosphere and from that a temperature profile [25.24].

These developments resulted in the routine use of WVTRL systems such as those on the Southern Great Plains (SGP) site of the US American Atmospheric Radiation Measurement (ARM) Program [25.25] in the US, in Payerne, Switzerland (operated by Meteo-Swiss [25.26, 27]), in Lindenberg, Germany (operated by the German Meteorological Service (DWD) [25.28]), and in Cabauw, The Netherlands [25.29]. An overview of other research systems is presented in Sect. 25.4.6, too.

25.3 Theory

In the following, we discuss the physical principles of Raman lidar as well as the equations that are used to describe Raman lidar signals.

25.3.1 Raman Lidar Equation

The Raman lidar equation is derived by replacing the elastic backscatter coefficient in the lidar equation (Chap. 25) with the Raman backscatter coefficient and accounting for the transmission at the Raman-shifted wavelengths during the return trip of the Raman signal. The resulting equation relates the photon number P_{Ram} of the received signal to system parameters, atmospheric properties, and the range r . This Raman lidar equation reads

$$P_{\text{Ram}}(r) = \eta \frac{E_0}{h\nu_0} \mathfrak{S}_{\text{las}} \mathfrak{S}_{\text{rec}} O(r) \frac{A}{r^2} \frac{c\Delta t}{2} \mathfrak{S}_{\nu_0}(r) \mathfrak{S}_{\nu_{\text{Ram}}}(r) \times \sum_i F(\nu_i) \beta_{\text{Ram}}(\nu_{\text{Ram},i}, r, T), \quad (25.1)$$

where

$$\beta_{\text{Ram}}(\nu_{\text{Ram},i}, r) = N_{\text{mol},i}(r) \frac{d\sigma_{\text{Ram},i}}{d\Omega}(\nu_{\text{Ram},i}, T) |_{\pi}. \quad (25.2)$$

Here, η is the quantum efficiency of the detector, E_0 is the laser pulse energy, h is Planck's constant, and ν_0 is the laser frequency. $\mathfrak{S}_{\text{las}}$ and $\mathfrak{S}_{\text{rec}}$ are the transmissions of the laser steering and receiver optics, respectively, $O(r)$ is the overlap function between the laser beam and the field of view of the receiver, $A = \pi r_{\text{tel}}^2$ is the area of the telescope (r_{tel} is the radius of the telescope), and Δt is the laser pulse duration. $\mathfrak{S}_{\nu_0}(r)$ and $\mathfrak{S}_{\nu_{\text{Ram}}}(r)$ are the atmospheric transmission functions up to r at the corresponding frequencies. The Raman line number is indicated by the index i . To improve the SNR, it is necessary to insert an interference filter or a grating spectrometer with an effective transmission function $F(\nu)$ into the path of the receiver, as this will constrain the signal to the spectral range of the vibrational and/or rotational Raman scattering lines of interest (Fig. 25.1).

The key to the Raman lidar technique is the information content of the Raman scattering coefficient β_{Ram} . This coefficient is the product of the number density of Raman scatterers $N_{\text{mol},i}(r)$ (e.g., water vapor molecules) and their differential scattering cross-section $d\sigma_i/d\Omega$ in the backward direction. The exact frequencies of the Raman lines depend on the vibrational and rotational quantum numbers of the scatterers.

25.3.2 Derivation of the Temperature Rotational Raman Lidar Equation

In temperature Raman lidar (TRL), the temperature sensitivity of the rotational Raman (RR) lines scattered by nitrogen and oxygen molecules around its fundamental frequency (the frequency of the laser transmitter) is used. In this case, the RR lidar equation can be written [25.22, 30] as

$$P_{\text{RR}}(r) = \eta_{\text{RR}} \frac{E_0}{h\nu_0} \mathfrak{S}_{\text{las}} \mathfrak{S}_{\text{rec}} O(r) \frac{A}{r^2} \frac{c\Delta t}{2} \mathfrak{S}_{\nu_0}(r) \mathfrak{S}_{\nu_{\text{RR}}}(r) \times \sum_i F(\nu_i) \beta_{\text{RR}}(\nu_{\text{RR},i}, r, T) \equiv \eta_{\text{RR}} \frac{E_0}{h\nu_0} \mathfrak{S}_{\text{las}} \mathfrak{S}_{\text{rec}} O(r) \frac{A}{r^2} \frac{c\Delta t}{2} \mathfrak{S}_{\nu_0}(r) \mathfrak{S}_{\nu_{\text{RR}}}(r) \times N_{\text{dry}}(r) \frac{d\bar{\sigma}_{\text{RR}}}{d\Omega}(T), \quad (25.3)$$

where N_{dry} is the number density of dry air and $d\bar{\sigma}_{\text{RR}}/d\Omega$ is the effective differential Raman scattering cross-section after summing over the relevant rotational Raman lines within the filter function.

Since the frequency shifts of the pure rotational Raman spectrum are usually within $\pm 200 \text{ cm}^{-1}$, the atmospheric transmission due to molecular and particle scattering can be considered to be the same for both the upward and downward paths of the photons. Note that WVTRL systems are designed such that there are no molecular absorption lines in the range of the Raman spectrum considered.

In order to eliminate the cross-sensitivity of this Raman measurement to system parameters such as the laser power, the size of the receiving telescope, transmission functions, and other atmospheric properties, two rotational Raman signals are measured at different frequencies. These signals have different temperature sensitivities. Thus, we obtain as TRL equation [25.30]

$$\frac{P_{\text{RR2}}}{P_{\text{RR1}}}(r, T) = \frac{\frac{d\bar{\sigma}_{\text{RR2}}}{d\Omega}[T(r)]}{\frac{d\bar{\sigma}_{\text{RR1}}}{d\Omega}[T(r)]} \equiv Q(r, T). \quad (25.4)$$

This equation can be rearranged to make it a function of the range-dependent temperature. A fit of the form

$$T(r) = f[Q(r), a, b, c] \quad (25.5)$$

is typically applied, which yields highly resolved and very accurate temperature profiles [25.30, 31]. The calibration constants a , b , and c are usually determined through comparison with radio soundings.

25.3.3 Water-Vapor Raman Lidar Equation

Water-vapor (WV) profiles are derived using the water-vapor Raman lidar equation [25.15, 16]

$$\begin{aligned}
 P_{\text{WVRL}}(r) &= \eta_{\text{WV}} \frac{E_0}{h\nu_0} \mathfrak{S}_{\text{las}} \mathfrak{S}_{\text{rec}} O(r) \frac{A}{r^2} \frac{c\Delta t}{2} \mathfrak{S}_{\nu_0}(r) \mathfrak{S}_{\nu_{\text{WV}}}(r) \\
 &\quad \times \sum_i F(\nu_i) \beta_{\text{Ram,WV}}(\nu_{\text{Ram,WV},i}, r) \\
 &= \eta_{\text{WV}} \frac{E_0}{h\nu_0} \mathfrak{S}_{\text{las}} \mathfrak{S}_{\text{rec}} O(r) \frac{A}{r^2} \frac{c\Delta t}{2} \mathfrak{S}_{\nu_0}(r) \mathfrak{S}_{\nu_{\text{WV}}}(r) \\
 &\quad \times N_{\text{WV}}(r) \frac{d\bar{\sigma}_{\text{WVRL}}}{d\Omega}, \quad (25.6)
 \end{aligned}$$

where N_{WV} is the number density of water vapor.

Normalization with a reference signal $P_{\text{mol}}(r)$ for the molecular number density of the atmosphere is performed to eliminate the system parameters and unknown atmospheric variables (similar to TRL). In most WVTRL systems, the nitrogen vibrational Raman signal is used; in some a temperature-independent linear combination of the two RRL channels

$$P_{\text{mol}}(r) = P_{\text{RR1}}(r) + BP_{\text{RR2}}(r) \quad (25.7)$$

to optimize the SNR. Here, the constant B is chosen so that this linear combination of RRL signals is independent of the temperature profile $T(r)$ [25.2]. This permits the derivation of a signal that only depends on the water-vapor mixing ratio M , a system constant C , and a function that corrects for the differential extinction between the laser transmitter and the water-vapor Raman scattering frequencies. The resulting WVRL equation reads

$$\frac{P_{\text{WVRL}}(r)}{P_{\text{mol}}(r)} = C \frac{N_{\text{WV}}(r)}{N(r)} \frac{\mathfrak{S}_{\nu_{\text{WV}}}(r)}{\mathfrak{S}_{\nu_0}(r)} = CM(r) \frac{\mathfrak{S}_{\nu_{\text{WV}}}(r)}{\mathfrak{S}_{\nu_0}(r)}, \quad (25.8)$$

where C combines the system efficiencies at the different frequencies as well as the ratio of the effective Raman scattering cross-sections. $N(r)$ is the molecular number density of the atmosphere at range r .

Depending on the width of the filter used to extract the water-vapor Raman signal, different rotational-vibrational lines of water vapor will be sampled, which may cause the collected signals to be temperature dependent. For instance, for a filter with a Gaussian transmission band that has a full width at half maximum of 18 cm^{-1} (corresponding to 0.3 nm for an initial laser wavelength of 354.7 nm), the temperature sensitivity is found to be 6.7% over the temperature range from 200 to 300 K [25.32, 33]. The temperature sensitivity

increases (decreases) for narrower (wider) filters. For example, a width of at least 120 cm^{-1} (corresponding to 2.0 nm for an initial laser wavelength of 354.7 nm) is needed to reduce the temperature sensitivity to $< 1\%$ over the temperature range $200\text{--}300 \text{ K}$.

Combined WVTRL has the advantage that the simultaneously measured temperature profile can be used to correct for this temperature dependence, thus facilitating the use of narrow filters to extract the water-vapor Raman signals, which in turn reduces the background signal and improves the SNR.

The ratio of the transmissions in (25.8) is readily derived and corrected for. To correct for the molecular contribution to differential extinction, the number density profile is needed, which can be calculated using TRL data, a simultaneously operating and colocated radiosonde, an atmospheric model, or an alternative source of data (as long as its level of accuracy is high enough). The aerosol contribution to the differential extinction can be derived and corrected for using simultaneously obtained and colocated measurements of the particle extinction coefficient provided by a temperature-independent Raman signal—either the vibrational Raman signal of nitrogen [25.4] or a temperature-independent combination of rotational Raman lidar signals [25.2]. After applying these corrections, the remaining uncertainty is small: $< 2\%$ for the water-vapor mixing ratio, even under the unfavorable conditions of a high aerosol load.

In summary, even with the correction operators, it is straightforward to derive $M(r)$ using water-vapor Raman lidar with a combination of two or three Raman lidar signals. The system constant C is usually determined by calibration with other sensors such as radio soundings or water-vapor differential absorption lidar (WVDIAL) [25.34, 35] and is constant for well designed Raman lidar systems over several months or even years. Furthermore, comparisons can be performed with continuously operating passive remote-sensing instruments such as microwave or infrared radiometers. Self calibration methods that do not require external reference water-vapor measurements have also recently been presented. These are based on either the response of the receiver to a lamp [25.36] or the daylight background signal measured by the WVRL [25.37]. Extensive field campaigns and comparisons with soundings have revealed a systematic error of $< 5\%$ for WVRL mixing ratio profiles.

25.3.4 Error Propagation

Errors in TRL and WVRL measurements can arise due to incorrect calibration (resulting in systematic errors) or errors due to system noise (resulting in statistical

errors). Systematic errors have been investigated in a large number of studies where different sensors were compared and the calibration of the WVRL was investigated [25.25, 26, 28, 37–45]. The systematic error in mixing ratio measurements performed throughout the troposphere over several years is generally < 5% if the system is well calibrated using the statistical techniques described in the publications above and state-of-the-art radiosondes or microwave radiometers (MWRs).

Measurement campaigns using TRL are rare because these systems have become available only very recently. However, it was demonstrated that the systematic error in temperature measurements is typically < 1 K [25.2, 22]. More recent studies have confirmed this accuracy as well as the long-term calibration stability [25.23, 31, 46–48]. More information on measurement accuracy will be gathered during the routine operation of WVRL and TRL systems in the years to come.

The statistical uncertainty in the measurements—the so-called noise error—is accurately characterized by the error propagation from Poisson photon statistics based on the Raman lidar equations given above. Using this, the relative noise error in the mixing ratio $\Delta M/M$ is given by

$$\frac{\Delta M}{M} \cong \sqrt{\left(\frac{\Delta P_{\text{WVRL}}}{P_{\text{WVRL}}}\right)^2 + \left(\frac{\Delta P_{\text{mol}}}{P_{\text{mol}}}\right)^2}, \quad (25.9)$$

and the absolute noise error ΔT in the temperature is obtained via

$$\Delta T \cong \frac{dT}{dQ} Q \sqrt{\left(\frac{\Delta P_{\text{RR1}}}{P_{\text{RR1}}}\right)^2 + \left(\frac{\Delta P_{\text{RR2}}}{P_{\text{RR2}}}\right)^2}. \quad (25.10)$$

Equation (25.8) demonstrates that the system noise in water-vapor mixing ratio measurements is mainly determined by photon statistics in the water-vapor Raman lidar channel because these signals are much weaker than the Raman reference signals. The resulting errors vary considerably depending on whether it is nighttime or daytime due to the different levels of daylight background in the water-vapor Raman signal, meaning that it becomes very important to suppress the daylight background. In contrast, (25.10) shows that TRL is less sensitive to the daylight background due to the stronger rotational Raman backscatter signals of nitrogen and oxygen and the much weaker dependence of this signal on the atmospheric conditions.

These errors are typically well described by Poisson statistics, so the 1- σ uncertainty ΔP in the signal P is \sqrt{P} . Consequently,

$$\frac{\Delta P}{P} = \frac{1}{\sqrt{P}}. \quad (25.11)$$

Using this relationship, the roles of individual error sources such as the background photons, which are incorporated into (25.9) and (25.10), can be studied. Hence, it is possible to derive an important equation that describes the relative error in each Raman signal [25.2, 23, 49, 50],

$$\frac{\Delta P_{\text{RL}}}{P_{\text{RL}}} \cong \frac{1}{\sqrt{klP_{\text{RL}}}} \sqrt{1 + \frac{P_{\text{B}}}{P_{\text{RL}}} + \frac{P_{\text{d}}^2 + P_{\text{a}}^2}{BG^2 e^2 P_{\text{RL}}}}, \quad (25.12)$$

where P_{RL} is an arbitrary Raman backscattering photon number, P_{B} is the daylight background photon number, and k and l are the number of range gates and laser shots used to integrate the signal, respectively. The last term in the square root in (25.12) becomes significant if analog signal detection is employed [25.49, 50]. Here, P_{d} and P_{a} are the detector and amplifier noise powers, respectively, e is the charge on an electron, and B and G are the bandwidth and gain of the detector, respectively.

The first three terms under the square root in (25.12) are denoted the *Poisson term*, the *background term*, and the *amplification term*, respectively. Obviously, for any particular laser power, it is better to use a single shot of high pulse energy. However, this approach is limited by the specifications of the laser and eye-safety considerations. The amplification term can be discarded if photon counting is performed, but it must be accounted for if analog detection is used. The number of photons is either measured directly or, if analog detection is used in the near range, the analog signal levels can be calibrated and *glued* to the photon numbers in the far range. Consequently, (25.11) can be applied in real time to derive the statistical error profile for each mixing ratio or temperature profile of the WVTRL. This is an important feature for process studies and data assimilation. State-of-the-art WVTRL systems provide excellent measurements during the daytime in the lower troposphere, even resolving turbulent fluctuations in water vapor and temperature [25.51–53] and, in combination with a Doppler lidar, fluxes [25.54].

25.4 Devices and Systems

A Raman lidar system consists of a laser transmitter, a telescope, a receiver, and a data acquisition system. Until recently, some of these components had limited lifetimes, which is why it has taken until very recently for a WVTRL to become commercially available. Previously, routinely operated WVTRL systems were employed for special research at scientific institutions; examples include those at the ARM SGP site in Billings (Oklahoma, USA), the MeteoSwiss site in Payerne (Switzerland), and the German Meteorological Service Observatory in Lindenberg (Germany).

25.4.1 Typical Setup of a Water-Vapor and Temperature Raman Lidar

The typical design of a WVTRL system is depicted in Fig. 25.2. For measurements performed in the lower tro-

posphere, it is best to operate the laser transmitter in the ultraviolet (UV) [25.30], e.g., at 355 nm, if a frequency-tripled Nd:YAG laser is applied. Wavelengths that are hazardous to the eyes, such as the first and second harmonics of the Nd:YAG laser transmitter at 1064 and 532 nm, can be eliminated during the propagation of the beam into the atmosphere by applying refractive optics such as a Pellin–Broca prism (PBP). The 355 nm beam is expanded to make it eye safe and reduce its divergence, and is transmitted into the atmosphere. Optionally, a 3-D scanner can be used to point the laser beam in different directions and receive the atmospheric backscatter signal from the same direction.

The elastically and Raman backscattered radiation is collected by a telescope and sent to a polychromatic receiver unit. The backscatter signal is separated, e.g., into the elastic signal, the water-vapor Raman chan-

Fig. 25.2 Setup of the WVTRL system of University of Hohenheim: photomultiplier tube (PMT), interference filter (IF), rotational Raman signals (RR1, RR2), lens (L), laser mirror (LM), beam expander (BE), beam dump (BD), and beam steering unit (BSU) (after [25.31] © E. Hammann et al., Creative Commons Attribution 3.0 License)

nel, and the two temperature-sensitive rotational Raman channels (which is the least number of signals needed for the variables listed in Table 25.1). The signals are detected with photomultiplier tubes and sent to a photon counting and/or analog data acquisition unit. The data are transferred to a computer, stored, and processed to give measurements at the selected temporal and spatial resolutions as well as the corresponding noise error profiles.

25.4.2 The Laser Transmitter

For WVTRL, powerful laser transmitters are needed to achieve acceptable photon statistics in the return signals. To perform measurements during the daytime and nighttime, an average power of 10 W is typically used to achieve a high SNR, along with a receiving telescope with a primary mirror diameter of 40 cm. A relatively low laser power can be compensated for to some extent by using a larger telescope; however, since both the background and backscatter signals scale with the telescope area whereas only the lidar backscatter signal scales with the laser pulse energy, a large pulse energy is preferable when there is significant background. Furthermore, the laser should be operated in the UV region, given that the Raman scattering cross-sections increase with the fourth power of the laser frequency (ν_0^4), equivalent to Rayleigh scattering. However, for systems that perform long-distance profiling in the stratosphere and mesosphere, laser wavelengths in the visible are more attractive [25.30].

The present standard laser material is Nd:YAG, as it allows a high pulse energy and reasonable repetition rates to be realized along with efficient frequency tripling to the UV. Commercial flash-lamp-pumped Nd:YAG lasers are available that provide pulse energies of 100–500 mJ and repetition rates of 10–50 Hz at a wavelength of 355 nm. The main drawback of these lasers is their high demand for cooling power, as flash lamps are rather inefficient in laser pumping. The lifetime of a flash lamp is limited to $\approx 10^7$ shots, so the flash lamps must be exchanged quite often, which always necessitates some realignment of the Raman lidar system.

Recently, new diode-laser-pumped Nd:YAG lasers (Fig. 25.3) have become available with a similar average power to the flash-lamp-pumped Nd:YAG lasers. These novel systems operate at high repetition rates such as 200 Hz (due to the duty cycle of the diode lasers) and at a pulse energy of > 100 mJ, leading to an average power of > 20 W in the UV.

Due to the very efficient and direct pumping of the laser material by diode lasers, the size, efficiency, stability, and cooling demand of a diode-laser-pumped

Fig. 25.3 Photo of a diode-laser-pumped, frequency-tripled Nd:YAG laser (photo © Innolas GmbH)

Nd:YAG UV laser make it considerably more attractive than a flash-lamp-pumped Nd:YAG laser for performing WVTRL in the field, on various platforms, and for automatized, unattended operation [25.55].

Since the average power of a diode-laser-pumped Nd:YAG laser is higher than that of a flash-lamp-pumped Nd:YAG laser, significantly better performance in terms of the SNRs of water-vapor and temperature measurements can be achieved with a diode-laser-pumped laser during the night. Its somewhat lower pulse energy increases the noise error during the day, but this effect is relatively small and is also compensated by the larger average power, meaning that the overall performance of a diode-laser-pumped laser transmitter is higher than that of a flash-lamp-pumped laser transmitter. Indeed, the performance of a diode-laser-pumped Nd:YAG laser meets the requirements of the World Meteorological Organization (WMO) for the temperature and humidity profiling needed for nowcasting and very short-range weather forecasts in the lower troposphere ([25.56]; Sect. 25.5). Consequently, the utilization of this new generation of laser transmitters with their improved stability, efficacy, and performance recently resulted in the first commercial WVTRL system [25.55], and should lead to the more widespread application of the WVTRL technique.

25.4.3 The Receiver

The central component of a Raman lidar is its receiver. A receiving telescope with a large primary mirror is typically used to collect the backscatter signal with high efficiency. As the cost of the mirror increases significantly with size, practical values for the diameter of the primary mirror range between 40 and 80 cm. Polychromators with either interference filters or gratings are used to extract the Raman signals from the backscatter signal. Polychromators with state-of-the-art interference filter technology are more common than those with gratings because they are easier to align and

handle, and they offer higher efficiency. Their costs, however, are typically higher.

At least four channels are required for WVTRL: one for the elastic signal, two for the rotational Raman signals with different temperature dependences, and one for the water-vapor Raman signal. Broadband daylight filters are usually combined with narrow-band multicavity interference filters to achieve both high out-of-band blocking and high transmission within the passband. To achieve highly accurate measurements in the presence of aerosol layers and clouds, elastic signal blocking of at least seven and ten orders of magnitude is advised for the rotational Raman channels [25.21] and the water-vapor channel [25.32, 33], respectively.

The optimum frequency bands for the rotational Raman signals depend on the temperature range of interest, the amount of blocking of the elastic backscatter signal in the Raman channels, and the background light conditions. Further details can be found in the literature [25.21, 57].

For the water-vapor signal, the optimum width of the frequency band depends on the background conditions of interest and on the maximum acceptable level of temperature dependence of the signals [25.34, 35]. If temperatures are measured with the same lidar, the measured atmospheric temperature profile can be used to correct for a possible temperature dependence of the water-vapor Raman signals. This means that it may be acceptable to collect several water-vapor Raman lines with high temperature dependences because they yield stronger signals and thus smaller statistical uncertainties in the water-vapor mixing ratio measurements. Typical bandwidths used in WVTRL systems for the water-vapor and temperature channels are 0.2–0.5 nm.

As Raman cross-sections are proportional to ν^4 , the higher the frequency, the stronger the signals for the same laser power. Thus, primary laser frequencies in the UV are preferred for WVTRL. Consequently, the rotational Raman signals are also in the UV, while the water-vapor Raman signals are in the blue part of the visible spectrum. Due to their high quantum efficiency, photomultiplier tubes (PMTs) are generally the preferred detector for these short wavelengths. A further advantage of PMTs is that their photosensitive area is quite large compared to, e.g., avalanche photodiodes.

25.4.4 The Data Acquisition System

Since the Raman signals are typically quite weak, only high-power instruments use analog signal detection. In general, photon counting is the preferred acquisition mode, especially at large ranges and under low-background conditions, because it significantly reduces

the effects of detector noise compared to analog detection. However, combined data acquisition systems that incorporate both modes (and thus their respective advantages) are also available on the market.

Typical resolutions of the raw data are 10–100 laser shots, resulting in one profile every 0.1–10 s, and a few meters for each range bin. Typical maximum ranges are several tens of kilometers, allowing them to reach distances for which the measured signal is nearly only due to the background light. The photon counting and/or analog signals of each range bin are quantified using data acquisition systems connected to computers, where the signals are stored on hard discs or (even more quickly) on solid-state drives.

25.4.5 Processing and Storage of Temperature and Water-Vapor Profiles

Once the raw signals have been stored, higher-level data products can be derived either during postprocessing or even in near real time if the computer is fast enough and the acquisition of raw signals is unaffected by further data processing. The first step in the processing of photon-counting signals is to correct for dead-time effects. Even though the Raman signals are weak (more than two orders of magnitude weaker than the elastic backscatter signals), they may be strong enough to be affected by detector nonlinearities. Depending on the detector and data acquisition system used, either a paralyzable or a nonparalyzable detector model must be applied (for further details regarding this topic, refer to [25.2, 53]).

After correcting for dead-time effects, the background is determined and subtracted from the signals to obtain the atmospheric backscatter signals. These corrected signals are averaged over time and range to reduce their statistical uncertainties. A simple moving box average is usually preferred in order to keep the weighting functions simple.

As described above, for photon counting, the statistical error is mainly due to shot noise. The statistical uncertainties in the temperature and water-vapor measurements of each profile can thus be determined from the measured numbers of photons for the signals using Gaussian error propagation. Of course, the contribution of the background must also be taken into account. As the background is determined over a rather large number of range bins in the far range (typically > 1000), the statistical uncertainty in the background level itself is very small. However, its contribution to the overall error can be significant during the daytime in the far range, as shown in (25.10). In state-of-the-art WVTRLs, data acquisition, signal averaging, and the

derivation of water-vapor mixing ratio and temperature profiles (including their error profiles) are performed routinely, which makes a WVTRL a powerful tool for many applications, such as the derivation of climatologies, model verification, process studies, and data assimilation.

25.4.6 The Main Features of Raman Lidar Systems

A recent overview of WVTRL systems is provided in [25.1], and a summary of operational systems is given in Sect. 25.2. Several other WVRL systems intended for research have been developed and are operated by various international scientific institutions, such as the Goddard Space Flight Center (GSFC) in Greenbelt, USA [25.34, 35], the Leibniz Institute for Tropospheric Research (IfT) in Leipzig, Germany [25.3], the Radio Science Center for Space and Atmosphere (RASC) in Japan [25.2, 22], the Università della Basilicata in Potenza, Italy [25.58, 59], the Max Planck Institute for Meteorology (MPI) in Hamburg, Germany, the Laboratoire des Sciences du Climat et de l'Environnement in Gif-sur-Yvette, France [25.60], the Amazon WVRL in Brazil [25.61], and the high-performance WVRLs with turbulence resolution at the University of Hohenheim (UHOH) in Stuttgart, Germany [25.31, 51, 52, 55]. Many of these systems are mobile and can be transported in special housings such as seatainers, allowing them to be applied in various field campaigns. Airborne systems are oper-

ated at the GSFC [25.5] and at the University of Wyoming [25.6].

TRL measurements have been extended to the daytime through the use of narrowband filters and UV primary wavelengths [25.2, 22, 23, 31, 46, 56, 58, 62]. A 3-D scanning combined WVRL and TRL system has been realized at the Institute of Physics and Meteorology (IPM) of the UHOH in Stuttgart, Germany. A new compact system with even better temperature profiling performance is presented in [25.55]. It was recently shown that convective boundary layer (CBL) turbulence studies are even possible at midday with the IPM TRL [25.51]. Furthermore, scanning ground-based operation has been applied to observe the 3-D structure of the temperature and its gradient at the top of the CBL [25.46] and in the surface layer [25.31]. Other WVTRL systems have also been demonstrated [25.47, 58], though they have considerably less resolution in profiling temperature.

Overall, the straightforward design of a WVTRL in combination with its high accuracy and range resolution makes this instrument very valuable for applications in the weather, climate, and Earth-system sciences. Using a commercially available high-power laser transmitter, well-designed receivers and receiver optics, and standard technology to receive the signals, measurements can be performed with high resolution and accuracy during the nighttime and daytime. Challenges related to calibration and its long-term stability have been solved. Therefore, we can expect applications of water-vapor and temperature Raman lidar techniques to expand significantly in the near future.

25.5 Specifications

When specifying the performance of a WVTRL system, it is important to note that the noise error profiles are range dependent. Furthermore, the error profiles are dependent on the temporal and spatial resolutions employed when deriving the results. Therefore, just specifying an error at a certain height provides misleading information, as the system will perform much better in the near range. The measurement performance is another source of confusion, as previous comparisons with other sensors (such as passive remote sensors) have often overlooked this issue with the noise error profiles. To our knowledge, the first comprehensive comparison of active and passive remote-sensing techniques was carried out in [25.1], where the differences between the methodologies used to derive (active) and retrieve (passive) water-vapor and temperature profiles were accounted for correctly.

A simulation of the expected performance of WVTRL in different climate zones for the least favorable background light conditions at local noon was recently performed [25.55]. The results are presented in Figs. 25.4 and 25.5.

Those results demonstrate that WVTRL can be performed in all climate zones while maintaining the breakthrough requirements of the WMO with respect to high-resolution numerical weather prediction (NWP) in the lower troposphere, which is particularly interesting from a data assimilation perspective. It can also be shown that the WMO breakthrough requirements for water-vapor and temperature profiling are fulfilled (for an overview of these requirements, refer to www.wmo-sat.info/oscar/observingrequirements). Figures 25.5 and 25.6 show that it is important to consider the strong dependence of the error profile on the range.

Fig. 25.4 Expected water-vapor mixing ratio measurement performance of WVTRL in different climate zones under the least favorable background light conditions at local noon

Fig. 25.5 Expected temperature measurement performance of WVTRL in different climate zones under the least favorable background light conditions at local noon

For instance, the errors are two orders of magnitude smaller at a height of 1000 m for water vapor and one order of magnitude smaller for temperature when compared with the errors at 4000 m. This is also why

turbulent moments in the CBL can now be derived with WVTRL. These properties explain why ranges are given for the noise errors in the corresponding spatial and temporal resolutions in Table 25.3.

25.6 Quality Control

In theory, it is possible to determine the calibration constants of moisture and temperature measurements by combining careful inspection of the efficiency of each Raman lidar channel with literature values of the respec-

tive backscatter cross-sections. In practice, however, this approach leads to excessive uncertainties (several tens of percent and several kelvins, respectively) because the uncertainties in the wavelength- and polarization-

Fig. 25.6 High-resolution temperature profiling with UHOH WVTRL at resolutions of 10 s and 100 m. Using these data, it was possible to study the evolution of the temperature structure in the CBL, including the location and strength of the interfacial layer

Table 25.3 Specification of the daytime performance of state-of-the-art WVTRL for temperature and water-vapor profiling. During nighttime, the specifications will be even better. The typical range of measurements is from the surface layer up to 3000 m in all climate zones. The range is also limited by optically thick clouds

Variable	Noise error	Range resolution (m)	Temporal resolution (s)	Systematic error
Mixing ratio	< 5%	10–300 m	10–600 s	< 5%
Temperature	< 0.2 K	10–300 m	10–600 s	< 0.5 K

dependent transmission of all the optical components as well as those in the detector efficiencies add up. Consequently, other approaches are used. Typically, several local radiosondes are compared with the Raman lidar measurements to determine an average calibration. This comparison is less affected by sampling errors because the measurements are performed at different times and locations and because averaging is carried out spatiotemporally between the drifting radiosonde, which measures along its path, and the lidar, which measures along its thin laser beam. As long as the laser wavelength and the spectral properties of the receiver (filter aging, changes in the incidence angles, etc.) remain constant, the calibration factors are also constant. Note that differences in the laser power cancel and have no effect; the dead-time correction is also unaffected by changes in laser power, as it solely depends on the number of detected photons, which is a known quantity.

Aside from radiosondes, methods used for calibration include comparisons with weather stations on the

ground or towers for scanning WVTRL systems, comparisons with WVDIAL, MWR, and airborne in-situ systems on unmanned aerial systems (UASs) or aircraft.

When assessing the quality of WVTRL data, international comparison campaigns are especially valuable [25.41, 42, 44]. These enable WVTRLs on different platforms to be intercompared directly, not just indirectly via questionable standards such as radiosondes. Airborne WVTRL comparisons are achieved by either designing specific flight modes with crossing points or by performing stacked flights, which result in even more data for comparisons. Such lidar-to-lidar intercomparisons significantly reduce the uncertainty due to sampling error when different types of systems are used for quality control. Upon compiling all of the results from intercomparison campaigns and routine long-term operations, systematic errors of < 5% in water-vapor mixing ratio profiles and < 0.5 K in temperature profiles have been discerned.

The quality of both the accuracy (systematic errors or biases) and the measurement precision (statistical uncertainties) can be controlled. Determining the statistical uncertainty using the Poisson method yields only the shot-noise error, but for each single-photon-counting range bin there is an alternative independent method of determining the mean statistical uncertainties in all error sources (such as the electric noise in the analog signals). This method [25.52, 63] uses the fact that fluctuations due to atmospheric turbulence are temporally correlated whereas the instrumental noise in one profile is uncorrelated with that in the next profile. Therefore, applying an autocorrelation analysis to a high-

resolution data set (temporal resolution of each profile ≤ 10 s; total duration of the data set 30–120 min) allows atmospheric fluctuations to be separated from instrumental noise. Historically, this method was first applied to Doppler lidar and WVDIAL data. These instruments use elastic backscatter signals that are only detected in analog mode, so they typically provide data products with a much higher temporal resolution than afforded by Raman lidars. However, it is not possible to calculate the Poisson error for these systems since no photon counting data are available for them.

The statistical uncertainty in analog signals of WVTRL systems that use combined analog photon-counting data acquisition systems can be estimated using the following approach. First, in a range interval in which both acquisition modes provide reliable

data, the analog data are scaled (*glued*) to the photon counting data. Then the attributed photon-counting numbers for the scaled analog data are used to calculate the uncertainties in the Poisson method. Because the major contributor to the statistical uncertainty is the shot noise, this approach is valid [25.39, 40, 64].

In recent years, WVTRL has reached the performance level required to study atmospheric turbulence in the daytime [25.51, 53, 65]. This allows the instrumental noise errors to be determined precisely and with error estimates for the uncertainties themselves. Using this approach, it is typically found that the photon shot noise is the main contributor ($\approx 75\%$) even to analog signals in the near range in modern high-power WVTRL systems, while other statistical error sources are comparatively small [25.51].

25.7 Maintenance

The maintenance of a Raman lidar mainly involves cleaning the exterior optics (such as the optical window for the transmitter and the receiver) and maintaining the laser. As explained above, the maintenance required for the laser largely depends on the laser technology used. More frequent maintenance is required if a flash-lamp-pumped laser is used. For instance, the lamps must be regularly replaced, which also necessitates subsequent realignment. On the other hand, if

a diode-laser-pumped laser transmitter is used, very little maintenance is required for around 3 years of continuous operation, at which point the diode laser bars will probably start to degrade and ultimately need to be replaced. However, the lifetimes of other optics are not as well known, so the experience gained by monitoring and inspecting currently operational WVTRL systems over the coming years will be important in this respect.

25.8 Applications

In the following, we discuss applications of WVTRL, including process studies, model verification and calibration of other sensors, and the assimilation of measured data into atmospheric models.

25.8.1 Monitoring

There are three main WVRLs that are currently monitoring the lower tropospheric water-vapor distribution. These WVRLs are located at the SGP site in Oklahoma (USA), in Payerne (Switzerland), and in Lindenberg (Germany). Data obtained by the SGP WVRL are available from the ARM data archive (see www.archive.arm.gov) and have been used for various studies of the evolution and variability of the water-vapor field.

The SGP and Payerne WVTRLs can also measure temperature profiles, with the Payerne WVTRL appear-

ing to provide the best resolution and accuracy among the three. The analysis and advanced calibration of these data are ongoing.

A new compact and automatized WVTRL has recently been developed at the UHOH. This system was shown to be capable of unattended 24/7 operation [25.56] and to possess better performance in terms of accuracy, temporal resolution, spatial resolution, and range during the daytime and the nighttime in all climate zones than previous systems (Sect. 25.5). A similar system is now available commercially [25.55]. Due to its capabilities, it is believed that operating and applying this type of WVTRL at individual sites and in networks will revolutionize our knowledge of the structure and evolution of the moisture and temperature fields in the lower to middle troposphere.

Table 25.4 Maintenance of humidity and temperature Raman lidar systems

Maximum interval	Temperature channel	Water-vapor channel	Laser transmitter	Receiver	Data acquisition system
4–8 weeks	None	None	Replace flash lamps if this technology is used	Clean window	None
3 months	None	None	None	None	None
3 years	Check instrument calibration and perform maintenance of diode-laser-pumped laser transmitter			None	None

25.8.2 Model Verification and the Calibration of Other Sensors

The high accuracy and resolution of state-of-the-art WVTRL systems make these systems highly suited to model verification as well as the verification and calibration of other in-situ sensors and remote-sensing techniques. This application was pioneered at the ARM SGP site because the SGP WVTRL was calibrated to a high level of accuracy using a large set of soundings and advanced MWRs that were operated at the site. This cross-referencing considerably increased the trustworthiness of the Raman lidar data and led to the acceptance of WVTRL as a reference standard of the WMO. Thus, WVTRL has been used to study radio soundings [25.25, 36, 37], MWRs [25.38], WVDIAL systems [25.66], and airborne in-situ measurements [25.67]. The accuracies of the WVTRL systems at the Meteo Swiss site in Payerne [25.26, 27] and the DWD site in Lindenberg [25.28] are also high enough to make these systems useful for cross-validating radio soundings and model output. Also, using data collected in field campaigns, WVTRL has been used to calibrate and verify spaceborne passive remote sensors such as the infrared atmospheric sounding interferometer (IASI) [25.68]. However, comprehensive comparisons with model output data obtained under a variety of meteorological conditions are still rare and should therefore be extended [25.69–71].

25.8.3 Data Assimilation

Due to the ability of WVTRL systems to accurately characterize vertical profiles with respect to bias and noise errors, and because of the high temporal and spatial resolutions of these systems, they are excellent candidates for data assimilation (DA). However, only a few impact studies have been performed so far, which is partly due to the limited availability of operational WVTRL data as well as the effort required to conduct DA studies, which depends on the DA method applied and the configuration of the model. To our knowledge, the first four-dimensional variational assimilation study with water-vapor lidar data is reported in [25.72], and the first assimilation of WVRL data is presented in [25.73], which used the MM5 4VAR and a triangle of WVRL systems. A significant positive impact on the analysis of water-

vapor fields was demonstrated through comparison with independent retrievals of integrated water-vapor data obtained by a network of ground-based global navigation satellite system (GNSS) receivers. This work was recently extended by performing the first assimilation of TRL temperature profiles [25.74]. Again, this had very encouraging effects on not only the vertical and horizontal distributions of the temperature field but also the atmospheric boundary layer (ABL) depth and the inversion strength. In that work, the data were assimilated in a 3-D variational (3DVar) rapid update cycle (RUC) using the Weather Research and Forecasting (WRF) model in combination with the land surface model NOAHMP developed at IPM. Recently, MeteoSwiss contributed to these impact studies by using the data of the MeteoSwiss WVTRL in Payerne in combination with the DWD kilometer-scale ensemble data assimilation (KENDA), based on a local ensemble transform Kalman filter (LETKF) [25.75]. IPM advanced those studies by incorporating a new operator for the mixing ratio in the WRF-DA that permits the simultaneous and independent assimilation of absolute humidity, mixing ratio, and temperature profiles [25.76]. In both studies, strong and positive impacts on the water-vapor and temperature field analyses were observed.

Therefore, it is clear that WVTRL data assimilation is a rapidly emerging field of research and applications. WVTRL data have a strong impact because they have high temporal and vertical resolutions, they can be used to resolve the inversion layer and lids, and they are highly accurate. It is expected that the utilization of WVTRL in networks and the assimilation of WVTRL data will have a large positive impact on NWP for now-casting and short-range NWP.

25.8.4 Process Studies

For decades, ground-based WVRLs have been successfully applied in various process studies. Raman lidar systems were utilized during almost all major field campaigns, such as the International Water Vapor Project (IHOP_2002, [25.77]), the Convective Storms Initiation Project (CSIP) during 2004–2005 [25.78], the Convective and Orographically-Induced Precipitation Study (COPS) in 2007 [25.79, 80], the HD(CP)² Observational Prototype Experiment (HOPE) in 2013 [25.81],

the Plains Elevated Convection at Night Field Project (PECAN) in 2015 [25.82], and the Land–Atmosphere Feedback Experiment (LAFE) in 2017 [25.83]. This list is certainly not exhaustive.

Applications of WVTRL systems include investigations of the long-term evolution of the atmospheric water-vapor field [25.25], fronts [25.84, 85], the dry line [25.86], stratospheric intrusion events [25.58], hurricanes [25.87], and convection initiation [25.88, 89]. Additionally, the combined use of WVRL and TRL has been exploited to perform measurements of relative humidity [25.57, 59, 90] (e.g., to characterize cloud condensation levels in the CBL and the microphysical properties of cirrus clouds).

25.9 Future Developments

The ability of WVTRL to measure water-vapor and temperature profiles from the surface to the lower and upper troposphere makes these systems indispensable for applications in the weather, climate, and earth-system sciences. Due to recent success to make these systems more stable, compact, and operational, there is a huge increase in the number of applications of WVTRLs, including the realization of automated, operational, ground-based, combined WVTRL

Due to the advances in daylight background suppression described above [25.52, 65, 67, 91], high-power Raman lidar can even be employed to monitor turbulent moment profiles in the daytime convective atmospheric boundary layer (CBL) up to the third order. This high resolution and accuracy of temperature profiling is demonstrated in Fig. 25.6. More recently, TRL was used to profile turbulent moments of temperature up to the fourth order for the first time [25.51]. Latent and sensible heat flux profiles simultaneously from these data have also been derived with an extensive error analysis [25.54, 83]. In addition, there is great potential to use the data to study L-A feedback [25.92] and its metrics [25.93].

systems designed for continuous operation in networks in all climate zones. Furthermore, WVTRL systems are ready for airborne applications [25.5, 6]. Last but not least, the operation of WVTRL systems on spaceborne platforms has been proposed, which is expected to fill an important gap in global observations of lower-tropospheric water-vapor and temperature fields with high vertical resolution and accuracy [25.7, 8].

Andreas Behrendt is Akademischer Oberrat (roughly equivalent to an associate professor) at the Institute of Physics and Meteorology, University of Hohenheim, Stuttgart. He heads the Remote Sensing Group, is Associate Editor of *Optics Express*, and coordinates the Earth and Climate System Science masters program. His current research focuses on the development and use of lidar systems for studying land-atmosphere feedback processes, boundary-layer turbulence, cloud formation, and convection initiation.

26. Water Vapor Differential Absorption Lidar

Scott M. Spuler, Matthew Hayman, Tammy M. Weckwerth

Water vapor is one of the fundamental thermodynamic variables that define the state of the atmosphere. It is highly variable in space and time and influences many important processes related to weather and climate. For more than two decades the importance of water vapor profiling has been underscored by the research and operational weather communities. The ability to measure the spatial and temporal variability of moisture in the lower troposphere is necessary to improve our understanding of many atmospheric processes, improve numerical weather prediction forecasting skills, study weather phenomena, and study regional climate variability. Differential absorption lidar can provide accurate, continuous high-resolution measurements of water vapor. The technique spans from complex research systems capable of 3-D scanning to truly autonomous field-deployable profiling devices.

Water vapor differential absorption lidar (DIAL) is an application of absorption spectroscopy. The technique isolates absorption by water vapor in the atmosphere from all other atmospheric constituents and instrument terms. With a known and quantifiable absorption coefficient, the number density of water vapor molecules can be inferred based on knowledge of the water vapor absorption spectrum and assumed, measured, or modeled temperature and pressure profiles.

When a lidar's transmission wavelength is tuned precisely to a water vapor absorption feature, the laser light will be attenuated according to the Bouguer–Lambert–Beer law, where the coefficient of absorption is proportional to the number of water vapor molecules seen by the transmitted light.

The challenge of obtaining absorption characteristics with a lidar is establishing a reliable reference for each point in range, where variations in backscatter, aerosol, and cloud extinction, and variability in instrument effects such as the geometric overlap function, all contribute to the observed profile. By itself, observations with a laser tuned to a water vapor absorption line are hopelessly entangled with the complex characteristics of the atmosphere and the instrument. However, the elegance of the DIAL technique is that by adding one wavelength that is largely not affected by water vapor absorption, all of these additional terms may be removed (the absorbing and nonabsorbing wavelengths are traditionally referred to as the *online*, and *offline* wavelengths, respectively).

26.1 Measurement Principles and Parameters

Ground-based water vapor DIAL uses elastic scatter as a distributed backscatter reflector, often referred to as Rayleigh scattering and Mie scattering—both of these scattering processes are several orders of magnitude stronger than inelastic Raman scattering (Table 26.1). A DIAL can therefore operate at significantly less laser power than a Raman lidar (Chap. 25) with similar performance assuming similar optical efficiency. Additionally, the DIAL technique benefits from enhanced aerosol loading in the atmosphere as the elastic scatter signal increases, whereas Raman Lidar gleans no benefit. However, a limitation of DIAL is that it can only operate at specific wavelengths, where a suitable water vapor absorption line exists.

Most modern ground-based water vapor DIAL instruments target specific absorption features within rotational–vibrational overtone bands in the near-infrared. The lines, shown in Fig. 26.1, are spectrally centered in bands (e.g., 730, 820, 940 nm) and have an overall trend toward stronger absorption as the wavelength increases. Developing a narrowband water vapor DIAL requires, first and foremost, a suitable laser source with narrow laser linewidth, high-frequency stability, and high spectral purity. The requirements to keep the systematic errors below 10% are a linewidth of < 400 MHz, a spectral purity of $> 99.5\%$ and a wavelength stability of $< \pm 200$ MHz [26.2, 3]. The availability of detectors with high sensitivity, or quantum efficiency, at the chosen absorption band is also important. Care in the specific absorption line selection is critical to DIAL performance. The chosen line should be free of interfering species, preferably isolated from other water vapor lines, and have an adequate line strength (e.g., to allow measurements in dry conditions). Additionally, to minimize temperature sensitivity, a water vapor DIAL typically targets an absorption feature with a line strength that is insensitive

to atmospheric temperature variations (e.g., the lower ground-state energy for the water vapor line should be ≈ 225 cm^{-1} to minimize sensitivity to temperature variations in the lower troposphere). These spectroscopic values, along with other parameterizations such as the air-broadened and self-broadened linewidth and spectral shift with pressure, are obtained via molecular spectral databases such as the high-resolution transmission molecular absorption database (HITRAN) [26.4]. The a priori spectral knowledge at both of the closely spaced, transmitted wavelengths allows a DIAL system to be disentangled from atmospheric effects, and, in that sense, it is a self-calibrating technique. A water vapor DIAL can achieve measurement errors of a few percent when utilizing surface measurements of pressure and temperature and assuming hydrostatic equilibrium and standard lapse rate. If real-time processing is not needed, improved accuracy can be achieved using atmospheric model reanalysis data.

The only way to obtain an independent measurement of water vapor is via narrowband DIAL, which requires a spectrally narrow, frequency stable (and agile), and high spectral purity laser source. Broadband DIAL is a simpler technological approach; however, it comes with the significant drawback of needing ancillary measurements (e.g., radiosondes or radiometers) for calibration. Narrowband DIAL is a unique active remote sensing technique in that it is self-calibrating and relies only on fundamental theory for its retrievals. In addition, by actively adjusting the wavelength pair for optimal atmospheric absorption, narrowband DIAL has the ability to make high-quality water vapor measurements over a wide range of atmospheric conditions (humid to dry).

Table 26.1 Measured parameters of water vapor DIAL

Parameter	Description	Unit	Symbol
Absolute humidity	Mass water vapor per volume moist air	g m^{-3}	a
Relative backscatter	Attenuated backscatter	arb. u.	β, α^a

^a Although the backscatter (β) and extinction (α) are intertwined, and cannot be separated without a high spectral resolution channel in the receiver [26.1], the qualitative information is useful for understanding the relative location of aerosols and clouds.

Fig. 26.1 Water vapor rotational–vibrational overtone absorption lines in the near-infrared spectrum

26.2 History

Water vapor DIAL was initially demonstrated in 1964 by *Richard M. Schotland* (1927–2006), with a temperature-tuned ruby laser just four years after its invention [26.5]. Schotland also performed the first error analysis of the technique in 1974, using the acronym DASE (differential absorption of scattered energy) for what would later become DIAL [26.6]. Progress since its inception has been continuous yet slow due to limited availability of suitable laser sources. In 1979, *Browell et al.* [26.7] had access to stronger absorption lines with a ruby-pumped dye laser, and in the early 1980s the groups of *Mégie* and *Cahen* [26.8, 9] advanced to using Nd:YAG-pumped dye lasers. CO₂ lasers, operating in the mid-infrared at 10 μm wavelength, were used from the mid-1970s to mid-1980s to demonstrate water vapor DIAL in both direct detection [26.10–12] and coherent detection [26.13]. In the near-IR $\approx 1.9 \mu\text{m}$ wavelength, there were efforts to develop a combined temperature and water vapor DIAL with a Nd:YAG-pumped optical parametric oscillator (OPO) [26.14, 15], and a water vapor DIAL with a tunable eye-safe Ho laser [26.16]. Ultimately, however, water vapor DIAL instruments for routine operation were built as direct detection systems based on injection-seeded solid-state lasers operating in the 720–940 nm wavelength region. The first such systems used Ti:sapphire and alexandrite lasers as described in [26.17, 18] in the mid-1990s. These efforts led to the modern ground-based water vapor DIAL systems, which use Nd:YAG and/or OPO-pumped Ti:sapphire lasers [26.19–22].

For the last two decades, these high-power solid-state laser water vapor DIAL systems have been used in research and provided valuable measurements. However, they are large, complex, and expensive instruments, which require highly trained people to continuously monitor and operate them. Efforts to develop a more autonomous, lower complexity, and lower-cost instrument were initiated in 2004 [26.23]. This early work used high pulse-rate, low pulse energy diode lasers—in what is known as a *micropulse* lidar architecture. The effort was followed by seminal research on semiconductor-based

lasers for water vapor DIAL from 2009–2012 [26.24–26]. These diode lasers inherently offer the advantage of low-cost and long lifetimes—years of unattended operation, compared to months obtainable with flashlamp-pumped solid-state lasers. (Note, diode-pumped solid-state lasers have become the choice of high-power DIAL systems because they offer much longer lifetimes compared to flashlamp-pumped systems; however, they have very high initial investment costs.) The first truly autonomous field-deployable diode laser-based water vapor DIAL was demonstrated in 2015 [26.27]. When compared to the high-power solid-state laser DIAL systems, diode laser micropulse systems have reduced temporal resolution due to the lower transmitter power, but are better-suited for large networks, e.g., they are cheaper to build, operate, and maintain.

Although this chapter is focused on ground-based water vapor DIAL, we briefly mention the history of two airborne systems. Airborne water vapor DIAL allows for the ability to probe the whole atmosphere—an instrument above the high humidity in the lower troposphere can measure very dry upper-tropospheric and lower-stratospheric air by targeting stronger absorption lines; however, it cannot provide the temporal continuity of ground-based systems. The first, developed at the NASA Langley Research Center, was initially discussed [26.28] in 1983 as utilizing two separate Nd:YAG-pumped dye laser systems. Later, as discussed in 1994, the airborne instrument used a solid-state alexandrite laser to generate its online wavelength and an Nd:YAG laser-pumped dye laser for its offline wavelength [26.29]. Finally, the DIAL used a double-pulsed Nd:YAG-pumped Ti:sapphire laser system [26.30]. The second airborne water vapor DIAL was developed by the German Aerospace Center (Deutsches Zentrum für Luft- und Raumfahrt; DLR). The instrument is described in [26.31, 32] in 1993 as a Nd:YAG-pumped dye laser that later evolved into a Nd:YAG-pumped OPO in the 940 nm wavelength region. DLR also demonstrated a Nd:YGG laser, with direct radiation at 935 nm, for possible future space-borne or airborne water vapor DIAL applications [26.33].

26.3 Theory

Approximating the lidar signal as perfectly elastic backscattered light, the detected photon counts in a narrowband DIAL system is described by

$$N(\lambda, r) = N_0(\lambda)G(r)\frac{A}{r^2}\eta(\lambda)(\beta_a(r, \lambda) + \beta_m(r, \lambda)) \times \exp \left[-2 \int_0^r (\alpha_a(R, \lambda) + \alpha_m(R, \lambda) + \alpha_{wv}(R, \lambda)) dR \right] + b(\lambda), \quad (26.1)$$

where N_0 is the transmitted number of photons, λ is the laser wavelength, $G(r)$ is the geometric overlap function of the instrument, A is the receiver collection aperture, r is the range between the instrument and sample volume, $\eta(\lambda)$ is the receiver system efficiency, $\beta_a(r, \lambda)$ is the aerosol backscatter coefficient, $\beta_m(r, \lambda)$ is the molecular backscatter coefficient, $\alpha_a(r, \lambda)$ is the aerosol absorption coefficient, $\alpha_m(r, \lambda)$ is the molecular absorption coefficient, $\alpha_{wv}(r, \lambda)$ is the water vapor (WV) absorption coefficient, $b(\lambda)$ is the background noise (from the sun, detector dark signal, etc.) and R is a variable for range integration in the exponent. The water vapor concentration is contained in the water vapor absorption term and given by

$$\alpha_{wv}(r, \lambda) = \sigma_{wv}(r, \lambda)n_{wv}(r), \quad (26.2)$$

where $\sigma_{wv}(r, \lambda)$ is the water vapor absorption cross section, and $n_{wv}(r)$ is the number density of water molecules. When near an absorption line this term is highly wavelength sensitive. The range dependence is a result of the absorption spectrum being temperature and pressure dependent. The pressure dependence of these features is generally small but the temperature dependence can be quite pronounced. Typically estimates of temperature from model reanalysis data, radiosondes or inferences based on an assumed lapse rate with ground station data are used. In order to mitigate inaccuracies in these estimates, water vapor lines with weak temperature dependence are generally used in water vapor DIAL.

For brevity, the analysis presented here will sometimes substitute the exponential term in (26.1) with atmospheric transmission given by

$$T_{atm}(\lambda, r) = \exp \left[-2 \int_0^r (\alpha_a(R, \lambda) + \alpha_m(R, \lambda) + \alpha_{wv}(R, \lambda)) dR \right]. \quad (26.3)$$

From (26.1) it becomes apparent that while we are only interested in one optical parameter, $\alpha_{wv}(r, \lambda)$, nature and the instrument are likely to throw any number of variable terms into the observation. Disentangling all of these other terms, which are varying across different time scales, is anything but trivial with a single observation channel. By operating at two closely spaced wavelengths, however, one can assume that all of the nonresonant terms are effectively the same (by closely spaced, we typically mean < 1 nm). Only the spectrally narrow components differ. By subtracting background returns at the separate wavelengths and taking their ratio, the water vapor retrieval is greatly simplified

$$\frac{N(\lambda_1, r) - b(\lambda_1)}{N(\lambda_2, r) - b(\lambda_2)} = \frac{N_0(\lambda_1)\eta(\lambda_1)}{N_0(\lambda_2)\eta(\lambda_2)} \times \exp \left[-2 \int_0^r (\alpha_{wv}(R, \lambda_1) - \alpha_{wv}(R, \lambda_2)) dR \right]. \quad (26.4)$$

All extraneous atmospheric terms are eliminated in this operation and we assume the geometric overlap is the same between the two observations (e.g., the same receiver channel is used for both online and offline wavelengths). Substituting (26.2) into (26.4) and solving for the water vapor number density reveals that the remaining instrument terms are eliminated after a derivative operation. The water vapor is obtained analytically by

$$n_{wv}(r) = -\frac{1}{2} \frac{1}{\sigma_{wv}(r, \lambda_1) - \sigma_{wv}(r, \lambda_2)} \frac{d}{dr} \times \ln \frac{N(\lambda_1, r) - b(\lambda_1)}{N(\lambda_2, r) - b(\lambda_2)}. \quad (26.5)$$

The derivative operation effectively eliminates the retrieval's remaining dependence on instrument parameters. This means, in principle, the two wavelengths can operate at very different transmit power regimes and the retrieval is still valid, but in practice, the two channels should be in roughly the same regime to help mitigate the effects of nonlinearities in detector response. From (26.5) we see that this water vapor retrieval depends on the assumed knowledge of the water vapor spectrum with instrument terms generally assumed to cancel in the ratio between the two observation channels. For this reason, narrowband water vapor DIAL is often described as being *self-calibrating* because no ancillary observations are used to tune or adjust the retrieval.

The approach to performing a derivative in (26.5) on what is generally discrete observational data varies. Often a standard difference approximation is used, but even then it is not clear if the derivative should be propagated to the observations or performed directly on the natural log (our own testing has suggested the two approaches give different answers in noisy regions, but one is no more accurate than the other). Savitzky–Golay filters can be employed to provide a derivative over a window region of three or more points [26.34]. The filters act as polynomial fits over a sliding window region, which have analytically defined derivatives. However, the window size and polynomial orders have to be tuned and the filter inherently acts to limit the bandwidth of the signal (which is not necessarily a bad thing). Also these filters have edge effects near profile edges that can be challenging to deal with. In general, however the derivative is obtained, the result from (26.5) needs low-pass filtering to sufficiently eliminate noise (though Savitzky–Golay filters do this implicitly where the bandwidth is reduced by increasing the window size or decreasing the order).

It should be emphasized that the equations used for this derivation (starting with (26.1) and ending with the result in (26.5)) assume a narrowband transmitter with a narrowband receiver (note that narrowband being defined as a laser linewidth or receiver bandwidth significantly narrower than the absorption feature of interest). In any DIAL system, this is an approximation. Molecular scattering causes spectral broadening that cannot always be ignored. This is called the Rayleigh–Doppler effect and is the principal factor in dismissing DIAL as a solution for measuring temperature. Although we refer to the spectral shape as simply Rayleigh–Doppler herein, the Rayleigh scattered light has a Doppler broadened central peak (called the Cabannes line), which is split into a triplet (from pressure or Brillouin shifts) and sidebands due to pure rotational Raman scattering [26.35]. A model of this temperature and pressure-dependent molecular scattering spectrum is found in [26.36].

26.3.1 Rayleigh–Doppler Broadening

The DIAL equation assumes that the backscattered light collected by the receiver is unchanged by the scattering event. However, scattering by particles in motion results in a momentum transfer between the particle and the incident photons, so a Doppler shift is imparted onto the backscattered light. For large particles (e.g., aerosols and clouds) this has a negligible effect, but for atmospheric molecules (i.e., nitrogen, oxygen and water vapor) their random thermal motion results in a significantly broadened backscatter spectrum with a width

approximated as

$$\Delta\nu_D = 4\nu_0 \sqrt{\frac{2N_A k_B T_{\text{air}} \ln(2)}{M_{\text{air}}}}, \quad (26.6)$$

where $\Delta\nu_D$ is the Doppler broadened backscatter at full width half max (FWHM), ν_0 is the optical frequency of the incident light and related to wavelength through $\nu = c/\lambda$ where c is the speed of light and λ is wavelength, N_A is Avogadro’s number, k_B is the Boltzmann constant, T_{air} is the temperature of the parcel of air, and the M_{air} is the average mass of air, or 28.84 g mol^{-1} .

Observations of the backscattered spectrum received by a narrowband DIAL show two distinct distributions (Fig. 26.2). The spectrum of backscattered light from clouds and aerosols is unchanged from the incident narrowband laser spectrum, but the molecular backscatter is significantly widened (on the order of gigahertz or a couple of picometers wavelength in the near-IR). This effect is directly leveraged by high spectral resolution lidar (HSRL) that separates measurements of molecular and combined (molecular and particle) backscatter signals, allowing one to directly disentangle extinction from backscatter and produce quantitative retrievals of cloud and aerosol scatter-

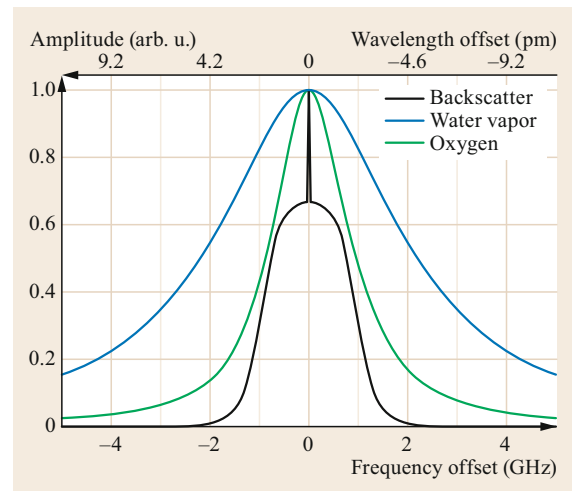

Fig. 26.2 Spectral distribution of backscatter at 828 nm (*black solid*) from a narrowband DIAL. In this case, the distribution is made up of an arbitrary mixture of two components: backscatter from clouds and/or aerosols (the spectrally narrow component) and backscatter from air molecules (the significantly broader component). The water vapor absorption line near 828 nm (*blue line*) and oxygen absorption line near 769 nm (*green line*) are overlaid for reference. All three spectra are for an atmosphere at 1 atm and 300 K. The wavelength offset is approximate for the near-infrared

ing properties [26.37–40]. In narrowband DIAL, the Rayleigh–Doppler effect can mean that the water vapor extinction characteristics are different on the return trip when observing light scattered by molecules.

The definitions in (26.1) ignore this effect, but this is not always a valid assumption. Omitting other constants that lack frequency dependence, the spectrum of photons on a detector is approximated by a convolution of the incident laser spectrum, the backscattered Rayleigh–Doppler spectrum and the particle spectrum after the initial trip up to the scattering volume

$$N(\nu, r) \propto \eta(\nu) T_{\text{atm}}(\nu, r) \{[\beta_{\text{m}}(\nu, r) + \beta_{\text{a}}(\nu, r)] * T_{\text{atm}}(\nu, r) I_0(\nu)\}, \quad (26.7)$$

where ν is the optical frequency, r is range from the instrument, $I_0(\nu)$ is the transmitted laser spectrum representing a frequency normalized $N_0(\lambda)$ in (26.1), $T_{\text{atm}}(\nu, r)$ is the atmospheric transmission as a function of optical frequency and range, $\beta_{\text{m}}(\nu, r)$ is the molecular backscatter coefficient with spectral shape determined by the local pressure and temperature, $\beta_{\text{a}}(\nu, r)$ is the aerosol and cloud backscatter coefficient with a spectral shape typically approximated as a delta function, $\eta(\nu)$ describes the transmission of the receiver as a function of optical frequency (e.g., filter functions) and $*$ is the convolution operator in frequency. If $\eta(\nu)$ is sufficiently narrow, the effects of Doppler broadening can be ignored because the broadened light that sees a different water vapor extinction never makes it to the detector.

Note that in (26.7) we include the laser linewidth term. For narrowband DIAL, this term becomes a delta function, but in broadband DIAL, we must account for this term.

The effect of the change in spectrum upon scattering breaks some of the relationship that cancels many of the atmospheric and instrument terms in (26.4). Now we are forced to account for the relative scattering contribution from molecules (causing Rayleigh–Doppler broadening) and particles (negligible effect).

Since all the other terms cancel when we take the ratio of the two wavelength channels, we are left with

$$N(r, \lambda_1) \propto \eta\left(\frac{c}{\lambda_1}\right) \beta_{\text{a}}(r) T_{\text{atm}}^2\left(\frac{c}{\lambda_1}, r\right) + \eta\left(\frac{c}{\lambda_1}\right) T_{\text{atm}}\left(\frac{c}{\lambda_1}, r\right) \times \int_{-\infty}^{\infty} \eta(\nu) T_{\text{atm}}(\nu, r) \beta_{\text{m}}(\nu, r) d\nu. \quad (26.8)$$

With some algebra we are able to remove the absolute scattering amplitudes and obtain a measurement dependence on the relative contributions of aerosols and molecules, most often described using the backscatter ratio $B(r)$.

$$N(r, \lambda_1) \propto \eta\left(\frac{c}{\lambda_1}\right) (B(r) - 1) T_{\text{atm}}^2\left(\frac{c}{\lambda_1}, r\right) + \eta\left(\frac{c}{\lambda_1}\right) T_{\text{atm}}\left(\frac{c}{\lambda_1}, r\right) \times \int_{-\infty}^{\infty} \eta(\nu) T_{\text{atm}}(\nu, r) \hat{\beta}_{\text{m}}(\nu, r) d\nu, \quad (26.9)$$

where $\hat{\beta}_{\text{m}}(\nu, r)$ is the frequency normalized molecular backscatter spectrum that describes the spectrum shape independent of amplitude.

Errors from Rayleigh–Doppler in water vapor retrievals can largely be mitigated, although in regions with strong gradients (e.g., cloud edges) one should be careful [26.41]. It has been shown that selecting an inflection point on the absorption line can effectively eliminate this error [26.42, 43], although operation at only an inflection point would limit a DIAL's ability to adapt to different environments. Note also that if the receiver passband is much narrower than the water vapor absorption line ($T_{\text{atm}}(\nu, r)$ is approximately constant over the passband of the receiver), the molecular term in (26.9) will approximate the aerosol atmospheric transmission within a constant. Thus operating with a narrow receiver system helps mitigate this error.

Our experience has been that Rayleigh–Doppler correction in water vapor DIAL is largely unnecessary for relatively narrow receiver systems (≈ 1 GHz FWHM or 2.5 pm bandwidth at 828 nm) compared to a broad water vapor line. However this effect is line specific and, more significantly, species specific. DIAL for molecules with higher mass will suffer more from its effect due to the decreased thermal broadening. This can be seen from Fig. 26.2, where the more massive oxygen (32 u) spectrum is of similar width to the Rayleigh–Doppler backscatter spectrum, while the water vapor (18 u) spectrum is considerably broader.

26.3.2 Broadband versus Narrowband DIAL

Where narrowband DIAL approximates aerosol backscatter as a delta function in frequency, broadband DIAL assumes the laser spectrum is so broad, that convolution with the molecular spectrum in (26.7) produces a negligible change in the laser spectrum. Applying this as-

sumption to (26.7) we obtain

$$N(r, \lambda_1) \propto (\beta_a(r) + \beta_m(r)) \times \int_{-\infty}^{\infty} \eta(v) l_0(v) T_{\text{atm}}^2(v, r) dv. \quad (26.10)$$

The assumption that the laser spectrum is much broader than the molecular spectrum allows the molecular and aerosol backscatter terms to be combined into a single spectroscopy term. However, the water vapor concentration is in the atmospheric transmission term behind the frequency integral. This prevents an analytic solution for the water vapor number density, requiring development of a different approach [26.44]. If the laser spectrum is known, the broadband DIAL equation can be solved numerically. This is often easier said than done because accurate knowledge of a broadband laser is not easily obtained without active monitoring. Diode laser mode structures tend to drift depending on environmental conditions and age. Even thermal instability outside of the laser diode itself can cause drifts in mode structure due to changes in feedback path lengths resulting from scattering on optic surfaces [26.45]. Multimode (broadband) lasers also suffer from mode-partition noise where the power in particular modes can vary considerably from pulse-to-pulse even though the total laser power may remain constant [26.46, 47]. In general, it is difficult to know the laser spectrum to sufficient accuracy to directly calibrate its effect. Instead, one uses other *a priori* data to nudge the retrieval into consistency with ancillary observations (such as radiosondes). Because of this, broadband DIAL retrievals are more akin to Raman lidar, which do not provide a truly independent retrieval of other observations.

The assumption that the backscatter spectrum is unaffected by molecular broadening (Rayleigh–Doppler) is key to retrieving water vapor with a broadband DIAL since it allows the collapse of molecular and aerosol terms into a one common spectrum solely dictated by the laser. Without this simplification the errors in the solution to the broadband DIAL equation compound at increasing range. The validity of this assumption will depend somewhat on the laser mode structure. The term *broadband* can be used to describe a variety of laser mode structures but they are rarely spectrally continuous. Very often broadband diode lasers lase at a large number of spectrally narrow frequency modes within a larger envelope. Depending on the mode spacing of the particular laser, Rayleigh–Doppler effects could change the evaluation of the frequency integral in (26.7). For any implementation of a broadband

DIAL, the designers should still confirm that the particular system is immune to Rayleigh–Doppler effects rather than just assume it is the case.

26.3.3 Accuracy and Precision

While the narrowband DIAL technique has the benefit of being self-calibrating, there are a series of factors that can still influence the instrument’s performance in terms of both accuracy and precision. The need and method to mitigate these effects will depend on the specifications for a particular system.

The precision of the instrument is influenced by a variety of noise sources where the dominant terms are system specific. The most common reduction in precision is caused by shot noise in low-power DIAL, which employ photon counting detectors. In high-power systems with analog detectors, detector noise can be significant. For systems with very narrowband transmitters, laser speckle can also be a source of random uncertainty. The complicating factor with zero mean noise sources is that the water vapor calculation requires a derivative operation, which is a high-pass filter and therefore a noise amplifier. Thus, there needs to be a cutoff frequency in the derivative operation (either low-pass filtering afterward or using a bandpass filter that approximates a derivative at low frequencies) to suppress noise and obtain a useful water vapor profile.

High-power DIAL systems are well suited to resolve power spectra at the necessary frequencies for estimating precision directly [26.48, 49]. This technique has the advantage of delivering statistical error estimates without needing to consider specific noise sources, but the system needs to have high enough signal at short time scales to resolve spectral features from atmospheric variability. Low-power micropulse DIAL systems typically do not have sufficient signal and therefore time resolution to employ this technique. Given their tendency to operate in photon counting regimes, shot noise is generally assumed to dominate the precision, which is well described by Poisson statistics. Given an observation of k photons in a bin, the associated variance in the estimate of the underlying signal is $k + 1$. Note that the variance in photon counting lidar signals is often incorrectly assumed to be k ; but if we observe $k = 0$ photons, this would suggest the variance is also zero, which is not the case because there is a nonzero probability of observing zero photons when the underlying signal is not zero. Framing the estimation problem correctly—what is the mean photons given an observation of k photons—results in a variance of $k + 1$. Thus the shot noise error is estimated from

the signal. Using first-order error propagation, the signal variances can be used to estimate the water vapor precision,

$$u_{n_{\text{wv}}}^2(r_i) = \frac{1}{4\Delta\sigma_{\text{wv}}^2\Delta r^2} \left(\frac{u_{N(\lambda_1, r_i)}^2}{N(\lambda_1, r_i)^2} + \frac{u_{N(\lambda_2, r_i)}^2}{N(\lambda_2, r_i)^2} + \frac{u_{N(\lambda_1, r_{i-1})}^2}{N(\lambda_1, r_{i-1})^2} + \frac{u_{N(\lambda_2, r_{i-1})}^2}{N(\lambda_2, r_{i-1})^2} - 2\frac{u_{N(\lambda_1, r_i)N(\lambda_1, r_{i-1})}}{N(\lambda_1, r_i)N(\lambda_1, r_{i-1})} - 2\frac{u_{N(\lambda_2, r_i)N(\lambda_2, r_{i-1})}}{N(\lambda_2, r_i)N(\lambda_2, r_{i-1})} \right), \quad (26.11)$$

where we use the notation u_x^2 for variance of x and u_{xy} to represent the covariance of x and y .

Typically, we assume all bins are independent, but if any prefiltering in range has occurred, a nonzero covariance needs to be accounted for in the error estimate. Background subtraction also creates nonzero covariance terms, but often times this is small enough to be ignored.

The limitation of (26.11) is that it is based on a first-order Taylor expansion, linearizing the nonlinear water vapor inversion formula in (26.2) about the estimated signals. When the argument of the log is noisy, this variance estimate will almost certainly incorrectly estimate water vapor uncertainty. Thus, uncertainty estimates using (26.11) are often the least reliable where signal-to-noise is the lowest. To mitigate this, we typically set a minimum signal threshold in our photon counting lidar, below which the data is masked.

Beyond random uncertainty, there are points where biases can come into DIAL estimates. The treatment we provide below is meant to provide some concept of how these errors fold into the water vapor estimates, the exact estimation methods will depend on the specifics of the system operation.

In order to estimate the water vapor absorption cross section in (26.5), we typically must assume a temperature and pressure for the given altitude. Pressure has the potential to impact the absorption feature shape. Temperature can impact both the spectrum shape and its strength. Obtaining accurate measurements from a DIAL requires that the selected water vapor line has a low temperature sensitivity within the expected temperature range. Typically, a well-designed DIAL can mitigate this error with proper line selection. In isolation, the error in estimated water vapor, $\Delta\sigma$, due to error in the assumed absorption feature is given by

$$\delta n_{\text{wv}} = -n_{\text{wv}} \frac{\delta\sigma}{\Delta\sigma + \delta\sigma}, \quad (26.12)$$

where $\delta\sigma$ is the error in the estimated online absorption term (the offline estimate typically does not have a significant dependence on temperature or pressure) and n_{wv} is the actual water vapor concentration.

As with most lidar products, we assume that the observed signal is linearly proportional to incident optical intensity. Regions of high signal can result in nonlinear detector responses, which generate biases in the retrieved water vapor. If the nonlinear response curve is monotonic and well known, this effect can be corrected to some extent, but additional uncertainties fold into the error analysis [26.50]. For example, dead-time corrections are often made in photon counting lidar systems, but that presumes the dead-time characteristics of the system are well known and the parameterization is a good fit to actual response behavior. The best parameterizations for nonlinear correction tend to be system specific. Data reported in [26.51] tended to fit one parameterization at low count rates but another at high count rates. The dominance of those curves will depend on the hardware employed in the instrument. Because of these uncertainties, nonlinear correction generally does not dramatically extend the dynamic range of the system. Overall, the effect of detector nonlinearities tend to be problematic around clouds and at low altitudes, which is a common theme in water vapor DIAL errors.

In some cases there are range-dependent differences in optical efficiency between the online and offline observations. Some of these are related to the optical system overlap function, which can result from different laser beam properties (e.g., pointing deviations, divergence or intensity distribution) between online and offline channels or slight differences in detector alignment (if separate detectors are used between the two channels). It has also been observed that narrowband filters may have range-dependent transmission spectra [26.3]. A well-designed optical system should have a field stop designed to limit the extent of this filter error, but the effect is certainly possible if the instrument has too wide of a field-of-view (FOV) or too small an etalon for the designed transmission bandwidth.

In all cases of differential overlap errors, the significance of the error depends more on the range gradient than its overall magnitude. An extreme example of this is a mismatch in scalar gain between online and offline channels, which contributes no error to the retrieved product irrespective of its magnitude (as long as detector nonlinearity is not an issue). The error contribution of any range-dependent term can easily be calculated from (26.1) and (26.5) and summarily described by

$$\delta n_{\text{wv}} = -\frac{1}{2\Delta\sigma} \frac{\partial}{\partial r} \ln \frac{\eta_{\text{on}}(r)}{\eta_{\text{off}}(r)}, \quad (26.13)$$

where δn_{wv} is the error in the water vapor concentration and $\eta_{\text{on}}(r)$ and $\eta_{\text{off}}(r)$ are the range-dependent efficiencies of the optical system for the online and offline channels, respectively. Notably, if the range-dependent efficiencies in the two channels are proportional to each other, they still contribute no error.

Many instances of the lidar equation (including that in (26.1)) omit the low-pass filtering effect of the laser pulse. In general, the ideal atmospheric signal needs to be convolved with the laser pulse (more generally called the instrument response function, which also includes receiver system effects) to capture the inherent smoothing operation resulting from a nonzero laser pulse width. Unfortunately, the convolution operation does not commute with the division operation we usually use for retrieving water vapor so the standard signal processing scheme is actually an approximation that assumes the filter operation has an insignificant impact on the return signal. This means that areas of significant backscatter gradient that have high frequency (relative to the laser pulse width) will poorly approximate the true signals and the retrieval will be biased (it should be noted that banded data collection and signal processing techniques also have this effect). Systems with relatively long pulse lengths are poorly suited for estimating water vapor near cloud edges where biases can be very large. Even worse is this effect is quite difficult to quantify without knowing the *unsmoothed* scene. At present we are not aware of a clear analytic definition for this effect, so the user needs to maintain some awareness of the backscatter scene when using DIAL data.

In many DIAL instances, the instrument switches between performing measurements at online and offline

wavelengths, but the DIAL retrievals assume that the atmosphere is unchanged between these observations. If the instrument dwells at one wavelength too long, biases will develop in regions where the atmosphere is changing. A well-designed instrument typically alternates wavelengths at time scales much faster than the variation of the atmosphere. Errors in the retrievals are not so much a result of variability as *inhomogeneous* variability. That is, when variations in backscatter are uncorrelated between range gates. That error is characterized by

$$\delta n_{\text{wv}} = -\frac{1}{2\Delta\sigma} \frac{\partial}{\partial r} \ln \left(\frac{\Delta\beta}{\beta(r)} + 1 \right), \quad (26.14)$$

where $\Delta\beta$ is the difference in observed backscatter coefficient in the online channel compared to the offline channel. For a given covariance spectrum, one can potentially estimate the error due to the interleave times of the wavelengths, but the rough estimate provided by Schotland [26.6] that interleave times should be < 8.5 ms, is often used as the standard. Observations performed by [26.52] suggest that the atmosphere is safely frozen for time periods $< 1\text{--}3$ ms, with decorrelation occurring in the $10\text{--}100$ ms range. Those measurements were performed on kilometer range scales though, so it is less obvious how short range correlations might be impacted. It is important to note that integration times used to generate the water vapor profiles can be much longer than these switching times. The transmitter and data acquisition system need to switch rapidly between wavelengths, but those channels can accumulate over much longer time scales without creating significant biases.

26.4 Devices and Systems

There are two basic types of ground-based water vapor DIAL devices in use currently in the atmospheric science community—*high-power* instruments that utilize Ti:Sapphire laser transmitters and *low-power* instruments that are semiconductor or diode laser-based systems (Table 26.2). Both are highly specialized research instruments and neither type of DIAL is commercially available at the time of this writing. However, industry is actively researching ways to develop commercially viable water vapor DIAL instruments. For example, ventures are underway to develop a $1.5\text{ }\mu\text{m}$ coherent DIAL system [26.53], exploring a broadband DIAL that operates in the near-infrared [26.54], and investigating short-range continuous wave DIAL via the Scheimpflug principle [26.55].

The high-power research DIAL systems in use today output several watts of average power and are capable of time resolutions of $1\text{--}10$ s with range resolutions of $30\text{--}300$ m while maintaining an error of $< 10\%$. Although complex laser transmitters are required, long-term measurements can be made with such systems [26.21, 56]. The fast temporal resolution of a high-power DIAL allows scanning for three-dimensional (3-D) water vapor field studies within the atmospheric boundary layer, which is required to improve our understanding of land atmosphere exchange processes. The current state-of-the-art 3-D high-power system is represented by the University of Hohenheim (UHOH) system [26.42, 57] and shown in Fig. 26.3.

Table 26.2 Advantages and disadvantages of the different methods

Device	Advantages	Disadvantages
High-power (narrowband)	Fast temporal resolution ^a Self-calibrating High range resolutions ^b	Expensive to build and maintain Not eye-safe Large and complex ^c
Low-power (narrowband)	Inexpensive to build and maintain Eye-safe Self-calibrating Compact	Coarse temporal resolution ^d Coarse range resolution ^e
Low-power (broadband)	Inexpensive to build and maintain Eye-safe Compact	Very coarse temporal resolution ^f High background ^g Requires periodic calibration

^a Approximately 1–10 s while maintaining an error of < 10%;

^b approximately 30–300 m while maintaining an error of < 10%; ^c typically requires highly trained staff to operate, and liquid cooling for laser; ^d approximately 1–5 min while maintaining an error of < 10%; ^e approximately 150–300 m while maintaining an error of < 10%; ^f approximately 20 min based on [26.54]; ^g no benefit to using a receiver filter narrower than transmitter width, which may limit range

Fig. 26.3 The current state-of-the-art high-power ground-based water vapor DIAL is represented by the UHOH 3-D-scanning WVDIAL. The instrument is housed inside a mobile trailer. The 80-cm 3-D scanner can be seen protruding out of the top left of the trailer (photo by Andreas Behrendt; used with permission)

Low-power research DIAL instruments in use today are designed for vertical profiling, output a few tens of milliwatts and have time resolutions of 1–5 min with range resolution of 150–300 m in both day and night while maintaining an error of < 10%. Compared to high-power DIAL, the instruments can be made more

Fig. 26.4 The current state-of-the-art low-power ground-based water vapor DIAL is represented by the micropulse DIAL (MPD) developed by NCAR and Montana State University. Photo taken March 2016, Boulder CO, USA (photo by Rich Erickson; used with permission)

compact, are lower cost to build, operate and maintain, and can run autonomously. These qualities make low-power water vapor DIAL promising candidates for large-scale networks. Future networks could be used to advance knowledge in the areas of measuring water vapor concentration and distribution, convection initiation, and could lead to improving our weather and climate forecasting skills. The current state-of-the-art low-power ground-based water vapor DIAL is represented by the MicroPulse DIAL (MPD) [26.27, 58] developed by National Center for Atmospheric Research (NCAR) and Montana State University (Fig. 26.4).

Both *high*-power and *low*-power water vapor DIAL instruments in use today are narrowband—they measure water vapor concentration with a narrow laser spectrum (e.g., ≤ 10 MHz or 0.02 pm at 828 nm). However, a broadband DIAL prototype has been demonstrated with a source much broader than a single water vapor absorption line [26.54]. Note that here broad-

band DIAL is distinguished from the differential optical atmospheric spectroscopy (DOAS) lidar hybrid technique [26.59, 60] as it does not spectrally resolve the backscattered light, e.g., with some type of fast gate spectrometer as a function of range. The broadband DIAL approach has the benefit of simplifying a number of the design constraints on the system with reduced need to actively control and stabilize the source wavelength and enabling the use of lower cost components. Furthermore, conventional thought is that the broadband DIAL is mostly insensitive to Rayleigh–Doppler effects. However, there is a performance cost to relaxing spectral requirements of the source. The spectrally broad source effectively limits our best tool for solar background rejection—narrowband filters in the receiver—so higher pulse energies are needed for day-

time operation, particularly when clouds are present. With broadband lasers, narrowing the receiver spectrum becomes a zero sum game, where reducing receiver bandwidth serves to equally attenuate background and signal. In that case, the only way to overcome this issue of detectability is to move to higher pulse energies and give up the eye-safe classification.

For practical implementations, as outlined in Sect. 26.3, the broadband DIAL retrieval requires calibration to a reference (e.g., radiosondes or radiometers) like Raman lidar. In that sense, a broadband DIAL is not considered self-calibrating and cannot provide independent observations. This means they typically agree quite well with the ancillary observations to which they are calibrated and are poorly suited to identifying the biases in those ancillary observations.

26.5 Specifications

Due to the lack of a commercial instrument, there are not well-defined performance parameters for ground-based water vapor DIAL. In general, the research DIAL systems currently in use are able to profile the entire lower troposphere (4–6 km range) in both day and night conditions. The high-power systems are capable

of temporal resolutions of 1–10 s and range resolutions of 30–300 m while maintaining an error of < 10%; whereas, low-power research DIAL instruments have time resolutions of 1–5 min with range resolution of 150–300 m while maintaining an error of < 10%.

26.6 Quality Control

For the narrowband DIAL technique, knowledge of the laser frequency is paramount, so it is continuously validated against a reference standard (e.g., a stabilized HeNe laser in a wavelength meter, or an absorption cell). The monitoring is typically done in near real time, on either the pulsed output or the injection seed laser, where the spectral conditions are preserved when amplified [26.17]. A second quality control factor for narrowband DIAL instruments is actively adjusting the laser frequency to minimize errors for the atmospheric conditions. The most straightforward method is via sideline tuning—adjusting the absorption cross section by changing the laser frequency away from line center—using accurate knowledge of the absorption lineshape from spectral databases (e.g., a Voigt profile can be used to estimate the absorption lineshape as a function of altitude). In this manner, the laser frequency is optimized for a wide range of moisture conditions. Note, that a one-way column optical depth (OD) of ≈ 1.1 is often used as rule of thumb for maximizing resolution in photon counting DIAL [26.61], although in practice the optimal OD will depend on a number of instrument and atmospheric factors. Only a small amount of wavelength tuning is typically re-

quired to optimize the DIAL; for example, at 828 nm, ≈ 5 GHz (or several picometers in the infrared) of sideline tuning adjusts the absorption cross section by an order of magnitude. Other quality control techniques involve identification of regions of high error, as defined in Sect. 26.3.3, such as low signal regions, regions with high gradients (cloud edges, lowest altitude range bins where the overlap function is changing rapidly), and regions with known nonlinear detector response (e.g., for photon-counting modules, count rates $> 5 \times 10^6 \text{ s}^{-1}$). These regions of high error are typically flagged or masked out of the data products for quality control.

Comparisons with radiosonde humidity profiles, infrared radiometer humidity profiles, or total water vapor column measurements from microwave radiometers, can also be useful tools for quality control. These comparisons can either identify quality control issues that originate from the narrowband DIAL or biases in the ancillary measurement. This is not the case for broadband DIAL—since it is not self-calibrating, it cannot provide truly independent observations or be used to identify biases in the techniques required for its calibration.

26.7 Maintenance

Due to the lack of a commercial instrument, there are not well-defined maintenance parameters for ground-based water vapor DIAL. In general, the high-power systems that use flashlamp-pumped lasers will require

maintenance every month. High-power systems that use diode-pumped solid-state laser and low-power systems are theoretically capable of operations for several years.

26.8 Applications

Standard observations of water vapor are obtained from the world-wide operational radiosonde network. Radiosondes are launched typically twice a day and are separated by hundreds of kilometers or more. This temporal and spatial resolution is not sufficient for many weather and climate research and forecasting applications. Satellite retrievals provide global coverage but are limited in terms of temporal and vertical resolution, particularly in the lower atmosphere where atmospheric moisture variability is most pronounced. Retrievals from ground-based global positioning system (GPS) receivers provide column-integrated precipitable water vapor without important range-resolved height information. Ground-based passive remote sensors include microwave and infrared radiometers. These can provide good profile information in the lowest 1.5 km but suffer from reduced resolution above that height. Active remote sensing systems are the most promising tools to close these observational gaps. Both DIAL and Raman lidar provide accurate range-resolved water vapor profiles; yet, to make a significant scientific impact, these systems need to be distributed on a wide scale [26.62].

Due to the limitations in water vapor measurement techniques described above, severe gaps in the observation of water vapor aloft exist [26.62–64]. The atmospheric research and operational weather forecasting communities have been advocating strongly for an instrument that can continuously profile water vapor at high temporal and vertical resolution in the lower troposphere (i.e., the lowest 3–4 km of the atmosphere). Furthermore, observations of the horizontal variability of water vapor are also important for both improved understanding of atmospheric processes and improved forecasting skill [26.65]. The measurements of small variations in the spatial, vertical, and temporal distribution of water vapor have been shown to be critically important for understanding and improving forecasts of, e.g., convection initiation and evolution, boundary layer processes, orographic precipitation, and tornadic storms [26.66–68].

An example of a vertical range-height indicator (RHI) scan of absolute humidity is shown in Fig. 26.5. This figure shows how the horizontal and vertical structure of water vapor can be measured over a range of

Fig. 26.5 RHI scan of absolute humidity obtained with the UHOH WVDIAL on 04.08.2014. The temporal and spatial resolution of the derived water-vapor field are 10 s and 300 m, respectively. Masked areas are in black (after [26.63] with permission from Wiley and Sons)

Fig. 26.6a,b Time series of relative aerosol **(a)** in arbitrary units (arb. u.) and absolute humidity in g m^{-3} **(b)** measured with the NCAR MPD. The temporal and spatial resolution of the derived WV field are 5 min and 150 m, respectively. The vertical profiles taken in Pilar, Argentina span two weeks starting 31.10.2018. Masked areas are in *white* and typically signify attenuated signal due to optically thick clouds

several kilometers. This example illustrates pronounced vertical stratification and moisture variability.

Figure 26.6 shows the continuous data collected by an MPD for two weeks during a field project in central Argentina. The top panel of the figure shows the relative aerosol backscatter—corrected for both range and geometric overlap—from near the surface to 12 km. The bottom panel of the figure shows the water vapor absolute humidity profiles from 300 m up to 6 km AGL. The red regions of relative backscatter illustrate cloud bases. Water vapor measurements via the DIAL are not possible through optically thick clouds, and these regions are masked white. These continuous observations reveal dramatic moisture variability, elevated moist and dry layers and moisture variations associated with the diurnal cycle.

While one instrument will not satisfy all of the measurement gaps inhibiting scientific understanding of atmospheric processes that are impacted by water vapor, combinations of sensors are highly valuable. For example, the collocated combination of DIAL with Atmospheric Emitted Radiance Interferometers (AERI) [26.69, 70] holds promise for providing complete clear-air profiles from the ground to the mid-troposphere. This combination will combine the high accuracy, high resolution AERI measurements at low levels with the extended range of DIAL measurements up to 3–5 km AGL [26.58]. Furthermore, the combination and integration of multiple water vapor sensors via data assimilation methods may provide 3-D moisture fields, which would likely benefit short-term convective weather forecasting skill.

26.9 Future Developments

26.9.1 Networks

Large-scale networks of ground-based passive and active remote sensing systems provide the most promising results to close the observational gap of water vapor aloft and are essential for continued progress in weather and climate research [26.62, 63]. Both DIAL and Raman lidar provide accurate range-resolved water vapor profiles; however, future networks need to be comprised of low-cost instruments to provide a sufficient density that is economically feasible. For a significant scientific impact, it is anticipated that several hundred instruments would be required to adequately cover an area the size of the continental United States [26.62].

Semiconductor laser-based DIAL instruments—with a reduced cost and enhanced simplicity, safety, and reliability, while still providing accurate quantitative data products—show promise to enable an autonomous and continuously operated large-scale network of water vapor profiling.

26.9.2 Temperature Profiling

The combination of water vapor and temperature profiles from the same instrument would provide atmospheric stability profiles and be valuable to the weather forecasting and severe weather communities. To date, the most successful active remote sensing temperature

profiling is provided by the rotational Raman technique [26.71, 72]. However, DIAL inherently has two significant advantages over Raman lidar: (1) in practical application, it requires no external calibration and (2) the elastic scattering cross section is several orders of magnitude larger than the Raman scattering cross section. This second advantage has opened the door to using low-power semiconductor lasers for the historically challenging DIAL laser transmitter. It is therefore a tantalizing prospect to investigate the potential of adapting the diode laser-based DIAL technique to include temperature profiling.

The potential to obtain atmospheric temperature profiles with the DIAL technique has been known for several decades [26.73–75]. The concept is to perform a DIAL measurement on the absorption of a line in the oxygen A-band that has a high ground-state energy. The number density of the O₂ profile can be estimated from surface temperature and pressure, and corrected for water vapor concentration (i.e., the water vapor profile needs to be simultaneously measured). The observed temperature-dependent absorption coefficient can then be solved for temperature. However, as outlined in the literature [26.76, 77], the major stumbling

block to implementing this technique stems from the Doppler broadened Rayleigh backscatter. In the oxygen A-band, at 770 nm wavelength, the Rayleigh–Doppler spectrum has a linewidth comparable to the O₂ absorption feature, while, the Mie backscattered linewidth maintains the same narrowband linewidth of the laser (Fig. 26.2). To accurately retrieve temperature profiles, the Rayleigh–Doppler broadened backscatter must be accounted for in the return leg of the optical path. The difficulty of how to adequately correct for this term has stymied O₂ DIAL-based temperature measurements.

One possible solution is to combine the high spectral resolution lidar (HSRL) technique into the micropulse DIAL architecture. The HSRL technique is capable of resolving the molecular to aerosol backscatter ratio without significant assumptions. A simplified version of an HSRL, based on the diode laser-based lidar architecture, was recently demonstrated [26.1]. In the future, a combined diode laser-based lidar—with HSRL, O₂ DIAL, and water vapor DIAL capabilities—may provide temperature profiling opportunities [26.78]. A retrieval technique based on a perturbative solution to the DIAL equation using such a system has been outlined by [26.79].

Scott M. Spuler

Earth Observing Laboratory
National Center for Atmospheric Research
Boulder, USA
spuler@ucar.edu

Scott Spuler is a Research Engineer in the Earth Observing Laboratory at the National Center for Atmospheric Research. He received MS and PhD degrees in Applied Optics/Engineering Systems from Colorado School of Mines in 1999 and 2001, respectively. His research interests include the development of innovative optical and laser-based instrument systems that can be applied to enhance the understanding of the atmosphere.

Matthew Hayman

Earth Observing Laboratory
National Center for Atmospheric Research
Boulder, USA
mhayman@ucar.edu

Matthew Hayman is an Engineer and Scientist in the Earth Observing Lab at the National Center of Atmospheric Research. He received his PhD in Electrical Engineering and Optics from the University of Colorado at Boulder in 2011. His research focuses on developing optical sensor and signal processing algorithms for environmental sensing applications.

Tammy M. Weckwerth

Earth Observing Laboratory
National Center for Atmospheric Research
Boulder, USA
tammy@ucar.edu

Tammy Weckwerth is a Scientist III in the Earth Observing Laboratory at the National Center for Atmospheric Research. She received a PhD in Atmospheric Sciences from the University of California Los Angeles in 1995. Her scientific research efforts are aimed at using observational data to understand mesoscale convective processes, in particular the initiation and evolution of precipitating convection.

Doppler Wind Lidar

Oliver Reitebuch , R. Michael Hardesty 

Wind lidars use the optical Doppler effect to measure atmospheric wind with high spatial and temporal resolution. In contrast to scalar quantities, such as temperature or humidity, the atmospheric wind is a vector quantity consisting of three components – usually referred to as vertical wind speed, horizontal wind speed, and the horizontal direction. This requires specific techniques for the measurement of each component, taking into account their different temporal and spatial variability in the atmosphere. Principles of wind lidars, including two complementary techniques using coherent and direct-detection approaches and their application for atmospheric research are discussed. Doppler wind lidars offer a wide range of applications from aircraft wake vortex detection and characterization to the measurement of turbulent quantities to resolving mesoscale atmospheric flows, and even global wind profiling from space with the Aeolus mission launched in August 2018.

This chapter introduces the principles and applications of measuring atmospheric wind speed with lidars (light detection and ranging) based on using the Doppler frequency shift – called Doppler wind lidar (DWL) as the most common approach. Other techniques for measuring wind speeds with lidars as cross-correlation techniques for aerosol and cloud movements or Doppler resonance fluorescence lidar used in the mesosphere are not

covered here. Both coherent and direct-detection DWL principles are discussed based on their physical principle of using spectrally narrow bandwidth aerosol and cloud returns, as well as broad bandwidth molecular returns. Both techniques are discussed with respect to their technical implementation and their specifications. Some applications for DWL are illustrated and potential new technologies and application areas are outlined.

27.1 Measurement Principles and Parameters

Optical remote sensing allows the observations of spatially resolved winds without disturbing the flow for all altitudes of the atmosphere, and, thus, complements conventional in-situ techniques (Chap. 9). Wind observations with lidars are used to study atmospheric flow on a large variety of temporal and spatial scales. Different types of wind lidars allow measurements in different altitude regions of the atmosphere from the atmospheric boundary layer with high aerosol content to the upper troposphere, stratosphere, and even mesosphere with molecules as backscattering targets [27.1, 2]. Optical remote sensing with lidars is a very powerful method for measuring the three-dimensional (3-D) atmospheric wind vector. It is possible to measure the horizontal wind vector as well as the vertical wind component with different viewing geometries. Wind lidars are operated from the ground, balloons, ships, or aircrafts and were deployed for the first time on a satellite platform within the Aeolus mission in 2018 [27.3, 4] (see Chap. 37 for airborne and satellite platforms).

The movement of the air is described by the wind vector $\mathbf{V} = (u, v, w)$, which is composed of three components. Usually, the wind vector is described by a vertical component w (positive for an updraft wind) and two horizontal components u, v . The horizontal wind vector (called *velocity* for a vector quantity) can be either described by the magnitude of the vector M (typically called *speed* for a scalar quantity; $M = \sqrt{u^2 + v^2}$)

and by the wind direction θ (angle between the horizontal wind vector and north; $\theta = \arctan(u/v)$; $\theta = 0^\circ$ for northerly wind, wind from north towards south, $\theta = 90^\circ$ for easterly wind, wind from east to west). Or it is decomposed into the two components along the west–east axis u (zonal wind component, positive if wind is blowing from west towards east, which is a westerly wind) and along the south–north axis v (meridional wind component, which is positive if the wind is blowing from south to north, which is a southerly wind).

The principal measurement from a DWL is the wind speed along the instrument viewing direction LOS (line-of-sight) similar to sodar (sound detection and ranging, Chap. 23) and wind profiler radar (radio detection and ranging, Chap. 31), called LOS wind speed or radial wind speed. The LOS wind speed is the component of the wind vector \mathbf{V} projected onto the pointing direction of the laser beam and the viewing direction of the telescope. In the following, only instruments are considered where both laser and telescope LOS directions are identical – typically called monostatic lidar instruments. By deploying different scanning strategies (Sect. 27.3.3), all components of the wind vector can be derived, which are listed in Table 27.1. Besides the derived LOS wind speeds, also the backscattered intensities, signal-to-noise ratio (SNR), or carrier-to-noise ratio (CNR), are derived from Doppler wind lidars and used for atmospheric scene classification similarly as

Table 27.1 Measured parameters of a Doppler wind lidar

Parameter	Description	Unit	Symbol
LOS speed	Wind speed in direction of the laser line-of-sight (LOS) or radial wind speed	m s^{-1}	v_{LOS}
Wind speed	Magnitude of horizontal wind speed	m s^{-1}	M
Wind direction	Angle for horizontal wind direction with respect to North, where wind is blowing from	$^\circ$	θ
Wind velocity components	Components of the wind vector with zonal wind speed (East–West) u , meridional wind speed (North–South) v , vertical wind speed w (up–down)	m s^{-1}	u, v, w
Signal intensity	Signal intensity of the backscattered signal	arb. u. or dB	I
Signal-to-noise ratio, carrier-to-noise ratio	Ratio of signal intensity (or carrier) to noise intensity for the relevant spectral bandwidth	arb. u. or dB	SNR, CNR

Table 27.2 Derived parameters from DWL measurements

Parameter	Description	Unit	Symbol
Backscatter coefficient	Aerosol and cloud backscatter coefficients	$\text{m}^{-1} \text{sr}^{-1}$	β
Boundary layer height	Height of the atmospheric boundary layer with respect to aerosol mixing or turbulence	m	z_i
Fluctuations of wind component	Fluctuations of the wind components around its mean value	m s^{-1}	u', v', w'
Turbulent quantities	Turbulent energy dissipation rate	$\text{m}^2 \text{s}^{-3}$	ε
	Turbulent kinetic energy	$\text{m}^2 \text{s}^{-2}$	TKE

Table 27.3 Principles of DWL and height range from boundary laser (BL), free troposphere (FT), to stratosphere (ST) and mesosphere (MS)

Type of DWL	Atmospheric backscatter		Altitude range		
	Aerosol, clouds	Molecules	BL	FT	ST/MS
Coherent DWL	×		×	× ^a	
Direct-detection DWL	×	×	×	×	×

^a in the case of clouds or elevated dust layers, e.g., desert dust or volcanic ash.

for backscatter lidars (Chap. 24). Thus, also the vertical extent and boundaries of aerosol and cloud layers, as well as the height of the atmospheric boundary layer are determined from Doppler wind lidars (Table 27.2).

In addition to the mean component of the wind vector, also its turbulent fluctuations around the mean can be derived from DWL measurements with high temporal resolution (Table 27.2). This is mainly the case for turbulent vertical wind fluctuations, where vertical pointing instruments are used. Also, quantities such as the turbulent energy dissipation rates can be determined with a DWL. An excellent review about the measurement and the derivation of turbulent quantities is provided in [27.5] and within a textbook about coherent DWL [27.6].

Through numerous deployments over the past four decades, the efficacy of wind lidars for a variety of atmospheric applications has been demonstrated. Here, only a selection of some references is provided as a first overview:

- Wind energy sector for site assessment, research on turbine wakes, wind turbine control, or power curve verification Chap. 51; [27.7–10] (Sect. 27.8.2)
- Airport surveillance for low-level wind shear and wake vortex detection for a number of airports, e.g., Hong Kong, Frankfurt, and Munich [27.11, 12] (Sect. 27.8.1)
- Aircraft safety and control: wake vortex characterization from ground and aircraft [27.6, 13–15] with applications for clear-air turbulence (CAT) detection and mitigation of gusts and turbulence by active control [27.16, 17]
- Long-range transport, dispersion monitoring, and determination of boundary layer heights [27.18–20]
- Research on atmospheric dynamics with flows in complex terrain, verification of boundary layer parameterization, e.g., recently within the Perdígão field campaign in 2017, where 26 DWL were deployed [27.21, 22], or vertical exchange processes for trace gases [27.23]
- Validation of numerical models from small scales (large eddy simulations), medium scales [27.24], and global scales for numerical weather prediction including assimilation of observations [27.25]

- Routine measurements of wind profiles at meteorological stations [27.26], e.g., German Meteorological Service, Richard-Aßmann-Observatory (DWD RAO) (Chap. 47)
- Research on stratospheric and mesospheric dynamics including gravity wave propagation [27.27, 28] (Sect. 27.8.3)
- Global wind profiling from space for improvement of weather forecasts [27.4, 29].

A DWL determines the wind speed of the air by using the collective motion of a large number of aerosols, cloud particles, and molecules within the air volume as tracers. Different methods are applied for using aerosol and cloud particles as tracers with a coherent-detection DWL and molecules as tracers with a direct-detection DWL. A direct-detection lidar relies on the measurement of the signal intensity or number of photons, whereas a coherent lidar additionally measures the phase and frequency of the backscattered signal. Overviews of DWL principles, techniques, and applications can be found in [27.1, 2, 6, 30–32].

Whereas coherent-detection DWL are applied for wind measurements in the aerosol-rich atmospheric boundary layer and for cloud movements in the boundary layer and troposphere (Table 27.3), direct-detection wind lidars using molecular backscatter allow the determination of wind speeds in the troposphere, stratosphere, and even up to the mesosphere. Thus, the direct-detection approach offers a unique capability to measure higher-altitude winds.

Coherent DWL are commercially available today and can be very compact and reliable, and high temporal resolution and high precision can be achieved, which even allows the determination of vertical winds, turbulent quantities, or aircraft wake vortices. Direct-detection DWL using molecular backscatter are the systems of choice for wind measurements in the upper troposphere and stratosphere but are considered as research instruments, which need qualified lidar experts for development and operation. A more comparative overview of both principles is discussed in Sect. 27.4.

As coherent DWLs rely on the measurement of the spectrally narrowband aerosol and cloud returns, they can, in principle, achieve higher precision for the

same SNR as direct-detection DWL, which rely on the backscatter of broad bandwidth molecular returns. Coherent DWL are usually operated with a pulsed laser source to achieve vertically resolved measurements for longer ranges. However, especially for shorter ranges

(< 500 m) also continuous-wave (CW) laser sources are in use, where the range resolution is achieved by focussing the laser beam for different ranges [27.33]. The principle and setup of coherent DWL are further elaborated on in Sects. 27.3.5 and 27.4.1.

27.2 History

First Doppler wind lidar techniques were pioneered for both direct and coherent-detection methods in the 1960s and early 1970s, shortly after the invention of the laser by *Theodore Maiman* (1927–2007) in 1960 [27.34].

27.2.1 History of Direct-Detection Wind Lidar

The principle of wind measurement with direct-detection Doppler lidar was pioneered by the group of *Giorgio Fiocco* (1931–2012) using a frequency-stabilized argon-ion laser emitting at 488 nm and a spherical Fabry–Pérot interferometer as the spectral analyzer [27.35]. These first atmospheric wind lidar observations (the authors used the term *optical radar*) were performed in 1971 at the European Space Research Institute (ESRIN) in Frascati, Italy. Today, ESRIN is part of the European Space Agency (ESA) and is responsible for the operational phase of the first wind lidar in space, *Aeolus*, which was successfully launched in August 2018. Measuring global atmospheric winds from space was initially proposed in the 1970s and its performance simulated for coherent detection at 10.6 μm using CO_2 lasers by *Milton Huffaker* (1934–2019) [27.36, 37] and for the direct-detection technique by *Vincent Abreu* [27.38] using frequency-doubled Nd:YAG lasers at 532 nm.

Direct-detection Doppler lidar make use of one or more narrowband filters and determine the Doppler frequency shift from the transmitted signal strength through this filter, called the *edge* technique, or from the radial-angular distribution or spatial movement of the interference patterns (*fringes*) of an interferometer, called the *fringe imaging* technique or interferometric techniques.

The commonly used double-edge technique – also applied on *Aeolus* – using two filters was pioneered by *Marie-Lise Chanin* in 1989 [27.39, 40] for stratospheric winds at the observatory of Haute-Provence, France, using the broadband molecular return with a laser wavelength of 532 nm. In parallel, it was exploited for tropospheric winds using laser wavelengths of 1064 and 532 nm for the narrowband aerosol return and 355 nm for the molecular return by *Laurence Korb* [27.41], and *Bruce Gentry* [27.42], respectively, at NASA. The first

airborne direct-detection Doppler lidar was developed by *Oliver Reitebuch* and his coworkers at DLR [27.43] as the airborne prototype for the satellite wind lidar on *Aeolus*. In 1999, the European Space Agency (ESA) decided to establish a DWL mission named Atmospheric Dynamics Mission ADM-*Aeolus* (nowadays called *Aeolus*) to fill the gap in the global observing system [27.4, 44], which is based on a direct-detection wind lidar operating with an ultraviolet wavelength of 355 nm [27.3].

The use of broadband molecular Rayleigh returns with a single Fabry–Pérot interferometer as a spectral filter to measure winds up to 65 km was first applied at the Arecibo Observatory, Puerto Rico, in 1990 by *Craig Tepley* [27.45, 46]. Another approach using only one filter, called the single-edge technique, can be realized by using iodine molecular absorption lines as narrowband filters for both molecular and aerosol backscatter at 532 nm. This technique was pioneered in the 1990s by *Jonathan Friedman* and *Craig Tepley* at the observatory Arecibo for stratospheric winds [27.47], and by *Zhishen Liu* for tropospheric winds [27.48]. These techniques were applied to measure sea-surface winds during the 2008 Olympic sailing games in Qingdao, China [27.49].

Other techniques for direct-detection DWL were also demonstrated in the 1990's. The fringe imaging technique was first proposed and realized by the group of *Vincent Abreu* [27.50, 51]. The use of the two-beam Mach–Zehnder interferometers as spectral analyzer was proposed by *Takao Kobayashi* [27.52] and in parallel by *Ronald Schwiesow* [27.53] for the narrowband aerosol signal and for the broadband molecular signal by *Didier Bruneau* [27.54, 55].

27.2.2 History of Coherent-Detection Wind Lidar

Prior to the development of the laser, coherent, or heterodyne, detection was utilized in receivers for radio and microwave systems. However, very soon after the invention of the laser, the potential application of optical heterodyning to estimate the spectral characteristics of optical radiation was suggested by *Theodore Forrester* (1918–1987) [27.56], who noted that:

the advent of oscillators generating visible or near infrared radiation with spectral widths and angular spreads much smaller than available from ordinary light sources makes possible the application of radio frequency receiver technology to the field of optics ...

Although the initial investigations of optical heterodyne detection involved the application of a single laser source and specular reflectors to generate the signal and local oscillator beams, *Gordon Gould* (1920–2005) [27.57] showed that the technique could also be applied to detection of radiation scattered by a diffuse reflector. Incorporation of coherent detection to observe the movement of particles suspended in air was reported by *Milton Huffaker* [27.58], who employed a continuous-wave (CW) argon laser source and a homodyne receiver to measure the mean velocity and velocity fluctuations of aerosol particles introduced into a wind tunnel. Subsequently, a CW coherent homodyne lidar that incorporated a 25 W CW carbon dioxide CO₂ laser transmitter operating at 10.6 μm was demonstrated for remote atmospheric wind measurements and was shown to compare well with corresponding observations from a cup anemometer [27.59]. From the early 1970s through to the 1980s, CO₂ lasers operating in the thermal infrared spectral region were utilized in most coherent lidar wind systems. Compared to visible wavelength sources, CO₂ lasers possess several advantages over visible wavelength sources, including a greater laser power conversion efficiency and frequency stability, reduced impact on performance from atmospheric turbulence, eye safety, and a superior capability of penetrating haze and fog.

During the 1970s, coherent lidars employing designs similar to the CW technique demonstrated in [27.59] were applied to investigate air motions associated with several dynamic phenomena, including hydrometeors [27.60] and dust devils [27.61]. Demonstrating the potential portability of coherent lidars, a lidar instrument was deployed on a small aircraft for measurements of wind velocities in waterspouts [27.62].

Although CW coherent lidar provides excellent range resolution, aperture size limitations limit the practical range of such systems to a few tens to a few hundreds of meters, which is insufficient to investigate many atmospheric phenomena. To provide measurements at more extended ranges, the development of pulsed coherent lidar systems began in the late 1970s, aided by the development of pulsed coherent laser transmitters and digital signal processing capabilities. Previously, CW lidar systems utilized analogue spectrum analyzers to extract the Doppler signal in the

return. In an early pulsed lidar developed by NASA, the 2 μs-long laser pulses were generated by passing the output of a chopped continuous wave CO₂ laser through a series of optical amplifiers to produce pulses with energies on the order of 5 mJ [27.63]. The atmospheric aerosol-backscattered signals were digitized and range-gated to provide measurements with 330-m-range resolution up to ranges of up to 30 km [27.64]. The NASA system, which was deployed on a Convair 990 aircraft, demonstrated the capability of pulsed lidars to map wind fields under uniform wind field conditions, as well as in the vicinity of thunderstorms and around cumulus clouds.

During the late 1970s, the potential capability to deploy a coherent Doppler lidar in space to measure wind profiles over the entire globe began to attract interest as a way to measure atmospheric winds over poorly sampled regions of the earth. A NOAA study developed concepts, suggested a notional design, and analyzed simulated performance for a proposed space-based lidar system based on a pulsed CO₂ laser [27.65]. Although the results of this study indicated that it was feasible for such a system to provide global winds, the development of frequency-stable high-energy (on the order of 10 J) pulsed lasers suitable for deployment in space was deemed necessary to achieve the performance identified in the study. Also required was an improved understanding of the structure of tropospheric atmospheric backscatter at CO₂ laser wavelengths. To address these issues, in the early 1980s NOAA developed a pulsed lidar system built around a pulsed transverse-excited, atmospheric pressure (TEA) laser that generated 100 mJ pulses at 10.6 μm. Over the next several years, the NOAA system, which was mounted in a mobile trailer, was operated frequently in Boulder, Colorado, and at a number of remote locations to investigate the performance characteristics of TEA Doppler lidars, obtain better information on atmospheric backscatter [27.66], and demonstrate the capability of Doppler lidars to improve the understanding and characterization of atmospheric phenomena. In 1985, the 100 mJ lidar transmitter was upgraded to produce pulses with 2 J of energy at up to 30 Hz pulse repetition rate [27.67], extending the system range to beyond 30 km under favorable aerosol loading. The transportable NOAA lidar was particularly effective in mapping out heterogeneous flows with length scales of several km, such as flows in complex terrain [27.68], severe downslope windstorms in the lee of the Rockies [27.69], and land-sea breeze circulations near Monterey, California [27.70]. Although the system was quite large, it was modified for deployment on a NASA DC-8 to enable both the aerosol characterization and the study of specific phenomena not easily investigated with a ground-based instrument [27.71].

Following the airborne deployments, the NOAA pulsed CO₂ lidar was returned to its container and utilized for field studies intermittently throughout the 1990s, until it was retired following the Vertical Transport and Mixing air quality study in Salt Lake Valley in 2000 [27.72].

During the late 1980s, the development of frequency-stable, coherent solid-state laser transmitters marked a significant advancement in the evolution of coherent lidar for wind measurements. Although the CO₂ laser transmitters used throughout the 1970s and early 1980s were attractive for Doppler lidar applications because of their relatively high gain, versatility, and operation at longer wavelengths where extinction and turbulence are less detrimental, solid-state lasers offered long-term reliability, operation at shorter wavelengths where aerosol backscatter coefficients are typically higher and where room temperature detectors can be employed in the lidar receiver, and the capability of inclusion in compact lidar systems. The first solid-state coherent lidar [27.73] incorporated a laser-diode-pumped Nd:YAG monolithic ring laser as a master oscillator and a flash-lamp-pumped zigzag slab amplifier to produce pulses with a peak power of 2.3 kW. A similar system with pulse energies of 5 mJ [27.74] produced wind-profile measurements to ranges of 3.75 km. Because eye safety issues severely limit lidar operation at 1.06 μm , an important step forward was the demonstration of a coherent lidar employing a Tm,Ho:YAG laser source at 2.1 μm [27.75]. This system transmitted pulses with an energy of about 22 mJ and measured winds in the atmosphere to horizontal ranges beyond 20 km.

Although some CO₂ systems were still operating in the late 1990s and early 2000s [27.76, 77], by this time, the community was well on the way to embracing solid-state sources in coherent lidars for wind measurements. Reliable instruments operating at wavelengths near 2 μm with pulse energies of a few mJ and pulse rates of several hundred Hz, which are capable of unattended, continuous observations to ranges of several km, were developed, e.g., [27.78] and deployed for a range of applications, including characterization of shear flow instability near the surface in the nighttime stable boundary layer [27.79], ship-based observations of the marine boundary layer winds [27.80], and wind shear detection at Hong Kong International Airport [27.11]. A significant advantage of this class of Doppler lidar instruments was the stability and narrow bandwidth of the laser pulse, achieved through injection seeding of a diode-pumped, solid-state power oscillator. This facilitates multipulse accumulation in the receiver to extract the Doppler shift from weak backscattered signals with low carrier-to-noise ratios [27.81]. The Hong Kong airport lidar deployment demonstrated that

a 2 mJ per pulse lidar system could be deployed for unattended operational use on a long-term basis to warn pilots of potentially hazardous wind shear conditions in the airport vicinity. Even though the pulse energy was significantly lower than that in the system described in [27.75], a high pulse rate and efficient signal processing enabled measurements in the range of several km.

The evolution of coherent wind lidars continued in the 2000s with the demonstration of all-fiber systems [27.82] producing tens of μJ of energy at pulse rates of 10 kHz or more. A common version of these low-energy, high-pulse repetition frequency (PRF) systems includes a master-oscillator, power-amplifier configuration with an erbium-doped fiber amplifier producing radiation around 1.55 μm wavelength for the transmitter. Although such systems were limited to a few km of range, the all-fiber design and general use of commercial off-the-shelf parts developed for the telecommunications industry significantly lowered the cost of constructing and operating a Doppler lidar, spawning the formation of private companies focused on producing and selling such instruments to a broader base of academic, government, and industrial users [27.83, 84].

Over the past two decades, the application of Doppler lidar in the wind-power industry has been widespread. Several significant issues associated with wind power are well matched to coherent lidar capabilities, including the characterization of winds to determine the suitability of proposed sites, the measurement of wind-turbine power curves, the warning in advance of wind characteristics such as sudden increases in wind speed and turbulence that can cause damage to turbine blades, the adjustment of wind-turbine blade pitch to mitigate blade fatigue, and the investigation of wake effects on wind properties downwind of large turbines. The synergism between wind energy needs and Doppler lidar capabilities has provided a significant market for small coherent lidars and has contributed substantially to the commercial viability of private companies producing and selling wind lidar systems.

Although much of the development of coherent lidars over the past three decades has been associated with the evolution and variations of pulsed systems, CW instruments also are being deployed. A system operating at 1.55 μm that provides short-range, high-range resolution, high-precision observations, was demonstrated in the early 2000s [27.85]. Instruments incorporating similar designs have found a useful niche to measure winds over scales equivalent to wind turbine rotor diameters. A significant advantage of CW systems, which are typically less expensive than pulsed instruments, in wind energy applications is the capability of measuring at very short ranges not accessible

using monostatic pulsed lidars. Continuous-wave lidar systems have been applied to measure winds and turbulence upwind of turbines [27.86]; instruments mounted at the hub of a spinning wind turbine have been investigated for observing approaching wind and turbulence at ranges and time scales suitable for active control of turbine blades, e.g., [27.87].

Currently, depending on the application, both continuous-wave and pulsed systems are being applied in observational campaigns. Pulsed systems provide maximum ranges up to several km but are limited in range

resolution, while CW instruments provide very high range resolution (a few m) at short ranges, but are limited to ranges of 100 m or so. With respect to the operating wavelength, new coherent lidar development seems to be focused primarily on systems operating in the 1.5 μm wavelength region. Some legacy systems developed earlier at 2 μm , including a high-power Doppler wind lidar designed primarily for airborne deployment but available for ground-based observations [27.88], continue to exist, but a clear trend toward shorter wavelengths in new systems is apparent.

27.3 Theory

This section introduces the physical basis for measuring winds by the Doppler effect and discusses the difference for the spectral lineshape of molecular and aerosol backscatter. Furthermore, the principle of measuring the wind vector and the foundations for coherent and direct-detection DWL are discussed.

27.3.1 The Doppler Effect

Most wind lidars rely on the Doppler effect, which was first described by the Austrian physicist *Christian Doppler* (1803–1853) in 1842 [27.89]. The Doppler effect can be observed for acoustic waves, which is used in remote sensing with a Doppler sodar (Chap. 23), and for electromagnetic waves used for Doppler radar (Chap. 31) and Doppler lidar. It describes the change in frequency (or wavelength) that is present when the source of the wave and the observer are in relative motion to each other. The correspondence of the frequency f_0 and the wavelength λ_0 of an electromagnetic wave is obtained using the speed of light c ($c = 2.99792458 \times 10^8 \text{ m s}^{-1}$ in vacuum)

$$f_0 = \frac{c}{\lambda_0}. \quad (27.1)$$

For a Doppler lidar (and also for any other Doppler remote sensing instrument) the Doppler effect occurs twice. First, when the light wave from the emitting laser

source with a frequency of f_0 is perceived by the moving, scattering particle (aerosol, cloud, and molecule) with f_1 ; the second Doppler effect occurs when the moving particle re-emits the scattered wave, which is perceived by the lidar receiver with f_2 . The Doppler frequency shift Δf or wavelength shift $\Delta \lambda$ is obtained from

$$\Delta f = f_2 - f_0 = 2f_0 \frac{v}{c} = 2 \frac{v}{\lambda_0}, \quad (27.2)$$

$$\Delta \lambda = \lambda_2 - \lambda_0 = -2\lambda_0 \frac{v}{c} = -2 \frac{v}{f_0}. \quad (27.3)$$

With the above definition of the Doppler frequency shift sign, the LOS wind speed is defined such that positive LOS wind speeds describe a movement towards the lidar instrument (*blue shift*, because the wavelength is shifted towards blue colors) and negative LOS wind speeds, when the wind is blowing away (*red shift*). The opposite definition for the sign of the LOS wind speed is also in use; then the above equations need to be multiplied by -1 . Due to this ambiguity in the sign definition, it is important to define the direction of the positive or negative LOS wind speeds.

The relative Doppler shift expressed as $\Delta f/f_0$ or $\Delta \lambda/\lambda_0$ is on the order of 10^{-7} – 10^{-8} for typical atmospheric wind speeds. It is very demanding to detect such small changes in the frequency or wavelength, which imposes high challenges for the laser sources and optical receivers used for a DWL. For illustration purposes, the Doppler shifts for typical wavelengths of a DWL are provided in Table 27.4. A 1 m s^{-1} LOS wind speed would change the wavelength from 2.02 to 2.020000135 μm by only 13.5 fm (1 fm = 10^{-15} m). These wavelength differences are much smaller compared to the size of the hydrogen atom ($\varnothing \approx 50 \text{ pm}$) and are comparable to the size of the hydrogen nucleus ($\varnothing \approx 1.2 \text{ fm}$), especially for wavelengths of 355 nm.

Table 27.4 Doppler shift for a LOS speed of 1 m s^{-1} for typical wavelengths of a DWL

λ_0 (μm)	f_0 (THz)	$\Delta \lambda$ (fm)	Δf (MHz)
0.355	844	2.37	5.63
1.55	193	10.3	1.29
2.02	148	13.5	0.99
10.6	28.3	70.7	0.189

27.3.2 Spectral Lineshape from Molecular and Particle Backscatter

The collective, mean movement of all molecules, aerosol, and cloud particles within a certain atmospheric volume is referred to as wind. This is superimposed by the random, thermal motion of the molecules and particles (*thermal Brownian motion*) and causes so-called Doppler broadening. This motion can be described by the Maxwell–Boltzmann velocity distribution, which is dependent on the atmospheric temperature T and the mass m of a single molecule (or particle). The mean velocity of the air molecules (a mixture of gases with mean mass $m = 4.79 \times 10^{-26}$ kg) is quite high, with a value of 459 m s^{-1} for a temperature of 15°C . If only one component in the LOS direction of the velocity distribution is considered, then it can be described by a Gaussian distribution with a standard deviation in velocity space σ_v or wavelength space σ_λ after applying the Doppler shift equation

$$\sigma_v = \sqrt{\frac{kT}{m}}, \quad (27.4)$$

$$\sigma_\lambda = \frac{2\lambda_0}{c} \sqrt{\frac{kT}{m}}, \quad (27.5)$$

with the Boltzmann constant k ($k = 1.380649 \times 10^{-23} \text{ J K}^{-1}$). The Gaussian approximation is only valid for dilute gases. For typical atmospheric densities, an additional Brillouin scattering effect on moving pressure fluctuations has to be considered, which is described by Rayleigh–Brillouin scattering [27.90–93]. The Gaussian velocity distribution is quite broad for air molecules with $\sigma_v = 288 \text{ m s}^{-1}$ and a full-width at half-

maximum (FWHM) of 678 m s^{-1} for 15°C (FWHM = $2\sqrt{2 \ln(2)}\sigma = 2.355\sigma$ for a Gaussian distribution with unit standard deviation). For aerosol and cloud particles, the width of the velocity distribution is several orders of magnitude smaller due to the larger mass of aerosols and cloud particles. The assumptions of typical particle radii of $0.1\text{--}1 \mu\text{m}$, which are of sizes relevant for Mie scattering at laser wavelengths, and of spherical water particles (density of 10^3 kg m^{-3}) lead to typical masses of 4.2×10^{-18} to 4.2×10^{-15} kg resulting in velocity widths σ_v of $30\text{--}1 \text{ mm s}^{-1}$. Thus, Doppler broadening is a factor of $10^4\text{--}10^6$ smaller for aerosol particles compared to molecules and can be neglected compared to other factors, which influence the line width from aerosol returns, mainly turbulent broadening and the line width of the emitted laser. This results in typical line widths of a few up to 10 m s^{-1} for the narrowband Mie return independent of the laser wavelength chosen, which is still two orders of magnitude smaller than the broad bandwidth molecular returns.

The mean of the Gaussian velocity distribution is given by the mean, collective movement of all molecules, which is referred to as the LOS wind speed. For the case that a laser emits a wavelength λ_0 , the backscattered light from molecules is spectrally broadly distributed, which is illustrated in Fig. 27.1, where the distribution of Doppler shifts is shown for a typical DWL wavelength of 355 nm . A broad bandwidth spectrum is obtained from molecules, whereas a narrow bandwidth spectrum is obtained from aerosol and cloud particles. In the case of a mean wind speed of the air volume, both the aerosol and the molecular spectrum are shifted in parallel along the wavelength axis.

Fig. 27.1 Spectral distribution of LOS wind speed v_{LOS} in m s^{-1} of a broad bandwidth molecular and small bandwidth aerosol signal; corresponding Doppler wavelength shifts in pm for an emitted wavelength of $\lambda_0 = 355 \text{ nm}$ (1 pm equivalent to 422 m s^{-1}), standard deviation σ_v and FWHM are indicated; one spectrum (dotted lines) is shown for a mean LOS wind speed of 0 m s^{-1} , while the other spectrum (bold line) is shown for a 180 m s^{-1} LOS wind speed (equivalent to a Doppler shift of 0.44 pm) (after [27.1])

27.3.3 Principle of Wind Measurement and Scanning

DWL instruments determine the component of the wind vector, which is projected onto the laser beam propagation direction – the so-called LOS with its unit pointing vector \mathbf{D} . The vector \mathbf{D} can be described by the zenith angle α , between the LOS direction and the zenith (for ground DWL, often also the elevation angle ($90^\circ - \alpha$) is used) or nadir (for airborne and spaceborne DWL) and the azimuth angle β between the LOS direction and the north direction in the horizontal plane. This LOS wind speed (or radial wind speed) component v_{LOS} , or v for short (in units of m s^{-1}) is obtained by the projection of the wind vector \mathbf{V} on the LOS direction \mathbf{D}

$$\begin{aligned} v_{\text{LOS}} &= \mathbf{D} \cdot \mathbf{V} \\ &= \sin(\alpha) \sin(\beta)u \\ &\quad + \sin(\alpha) \cos(\beta)v + \cos(\alpha)w, \end{aligned} \quad (27.6)$$

$$v_{\text{LOS}} = \sin(\alpha) V_{\text{h},\parallel} + \cos(\alpha)w. \quad (27.7)$$

When only the horizontal wind speed $M = V_{\text{h},\parallel}$ in the plane of the LOS direction is considered, then v_{LOS} is determined by the off-nadir or off-zenith angle α . Thus, for a measurement of the vertical wind w and its fluctuations, the laser beam has to be directed vertically ($\alpha = 0^\circ$), whereas for the horizontal wind vector, a minimum of two, preferably orthogonal, LOS directions tilted towards the horizontal plane with an angle of α is used. If the LOS direction and the wind vector are perpendicular, then no LOS wind speed is observed. Depending on the pointing direction \mathbf{D} towards zenith from the ground or nadir from space, the sign of the above equations has to be adapted to be consistent with the meteorological definition of the sign for u , v , w , and the sign definition for v_{LOS} in the Doppler shift equations.

The pointing of the laser beam and the receiving telescope is achieved via a combination of several telescopes or an optomechanical scanning device usually composed of two reflecting mirrors or prisms, which can be moved independently and, thus, different scanning patterns are achieved, depending on the application. The scanning device is used to steer the laser beam towards different zenith α and azimuth β angles. For the measurement of the horizontal wind vector the Doppler beam swinging (DBS) method and the velocity azimuth display (VAD) scan techniques are used [27.94, 95]. Both techniques rely on the assumption that the horizontal wind speed is homogenous over the atmospheric volume, which is covered by the scan, and does not vary temporally during the scanning duration. This assumption on homogeneity needs to be verified within the retrieval algorithms, e.g., using cloud

screening for partial cloud coverage or screening on large vertical wind components for some LOS directions.

Doppler beam swinging (DBS): for the determination of the three components of the wind vector, the LOS wind speed needs to be measured in at least three independent, noncollinear directions. Usually up to five directions are chosen for the DBS technique. Here, the beam is pointed with constant zenith angle in four different azimuth directions, which are separated by 90° and, thus, cover four azimuth directions or even the four cardinal directions. In addition, also a fifth vertical pointing direction can be applied. As every other beam is separated by 180° , the difference and the sum of the LOS wind components V_{LOS} are used to derive horizontal and vertical wind speed and directions. The chosen zenith angles are typically between 15° and 30° .

Velocity azimuth display (VAD): here, the beam is pointed with a constant zenith angle, but varying azimuth angle, with a conical scanning pattern covering azimuth angles from 0 to 360° . This is either achieved by continuously steering the beam in different azimuth directions or by step-and-stare scans, where the laser beam is stepped in small angular increments (e.g., $10^\circ - 20^\circ$). Here, the horizontal and vertical wind components are retrieved by least-squares fitting a sinusoidal function to the measured V_{LOS} components, where the phase and the amplitude of the sinus function are related to the horizontal wind direction and speed, respectively. The constant offset from the sinus function from 0 m s^{-1} is related to the mean vertical wind speed over the scanning volume.

Two other principle scanning techniques are applied to sample the atmospheric volume with either high spatial resolution in height for a given direction or horizontally for a given zenith angle.

Range height indicator (RHI): here, the azimuth direction is kept constant, and the zenith angle is varied from 0 to 90° (or even to 180°), which allows sampling of a vertical curtain through the atmosphere.

Plan position indicator (PPI): similarly as for the VAD scan, the azimuth angle is varied for constant zenith angles. In addition to the classical VAD scan, different conical scans using different zenith angles are applied for a PPI.

The limitations of sensing the 3-D wind vector by pointing to different spatial LOS directions for different time periods is obvious. Assumptions about spatial homogeneity and temporal stationarity have to be made, which limits the derivation of turbulent quantities. To overcome these limitations the LOS beams from several DWL instruments can be pointed towards one volume, which is referred to as multiple Doppler techniques [27.19] or virtual towers [27.96]. Significant

progress was achieved with this approach in the past decade due to the widespread use of commercial coherent DWL instruments [27.22, 97], the synchronization of the laser beam pointing of several instruments and analysis techniques for wind retrievals [27.98]. Multiple Doppler techniques allow high temporal sampling of turbulent wind fluctuations [27.99] and resolving structures with high spatial resolution, e.g., wind rotor wakes [27.100] or mountain rotors [27.101]. The use of multiple DWL instruments combined with multiple Doppler techniques enables highly spatial and temporally resolved observations of the atmospheric flow in complex terrain to improve and validate high-resolution numerical models [27.21, 22].

27.3.4 Lidar Basics Relevant for Doppler Wind Lidar

The theory of interaction of laser light with atmospheric constituents as aerosol and cloud particles and molecules is discussed in Chap. 24 for backscatter lidars. This includes Mie scattering on particles (aerosol, clouds) and Rayleigh scattering on molecules, particle and molecular extinction, and absorption by molecules. The received power or energy from the backscattering of laser light in the atmosphere as a function of range R is described by the lidar equation (Chap. 24), which depends on both instrument parameters (laser energy or power, telescope area, instrument efficiency, range gate resolution ΔR) and atmospheric parameters (altitude-dependent backscatter and extinction coefficient).

The range of the atmospheric volume R is determined by the round-trip travel time t of the laser pulse, whereas the range resolution is determined by the temporal resolution T

$$R = \frac{ct}{2}, \quad (27.8)$$

$$\Delta R = \frac{cT}{2}. \quad (27.9)$$

In order to obtain the altitude H of the atmospheric return or the altitude resolution ΔH , the range R or range resolution ΔR needs to be multiplied by the cosine of the elevation angle or sine of the zenith angle, due to the non-zenith pointing for most scanning modes of a DWL.

The range resolution ΔR is usually referred to as the difference of the centers of successive range gates. The resolution T is usually determined by the applied time-gating within the retrieval algorithms, where a number of n digitized values are processed for the information from one range gate. For typical backscatter or differential-absorption lidars (DIAL), this time T is significantly larger than the typical laser pulse length τ

Table 27.5 Range resolution as a function of range gate time for typical laser pulse lengths

$T = \tau$ (ns)	ΔR (m)	Application
5, 10, 20, 30	0.75, 1.5, 3.0, 4.5	Backscatter lidar, DIAL, direct-detection DWL
50, 100, 200, 500	7.5, 15, 30, 75	Coherent DWL

(from several ns to 10–20 ns often determined by the FWHM of the temporal pulse shape). This is not the case for DWL, especially for coherent DWL, where considerably longer pulse lengths are applied (from several 100 ns to μ s). Coherent DWL rely on the spectral narrowband return from aerosol and clouds. The overall spectral width of the return is determined from the convolution of the laser pulse spectral width with the bandwidth of the atmospheric return. Thus, it is necessary for coherent DWL to transmit spectrally narrowband laser lines. In order to achieve this, long pulses are required, because the spectral width of a laser pulse is inversely proportional to its length. Thus, the physical range resolution for DWL is determined by the laser pulse length $T = \tau$. Typical examples of laser pulse lengths and range resolutions are provided in Table 27.5. In coherent lidar systems, the data sampling window for a single range gate is often matched to the pulse length. Because the pulse travels in space during this sampling interval, the range weighting function, given uniform weighting for each sample, has the shape of a triangle extending plus and minus $c\tau/2$ m from the center of the range gate. Therefore, ΔR in Table 27.5 represents the range gate as specified by its half power points. For direct-detection DWL, which derive wind speeds from molecular Rayleigh backscattering, the requirements on the spectral width of the laser pulse are not as strict as for coherent DWL, as the spectral width of the molecular return is significantly larger in any case. Thus, an additional broadening by the laser pulse width is not considered as a significant contributor to the overall spectral width, and shorter laser pulses can be used.

27.3.5 Coherent-Detection Doppler Wind Lidar

The fundamentals of coherent DWL are based on heterodyne techniques developed for radar during the first part of the twentieth century. Figure 27.2 shows a simplified block diagram of a heterodyne receiver. The atmosphere is irradiated by energy from a frequency-stable, single-longitudinal mode, narrowband laser transmitter typically operating in the thermal or near-infrared spectral region at wavelengths $\gtrsim 1.5 \mu\text{m}$, where eye safety issues are less restrictive. A portion of the

Fig. 27.2 Simplified block diagram of a coherent DWL receiver

energy is scattered back to the receiver by aerosol particles, where it is collected by a telescope and mixed on a photodetector with the field from a local oscillator (LO) laser at the same wavelength as the transmitted signal (homodyne detection) or slightly offset (heterodyne detection). The photodetector converts the resulting optical beat signal to a radio-frequency photocurrent, which frequency is equivalent to the frequency difference between the laser transmitter and the local oscillator laser, plus or minus the Doppler shift resulting from movement of the scatterers in the radial direction. The photocurrent signal is then processed to determine the Doppler shift. Although analogue signal processors, such as filter banks or surface acoustic wave devices, were used during the early years of Doppler lidar, processing today is primarily digital, where the signal from the photodetector is sampled by an analogue-to-digital converter and then analyzed using digital signal processing techniques.

A brief description of the theory of the coherent wind lidar is provided here to illustrate design issues and performance characteristics of coherent systems. For a more detailed theoretical discussion, the reader is directed to [27.31].

The fundamental building blocks of a coherent lidar are the laser transmitter, transmitting optics to direct the laser energy into the atmosphere to collect the backscattered radiation and the heterodyne receiver. As will be shown, coherent lidars achieve best performance when the laser transmitter is single frequency or very narrowband. The transmitted energy, which can be either continuous-wave or pulsed, propagates into the atmosphere, where a portion is scattered back to the lidar by atmospheric aerosols and molecules. Although coherent lidars can, in principle, detect both aerosol and molecular-backscattered radiation, the systems are highly sensitive to aerosol scatter, where spectral broadening of the scattered signal, resulting from the turbulent motions of the aerosol particles irradiated by the beam, is quite small, typically equivalent to a few m s^{-1} . In contrast, the molecular scattered signal band-

width is due to the thermal motions of the particles and is on the order of 300 m s^{-1} . Because the performance of spectral frequency estimation techniques used in coherent receivers improves as the signal bandwidth decreases, coherent wind lidars are primarily used to measure winds based on scatter from aerosol particles.

The radiation scattered by the ensemble of aerosol particles irradiated by the transmitted pulse and collected at the receiver is the superposition of the fields scattered by each particle within the scattering volume illuminated by the transmitted pulse. Because the particles are randomly distributed, and move relatively to each other due to turbulent motions, the field in the receiver plane is represented by a speckle or interference pattern with areas of spatially-correlated amplitude and phase that vary randomly in time and space as a function of the relative motion of the scatterers. Efficient coherent lidar systems are designed such that the backscattered optical field across the receiver aperture is correlated over a region corresponding to the area of the aperture, i.e., a single speckle is roughly the size of the receiver aperture. The backscattered optical signal is mixed with the LO field and focused on the detector. Following [27.31], we can represent the complex optical field resulting from backscattering of the transmitted energy at a point on the detector as

$$U_s(x, y, t) = A_s(x, y, t) \exp(i2\pi ft + i\phi_s(x, y, t)), \quad (27.10)$$

where A_s represents the random, time-varying (t) amplitude of the resultant field at a point (x, y) on the detector, and $\phi(x, y)$ is the random, time-varying phase, f is the frequency ($= c/\lambda$), and $i = \sqrt{-1}$. The wind information in the optical field U_s resulting from the superposition of radiation scattered by each of the scatterers is contained in the time-varying amplitude and phase terms.

Similarly, the local oscillator field at a point (x, y) on the detector is

$$U_L(x, y, t) = A_L(x, y, t) \times \exp(i2\pi(f + \Delta f_L)t + i\phi_L(x, y, t)), \quad (27.11)$$

where Δf is the frequency offset between the transmitter laser and the local oscillator laser. The total field is the sum of the signal and LO fields

$$U = U_s + U_L. \quad (27.12)$$

The photodetector produces a current proportional to the irradiance, which at a point on the detector is

$$I(x, y, t) = |U(x, y, t)|^2. \quad (27.13)$$

For photovoltaic detectors used in contemporary wind lidars, the total photocurrent produced by the spatially integrated irradiance across the detector is

$$i(t) = \iint R(x, y)I(x, y, t)dx dy, \quad (27.14)$$

where

$$R(x, y) = \frac{e\eta_q(x, y)}{hf} \quad (27.15)$$

is the detector responsivity in amperes/watt, $e = 1.602 \times 10^{-19}$ C is the electron charge, and η_q (electrons/photons) is the detector quantum efficiency.

The spatially and temporally varying irradiance has two direct current baseband components: a local oscillator irradiance term and a signal irradiance term, plus a radio frequency (RF) irradiance term resulting from the interference between the backscattered and LO fields. If, for simplicity, spatial variations in the detector response are ignored and complete coherence of the signal and LO fields across the detector is assumed, the heterodyne photocurrent produced by the RF irradiance, which carries the Doppler, is

$$i_H(t) \propto \frac{2e\eta}{hf} \left(\sqrt{I_s(t)I_L(t)} \cos(2\pi\Delta\nu t + \Delta\phi(t)) + I_s + I_L \right), \quad (27.16)$$

where the first term in (27.16) is the time-varying RF heterodyne signal that carries the Doppler signal information, and the second and third terms are baseband signals that are removed by high-pass filtering. Although the DC components of the photocurrent are removed before processing, they still contribute to the total noise in the RF signal current. In a well-designed coherent system, the local oscillator irradiance I_L is much larger than the backscattered signal irradiance I_s , such that the local oscillator shot noise, produced by the random generation of local oscillator-induced photoelectrons, dominates shot noise from both the backscattered signal and heterodyne irradiance terms.

In order to compute the mean Doppler shift in the backscattered signal relative to the transmitted signal frequency, analysis of the heterodyne signal term in (27.16) must be performed. Although some early versions of coherent lidars incorporated analog processing techniques, such as spectrum analyzers, processing in current lidar systems is generally done digitally, taking advantage of the high bandwidth of analog digital converters and high-speed digital processors available today. Because the signal is formed from the superposition of returns from a large number of aerosol particles with random position and motion relative to each other, the heterodyne signal for aerosol atmospheric backscatter takes the form

of a narrowband Gaussian random process with a spectral bandwidth defined primarily by the distribution of velocities within the pulse volume and the spectral characteristics of the transmitted pulse. Figure 27.3 shows the mean power spectra of atmospheric returns from the ≈ 7 km range produced by a low pulse energy, a high pulse-repetition rate coherent Doppler lidar developed at NOAA in Boulder, CO. The spectra are computed by Fourier transformation of the coherent lidar returns from a given range gate and averaged over multiple pulses to smooth out speckle and noise-induced variability. The ratio of signal power to total noise power over receiver bandwidth (carrier-to-noise ratio, or CNR, discussed below) of the return is ≈ -33 dB. The spectra for both 10 000 averages (0.5 s) and 80 000 accumulations (8 s) are shown. The objective of the signal processor is to identify and measure the mean frequency of the atmospheric return, which when adjusted for the LO-transmit pulse frequency difference represents the Doppler shift from which the mean radial component of the wind can be computed. The shape and width of the signal spectra shown in Fig. 27.3 are related to the distribution of velocities within the pulse volume. It is important to note that Fig. 27.3 shows the mean spectra computed by averaging the spectra from multiple pulses. Each spectral component in a single realization of the signal spectrum is a random variable due to the speckle, i.e., the random phases of the backscattered signals from the individual particles moving with velocities that produce the given Doppler shift; only by averaging multiple spectra can the smooth mean spectra shown in Fig. 27.3 be obtained.

Also shown in Fig. 27.3 is a white noise component, resulting from the wideband local oscillator shot noise that is always present in coherent lidar receivers. Both the signal and noise currents can be characterized as complex Gaussian processes, such that the power in a given spectral component for a single realization is an exponentially distributed random variable with a mean equal to the mean signal power plus mean noise power within that spectral region and variance equal to the mean. The randomness in the power spectrum components introduces uncertainty in the detection and estimation of mean signal frequency, which is reduced by accumulating spectra from multiple pulses before performing the estimate.

A key indicator of system performance for coherent receivers is the carrier-to-noise ratio (CNR), defined as the mean signal power delivered to the processor divided by the mean noise power. For an LO shot-noise limited system, a simplified expression for the CNR is [27.31]

$$\text{CNR} = \frac{\eta_r P_s}{hfB}, \quad (27.17)$$

Fig. 27.3 Power spectrum of atmospheric returns showing extraction of a weak Doppler signal by accumulating multiple spectra. Each colored spectrum represents an accumulation of spectra from 10 000 pulses, while the solid black line represents an average of 80 000 pulses (figure courtesy of Alan Brewer, NOAA Chemical Sciences Division)

where P_s is the total received signal power, hf is the photon energy, B is the receiver bandwidth, and η_r represents the receiver efficiency, which accounts for factors such as detector efficiency losses in the receiving optics and components and losses resulting from spatial mode mismatching between the LO and backscattered signal at the detector. The CNR as defined in (27.17) is not a function of the signal bandwidth B_s , which is important in determining the performance of the processor to estimate the mean frequency. The narrowband CNR_n, defined as the ratio of signal power to noise power within the signal bandwidth, is

$$\text{CNR}_n = \frac{\eta_r P_s \tau_s}{hf}, \quad (27.18)$$

where $\tau_s \propto 1/B_s$ is the signal coherence time. The capability of measuring the mean frequency is a function of the signal bandwidth, the total bandwidth, the signal power, and the number of pulses accumulated in the signal processor, and varies somewhat depending on the processing algorithm employed. Detailed examinations of the performance of mean frequency estimators under different CNR regimes are given in [27.102, 103]. In general, the randomness of the backscattered signal due to speckle effects, even at high CNR, impacts the estimate and is a factor in optimizing the design for a given pulsed Doppler system. Under conditions where the narrowband CNR_n is $\gtrsim 2$, increased multipulse accumulation to average out these random fluctuations is more

effective than increasing transmitter pulse energy (thus increasing CNR_n) to improve the precision of a Doppler estimate. This implies that under a constraint of constant average transmitter power output, increasing the pulse rate and decreasing the pulse energy until the expected CNR_n is 2. Conversely, when narrowband CNR_n is $\lesssim 2$, increasing pulse energy to overcome the LO shot noise and increase the CNR_n while decreasing the pulse rate has a greater benefit. This tradeoff becomes important in designing a system when the average power available is somewhat fixed due to, e.g., laser pump power, peak power limitations, etc., but can be partitioned into either pulse energy or pulse rate. Because optimum performance is achieved when narrowband CNR_n ≈ 2 , one should trade off pulse energy and pulse rate to ideally achieve this value. In practice, because CNR_n varies as a function of range for a pulsed system, at best one can only optimize system design for a single range and must accept suboptimal performance at other ranges.

The transmitter pulse bandwidth, pulse energy, pulse repetition frequency, and phase matching between the received signal beam and the local oscillator at the detector are all important in developing design for a coherent system. For a pulsed system, the transmitter should transmit a pulse whose bandwidth, defined both by the frequency characteristics of the laser pulse and the pulse width, is on the order of the bandwidth of the atmospheric return, as computed by converting the anticipated distribution of radial velocities to

Doppler shift ($\delta f \propto 2\sigma_v/\lambda$). This requires a laser transmitter design that incorporates a technique to generate narrowband pulses, such as injection seeding a power oscillator or chopping a continuous-wave master oscillator and directing the chopped signal into a power amplifier. These output pulses have to be temporally long enough to be sufficiently narrowband. The tradeoff between pulse energy and pulse repetition frequency, as discussed earlier, should be carried out so that the CNR_n will approach the optimum value.

An important aspect of transmitter/receiver design is the need for phase coherence of the local oscillator and backscattered signal beam at the detector. Although analysis of system performance can be carried out by theoretically calculating the backscattered field at the detector and applying (27.10)–(27.13), performance has frequently been studied by backpropagating the local oscillator beam from the detector to the target plane and performing the analysis of the mixed signal in that plane, e.g., [27.104]. Backpropagated local oscillator (BPLO) analysis shows that high performance is obtained when the transmit beam spot size at the range of interest approaches the diffraction limit of the telescope and the transmitter and BPLO beam profiles overlap, are both spatially coherent across the telescope aperture, and are roughly matched in size. Modern coherent lidars share several fundamental design properties based on these requirements: highly spatially coherent transmitted and LO beams, high optical quality telescopes and optical components (better than $\lambda/20$ irregularity specification is typical) to maintain that coherence, monostatic design in which the transmitter and BPLO paths are coincident, and implementation of a lens or off-axis telescope to avoid loss of coherence caused by obstruction of an obscuring secondary element [27.105].

Refractive turbulence resulting from atmospheric temperature fluctuations encountered by the propagating beam degrades the performance of coherent wind lidars by introducing random irregularities in the phase front of the propagating transmit beam. Because these irregularities produce scintillation in the irradiance at the target plane and also enlarge the beam relative to the diffraction-limited beam's size, both of which reduce mixing efficiency, system performance is reduced [27.106–108]. The deleterious impact of turbulence is more pronounced at shorter wavelengths and longer ranges, and because it produces a reduction in the transverse coherence of the backscattered signal, turbulence has the practical impact of limiting the effective size of the telescope aperture. Telescopes in contemporary pulsed coherent lidars operating in the 1.5–2 μm wavelength region are typically ≈ 5 –10 cm in diameter. Incorporating larger diameter telescopes

does not generally provide increased performance except under rare zero-turbulence conditions.

The discussion in the previous paragraphs greatly simplifies or does not address many of the issues involved in optimizing the mixing between the received signal and the local oscillator with respect to issues such as the illumination profile of the LO on the detector and the loss of mixing efficiency at near ranges when the telescope is focused at infinity, which is typical for pulsed systems. A more detailed analysis, including more detail on the concept of backpropagating the local oscillator beam to the target plane and doing the analysis in that plane, is presented in [27.31].

27.3.6 Direct-Detection Doppler Wind Lidar

Compared to coherent DWL, where heterodyne detection by optical mixing is used as the principle, the direct-detection approach uses optical bandpass filters or, alternatively, an interferometer as the spectral analyzer. Here, the Doppler frequency shift is not obtained from the spectral analysis of the measured signal as for coherent detection, but a signal that is proportional to the frequency shift is obtained. Thus, a calibration is needed for most types of direct-detection DWL, which determines the relationship between the measured signal or instrument response R to the Doppler frequency shift Δf in the atmosphere. In principle, the Doppler frequency shift Δf is determined as the difference between the frequency of the received atmospheric signal f_a and the transmitted laser pulse signal f_i , usually measured during transmission via an internal optical path (called internal reference),

$$\Delta f = f_a - f_i = 2f_0 \frac{v}{c} = 2 \frac{v}{\lambda_0}. \quad (27.19)$$

Assuming that the measured instrument response $R(f)$ is to a first order linearly dependent on the frequency, the response can be written as

$$R(f) = af + b + \gamma(f), \quad (27.20)$$

where a describes the slope, also called sensitivity, b the intercept (response for frequency differences of 0 MHz), and $\gamma(f)$ contains all higher-order, nonlinear terms. As the instrument response $R(f)$ function depends on both instrument optical parameters (e.g., illumination of interferometers) and atmospheric parameters (e.g., spectral width) the functions are different for the atmospheric return and internal reference path. Thus, the Doppler frequency shift is obtained from

$$\Delta f = f_a - f_i = \frac{R_a - \gamma_a(f) - b}{a_a} - \frac{R_i - \gamma_i(f) - b_i}{a_i}. \quad (27.21)$$

The process of determination the response R as a function of frequency f is called response calibration. This can be achieved by measuring the response R for varying laser frequencies f for atmospheric conditions with zero frequency shifts, e.g., pointing vertically and assuming negligible vertical winds for the measurement period. Or it is achieved by simulation of the response function $R(f)$ using the knowledge of the instrument spectral transmission and spectral properties of the atmospheric signals. This response calibration is not needed for coherent DWL, where this relationship $R(f)$ is obtained via a spectral analysis (e.g., Fourier transformation) of the measured time series from the heterodyne signal. Also some specific implementations of the direct-detection technique (two-beam interferom-

eters) allow the determination of the Doppler frequency shift without the need for regular response calibrations (Sect. 27.4.2).

As the response function for atmospheric signals R_a depends on the spectral width of the signals, the response functions differ for narrowband Mie signals and broad bandwidth Rayleigh signals. In addition, the spectral width of the broad bandwidth Rayleigh signal depends on the atmospheric temperature (Sect. 27.3.2). Thus, the responses measured for broad bandwidth Rayleigh signals depend on the atmospheric temperature (and to a small degree on the atmospheric pressure due to Brillouin scattering), and, thus, this temperature (and pressure) dependency needs to be accounted for in the determination of the derived LOS wind speed [27.109].

27.4 Devices and Systems

Here, the two most common techniques and devices for a DWL applied today are described and a comparative overview is provided.

27.4.1 Coherent-Detection Techniques and Systems

Coherent wind lidar systems can fundamentally be categorized by their operating wavelength and by the form of the transmitted energy, i.e., pulsed or continuous wave (CW). Other characteristics that distinguish different system implementations include output power, optics size, use of free space or fiber coupling, and (for pulsed systems) use of injection-seeded power oscillators or master oscillator-power amplifier configurations (Fig. 27.4). Although these characteristics can vary for different system designs, one common factor among most systems currently used is the average power transmitted to the atmosphere, which tends to be on the order of 1 W, or so. To illustrate differences among implementations, we discuss three currently applied system designs: CW wind lidars for short-range wind measurements; high pulse repetition frequency (PRF ≈ 10 kHz),

very low pulse energy ($\approx 100 \mu\text{J}$) pulsed systems that incorporate commercial off-the-shelf components used in the telecommunications industry, and moderate pulse energy ($\approx 2\text{--}5$ mJ) with moderate pulse repetition frequency (PRF $\approx 200\text{--}500$ Hz).

As was noted earlier, coherent systems have historically operated within three wavelength regions: the 9–11 μm thermal infrared region, and near IR regions around 1.5 and 2 μm . Operation at shorter wavelengths is precluded because eye-safety considerations limit coherent wind lidar operation to wavelengths $> 1.4 \mu\text{m}$, where water absorption in eye tissue blocks light from reaching the retina. Unlike direct-detection wind lidar systems, coherent lidar beams cannot be expanded to reduce energy density without impacting system performance because maximum efficiency is achieved when the beam is focused or collimated at the target. Currently, development of coherent lidar for wind measurements is concentrated at 1.5 μm wavelengths, taking advantage of technological advances in the aftermath of the late 1990's telecommunication revolution, such as coherent optical erbium-doped fiber amplifiers for application in coherent laser transmitters. Incorporation of a fiber architecture offers several advantages, including ease of adjustment, mechanical reliability in a vibrating environment, and the option to spatially separate different subcomponents of the lidar system.

Continuous Wave Coherent Doppler Lidars

CW coherent lidars are highly effective for short-range wind profiling in support of the wind energy industry and other boundary layer applications. Figure 27.5 shows a block diagram of a notional fiber-coupled CW Doppler system incorporating the master oscil-

Fig. 27.4 Different implementations for coherent DWL

Fig. 27.5 Block diagram of a fiber-coupled CW Doppler system (after [27.110] with permission from the Optical Society of America)

laser power amplifier (MOPA) configuration used in many current CW and pulsed lidars operating at $\approx 1.55 \mu\text{m}$. The CW output from the master oscillator passes through a beam splitter where a small portion of the optical power is split off to form the local oscillator (LO) beam. This beam is coupled to a fiber beam combiner, where it mixes with the signal backscattered from the atmospheric aerosols and is coupled onto the detector. Most of the energy passing through the beam splitter is used to generate the optical beam transmitted to the atmosphere. In order to preserve the sign of the wind, the beam is coupled through a frequency-shifting element, typically an acousto-optic modulator (AOM) that shifts the frequency by f_{if} relative to the LO frequency. For homodyne systems, this element is eliminated, but the sign of the Doppler shift is lost unless a more complex detection scheme is implemented (see [27.110] for a discussion of homodyne detection in CW Doppler systems). The beam from the AOM is coupled onto an erbium-doped fiber amplifier (EDFA) through an optical circulator element that functions as a transmit/receive switch and into the system telescope or lens, where it is expanded and transmitted into the atmosphere. The scattered energy is collected by the telescope, focused, and directed back to the circulator, where it is isolated from the transmitter beam path and directed into the beam combiner for mixing with the LO beam. The combined beam is coupled onto the photodetector, which must have sufficient bandwidth to respond to the backscattered signal/LO beat signal at frequency $f_{\text{if}} \pm \Delta f_{\text{d}}$, where Δf_{d} is the mean Doppler shift due to the motion of the particles (typically in the MHz to tens of MHz range for operation at $1.55 \mu\text{m}$). The photodetector converts the optical signal to electrical current for spectral analysis. In current systems, the detector output is generally digitized for processing using digital signal processing techniques, such as Fourier analysis, to estimate the spectrum and determine the Doppler shift.

A typical signal processing implementation is described in [27.111] for a homodyne CW lidar operating at $1.55 \mu\text{m}$. The detector output signal is digitized at

100 MHz, permitting spectral analysis to maximum frequency of 50 MHz, corresponding to a wind speed of 38.8 m s^{-1} . By applying a 512-point discrete Fourier transform (DFT) to the sampled time series, representing $\approx 5 \mu\text{s}$ of data, each spectral bin has a frequency width of $\approx 200 \text{ kHz}$. To lower the effects of random fluctuation in the shot noise multiple spectra are typically averaged; for a data rate of 20 Hz (corresponding to 20 ms of processing time), ≈ 4000 spectra can be averaged, assuming a 100% duty cycle, which is achievable using field programmable gate arrays (FPGA) technology.

CW coherent lidars transmit coherent energy continuously into the atmosphere, achieving spatial sensitivity by focusing (ideally) the Gaussian beam output from the EDFA at various points in range. Following [27.111], the range-weighting function along the beam is given by a Lorentzian function

$$F = \frac{\Gamma/\pi}{\Delta^2 + \Gamma^2}, \quad (27.22)$$

where Δ is the distance from the focus position along the beam direction, and Γ is the half-width of the weighting function (to the half-maximum). Here, F is normalized such that the integral along the entire beam gives unity. The half-width Γ is approximated by

$$\Gamma = \frac{\lambda R^2}{\pi A^2}, \quad (27.23)$$

where λ is the laser wavelength, R is the distance to the focus from the output lens, and A is the beam radius at the output lens for an axially symmetric two-dimensional (2-D), Gaussian beam. For the commercial system described in [27.111], $A = 24 \text{ mm}$, producing a probe length in the radial direction of 17 m at 100 m range (note that the probe length decreases with decreasing range). A major advantage of CW systems is their very high range resolution at close ranges and their capability of obtaining measurements very close to the lidar transceiver.

Fig. 27.6a,b Photo of commercial CW Doppler lidar systems: (after [27.112] with permission from METEK GmbH) (a) (after [27.113] with permission from ZX) (b)

Figure 27.6 shows two commercially available CW Doppler lidar systems designed to provide near-range measurements in the boundary layer. Per the specifications available from the manufacturer [27.112] the METEK instrument provides measurements in the 10–100 m range, with a range resolution ranging from 0.16 m at 10 m range to 16 m at 100 m range. The lidar beam is offset 10° from the vertical, with wind measurements computed from continuous VAD scans at a rate of 1 revolution/s. Spectra are computed every 0.01 s, providing an angular resolution of 3.6° . The ZX lidar advertises a 10–200 m range with range resolution varying from 0.07 m at 10 m range to 7.70 m at 100 m range, with a 360° scan completed every second [27.113]. Such instruments can be used for wind energy, air quality, and other applications where high resolution wind profiles near the surface are required.

Microjoule Pulsed Coherent Doppler Lidars

Although CW lidars provide excellent measurement at near ranges, their utility decreases for applications where more range is required. Currently, pulsed lidars utilizing erbium fiber technology in the wavelength region around $1.5\ \mu\text{m}$ are available from commercial vendors (HALO Photonics, UK; Leosphere, France; Seaglet, China) and have also been developed for research purposes [27.114]. Conceptually, the instrument design for most systems is similar to that shown in Fig. 27.5, except that the AOM serves to both shift the frequency of the outgoing pulse and to form pulses from the CW output of the master oscillator, while providing

high isolation between the on and off states. Figure 27.7 shows a schematic of a pulsed, microjoule, coherent, polarization-diversity lidar proposed for the investigation of wind turbine properties [27.115]. This lidar utilizes the MOPA configuration common to fiber-based systems operating in this wavelength region. The pulse formed by the AOM from the output of the narrowband CW master oscillator laser is amplified, coupled to the circulator, and expanded and focused (or collimated) by the telescope for transmission into the atmosphere. The scattered signal comes back through the telescope and circulator and is directed to the beam combiner, where it is mixed with the LO beam and directed onto the detector. The detector output, corresponding to a time series of the return for each transmitted pulse, is digitized and spectrally processed to estimate the Doppler shift in the return.

Doppler systems using fiber amplifiers are peak-power limited because stimulated Brillouin scattering (SBS) at powers above a certain threshold in the fiber can cause reflection of the amplified signal back toward the local oscillator and cause damage to the optical components. The SBS threshold can be increased by shortening the fiber length, reducing the laser intensity, or broadening the laser spectrum by lengthening the pulse [27.114]. Presently, both commercial and research microjoule-type Doppler lidar systems typically operate with average power levels $\approx 1\ \text{W}$ at PRF of 10–20 kHz and pulse energies of 50–100 μJ , or so. Although the relatively low pulse energy in these fiber-based coherent lidars results in quite weak backscat-

tered signals available at the lidar receiver (carrier-to-noise ratios < 1), even from close ranges, the frequency stability and high PRF enables efficient spectral averaging of multiple pulses. Generally, depending on aerosol conditions, such systems can typically measure out to 3–5 km, in the boundary layer with a time resolution on the order of 1 s and a range resolution of a few tens of m.

Figure 27.8 shows two commercial systems currently available for purchase and deployment. The systems are similar in design and capability. A common, notable feature of these instruments is the availability of a two-axis, full hemispheric scanner that enables the beam to be directed in any direction. This robust scanning capability enables the instruments to be used to profile winds and turbulence using conical (VAD)

scans, vertical (RHI) scans, as well enabling it to be directed and fixed for staring type measurements to measure, e.g., profiles of vertical and horizontal winds and turbulence from a specific direction.

Millijoule Pulsed Coherent Doppler Lidars

Although the microjoule-type lidars described in the previous section are currently widely used because of their robustness, reliability, and affordability, applications exist for which the energy limitations available from these fiber-based laser systems do not provide sufficient range to address the measurement needs. Consequently, systems with pulse energies in the mJ range are used for specific applications, such as wind shear and wake vortex modeling, and for measurements where backscatter coefficients are low, such as from high flying aircraft. An example of an mJ class system is the NOAA High Resolution Doppler Lidar (HRDL) developed in the mid 1990s, which was still being used as recently as in 2016 [27.78, 116]. The primary difference between HRDL and the fiber laser microjoule instruments is in the transmitter design and the output wavelength. The HRDL instrument incorporates a master–slave configuration in which a diode-pumped, Tm,Lu:YAG laser cavity is stabilized using a phase modulation technique to produce 220 ns-long, frequency-stable pulses with 2 mJ of pulse energy at 200 Hz PRF. The 2.022 μm output wavelength of the HRDL instrument is matched to an atmospheric window region to provide maximum range. Although the laser transmitter incorporates free space rather than fiber coupling, frequency stability is sufficient to allow operation from both ship and aircraft platforms.

Operational instruments similar to the HRDL instrument have been developed commercially and applied for airport wind shear [27.11, 12] and airborne lidar applications [27.13, 28]. As low-cost optical components, such as distributed feedback diode master oscillator lasers resulting from advances in optical telecommunications, became more available, mJ-class Doppler lidars followed the path of the microjoule instruments and evolved to operate in the 1.5 μm spectral region [27.117]. A commercially-available pulsed Doppler lidar employs a 1.6 μm Er:YAG power oscillator to produce 2.3 mJ pulses at a 750 Hz pulse repetition rate. A version of this instrument, which has potential applications to wind shear detection and wind energy, utilized a 12.5 cm receiver aperture to demonstrate wind measurements to beyond a 33 km horizontal range [27.117]. Similar results were achieved with a MOPA-based design through the use of an amplifier chain consisting of an EDFA, whose output is coupled into an Er:YAG-doped fiber amplifier followed

by an Er,Yb:glass planar waveguide amplifier [27.118]. This transmitter produced pulses with 1.4 mJ energy at a pulse repetition frequency of 750 Hz and also demonstrated wind measurements to beyond 30 km range using a 15 cm diameter telescope aperture.

27.4.2 Direct-Detection Techniques and Systems

Direct-detection filter techniques make use of one or more narrowband filters and determine the Doppler frequency shift from the transmitted signal strength through this filter, called the *edge* technique [27.40, 119]. In the commonly used double-edge technique, two filters are used, which are often Fabry–Pérot interferometers [27.120]. Single-edge techniques use only one filter, which can be realized by narrowband atomic or molecular absorption lines [27.121–123].

Interferometric techniques can be divided into two principles, using either multiple-path or two-beam interference. For multiple-path interferometers, the radial-angular distribution or spatial movement of the interference patterns (*fringes*) is measured, which is called *fringe imaging*, using either a Fabry–Pérot interferometer [27.124–126] or a Fizeau interferometer [27.1, 43, 127]. Alternatively, two-beam interferometers are used to measure the phase shift between the two beams, which is proportional to the frequency shift. This can be realized by Mach–Zehnder interferometers [27.52, 54, 55, 128, 129] or by Michelson interferometers [27.130, 131].

Due to the difference in the spectral width of the aerosol/cloud and molecular signals by two orders of magnitude, the implementation of direct-detection filters or interferometers must be optimized to either the Mie or Rayleigh spectral line width. From this, it is obvious that a large variety of different direct-detection DWL principles are in use (Fig. 27.9). In the following, the basic principles of filter and interferometric techniques are introduced.

Filter Technique

The filter method is described using a common approach called the double-edge technique [27.40, 42, 119, 132–134], which is also used for the spaceborne DWL on Aeolus [27.3, 4]. The double-edge technique uses two bandpass filters that are placed symmetrically around the maximum of the molecular spectral line with their maximum filter transmission at the edges of the line around the inflexion point (Fig. 27.10a). The signal transmitted through each of these filters is detected, which is proportional to the convolution of the spectral filter transmission and the backscattered

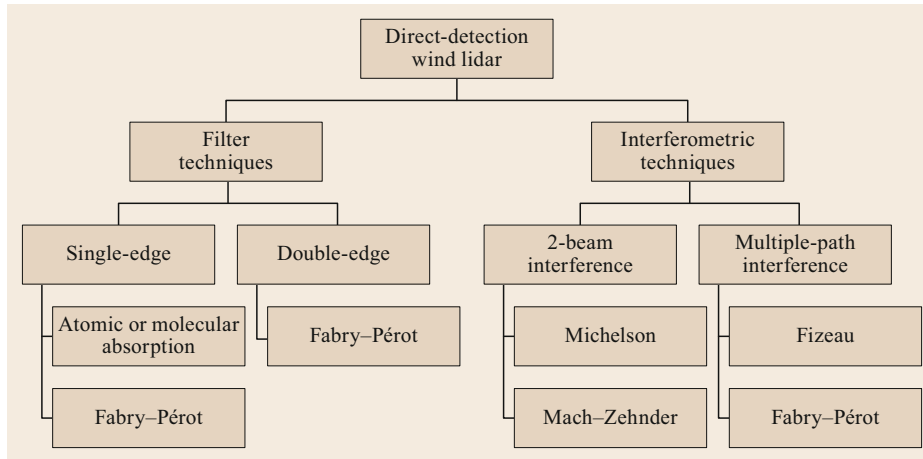

Fig. 27.9 Different implementations for direct-detection DWL

line shape from the atmosphere. In the case that both filters A and B have equal transmission characteristics ($T_A(\lambda) = T_B(\lambda + \Delta\lambda_{A,B})$) and are symmetrically placed around the Rayleigh spectral line with a separation of $\Delta\lambda_{A,B}$, both filters measure the same signal $I_A = I_B$, for a zero LOS wind speed. In the case of a Doppler shift $\Delta\lambda$, the signal transmitted through one filter would be higher than that transmitted through the second one (Fig. 27.10a, bottom). The ratio or contrast of I_A and I_B is used as a measure for the Doppler shift and is called the response R

$$R = \frac{I_A}{I_B} \quad \text{or} \quad R = \frac{I_A - I_B}{I_A + I_B}, \quad (27.24)$$

$$R = f(T_A(\lambda), T_B(\lambda), I_{RBS}(\lambda, \Delta\lambda, T, p)). \quad (27.25)$$

The response R is a function of both filter transmissions $T_A(\lambda)$, $T_B(\lambda)$, and the Rayleigh–Brillouin line-shape from the backscattered signal $I_{RBS}(\lambda, \Delta\lambda, T, p)$ depending on wind-induced Doppler shift $\Delta\lambda$, atmospheric temperature T , and pressure p (Sect. 27.3.2). Exact knowledge of the actual filter transmissions of the instrument is more critical for wind retrieval than the knowledge of the sensitivity to the atmospheric temperature and pressure, which is applied as a correction to the retrieved wind speed or included in the calibration approach [27.109].

The Doppler shift frequency Δf or wavelength $\Delta\lambda$ is to a first approximation linearly proportional to the response measured

$$\Delta f, \Delta\lambda \propto R(f, \lambda). \quad (27.26)$$

Certainly the bandwidth of filters A and B have to be smaller than that of the molecular return signal (e.g., FWHM = 1.6 pm at 15 °C for a wavelength of 355 nm),

which can be realized by a Fabry–Pérot interferometer. A plane Fabry–Pérot interferometer consists of two plane parallel optical plates (called the *etalon*) with high reflectivity and separated by distance d [27.120]. Multiple-beam interference of the incoming light leads to positive interference patterns (called *fringes*), if the wavelength λ is a multiple k of the optical path $\lambda = 2dn \cos(\varphi)/k$ (k : integer, n : refractive index, φ : incidence angle on plates).

When using a Fabry–Pérot interferometer as a filter, only the central ring ($\varphi = 0$) and not the complete, radial interference pattern is used. The two filters can be realized with the same Fabry–Pérot interferometer but with slightly different distances d_A and d_B at different parts of the Fabry–Pérot interferometer (Fig. 27.11a).

Another possibility to realize the filter technique is to use specific, very narrowband molecular or atomic absorption lines. With absorption lines, only one filter can be realized (*single-edge technique*), which relies on the change in absolute intensity through this filter. The technique is limited to spectral regions where narrow bandwidth absorption lines occur at the emission wavelength of lasers. This is realized in the green spectral region at 532 nm and with iodine I_2 absorption lines ([27.48], see the comparative overview in [27.122]). The iodine filter technique is also used for wind and temperature measurements up to 80 km at the Alomar observatory in northern Norway [27.123, 135] using two large 1.8 m diameter telescopes and a powerful laser emitting at 355, 532, and 1064 nm.

Interferometric Techniques – Multiple-Path Interference

Another implementation of the direct-detection DWL uses the spatial location of interference patterns (*fringes*) and its spatial displacement when a Doppler

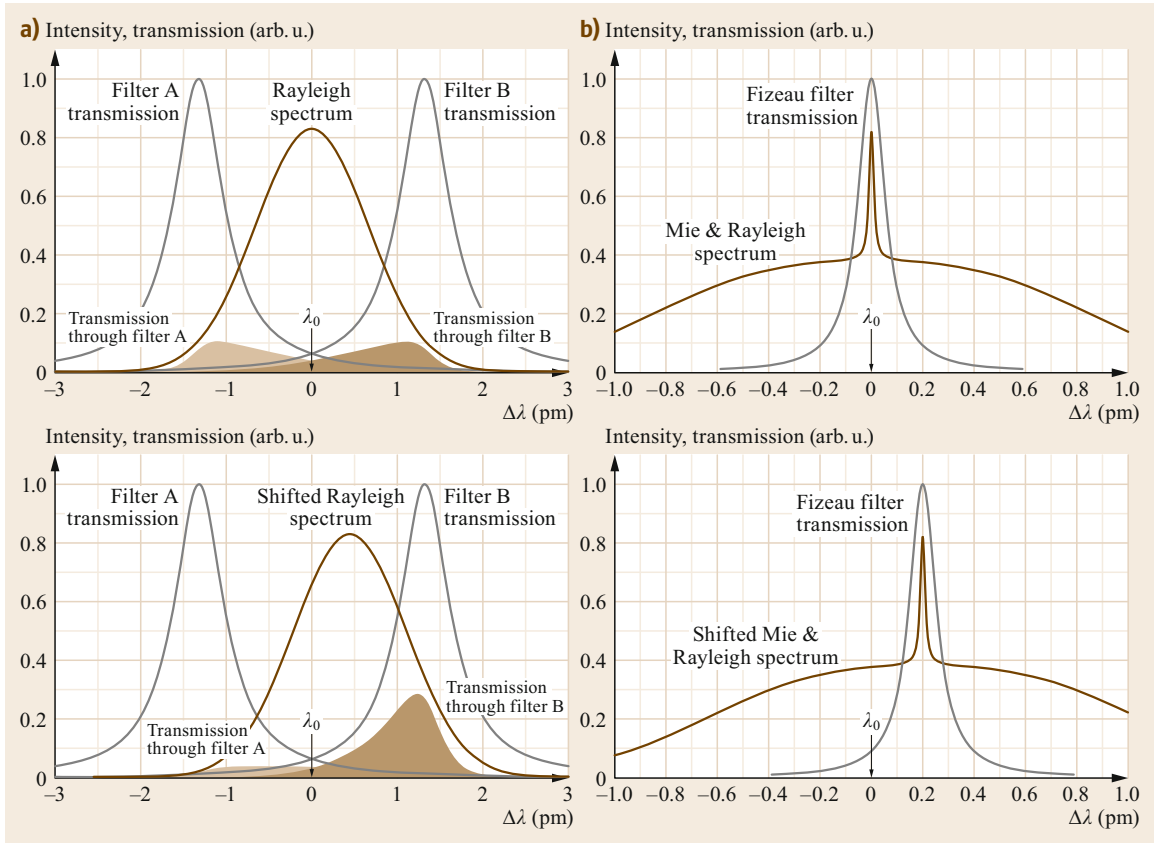

Fig. 27.10a,b Principle of direct-detection DWL with double-edge technique (a) and the fringe-imaging technique (b) used in the spaceborne lidar mission Aeolus; Rayleigh spectrum from molecular backscatter (a, brown line) and double-edge filter A and B transmission (a, gray lines) and additional Mie spectrum from aerosol backscatter (b, brown line) and Fizeau filter transmission (b, gray line) for zero LOS speed (top) and Doppler shifted spectrum (bottom) for a wavelength of 355 nm; note the different wavelength scales on (a) and (b). The different signal levels transmitted through filters A and B (a, light- and dark-brown areas) are used to determine the Doppler shift from molecules; the signal transmitted at different spatial locations of the Fizeau filter transmission (b, gray lines) is used to determine the Doppler shift from aerosols; the spectral transmission for the Fizeau filter is equal for different wavelengths (gray lines), but the maximum of the transmission is located at different spatial locations of the Fizeau filter wedge (b, top and bottom), which needs to be resolved by linear detector array or charge-coupled device (CCD) (after [27.1])

shift is present. Thus, the measured instrument response R is a function of the spatial displacement x of the fringe and a measure of the Doppler shift

$$\Delta f, \Delta\lambda \propto R(x). \quad (27.27)$$

This can be realized by a Fabry–Pérot interferometer, where the movement of the radial-angular pattern of interference rings is used to determine the Doppler shift [27.16, 38, 50, 124–126]. Another approach is based on a Fizeau interferometer, as for the satellite mission Aeolus, to determine the Doppler shift from the narrow bandwidth aerosol return (Fig. 27.11b) [27.3].

A Fizeau interferometer also consists of an etalon, but contrary to a Fabry–Pérot interferometer, where both etalon plates are plane parallel with constant distance d , one of the plates is tilted at a small angle. The resulting variation in distance d results in a distinct spatial location of an interference pattern where the condition for positive interference is fulfilled. A Doppler shift of the signal will result in spatial displacement of the fringe, which is imaged onto a detector (Fig. 27.10b). Therefore, a detector with several sensitive areas (e.g., a charge-coupled device CCD, as is nowadays used in digital cameras) to provide pixel-wise discrete, spectral channels is needed for the fringe-imaging technique [27.136].

Fig. 27.11a,b Photo of the optical receiver of the ALADIN (atmospheric laser Doppler instrument) airborne demonstrator A2D of the Aeolus satellite mission with (a) a Rayleigh spectrometer (RSP) and its optical paths for filters A and B, and (b) Mie spectrometer (MSP). Optical beam paths towards the CCD detector are indicated by blue lines, the distances d_A and d_B of the Fabry-Pérot etalons (a) and Fizeau etalon (c) are indicated by arrows (after [27.1])

Interferometric Techniques – Two-Beam Interference

The use of a Fabry-Pérot or Fizeau interferometer is based on multiple-beam interference (within the etalon), while two-beam interference is used for both Mach-Zehnder interferometers [27.52, 54, 55, 128, 129] and Michelson interferometers [27.130, 131]. Those are either realized as two-channel or four-channel spectral analyzers or as a fringe-imaging device. Two-beam interferometers are based on the optical interference of the incoming electromagnetic wave with a time-lagged optical copy of the same signal. It is, thus, also referred to as an autocovariance technique, because, essentially, the optical autocovariance function is measured [27.129]. An optical beam splitter essentially creates the optical copy of the signal, while the time lag is introduced by an optical path difference (OPD) between the two arms of the interferometer. This OPD L_{OPD} has to be adapted to the spectral width of either the narrowband aerosol backscatter signal (large OPD on the order of several 10 cm) or the broad bandwidth molecular signal (smaller OPD on the order of several cm). Essentially, this mixing of two waves and measuring the differential phase shift $\Delta\Phi$ is, in principle, comparable to heterodyne detection of the backscatter with the local oscillator signal of a coherent DWL. Thus, this specific implementation of a direct-detection wind lidar does not need a response calibration, especially for optical designs with low sensitivities to angular beam variations. The Doppler frequency Δf shift is determined by the phase shift $\Delta\Phi$ via

$$\Delta f = \frac{c \Delta\Phi}{2\pi L_{OPD}}. \quad (27.28)$$

The phase shift is determined by the difference of the phase or fringe position between the emitted laser beam and the backscattered signal.

27.4.3 Comparative Overview of Coherent and Direct Detection

Due to the large variety of DWL principles and realized instruments, a generalization of differences between the two techniques needs to focus on major aspects. An attempt was made in Table 27.6 to compare a number of relevant differences between coherent and direct-detection DWL with respect to implementation, error characteristics, operation, and its advantages and disadvantages. It is clear that such a condensed overview will need some simplifications, which might not be relevant for all instruments in use. Nevertheless, it provides a generalized discussion of the relevant criteria for the application.

The Cramer Rao lower bound (CRLB), which provides an estimate of the ideal performance of a mean frequency estimator, is often employed to evaluate performance of a given Doppler lidar or to compare performance of different instruments. The CRLB, along with the factors that impact the precision of Doppler lidar velocity estimates, is discussed in [27.137–140]. Exact and approximate expressions for estimating the CRLB for maximum likelihood spectral peak estimators were developed in [27.137], variations of which are employed in most coherent Doppler wind systems currently being used and applied to demonstrate estimated behavior for different signal characteristics and estimator applications. Estimator performance was shown to depend on the wideband signal-to-noise ratio (SNR), the width

Table 27.6 Comparative overview of different wind lidar techniques

	Coherent detection	Direct detection
Wavelengths and lasers	CO ₂ gas lasers 10.6 μm for earlier instruments, solid-state lasers with Tm:LuAG or Tm,Ho:YAG at 2 μm, Er-doped fiber laser at 1.5–1.6 μm	Nd:YAG at 1064 nm, frequency-doubled at 532 nm, and -tripled at 355 nm
Laser operation	Continuous wave or pulsed with repetition rate of 200–500 Hz (solid-state laser) and up to 10–40 kHz (fiber laser)	Pulsed with repetition rate of 10–100 Hz
Laser eye safety	Achieved outside instrument housing for applied infrared wavelengths and laser power	Typically not achieved for green wavelength (532 nm) within some km; achieved for ultraviolet (355 nm) after some km range
Atmospheric backscatter	Aerosol and cloud particles with narrow bandwidth line shape	Molecules with Rayleigh–Brillouin lineshape (broad bandwidth), aerosol, and cloud return (narrow bandwidth)
Altitude range	Boundary layer and clouds or elevated aerosol layers in the troposphere	Troposphere, stratosphere, mesosphere
Receiver	Mainly heterodyne detection some earlier systems used homodyne detection	a) Filter techniques, e.g., double-edge or iodine filter b) Multiple-path interferometer, e.g., Fizeau c) Two-beam interferometer, e.g., Mach–Zehnder
Dominating noise sources	Photon noise of local oscillator, speckle noise, atmospheric turbulence, receiver sensitive to phase distortions	Solar background light and signal photon noise, receiver sensitive to intensity distortions, e.g. angular fluctuations
Calibration	No calibration needed, as relation between Doppler frequency shift and detected signal is obtained by spectral analysis (e.g., Fourier transformation), no bias introduced by approach	Calibration needed to obtain relationship between Doppler frequency shift and detected signal or instrument response (except for some specific instrument implementations), constant and wind-speed-dependent bias introduced by calibration
Random error for LOS speed	Low random errors ($< 0.5 \text{ m s}^{-1}$) achieved due to small spectral bandwidth	Low random errors ($< 0.5 \text{ m s}^{-1}$) for aerosol/cloud; higher random errors of 1–3 m s^{-1} for broad bandwidth molecular returns
Systematic errors for LOS speed	Low systematic errors ($< 0.1 \text{ m s}^{-1}$) as no calibration is needed	Typically 0.5–1 m s^{-1} determined by accuracy of response calibration
Need for additional parameters	No additional parameters needed for wind retrieval	Atmospheric temperature and pressure needed for retrieval of wind from molecular backscatter
Operation	Instrument commercially available from several suppliers, autonomous with 24/7 operation	Research instruments usually only with lidar expert operator, autonomous for satellite lidar on Aeolus
Platforms	Ground, wind rotors, trucks, ships, aircrafts	Ground, aircraft, satellite
Main applications	Need for high precision and high temporal resolution, aircraft wake vortex, turbulence, wind turbines; boundary layer winds, vertical wind speed, and turbulent fluxes	Wind sensing for higher altitudes of upper troposphere, stratosphere and mesosphere, global wind observations from space
Advantages	Higher precision and accuracy possible, higher temporal resolution achievable for turbulent quantities, autonomous, commercial instruments available for 24/7 operation, eye-saving laser wavelengths in IR	Unique method for sensing winds for higher altitudes with molecular backscatter
Disadvantages	Limited to altitude regions with aerosol and clouds, mainly for boundary layer and tropospheric clouds	Need for calibration for most instrument implementations, which is suspicious to systematic errors, potentially lower precision and accuracy for molecular DWL, issues with eye-safety for laser wavelengths in use, additional temperature profile needed for retrieval of winds from molecular backscatter; complex research instruments operated by lidar experts

of the Doppler signal, the number of spectral bins in the frequency estimate, and the number of pulse returns accumulated. Figure 27.12 shows a comparison of the standard deviation in mean frequency estimates computed after averaging 10 000 returns from a microjoule-type coherent lidar system operating at a 20 kHz pulse

rate. The estimate precision, computed using two different methods, versus wideband SNR follows the CRLB curve fairly closely until the CNR drops below -20 dB but then diverges rapidly with further decrease in CNR. At signal-to-noise ratios above -15 dB the velocity precision exceeds 0.05 m s^{-1} . Figure 27.12 illustrates the

value of the multipulse averaging employed in high pulse rate systems to improve the estimate precision and extending the range. The -20 dB threshold corresponds to approximately one photon detected for every four pulses transmitted, illustrating the sensitivity of coherent systems.

The CRLB for a direct-detection system utilizing optical techniques, such as Fabry–Pérot or Fizeau interferometers that provide estimates of energy in spectral bins by developing fringes on imaging detectors, is also addressed in [27.137]. Their expression, aimed at providing a method of comparison between coherent and direct-detection systems, assumes a Gaussian shaped detected signal spectrum in a photon-limited direct-detection system. They show that for equal number of detected photons, and equivalent signal spectral width the CRLB is lower for the direct-detection implementation. In practice, the equivalence of signal and spectral width for direct comparisons is not met because the transmitted laser bandwidth, the presence of additional noise sources, and the system throughput tend to differ significantly for direct and coherent systems. In the infrared region beyond $1.5\ \mu\text{m}$, where eye-safety issues permit higher pulse energies, coherent systems are preferred for aerosol backscatter applications because of their high throughput and lack of susceptibility to background and detector noise. However, a major advantage of direct-detection systems is their capability to provide measurements from both aerosol and molecular backscatter through the use of a single laser operating in the visible or UV spectral regions and separate

Fig. 27.12 Comparison of standard deviation of mean frequency estimates after averaging 10 000 returns from a microjoule-type coherent, 20-kHz pulse rate lidar (triangles) with CRLB (dots) (courtesy of Paul Schroeder, NOAA)

direct-detection receivers. This approach is used in the Aeolus mission [27.3], which employs a lidar operating in the ultraviolet at 355 nm and two direct-detection receivers to measure winds from space.

27.5 Specifications

The requirements for wind measurement precision, accuracy, and temporal and spatial resolution vary widely depending on the application. The specifications achievable for the random error depend on the vertical and temporal resolution applied, as well as the atmospheric properties, mainly backscatter and extinction coefficients, and the influence of turbulence. Typical values for a number of specifications for DWL instruments are listed in Table 27.7. The relevant ISO norm [27.32, annex D] defines three classes of accuracy of horizontal wind velocity with better than $0.1\ \text{m s}^{-1}$ (wind energy), from 0.1 to $0.5\ \text{m s}^{-1}$ (meteorological applications) and from 0.5 to $1\ \text{m s}^{-1}$ numerical weather prediction (NWP).

To derive horizontal wind speed and direction different scanning strategies are applied (Sect. 27.3.3), resulting in an additional error source related to the atmospheric homogeneity for the sampling of a larger

volume. The atmospheric sampling error adds a contribution, which mainly depends on atmospheric properties (e.g., homogeneity, turbulence, cloudiness) and the sampling volume (range resolution, elevation angle). On the other hand, the error for the horizontal wind speed decreases with the square root of the number of LOS wind speeds. Therefore, longer temporal periods are needed to measure horizontal wind speeds (if no multiple-Doppler techniques are applied).

High precision and accuracy are needed for wind-energy site assessments (Chap. 51), which are comparable to in-situ wind sensors (Chap. 9) or even traceable to standards. Other applications require mainly high temporal resolution for turbulence measurements, e.g., vortex characterisation for aircrafts and wind energy rotors. On the other hand, the requirements for global wind profiling is not that stringent for random errors [27.141], as the current satellite and ground-based observations

Table 27.7 Typical values for coherent (continuous-wave (CW) and pulsed) and direct-detection DWL

Method	Coherent DWL	Direct-detection DWL
Random error LOS (m s^{-1})	0.1–0.5	0.5–3
Systematic error LOS (m s^{-1})	< 0.1	0.5–1
Random error horizontal wind speed (m s^{-1})	0.1–1	0.5–3
Vertical resolution (m)	0.1–20 (cw), 20–100 (pulsed)	100–2000
Temporal resolution LOS (s)	0.1–1	1 to several 10
Wind speed range (m s^{-1})	30–100	150
Temperature operation range ($^{\circ}\text{C}$)	–25 to +45 for commercial DWL	Instruments operated in temperature stabilized container or housing
Scanning device common for both techniques		
Scan speed ($^{\circ}/\text{s}$)	up to 360 (cw), up to 30–40 (pulsed)	
Scan angle range ($^{\circ}$)	360 (in azimuth), –10 to 190 (in elevation)	

for NWP show a large gap in wind-profile observations [27.142]. On the other hand, the requirements for systematic errors are strict for NWP applications, because these would be detrimental for forecast quality.

The maximum range of a DWL is both determined by instrumental parameters (e.g., laser energy, telescope diameter, and optical efficiency), the method used (coherent DWL with aerosol backscatter or direct detec-

tion with aerosol and/or molecular backscatter), and the atmospheric properties. Thus, typical values for maximum ranges are not provided here, because they depend strongly on atmospheric properties and the temporal and spatial resolutions applied. Typical values for the availability of measurements as a function of range and the maximum range for a defined availability (e.g., for 50 or 80%) are discussed in [27.32, 143] for coherent DWL.

27.6 Quality Control

The quality of the wind measurements for LOS winds or vector winds depends on the DWL instrument hardware and retrieval algorithms, as well as on the pointing accuracy of the scanning device. The instrument performance of the DWL hardware, as well as the scanning device, needs to be regularly assessed (Sect. 27.7), including the leveling of the instrument to ensure the quality of the wind product retrieved.

In contrast to in-situ wind sensors (Chap. 9), which are calibrated and validated using wind tunnels, this is not possible for remote-sensing instruments due to their range resolution and volume-sensing approach.

27.6.1 Calibration and Validation with a Nonmoving Target

For calibration and validation, a target with known properties can be used for remote-sensing devices. This is achieved by nonmoving targets for wind lidars, where the LOS wind speed measured should be 0 m s^{-1} . This can be performed for an initial assessment of the performance of the instrument but can be repeated once the instruments are set up in the field.

In addition to validation of the zero-wind measurement by using a hard target, also the pointing accuracy of the scanning device can be calibrated and validated using hard targets in a known distance. Here, the knowl-

edge of the geographical position of the lidar instrument and the position of the hard target is used to infer the azimuth angle for the pointing direction, as well as the range.

Some care needs to be taken with the calibration or validation of the zero-wind measurement capability by using a nonmoving target. The target should ideally fill the complete sensing volume to avoid contamination with atmospheric returns, which would add a contribution from moving particles. Hard targets can be buildings or landmarks as hills (ideally without vegetation, which can move with the wind).

As for any remote-sensing instrument the sampled signal from a certain range is composed of a volume of a conical section with diameter D and a length depending on the range gate resolution ΔR . Thus, it needs to be assured that the hard target is ideally larger in size than the diameter D of the beam, which is approximated by the range R and the laser divergence or instrument field-of-view θ with $D = R\theta$; for a typical laser divergence of 1 mrad and a range of 1 km, this will result in a beam diameter of only 1 m. The range gate resolution for the analysis needs to be set such that the reflection of the laser pulse at the hard target is ideally centered in the range gate in order to avoid the effects of a possible laser chirp (changing laser frequency within the laser pulse). The range gate resolution should ideally be optimized

such that it covers only the laser pulse length and avoids atmospheric volume backscatter before the target.

The derived mean wind speed of the target return provides an assessment of the systematic error (bias), while the standard deviation of the target return provides an assessment of the random error (precision) for high signal-to-noise ratios.

27.6.2 Validation by Vertical Pointing Measurements

The measurement of the vertical wind is performed by pointing the laser beam to the vertical. Here, the assumption can be used that the vertical winds should be close to 0 m s^{-1} in the atmospheric boundary layer for sufficiently long averaging periods, which depends on the atmospheric conditions. Situations with nonzero vertical winds need to be avoided, e.g., the presence of gravity waves, orographically induced vertical movements, or synoptic scale vertical winds.

The advantage of the vertical pointing measurement compared to a hard target is that several altitude ranges can be assessed and also atmospheric volume backscatter is used with more representative SNR values. The derived mean vertical wind speed from the DWL should be zero for longer averaging periods over the altitude range.

For the case that high temporal resolution vertical wind measurements can be performed, the random error of the instrument can be assessed without any other instruments for comparison [27.6, 32, 144]. From the time series of the vertical wind measurements, the power spectra can be derived for each altitude. For the case of well-developed turbulence in the boundary layer, the power spectrum should follow a $f^{-5/3}$ law for a Kolmogorov spectrum (at least over the *inertial spectral range*). In the case of uncorrelated instrument noise, the power spectrum will show a constant, nonfrequency-dependent offset (white noise) for higher frequencies,

which is equivalent to the variance of the instrument wind speed random error.

These vertical pointing measurements are used for validating the performance of coherent DWL in the boundary layer but are used in addition to calibrate the instrument response for direct-detection DWL throughout the troposphere and stratosphere (Sect. 27.3.6.)

27.6.3 Quality Control for Line-of-Sight Wind Speeds and Vector Winds

The main purpose of the control of the quality of the derived LOS wind speeds or the derived wind vectors should be to flag or filter gross outliers, which deviate from a Gaussian distribution. Typically, they occur for values larger than $\pm 3\sigma_v$ (σ_v : random error) from the mean.

As both the probability of gross errors and the instrument random error depend on the SNR or CNR [27.140], this quantity can be used for quality assessment. Both flagging as invalid LOS winds that are below a certain SNR threshold or weighting LOS wind speeds with SNR^{-1} for further processing (e.g., during VAD least-squares fit) can be applied. One should be aware that also the derivation of SNR or CNR from the digitized signal itself is prone to systematic and random errors, especially for low SNR or CNR conditions.

Other quality control (QC) methods come into place when deriving horizontal wind vectors from VAD or DBS using the consistency checks for single LOS winds in different azimuthal direction (e.g., deviation from the sinusoidal fit). They can be used to check the assumption on horizontal homogeneity for situations with partial cloud coverage affecting only a fraction of the LOS winds.

As a final step also QC can be applied to the derived horizontal wind vector (speed and direction) by applying consistency or continuity approaches as performed for radar wind profilers [27.145] (Chap. 31).

27.7 Maintenance

The maintenance efforts for wind lidar instruments strongly depend on its maturity and complexity. On the one hand, there are commercial instruments, which are operable 24/7, unattended, and require only a minimum of maintenance. Also, these instruments are usually operable without any restrictions on laser eye safety. On the other hand, there are research instruments that require expert users for lasers and/or lidars and specific operations and maintenance procedures, which strongly vary for each instrument.

Thus, only some basic maintenance operations for commercial instruments, which are all based on coherent-detection technology, are summarized in Table 27.8. They include visual, functional, and performance inspections, and automatic or semiautomatic checks on instrument parameters (e.g., laser energy, temperatures).

The instrument performance of the lidar instrument is influenced by the cleanliness of the output window, which is used to separate the outside envi-

Table 27.8 Maintenance intervals of autonomous, commercial DWL systems

Interval	Visual inspection	Functional inspection	Performance verification
1–4 weeks		Check instrument housekeeping data, e.g., laser, temperatures, operation flags	Check typical measurement range and data quality
1–3 months	Inspect window, scanning device, electrical power supply, cooling, site and environment with respect to laser viewing direction, desiccants in housing	Check mechanical scanner, laser pointing verification (leveling, and north direction)	Verify laser power and receive path alignment
6–12 months	Lubricants or greasing for mechanical parts of scanner need to be checked and refilled; check of sealing of instrument housing		
1–2 years	Performance verification by manufacturer: laser power, receive path alignment, subunit performance, overall performance		

ronment from the delicate optics inside and to allow thermal control of the units. This window is contaminated by dust, precipitation, snow, and ice from the outside or condensed humidity from the inside. Usually, commercial DWL are equipped with a device to automatically clean this window (e.g., by a wiper). Nevertheless, visual inspections should check the cleanliness of the protecting output window. Furthermore, the site should be inspected regularly with respect to visibility for the laser beam (e.g., blocking by growing vegetation), the conditions of the ground site and instrument setup, leveling (horizontally, vertically), and alignment with respect to the north direction. This includes verification of the laser beam pointing – as is usually performed when setting up the instrument, e.g., by use of returns from hard targets (e.g., buildings) from a known azimuthal direction. Furthermore, a proper electrical power supply, lightning protection, and clearance of the opening for blowers and cooling devices needs to be ensured. Some suppliers use cleaning agents for the window, whose tanks need to be checked. In order to preserve low humidity conditions inside the housing, specific desiccants are used, which need to be checked.

27.8 Applications

A variety of applications of DWL is listed in Sect. 27.1. Here, three typical examples are discussed in more detail, from coherent wind lidars towards the observation of gravity waves in the stratosphere with direct-detection methods.

27.8.1 Hazard Detection at Airports

Doppler lidar techniques are well matched for detecting and characterizing air motions, such as low-level wind shear, wake vortices, and turbulence at airports that can

Functional verifications mainly include the mechanical parts of the scanning device (including lubricants, greasing), the instrument housing, temperature stabilization, or electrical power supply. Basic functional verifications of the lidar instrument should include measurements of the outgoing laser power. Automatic monitoring of instrument parameters is a prerequisite for autonomous operation but should also be verified regularly by the user. The verification of the performance of the instrument is mainly based on the assessment of the typical measurement range and quality of the observations. As this strongly depends on the atmospheric conditions (e.g., the presence of clouds and aerosol as backscatter targets), it varies strongly during the course of the day and from day to day. Thus, experience in assessing the range performance is needed.

Optical performance verifications, such as optical transmission, laser performance, or alignment verifications, should primarily be performed in a laboratory environment. This includes the verification of the performance and functions of the scanning device. Thus, the lidar instrument's optical performance and the scanning device need to be verified by the supplier, typically every year or every other year.

represent a threat to arriving and departing aircraft. Because wind shear encountered on takeoff or landing can result in a sudden change in airspeed necessitating corrective action to maintain lift and aircraft control, timely and accurate reporting of significant shear is important. Significant low-level wind shear is defined as a change in headwind of 15 kn (knots) or more at an altitude < 1600 ft (feet) within 3 nmi (nautical miles) from the runway threshold [27.146]. Because such conditions are ideally observed by Doppler lidar, these have been installed and operated at a number of airports

where local conditions are conducive to the generation of hazardous shear conditions, including Hong Kong, Munich, Sendai, Beijing, Frankfurt, and Las Vegas.

One of the earliest installations of a Doppler lidar intended for operational use was at Hong Kong International Airport (HKIA) in 2002 [27.11]. The orography at HKIA, especially the presence of the Lantau island to the south, is conducive to generation of wind shear in a variety of different weather conditions, including the generation of gravity waves under stable conditions, terrain-induced disruption of airflow under northeast and southwest flow, sea breeze, and severe convection and tropical cyclone events. At the beginning of 2002, a 2 mJ per pulse, 500 Hz pulse repetition frequency commercial Doppler lidar operating at 2 μm wavelength was installed on a rooftop near the center of HKIA. The lidar operated with high reliability (> 98%) over several years, with brief interruptions of a few hours for servicing. Long-term assessment of lidar performance showed that the lidar provided measurements to beyond 6 km range at least 70% of the time. Comparisons of the lidar measured wind with a tower-mounted cup anemometer showed negligible bias in the mean line-of-sight wind measurements and standard deviations on the order of 1 m s^{-1} . In October 2006, a second lidar was installed to provide better coverage along the north runway, where most aircraft approaches are made.

Characterizations of wind shear flow patterns observed by the HKIA lidar superimposed on a map of terrain and showing airport runways can be seen in Fig. 27.13 for different generating phenomena. The measurements show the capability of the lidar to detect potentially hazardous shear events. Lidar observations were also used to develop and test a lidar-based wind-shear alerting system intended to provide automatic wind-shear detection and alerts, based on the observation of a sustained change in headwind along the glide path. The lidar warning system at HKIA was recently upgraded by installing a new pulsed system based on a 1.5 μm fiber-based lidar transmitter and a high power planar waveguide laser [27.147]. The new instrument has demonstrated measurement to ranges of 30 km and heights of 12 km, which should significantly extend the range for wind-shear detection. Similar commercial instruments are scheduled for installation over the next few years at Nice, Beijing, and Antalya, Turkey, airports.

Application of both CW and pulsed coherent lidars to observe aircraft wake vortices has been demonstrated in several studies [27.13, 148]. Currently, the need to avoid wake vortices establishes separation distances between leading and following aircraft during takeoff and landing. Because the persistence of wake vortices is a function of local atmospheric conditions and can vary

significantly, information on vortex behavior under different atmospheric conditions can aid in updating separation distances and evaluating the impacts of implementing changes in operational procedures. Lidar investigations of wake vortices have typically focused on detection of the vortices and characterization of key parameters, including horizontal and vertical position and information on the strength of the vortex circulation.

Although CW lidars can provide excellent range resolution when a wake vortex is located close to the lidar, the lack of ranging capability precludes the use of a single CW lidar to track evolution of vortices as they move away from the lidar. In [27.13], the use of a scanning 2 μm , 2 mJ pulsed coherent lidar with a range resolution of 88 m was investigated to characterize vortex pairs, including trajectory, core separation, tilt angle, and circulation from large transport aircraft. Although the pulse duration defined a range resolution of 88 m, computation of a periodogram at 3 m intervals facilitated identification of the vortex core at higher spatial resolution. The range capability of the pulsed instrument enabled observation and tracking of the vortex pair over a time interval from generation by the aircraft to decay. Recently, in [27.149] a microjoule-type instrument with an average power of 1 W and 18 kHz pulse repetition frequency to observe vortices produced by a Boeing 767 aircraft was demonstrated by applying a retrieval method based on iterative optimization of the state variables describing vortex properties to a Doppler spectrum computed from scanning lidar observations. Field studies at Narita International Airport showed the capability of the technique to estimate the horizontal and vertical positions and radii-averaged circulation of the vortices observed.

Coherent Doppler lidars have also been proposed as part of an observing system to measure wind and turbulence at airports for better mitigation of wake vortex hazards [27.150]. The concept combines a pulsed lidar and X-band radar to estimate wind vectors and the eddy dissipation rate, key parameters for predicting wake vortex evolution after generation. Experiments at Toulouse airport demonstrated the potential capability of the proposed instrument combination to provide the necessary measurements for both wake vortex mitigation and for assimilation into NWP models to improve short-term forecasts.

27.8.2 Wind Energy

Over the past decade, the availability of compact, reliable commercial coherent Doppler lidar systems has contributed to their widespread use for a variety of diverse applications in the wind energy industry, including the evaluation of potential energy yield of wind

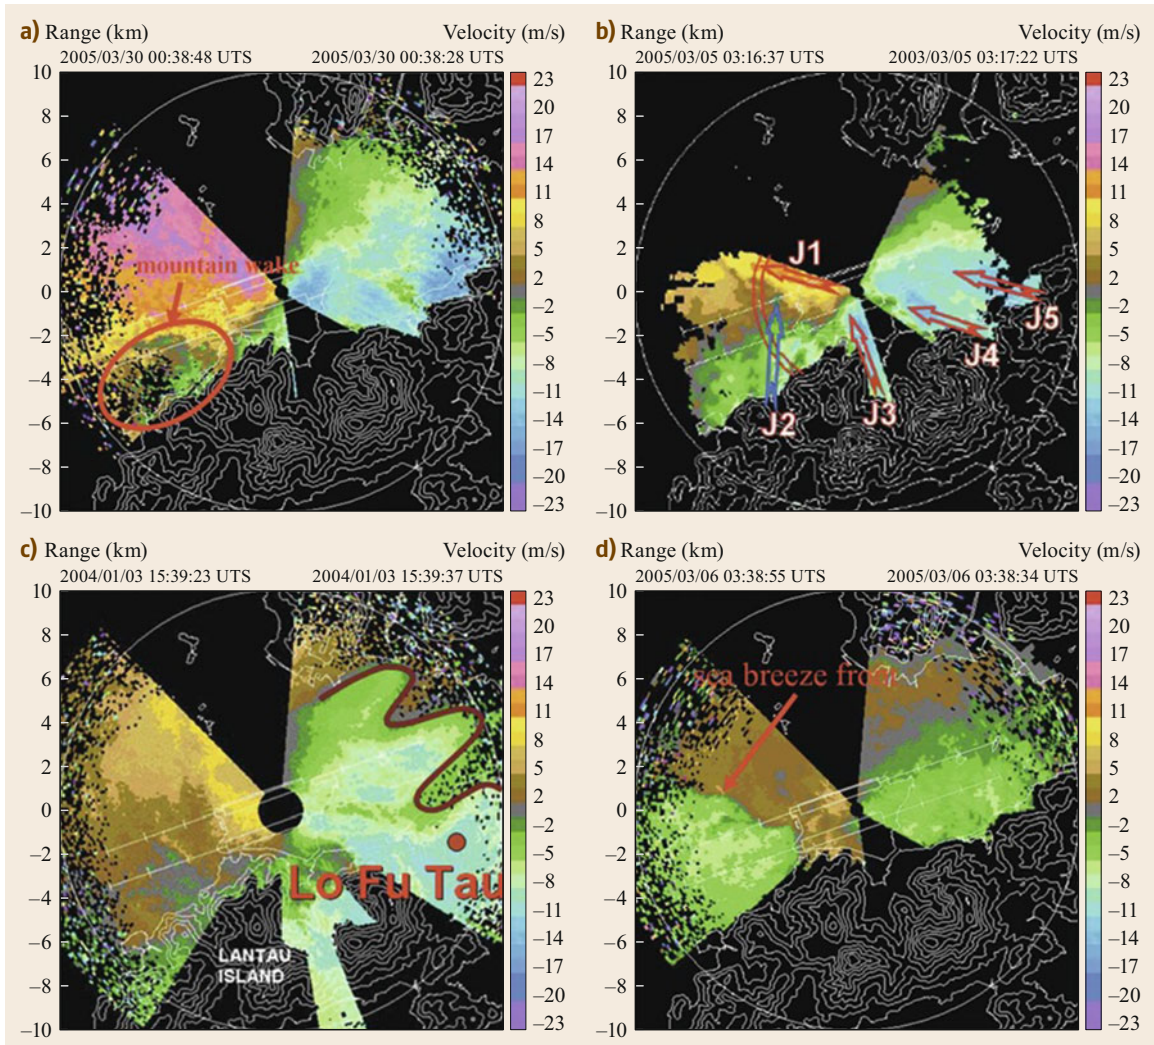

Fig. 27.13a–d Characterizations of wind shear flow patterns observed by the HKIA lidar superimposed on a map of terrain and showing airport runways, for (a,c) mountain waves; (b) accelerated gap flow; (d) westerly sea breeze against easterly winds (after [27.11] © American Meteorological Society; used with permission)

energy sites, the investigation of the effects of turbine wakes on power production of turbines downwind, and active turbine control to reduce blade load and increase energy capture. Both pulsed and CW instruments have been extensively applied and are becoming widely accepted in the industry as a reliable source of wind information.

Effective decisions on the development of new wind farms and optimization of their design require reliable measurement of winds and turbulence, which can be provided by lidar techniques. Traditionally, the wind energy industry has relied on in-situ instruments, such as the cup and vane anemometers deployed on mete-

orological masts to provide these wind measurements (Chaps. 9 and 51). However, as turbines have become larger, the application of in-situ instruments on high masts has become increasingly impractical due to cost and safety issues. Doppler lidars are well suited to remotely characterize winds for the assessment of the wind-energy power generation potential. A study in which a CW lidar was deployed for 1 year at an onshore site near Lake Erie to measure winds at the hub height of two potential wind turbines is described in [27.151]. Following the study, two commercial wind turbines were constructed at the site and provided power capacity data for comparison with the power capacity

estimated from the lidar measurements. The year-long study revealed strong seasonal variabilities in wind speed, with higher wind energy potential available in the winter. The lidar measurements also indicated the general presence of a high level of turbulence at the test site, with more turbulence observed at the greater height. A comparison of capacity factors, defined as the average power output to the rated power output of a generator, estimated from the lidar data with those from the actual in-service turbines showed agreement to within 10%, demonstrating the effectiveness of lidar for predicting energy output at a given site.

Because a CW lidar measures the wind profile above a single location, effectively duplicating measurements from a fixed tower, the representativeness of profile measurements observed by a single lidar for potential wind farm assessment is limited in regions of complex terrain. A scanning pulsed lidar system, which can survey winds over a significant area, addresses the representativeness issue by observing the horizontal variability of the wind across a potential farm site. The capability of a single scanning Doppler lidar to measure spatial and diurnal variability of winds for wind farm assessment by evaluating results on terrain following surfaces at multiple heights across a region of complex terrain was demonstrated in [27.152]. The authors applied an optimal interpolation algorithm to estimate the 2-D wind field from lidar radial velocity measurements. From this, wind power production at every location across the region was predicted (Fig. 27.14)

Fig. 27.14 Estimated wind power production across a region of complex terrain estimated from Doppler lidar scans. The color bar represents the power in kilowatts (after [27.152] reprinted with permission from John Wiley & Sons)

based on the average wind at 80 m hub height and was used to develop the layout for a notional wind farm.

A key issue in optimizing power output from large wind farms is minimizing the effects of turbine wakes on downwind turbines because the reduced wind speeds and increased turbulence in turbine wakes affects power generation from the downwind turbines. Doppler lidars are very well matched to study the properties of turbine wakes and have been employed in several studies in recent years [27.10, 153–155]. In one study [27.154], a ground-based scanning lidar was used to investigate wakes from a row of four turbines on a wind farm deployed in central Iowa. Figure 27.15 shows an example of wakes as observed by the lidar, where the velocity deficits in the wakes are clearly observed. Because wakes erode quickly under unstable conditions, wakes in this study were observed primarily under stable conditions. The lidar was used to estimate wake parameters, such as velocity deficits, the size of the wake boundaries, and wake centerlines. The measurements showed the effects of wind veer on the wake centerline location and the vertical structure of the wakes, and also revealed significant differences between the wakes from turbines in the center of the row compared to those at the edge.

Turbine wake characterization can also be addressed with nacelle-mounted lidars [27.153]. In this study, two lidars were mounted on the nacelle of a 2.5 MW wind turbine, with one pointed upstream to characterize the inflow, while the other looked downstream to characterize the wake. Observations from various scan patterns were processed to study the relationships between wake growth rate, wake width at the rotor plane, wake length, and turbulence intensity, which were compared with predictions from an analytic wake mode. In a different study [27.156], results from deployment of an upwind looking, nacelle-mounted CW Doppler lidar are described to detect the presence of upstream wakes for use in yaw steering of the wind turbine.

Wind information from Doppler lidars can be potentially utilized for wind turbine control, whereby the lidar-measured wind data provides information used in a feed-forward loop to improve turbine power output and increase reliability and lifetime. A CW Doppler lidar mounted at the tip of a rotating spinner to measure winds and turbulence ≈ 100 and 45 m upwind of the turbine blade is described in [27.87]. The spinner-mounted lidar observed the line-of-sight wind field in the rotor plan, revealing substantial variation in the rotor plane inflow under some conditions. The lidar-measured *pre-view* of the wind field provided potentially useful information for the optimization of yaw, blade pitch, and

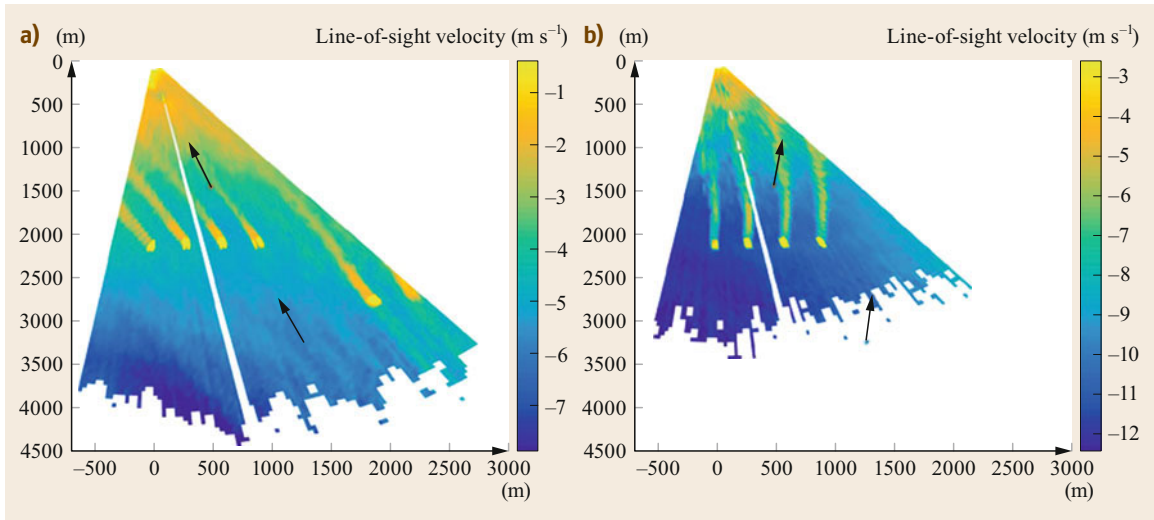

Fig. 27.15a,b Color maps showing line-of-sight wind velocities and wake effects from a line of wind turbines as measured by a scanning Doppler lidar: **(a)** 23.08.2013, 11:57:40, elevation angle = 1.50°; **(b)** 26.08.2013, 02:33:34, elevation angle = 2.80°. speed control to improve power output and mitigate the effects of strong wind shear and yaw errors.

27.8.3 Gravity Waves in the Stratosphere

Atmospheric gravity waves describe a perturbation of the atmospheric state in temperature, density, pressure, and wind, which are not of pure random nature and show some periodic behavior with temporal (minutes to hours), vertical (2–30 km), and horizontal (10–1000 km) spatial structures. Gravity waves, where gravity and buoyancy act as restoring forces, are characterized by their wavelength, dispersion relation, and propagation in the atmosphere. These are ubiquitous in the atmosphere and play important roles in influencing its state by transporting energy and momentum between widely separated regions and generating turbulence by breaking of the waves and dissipation of energy. These waves can be generated via different mechanisms, e.g., orographically by disturbances of the atmospheric flow by mountains or islands, by convection, or by instabilities and wind shear within regions of high wind speeds (*jet streams*).

Depending on the atmospheric stability, they propagate vertically and horizontally from their origin, are damped or filtered within atmospheric layers, or break at certain levels. The major wave influences occur in the stratosphere and mesosphere between 10 and 110 km (denoted as the *middle atmosphere*), because of increasing wave amplitude with altitude for vertically

propagating waves due to decreasing density. Thus, gravity waves of large amplitudes are observed in the stratosphere and even mesosphere, and are observed by lidars for the atmospheric temperature as well as wind. An extensive review of gravity wave dynamics and observations is provided in [27.157].

While numerous case studies and climatologies on gravity waves using Rayleigh lidars for measurement of the atmospheric temperatures up to the mesosphere are reported, only few wind lidar observations of gravity waves have been reported for the stratosphere [27.27, 158–160]. Here, an example of the temperature and wind lidar deployed at the ALOMAR (Arctic Lidar Observatory) observatory in northern Norway is discussed, which is operated by the Leibniz Institute of Atmospheric Physics, Germany [27.123, 135]. Figure 27.16 shows zonal and meridional winds retrieved from measurements between 21.01.2012 09:00 UT and 23.01.2012 11:00 UT with clear signatures of gravity waves for both the mean flow as well as the perturbations. These perturbations are calculated by subtracting a representative value for the mean wind speed for each altitude. Between 21.01.2012 16:00 UT and 22.01.2012 10:00 UT, the zonal and meridional winds in the altitude range of 60–70 km show both downward phase progression with $\approx 0.2 \text{ m s}^{-1}$ ($\approx 0.8 \text{ km h}^{-1}$), a vertical wavelength of 8 km, and an observed period of $\approx 11 \text{ h}$. The wave signatures are very similar in the two wind components with comparable vertical wavelengths and phase speeds [27.27].

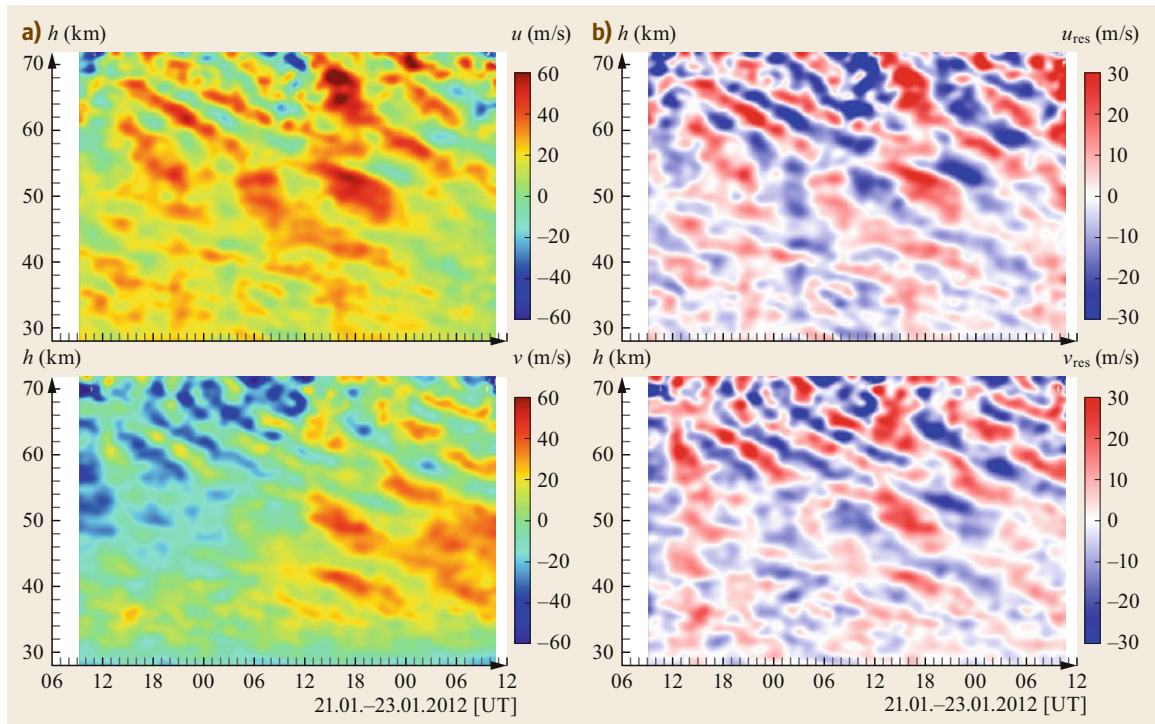

Fig. 27.16a,b Zonal (*top*) and meridional wind (*bottom*) measured between 21.01.2012 and 23.01.2012 at the Alomar observatory for total winds: **(a)** data are smoothed with a Gaussian kernel of 2 km and 2 h FWHM and **(b)** their perturbations from the mean flow (after removing low-frequency observations) (figure courtesy of G. Baumgarten, IAP, Kühlungsborn)

27.9 Future Developments

In the past decade coherent wind lidar instruments matured significantly and were widely applied in the wind energy sector. This was driven by developments for fiber laser technologies emerging from the telecommunications sector. Coherent DWL are operable unattended and continuously by trained persons, and are affordable, with lower investment and maintenance costs. This trend continues with smaller instruments (weight, volume) and lower investment costs, especially with instruments for specific applications, e.g., lower ranges of only up to 100 m for wind turbine control.

Small and cheap lidar instruments for ranging application are developed for the automotive sector, enhancing the capabilities of autonomous driving. Technology concepts are currently being studied to enhance these ranges with Doppler capabilities for speed detection. It can be anticipated that also the atmospheric wind-sensing application would benefit from these developments in the future.

The demands from air traffic for monitoring of low-level wind shears and wake vortex in the vicinity of airport runways during clear air conditions will foster the further application of wind lidars. Research on wind lidar sensors onboard aircraft has been ongoing for more than two decades. Long-range wind lidars with a range of ≈ 10 km could be used for the detection of clear air turbulence (CAT), while short-range wind lidars for ranges of around 50–300 m could be used for active control of aircraft in the future.

Atmospheric monitoring networks for meteorological or pollution transport purposes will make growing demands on wind lidars in combination with other remote sensing sensors. These would be used to measure horizontal transports of gases or particles, as well as turbulent fluxes for vertically pointing instruments for research applications.

Besides deployment of wind lidars on the ground, these instruments have already been used on a num-

ber of different platforms for research purposes, such as on ships, truck-mounted systems (e.g., for tornado research), and aircrafts. With further ruggedizing of these instruments, these research applications will expand to new platforms, e.g., balloons, UAS (unmanned aircraft systems), or even commercial aircraft.

The exploitation of global wind profiling by the use of spaceborne wind lidars just started with the launch of Aeolus in August 2018 [27.161]. Several space lidar mission concepts have been studied and developed,

mainly in Europe, the USA, Japan, and China. Aeolus is considered as a demonstration mission for future operational missions, serving the need for global wind profile observations for numerical weather prediction. Future operational capabilities of global wind profiling will, ideally, require a number of two to three polar-orbiting wind lidar satellites to achieve sufficient horizontal and temporal coverage [27.162]. International collaboration among meteorological satellite agencies will be needed to achieve this objective and fill the gap in the global observing system for wind profiles.

27.10 Further Readings

A comprehensive textbook including theory and application for turbulence research is recommended for readers interested in coherent DWL:

- V. Banakh and I. Smalikho: *Coherent Doppler Wind Lidars in a Turbulent Atmosphere* (Artech House, Boston, London 2013)

An ISO guideline for coherent DWL for the commonly used pulsed systems has been established (and replaces the earlier VDI 3786, part 14, 2001):

- ISO 28902-2:2017: *Air Quality—Environmental Meteorology—Part 2: Ground-Based Remote Sensing of Wind by Heterodyne Pulsed Doppler Lidar* (International Standard Organization, Geneva 2017)

Both coherent and direct-detection wind lidars are covered in an extensive book chapter by:

- S.W. Henderson, P. Gatt, D. Rees, R.M. Huffaker: Wind lidar. In: *Laser Remote Sensing*, ed. by T. Fujii and T. Fukuchi (CRC Press, Boca Raton 2005), pp. 487–740

Shorter introductions to coherent and direct-detection wind lidars can be found in:

- M. Hardesty: Lidar: Doppler. In: *Encyclopedia of Atmospheric Sciences*, 2nd edn., Vol. 3, ed. by G.R. North, J.A. Pyle, F. Zhang (Academic Press, London 2015), pp. 289–295
- O. Reitebuch: Wind lidar for atmospheric research. In: *Atmospheric Physics – Background, Methods, Trends*, ed. by U. Schumann. Springer Series on Research Topics in Aerospace (Springer, Berlin, Heidelberg 2012), pp. 487–507
- C. Werner: Doppler Wind Lidar. In: *Lidar – Range-Resolved Optical Remote Sensing of the Atmosphere*, ed. by C. Weitkamp (Springer, New York 2004)

R. Michael Hardesty is a Senior Research Scientist with the Cooperative Institute for Research in Environmental Sciences at the University of Colorado Boulder, where he serves as Associate Director for Environmental Modeling, Observations, and Forecasting. He received his PhD in Electrical Engineering and Meteorology from the Naval Postgraduate School (1985). He is a recipient of the NOAA Distinguished Career Award. His research interests focus on the development and application of lidar techniques for remotely sensing the atmosphere.

Spectrometers

28. Spectrometers

Klaus Schäfer , Mark Wenig , Mark A. Zondlo , Axel Murk , Konradin Weber 

Spectrometers are used to determine the chemical composition and temperature of the atmosphere, exhausts, and gas releases. A relevant part of the electromagnetic spectrum is detected via absorption spectroscopy by means of artificial (e.g., lamps and lasers) or natural light sources (e.g., the Sun), as well as via emission spectroscopy using temperature differences or atmospheric radiation. The currently preferred spectrometer techniques are Fourier transform infrared spectroscopy (FTIR) in the infrared (IR) and visible (VIS), differential optical absorption spectroscopy (DOAS) in the VIS and ultraviolet (UV), as well as microwave radiometry (MWR). To achieve high sensitivity, tuned or broadband lasers are employed in laser spectrometers. Radiation absorption and scattering can be detected using spectrometers by an open-path configuration either through a single pass or multiple passes by steering optics in the atmosphere or exhausts. Analysis of the measured spectral features can be used to detect atmospheric gas concentrations, temperature, pressure, as well as aerosol scattering and absorption. The basic theory with equations and retrieval algorithms for processing measured spectra is described. In addition to characteristic parameters, quality assurance and quality control, calibration, and the necessary maintenance associated with the different measurement principles are presented.

This chapter deals with ground-based spectrometers for in-situ or remote sensing measurements of trace gases, aerosols, and atmospheric state parameters such as temperature and pressure. Ground-based remote sensing (Chap. 1) using spectrometers enables highly sensitive, spectrally resolved radiation measurements

(Chaps. 11, 29, and 40) and provides chemical compositions and temperature distributions of the atmosphere, exhausts, and gas releases. Path-averaged and vertical distributions of chemical compound concentrations and temperature can be detected. When coupled with meteorological conditions, the concentrations are used to

derive emission source strengths of air pollutants and greenhouse gases as well as their changes due to anthropogenic and natural influences.

Most important is the capability to detect the sought-after parameters simultaneously from measured spectra. Furthermore, nonintrusive detection is advantageous because several tasks of atmospheric and environmental investigations cannot be solved by air sampling through an inlet or sampling manifold because it is technically impossible or not representative. Samples

of air can change chemically within the probe extraction system before reaching the analytical equipment, and perturbations of the flow of exhausts by the sampling manifold are often degraded or lost.

Temperature measurements provide essential information for transport processes and stability of the atmosphere. The temperature information of exhausts and gas releases allows conclusions about the originating emission processes and provides data for calculation of pollution transport and dilution.

28.1 Measurement Principles and Parameters

Spectrometers are used to detect relevant parts of the electromagnetic spectrum via absorption spectroscopy by means of artificial (e.g., lamps and lasers) or natural light sources (e.g., the Sun) as well as via emission spectroscopy using temperature differences or atmospheric radiation (Chaps. 29 and 40). Fourier transform infrared spectroscopy (FTIR) is currently the preferred method

in the infrared (IR) and visible (VIS) (Chap. 37), and differential optical absorption spectroscopy (DOAS) in the VIS and ultraviolet (UV) (Chap. 37). To make high-sensitivity absorption measurements, tuned or broadband lasers can also be employed in an open-path configuration as laser spectrometers (Chap. 16). Radiation absorption and scattering can be detected via open-path

Table 28.1 Measured parameters by open-path absorption measurements

Parameter	Description	Unit	Symbol
Gaseous compounds	Path-integrated mixing ratio	ppm m, ppb m, ppt m	X
Gaseous compounds	Path-integrated mass concentration	kg m^{-2}	C_m
Gaseous compounds	Path-integrated number density	molecules m^{-2}	C_n
Gaseous compounds	Mixing ratio by volume	ppmv, ppbv, pptv	x
Gaseous compounds	Mass concentration	kg m^{-3}	c_m
Gaseous compounds	Number density	molecules m^{-3}	c_n
Aerosol	Path-integrated mass concentration	kg m^{-2}	C_m
Aerosol	Path-integrated number density	particles m^{-2}	N
Aerosol	Mass concentration	kg m^{-3}	c_m
Aerosol	Number density	particles m^{-3}	n

Table 28.2 Measured parameters by emission measurements

Parameter	Description	Unit	Symbol
Temperature	Temperature of atmosphere, exhausts, released gases	K	T
Gaseous compounds, aerosol	Mass column density	kg m^{-2}	S_m
Gaseous compounds, aerosol	Number column density	molecules m^{-2} , particles m^{-2}	S_n

Table 28.3 Principles of gas and aerosol concentration, as well as temperature measurements and applications

Type of sensor	Measurement principle	Application			
		Gas conc.	Aerosol conc.	Temp.	Pressure
FTIR	Absorption	\times	\times	\times	\times
	Emission	\times		\times	
DOAS	Absorption	\times	\times

Microwave spectrometer	Absorption	\times			
	Emission	\times		\times	

configurations (directed or folded) in the atmosphere (Chap. 1). Spectrally high-resolved microwave radiometers (MWR) (Chaps. 29 and 41) provide the line shape of the pressure-broadened emission lines so that by using inversion techniques, vertical profiles of trace gas concentrations in the middle atmosphere are determined.

28.1.1 Measured Parameters

The fundamental measurand in spectrometers is the change of intensity of electromagnetic radiation, typically given by a detector voltage or current. For trace gases, the change of light intensity is converted into an optical absorption or emission, which is then converted into a concentration (e.g., molecules per volume) or column abundance (e.g., molecules per area) through the Bouguer–Lambert–Beer law directly or as a part of radiative transfer codes. For aerosol measurements,

the extinction by scattering is fit to complex aerosol radiation transfer codes (e.g., Mie scattering) to yield information on particle size, phase, and composition. For measurements of state parameters (e.g., temperature, pressure), the spectral data are fit to complex line shape/line strength codes for the species of interest. Tables 28.1 and 28.2 describe absorption measurements by open-path measurements and by emission measurements, respectively. The measured parameters are described and the units and symbols are also provided (Chap. 5).

28.1.2 Principles of Measurements

The applications of different techniques (FTIR, DOAS, microwave and laser spectrometer) that detect gas and aerosol concentration, as well as temperature, are given in Table 28.3.

28.2 History

Scientific applications of spectroscopic methods increased rapidly with more and more remote sensing of the atmosphere. As radiation is the sounding method for atmospheric composition and meteorological parameters, spectrometers allow for nonintrusive task monitoring.

28.2.1 FTIR Measurement Methods

In 1881 *Albert A. Michelson* (1852–1931), the first US Nobel Prize winner in physics in 1907, invented the interferometer and in 1949 *Peter Fellgett* (1922–2008) measured the first IR spectrum by using a FTIR spectrometer: the spectral determination by Fourier transformation of the measured interferogram. The application of FTIR spectrometry was limited in that time by computer capacity and carried out by research scientists only.

In the late 1960s, commercial FTIR spectrometers and DOAS systems were developed on the basis of microcomputers and used in the atmosphere because these methods enabled remote sensing and provided lower detection limits. In 1966 *James William Cooley* (1926–2016) and *John Wilder Tukey* (1915–2000) developed an algorithm for quickly calculating the Fourier transform of interferograms to determine spectra. Further technological developments like imaging spectrometers using scanning mirror systems or detector arrays increased the availability and enhanced the capabilities of FTIR spectrometers. During the

1990s, very high-resolution FTIR spectrometry well below the molecular (Doppler-broadened and pressure-broadened) line width of atmospheric trace gases became applicable, both from the experimental and theoretical side.

28.2.2 DOAS Measurement Methods

Alfred Pérot (1863–1925) and *Charles Fabry* (1867–1945) invented the Fabry–Pérot interferometer in 1899 using a transparent plate with two reflecting surfaces, or two parallel highly reflecting mirrors (also called etalon) to study interference fringes in the transmission spectrum. Later in 1913 *Charles Fabry* and *Henri Buisson* (1873–1944) discovered the ozone layer using a Fabry–Pérot interferometer. In 1924 the Dobson spectrometer was invented by *Gordon Dobson* (1889–1975), allowing column as well as profile measurements of atmospheric ozone by measuring the relative intensity of UVA and UVB radiation [28.1]. He used his invention together with *Paul Götz* (1883–1962) and *Alfred Roger Meetham* (1910–1994) in 1930 to determine the height of the ozone layer using the Umkehr effect, which is based on the dependency of the ratio of radiances of scattered sunlight at two ultraviolet wavelengths, where the shorter one is more strongly absorbed by ozone than the longer one, on the solar zenith angle. This dependency exhibits a minimum at a certain zenith angle that allowed them to determine the ozone layer height to be about 25 km. *Erich Regener* (1881–1955) used UV

Fig. 28.1 Schematic of laser and optical system for open-path monitoring of atmospheric pollutant gases

spectrographs on balloon sondes to measure the vertical distribution of the ozone layer. In 1948 *Marcel Migeotte* (1912–1992) discovered the presence of methane in the Earth's atmosphere by its infrared absorption band in the solar spectrum [28.2].

John F. Noxon (1928–1985) used visible spectroscopy to measure stratospheric and tropospheric nitrogen dioxide NO_2 [28.3] and started in 1975 to map the latitudinal variability of NO_2 . He discovered a sharp decrease towards the Arctic, a phenomenon now called the Noxon Cliff in his honor. *Dieter Perner* (1934–2012) and *Ulrich Platt* refined the spectroscopic measurement technique towards the DOAS technique to measure OH in the atmosphere [28.4], as well as nitrous acid HNO_2 [28.5]. Since then the DOAS technique has been applied in numerous different setups, both ground-based, airborne and satellite-based (Chap. 37), to measure a variety of different trace gases.

28.2.3 Laser Spectrometer Measurement Methods

Open-path laser spectrometers were first developed in the 1970s [28.6, 7]. Figure 28.1 shows a schematic of laser and optical system for open-path monitoring of atmospheric pollutant gases with laser diode. With the widespread availability of lasers in the 1990s, open-path laser spectrometers blossomed. Methods like tunable diode laser absorption spectroscopy (TDLAS) became common because laser pricing, availability, and reliability rapidly improved (Chap. 16). Initial systems used Pb-salt lasers that required cryogenic cooling, followed by room-temperature telecommunication lasers, and now interband cascade and quantum cascade lasers.

28.2.4 Microwave Spectrometer

The measurement principles and history of MWR are described in Chaps. 29 and 41. All MWR instruments

for atmospheric remote sensing include a microwave spectrometer, which allows observations in more than one frequency channel. For the profiling of tropospheric temperature or humidity a small number of channels (3–12) with a relatively coarse frequency resolution (≈ 100 –2000 MHz) is enough. These are typically realized in the form of a discrete filter bank. The retrieval of trace gas concentration or temperature profiles in the middle atmosphere requires spectrometers with more channels and a significantly higher frequency resolution. The first ground-based and spaceborne limb-sounding MWR instruments for this altitude region were still using conventional filter bank spectrometers as described in Sect. 29.4.2. For practical reasons they have typically less than 100 individual channels with a resolution on the order of 0.1–1 MHz close to the center of the emission lines, and between 10–100 MHz on the line wings. The first ground-based microwave radiometers were all based on filter bank spectrometers, as well as many spaceborne radiometers for atmospheric measurements such as the microwave limb sounder (MLS) [28.8].

Starting in the 1980s acoustooptical spectrometers (AOS) [28.9], chirp transform spectrometers (CTS) [28.10], and auto-correlation spectrometers (ACS) [28.11] became available for atmospheric remote sensing. They provide a much higher frequency resolution with a few thousand channels over a bandwidth between 50 MHz to 1 GHz. They were widely used in ground-based microwave radiometers [28.11, 12], as well as on several space instruments such as the Swedish Odin satellite [28.13].

Today digital fast Fourier transform spectrometers (FFTS) are the preferred high-resolution spectrometers for microwave radiometry. They started to become commercially available in 2005 with 16k channels over a bandwidth of 1 GHz [28.14, 15]. In the meantime, they can provide more than two times higher resolution and bandwidth [28.16].

28.3 Theory

Remote sensing by application of spectrometers is an indirect task and the challenge is the measurement data analysis. It requires numerical simulations that are adapted to source characteristics.

28.3.1 FTIR

IR spectroscopy of gases and vapors makes use of the physical principle that these molecules exhibit characteristic spectral structures in the IR, originating from energy transitions between specific vibrational and rotational levels, and the corresponding absorption and emission of radiation. Radiation scattering occurs for both molecules and aerosols. Elastic scattering of light by molecules is called Rayleigh scattering, which may be neglected in most cases in the infrared spectral range. Aerosol scattering is wavelength-dependent for small aerosols and nearly wavelength-independent for large aerosols. This is called Mie scattering and can influence infrared radiation transfer. Inelastic scatter results in a wavelength shift between incident and scattered radiation. One type is Raman scattering with an efficiency that is proportional to the inverse fourth power of wavelength as Rayleigh scattering.

The propagation of monochromatic infrared radiation in the atmosphere and in exhaust plumes is described by the equation of radiative transfer [28.17].

In the case of homogeneous absorption measurement the radiation damping of a broadband infrared light source is used. In this case of active measurements, the incoming radiation $I_{\Delta\nu}$ in a certain spectral interval $\Delta\nu$ is given by the Bouguer–Lambert–Beer law

$$I_{\Delta\nu} = \varepsilon B_{\Delta\nu}(T_{GB})\tau_{\Delta\nu}(l), \quad (28.1)$$

where T_{GB} is the temperature of the radiation source (e.g., a globar with emissivity ε), ν the wavenumber and $B_{\Delta\nu}$ the radiation of the source as the Planck function in the spectral interval $\Delta\nu$. The term $\tau_{\Delta\nu}$ is the transmittance along the path l from the radiation source to the

detector in the spectral interval $\Delta\nu$, and so

$$\tau_{\Delta\nu}(l) = \int_{\Delta\nu} \prod_{i=1}^N e^{-k_i(\nu)n_i l} d\nu e^{-k_a(\Delta\nu)n_a l}. \quad (28.2)$$

Here k_i is the monochromatic absorption coefficient of the trace gas i , n_i the corresponding number density, N the number of trace gases, k_a the aerosol extinction coefficient, and n_a the aerosol number density.

The basic optical configuration for the emission measurements is illustrated in Fig. 28.2. The radiative transfer through an exhaust plume can be approximated as a three-layered radiative transfer problem: The radiation of the background I_B is transmitted through ambient air (transmittance τ_F and temperature T_F), the plume (τ_P , T_P) and another ambient air layer (τ_F , T_F) to the spectrometer. For those passive measurements the radiation transfer has the index $\Delta\nu$ removed

$$I = I_B \tau_P \tau_F + I_P \tau_F + I_F. \quad (28.3)$$

The plume radiation I_P is given by

$$I_P = B(T_P)(1 - \tau_P). \quad (28.4)$$

The plume as well as the foreground transmittances are calculated according to (28.2) and the foreground radiation according to (28.1), using the assumption that the foreground is a homogenous layer. Only in the case of very hot plumes such as from aircraft engines can the background radiation be neglected. Additionally, it was shown on the basis of a successive order multiple-scattering scheme that aerosol scattering and precipitation contributions to radiation are not important for the infrared spectral signatures of gases [28.18].

A radiometric calibration of the measured raw spectra to absolute radiation units is necessary for further data interpretation of emission measurements [28.19, 20]. This calibration follows the conventional procedure of recording spectra of a blackbody at different

Fig. 28.2 Setup for emission measurements. The radiation of the background I_B is transmitted through ambient air with transmittance τ_F and temperature T_F , the plume (τ_P , T_P), and another ambient air layer (τ_F , T_F) to the spectrometer

temperatures. Also, the instrumental line shape (ILS) function can be determined by measurement of absorption lines of a well-known gas. The ILS must be known for folding calculated transmittances as given in (28.2) [28.21, 22].

The retrieval of measured spectra to determine gas concentrations is performed normally by using reference spectra from a library [28.23]. More than 100 inorganic gases (i.e., HCN, HF, SF₆) and VOCs are available in these libraries. But comparing a spectrum recorded from an instrument with one from a reference database requires knowledge of the instrument's spectral resolution and other factors (e.g., detector sensitivity), all of which cause the observed spectrum to deviate from the true spectra line shape derived from a spectra database. This ILS is challenging to deduce theoretically, and spectra at high resolution are not necessarily available, such that the accuracy of these retrievals is not very high by just comparing the databases with the observed spectra.

The most common approach is to measure a set of reference spectra acquired by the same instrument. This set is then used in comparison to the observed spectra to deduce concentrations. In this way, the instrument response function is fully normalized through the collection of the reference spectra. Different algorithms for calculation of gas concentrations from measured spectra with reference spectra are applied, including classical least-squares fitting and partial least-squares fitting. One drawback of this method is the capability to acquire measured reference spectra in a carefully controlled environment (concentration, pressure, and temperature). For open-path spectrometers that sample over a range of conditions, or for highly reactive species, this may not always be readily feasible.

An alternative approach is a radiative transfer and retrieval software with algorithms based upon a line-by-line calculation procedure using a molecular spectral line database and considering the ILS function [28.20, 24–26]. Furthermore, these algorithms are necessary for the interpretation of spectra from IR spectroscopy of gas plumes with inhomogeneous temperature distribution as warm exhausts, as well as from solar absorption spectroscopy, which cannot be retrieved with reference spectra because the necessary spectra for different temperatures are not available. Commercially available, modified, or self-written line-by-line computer codes are used to derive absorption coefficients in dependence from gas concentration, temperature, and pressure [28.18, 26, 27] with molecular line parameters (position of line center, line intensity, line half width, and energy of the lowest energy transition) [28.28]. These data are then used to calculate synthetic spectra that are fitted to the measured spectra by fitting

routines or nonlinear regression algorithm. Continuum absorption by H₂O and CO₂ as well as aerosol and rain contributions should be included. In the simplest case the gas plume is considered as one homogeneous gas layer, whereas the most sophisticated models use Gaussian profiles or calculate profiles of temperatures and species from flow fields and use validated approximations to ensure fast radiative transfer calculations with maximum accuracy.

28.3.2 DOAS

The DOAS technique is another widely used spectroscopic technique for the measurement of stratospheric and tropospheric trace gases [28.3, 5, 29–31].

The DOAS technique measures the absorption of multiple trace gases. It is based on a modified version of the Bouguer–Lambert–Beer law (Sect. 28.3.1)

$$I(\lambda) = I_0(\lambda)e^{-\sum_i \sigma_i(\lambda) \text{SCD}_i} g(\lambda) \quad (28.5)$$

with the sum in the exponential running over all trace gases i , σ_i being the absorption coefficient of each gas i , λ the wavelength, c_i being the concentration of the gas i , integrating over all possible light paths l , and $g(\lambda)$ describing additional attenuation by the optical system, as well as by Rayleigh and Mie scattering in the atmosphere and all other broadband-structured influences, like the reflection on the ground. SCD _{i} (slant column density) is

$$\text{SCD}_i = \int c_i(l) dl. \quad (28.6)$$

Equation (28.5) is linearized with respect to the SCDs and $\ln g(\lambda)$ is modeled by a polynomial, allowing linear retrieval of the SCDs of the involved gases. Eventually, for uncertain wavelength mapping, or utilizing an additive polynomial modeling of other instrument characteristics, the fit becomes a nonlinear optimization. This may introduce error sources, like the undersampling effect [28.32], which have to be corrected for. For a comprehensive description of the DOAS technique see [28.33].

28.3.3 Laser Spectrometer

Laser-based spectrometers are becoming increasingly common due to the narrow spectral bandwidth of a laser (\ll line widths at atmospheric pressures), fast spectral tuning capabilities (kilohertz to megahertz), and high optical powers (one to hundreds mW). These attributes allow for high-resolution and high-sensitivity detection schemes that generally exceed those of broadband FTIR

spectrometers [28.34]. By scanning the laser at high frequencies (f , typically kilohertz to megahertz) across a narrow spectral region (e.g., on the order of an absorption line width at STP), characteristic flicker ($1/f$) noise can be reduced significantly. Improvements in optical absorption detection limits over FTIR spectrometers of one to two orders of magnitude are generally obtained. Typical optical detection limits are one part in 10^5 absorption for a one second integration period for field-based instruments. These detection levels are about an order of magnitude or two better than typical broadband FTIR-based spectrometers but are still about two orders of magnitude above the shot-noise limits of infrared detectors [28.7, 34]. Other sources of error such as optical interference fringes, temperature stabilities of the laser and detector, inhomogeneities of the atmospheric state and concentrations, and accurate measurements of state parameters across the optical path (temperature, water vapor, pressure) practically limit field-based observations to this one in 10^5 level. Indeed, these significant, real-world field issues distinguish this chapter of laser spectrometers in open-path configurations from those described previously in Chap. 16. Because the techniques themselves for closed-path (i.e., one containing a sampling cell) laser spectroscopy are identical, the governing equations will not be repeated in this chapter but instead focus on challenges for laser spectrometers in the atmosphere.

28.4 Devices and Systems

The relevant characteristics of devices and systems will be shown.

28.4.1 FTIR

To detect trace gases in the near-surface atmosphere and exhausts, the minimum required spectral resolution is 0.2 cm^{-1} due to the line width of the absorption lines in the lower atmosphere and the spectral range is $600\text{--}4500\text{ cm}^{-1}$. To obtain high sensitivity, detectors made from mercury cadmium telluride and indium gallium arsenide must be used, which are cooled by liquid nitrogen, gaseous nitrogen via the Joule–Thomson effect or Stirling coolers.

A spectrometer with telescope is necessary to receive radiation from a source or exhaust plume (distances up to 500 m) or on long open paths (50 up to 1000 m) [28.18]. The diameter of exhaust plumes is determined from the inner diameter of the smoke stack or another exit of the plume release. For that reason and to avoid high optical thickness due to water condensation

28.3.4 Microwave Spectrometer

The physical principles of microwave radiative transfer are described in Chaps. 29 and 41. The combination of a microwave radiometer with a high-resolution spectrometer allows to resolve the line shape of pressure-broadened emission lines. Using the optimal estimation method or other inversion techniques it is possible to derive from the line shape vertical profiles of trace gas concentrations in the middle atmosphere.

The altitude range over which vertical profiles can be retrieved from ground-based measurements depends on different factors. The total bandwidth of the spectrometer must be wider than the line width at the lowest pressure level of interest. The frequency resolution of the spectrometer needs to be small enough to resolve the line center at the highest altitudes. The maximum altitude is also fundamentally limited by the thermal Doppler broadening of the emission lines. Above a certain pressure level, it exceeds the pressure broadening and prevents the retrieval of vertical profiles above that altitude. The Doppler broadening increases with the frequency, and for that reason emission lines at lower frequencies allow retrievals at higher altitudes. This limitation does not exist for limb-sounding observations from a satellite platform, where the vertical information is obtained by pointing the antenna to different tangent heights (Sect. 41.4.3).

in the exhaust plume, the field-of-view of the telescope is orientated near the top of the smoke stack, the nozzle exits of a turbine, or the top of the flame of a flare by use of a tracking mirror (Fig. 28.2) [28.35].

The spectrometers can be coupled with a White cell or multipass-reflection mirror system of up to several 100 m absorption path length for the investigation of trace gases.

The vertical distribution of trace gases can be retrieved from the shape of solar absorption lines by using software [28.36, 37] (Chap. 63) to analyze atmospheric multilayer problems (solar absorption) with input files for pressure–temperature, volume mixing ratios, and optical path parameters.

28.4.2 DOAS

There are many different configurations for DOAS instruments ranging from active DOAS instruments with their own light source to passive instruments sampling the sky or scanning the Earth from space.

Fig. 28.3a–c Schematic diagram of the experimental setup of the (a) long-path DOAS, (b) cavity-enhanced DOAS, and (c) multi-axis DOAS instrument

A long-path DOAS (LP-DOAS, see Fig. 28.3a) instrument has a light source that sends out a light beam using a telescope. A xenon-arc lamp used to be very popular as a light source, covering the ultraviolet and visible spectral range. However, in recent years LEDs have become powerful enough, at least in the limited spectral range used for a DOAS fit, to be useful for DOAS measurements. Another recent DOAS innovation is the use of y-fibers instead of mirrors to send the

signal from the light source to the telescope and then the reflected signal to the spectrometer. A shutter in front of the y-fiber is used to measure the lamp spectrum (I_0 in (28.5)).

Another active DOAS-type instrument that has recently been developed is the cavity-enhanced DOAS (CE-DOAS, see Fig. 28.3b), which is a cavity-assisted device to provide long absorption paths necessary for the detection of ambient atmospheric trace gases by

multiple reflections in a small optical resonator composed of two highly reflective concave mirrors between a concentric and confocal setup [28.38–40]. Using this technique in combination with a continuous light source allows applying the DOAS retrieval method to in-situ measurements [28.41, 42].

A passive DOAS method using sunlight as the light source is the multi-axis DOAS (MAX-DOAS, see Fig. 28.3c) measurement technique introduced by [28.43]. The authors in [28.44] showed that this technique represents a significant advance on the well-established zenith scattered sunlight DOAS technique, which is mainly sensitive to stratospheric absorbers. Ground-based MAX-DOAS, however, is highly sensitive to absorbers in the lowest few kilometers of the atmosphere and vertical profile information can be retrieved by combining the measurements with radiative transfer model calculations. Those calculations depend on aerosol parameters and [28.45] showed how DOAS retrievals of the oxygen dimer O_4 can be used to derive the needed vertical aerosol profile information. However, most inversion scenarios consist of an underdetermined system; therefore, regularization techniques which are typically based on a priori profile information are needed.

The MAX-DOAS has become a widely and successfully used technique for the remote sensing of tropospheric trace gases and aerosols, e.g., by [28.45–52].

Typical MAX-DOAS observations are performed at fixed locations, which allow retrieving the diurnal variation of tropospheric species at that location, but MAX-DOAS measurements can also be made on mobile platforms like aircrafts [28.53], ships [28.54], or cars [28.55, 56].

28.4.3 Laser Spectrometer

Depending upon the application, common lasers used in open-path spectrometers include near-IR telecommunication lasers, vertical cavity surface emitting lasers (VCSELs), antimonide (Sb) lasers, interband cascade lasers (ICLs), and quantum cascade lasers (QCLs). Telecommunication lasers are readily fiberized (for cases where the laser is not located at the point of sampling location), relatively inexpensive, and have mature optical technologies associated with them. Their downside is the fairly weak linestrengths that can be probed in the near infrared spectral region. VCSELs have large current tuning ranges (15 cm^{-1}) for multiple absorption lines to be probed and consume lower power (e.g., lower-power applications), but their low optical power ($\approx 1\text{ mW}$) and narrow wavelength ranges ($< 3\text{ }\mu\text{m}$) limit their widespread field use. Anti-

monide lasers probe the $2\text{--}4\text{ }\mu\text{m}$ region not accessible by telecommunication lasers but still near the lower limit of the cascade lasers. For highest sensitivity, probing the mid-infrared spectral region is critical, and advances in interband cascade ($3\text{--}6\text{ }\mu\text{m}$) and quantum cascade lasers ($> 4\text{ }\mu\text{m}$) have allowed sampling of trace gases at unprecedented sensitivities. Interband cascade lasers consume lower power ($< 1\text{ W}$) than quantum cascade lasers (with lower but sufficient optical power generally in the milliwatt range), but their spectral range is still limited at the higher end. Quantum cascade lasers probe the fundamental rovibrational bands of trace gas species and also have high optical powers ($> 100\text{ mW}$). The downsides of ICLs and QCLs are the less mature optical technologies (packaging, lenses, coatings, fibers) for the mid-infrared spectral region compared to the near-infrared lasers. Advances in the optical efficiencies (power consumption versus optical power), tuning rates, and wavelength ranges continue for both ICLs and QCLs, in particular.

Direct absorption spectroscopy (DAS) is often employed for laser spectrometers. At fast sweep rates ($> \text{kilohertz}$), laser excess noise can achieve detection sensitivities in the 10^{-4} range [28.57]. DAS is particularly advantageous because if laser/detector systems are well characterized, a direct and accurate measurement of concentration can be derived from the Bouguer–Lambert–Beer law based upon first principles of spectroscopy. In contrast, modulation techniques such as wavelength modulation (WMS) and frequency modulation (FMS) employ a rapid (tens of kilohertz to megahertz) modulation of the laser frequency while scanning across a selected absorption feature at slower rates (kilohertz) [28.58]. The detector signal is demodulated at different harmonics of the modulation frequency to yield much better detection sensitivities over DAS by about an order of magnitude. The drawback of WMS and FMS systems are that they often require calibrations in field environments as tracing back to first principles of spectroscopy employs more difficult to characterize transfer functions.

Optical cells include single path lengths (laser shining to a detector), a retroreflector/mirror arrangement (laser to mirror back to the instrument), perimeter monitoring with a configuration of mirrors, and in-situ sensors with folder optical cavities (e.g., White cells, Herriott cells, astigmatic cells) [28.59–61]. Because in all cases, at least some components of the optical system are always exposed to the environment, the optical qualities of those surfaces are of primary concern (e.g., cleanliness, alignment) and can introduce deleterious measurement artefacts (e.g., increased noise from low signal on the detector due to degraded optics, drifting in calibration due to optical fringing).

Finally, because laser spectrometers are exposed to the changing atmospheric environments, care must be taken to ensure that other influences on the spectroscopy are well characterized. For example, measurements of greenhouse gases such as methane or carbon dioxide require a precision and accuracy of one part in 1000 which is desirable in many cases. While open-path laser spectrometers often exceed the precision metric, other factors will influence the overall accuracy. First, one needs to ensure that calibrations taken in the laboratory and field conditions accurately represent the instrument at all other conditions. Allan variance plots [28.62, 63] may show a system is stable in the laboratory up to a certain length of time, but the same system outdoors may not show the same level of stability due to changes in temperature on electronic components, laser and detector temperature control, and optical alignment issues (e.g., fringes).

Even if the system characteristics remain stable, one needs to consider changing environmental conditions during a measurement. A change of one degree in temperature at ambient conditions will change the retrieved concentrations by about one part in 300 simply because of the ideal gas law. Dilution effects such as changes in water vapor also need to be included (e.g., H₂O mole fraction change from 1% to 1.5% also changes the retrieved concentrations by 0.5%). Spectroscopic effects from water vapor broadening, linestrength temperature dependences, and line shapes from pressure also need to be considered. Even with accurate measurements of these state parameters, it is necessary to know how representative such measurements are over the path-integrated domain of the laser spectrometer (e.g., one measurement over a 500 m path length may or may not be representative). Finally, there are few truly isolated absorption features in the atmosphere that are not influenced by other trace gases, and these effects need to be accounted for, not just under typical conditions but also more extreme cases (e.g., very polluted, atypical temperatures, high humidity, etc.). In summary, to achieve high stability and precision for open-path laser spectrometers, great attention to system performance and environment variables is needed over the wide range of environmental conditions in which one samples.

28.4.4 Microwave Spectrometer

The basic setup of a microwave radiometer with a single channel or a filter bank spectrometer is described in

Sect. 29.4.2. In an acoustooptical spectrometer (AOS) a piezoelectric transducer converts the radio frequency signal into a sound wave propagating in an optical crystal. This leads to a spatial variation of the refractive index with a periodicity that is given by the radio frequency. A collimated laser beam that illuminates this Bragg cell is diffracted by the resulting phase grating. The intensity distribution of the diffracted light is observed with a linear charge-coupled device (CCD) detector array and represents the microwave spectrum.

A chirp transform spectrometer (CTS) multiplies the radio frequency signal with a chirped waveform. The down-converted signal is compressed by a second chirp filter with matching slope, which converts each Fourier component of the incoming signal to a pulse in the time domain. The complete spectrum can be sampled directly by an analog digital converter (ADC) without the need for further digital signal processing. The chirp filters are usually realized with surface acoustic wave devices.

In a digital FFT spectrometer the radio frequency signal is sampled directly with an ADC. The data stream is processed in real-time with a discrete FFT algorithm implemented on a field programmable gate array (FPGA) processor. A standard FFT without apodization window results in a channel response of $|\sin(x)/x|^2$. The channel selectivity can be improved by applying different window functions to the waveform, but this leads to a loss of resolution and sensitivity. Modern digital spectrometers use a polyphase filter-bank (PFB) algorithm instead of the FFT. This requires more computational resources, but results in an almost ideal top-hat channel response with a much smaller spectral leakage and without loss of sensitivity.

The main advantages of the digital spectrometers compared to AOS or CTS are the higher frequency resolution, the improved stability, as well as the uniform and well-defined channel response. In addition, they are readily available since they are based on commercial off-the-shelf hardware.

28.4.5 Comparison of Methods

The advantages and disadvantages of the different methods are described in Table 28.4. This refers to typical applications of the extractive and open-path spectrometer techniques.

Table 28.4 Advantages and disadvantages of the different methods

Devices	Advantages	Disadvantages
Active FTIR	Detection of the relevant gas concentrations for atmospheric radiation budget and for air pollution	No required measurement quality (signal typically too small) to derive relevant aerosol parameters
Passive FTIR	Detection of gas concentrations and temperature	Higher detection limit of concentrations than active FTIR (up to a factor of 10)
Active DOAS	Detection of the relevant gas concentrations for air pollution	No significant spectral features for detection of gases relevant for atmospheric radiation budget like N ₂ O
Passive DOAS	Vertical profiling of gas concentrations	Higher detection limits than active DOAS, limited to daytime measurements as sunlight is used
Laser spectrometer	Better detection limits than FTIR and DOAS	Laser system characteristics must be known very precisely and with high stability. Generally limited to a few spectral features and so one or a few compounds per sensor
Passive microwave spectrometer	Vertical profiles of gas concentrations and temperature, independent of sunlight, not affected by clouds or fog	Only molecules with a dipole moment can be observed (e.g., H ₂ O, O ₃ , ClO, HCl)

28.5 Specifications

The use of gas cells for quality assurance and quality control (QA/QC) is required according to the German or US Environmental Protection Agency (EPA) guideline for FTIR absorption spectroscopy [28.64, 65] and DOAS [28.66] (Chaps. 3 and 4). Also, the relationship to well-known conventional air pollution monitoring stations in networks and to laboratory analysis by gas-chromatography and NDIR instruments of canister sampling along the open-path measurement were investigated [28.18]. The retrieval results from ambient air measurements were compared also with experimental setups of a White cell and calibration gases using a FTIR spectrometer or DOAS (Table 28.5). Furthermore, the passive measurement method was evaluated with in-situ measuring methods (continuous emission

monitoring) in smoke stacks, experiments with gas burner, and laboratory analysis of exhausts [28.27, 67]. The temperature and pressure dependences of spectral lines or features are also considered in these QA/QC studies.

The specifications of different measurement methods for gas and aerosol concentrations and atmospheric temperature under real-world conditions, including error, concentration range, and temperature range, are given in Table 28.5 (provided by producers and in papers). Under ideal conditions, all methods can produce lower uncertainties than stated in the table. The errors of laser spectrometers are for instance limited by the ability to precisely control laser and detector temperatures.

Table 28.5 Typical specification of different measurement methods for gas and aerosol concentrations and temperature

Method	Error ^a in %	Range of concentration detection	Range of atmospheric temperature detection
Active FTIR	± 5	ppb up to vol%	Ambient up to 1300 K (corresponding to HITEMP ^b)
Passive FTIR	± 20	ppb up to vol%	Ambient up to 1300 K (corresponding to HITEMP ^b)
Active DOAS	± 5	ppt up to vol%	Not
Passive DOAS	± 20	ppb up to vol%	Not
Laser spectrometer	± 5	ppt up to vol%	Ambient up to 1300 K (corresponding to HITEMP ^b)
Passive microwave spectrometer	± 5–30	ppt up to ppm	Ambient

^a Total accuracy dominated by the limitations in trueness not precision. ^b <https://hitran.org/hitemp/>, Accessed 13 July 2021

28.6 Quality Control

Quality control is an important measurement, and so the relevant international guidelines are cited. The methods change depending on the technical development of devices and systems.

28.6.1 Quality Control Principles

A well-characterized ILS is a prerequisite for accurate results of FTIR retrieval algorithms [28.22] because the instrument cannot be perfectly aligned or the ILS is degraded by aberrations. This is realized by insertion of a short-path gas cell into the optical path in front of the interferometer. The experimental setup for measurements of absorption spectra includes a thermal radiation source, the gas cell filled with, e.g., CO at ambient air temperature, and the interferometer. Using this setup, the cell measurement provides gas absorption spectra with the current status of the interferometer. It is not necessary for the retrieval of the ILS to open the spectrometer. A software module includes the model for the inherent apparatus function and the fitting algorithm on the basis of the measured spectra with the gas cell to determine the real ILS of the spectrometer.

For most DOAS systems, no classical calibration is needed, since the cross sections of the molecules

only have to be measured once (which has the role of the basic calibration here) and the ILS as the second part of the procedure can be determined correctly. Neglecting classical calibration is possible if the absorption coefficient of each component for the selected wavelengths, the ILS, and the length of the monitoring path are known (as for FTIR, see above). The differential absorption technique, applied for all retrieval algorithms of spectrometers, provides the advantage that all instrumental effects depending on changes in the environment or aging of the instrument, as well as the background influence, will be modeled by the broadband fit function and therefore taken out of the equation. The only exception is the CE-DOAS because the retrieval results are influenced by the effective length of the measurement path generated in the cavity, which depend on the reflectivity and alignment of the mirrors, so that the output of the cavity does not follow the Bouguer–Lambert–Beer law directly as it is a mixture of different path lengths. Although, the DOAS fitting technique may be identical under certain conditions to the other DOAS instruments. Since all the aerosols are filtered out of the incoming air, the effective path length without absorbers can be determined using clean air and helium as two reference gases with different Rayleigh scattering coefficients [28.68].

Table 28.6 Typical test criteria

Method	Error	Reason/Action
Active FTIR	Too low radiation intensity or too high signal noise	Misalignment/adjustment of instrument radiation throughput and ILS determination
Passive FTIR	Too low radiation intensity or too high signal noise	Misalignment of optics/adjustment of instrument radiation throughput and ILS determination
Active DOAS	No convergence in the DOAS fit	Too high SNR or interfering spectral structures by the optical components/adjustment of instrument radiation throughput and ILS determination
Passive DOAS	No convergence in the inversion scheme	Inadequate a priori profile used for the regularization/selection of adequate a priori profile
Laser spectrometer	Degraded accuracy from the calibration condition	Changes in temperature, pressure, water vapor, or other trace gases not representative of calibration conditions; drifting due to changes in the magnitude and phase of optical interference fringes from alignment or scattering of beam/calibration under real conditions
	Degraded precision	Low light due to misalignment of optics or degraded optical surfaces/adjustment of instrument radiation throughput and ILS determination
Microwave spectrometer	Degraded precision	Degradation of microwave components in the radiometer or contamination of windows or reflectors/replace defective parts or cleaning
	Degraded accuracy	Baseline errors on the calibrated spectra and fit residuals, mostly caused by reflections on the blackbody calibration targets/improve calibration targets

For laser spectrometers, because the ambient environment changes, the metrics of instrument noise, precision, and calibration are often obtained through a separate optical channel where a beam splitter sends part of the signal to the sample path and a small fraction to a separate reference channel. The reference channel may contain an equivalent absorption signal as that expected in the sample environment or be replaced with a similar optical path length as the sample path length through a multipass optical cell. Similar procedures are noted as above, which use gas cells and calibration standards. For long-path measurements, care must be taken to ensure that the introduction of a cell or separate optical path has the same optical characteristics (e.g., fringing) as the long path in the field. Allan deviation

experiments [28.62, 63] are often conducted in the laboratory under controlled environments to identify noise and system drift, but the same controlled conditions in the laboratory are rarely duplicated in the outdoor field environment and extrapolating them to field environments are often not representative.

28.6.2 Quality Control Procedures

Table 28.6 gives some sensor-specific criteria that may be applied in quality control procedures (Chap. 3). If the reason for invalid data can be determined and rectified, then a corresponding troubleshooting action is required, and if not, the sensor and measurement setup should be checked.

28.7 Maintenance

The maintenance tasks for spectrometers are given in Table 28.7.

Table 28.7 Maintenance of spectrometers

Maximum interval	Active FTIR	Passive FTIR/MW spectrometer	Active DOAS	Passive DOAS	Laser spectrometer
Every measurement	Check of all internal parameters like wavelength, radiation intensity. Plausibility check of key compounds depending on the spectrometer type like CO ₂ , CH ₄ , N ₂ O, NO ₂ or water vapor. Effective path-length calibration has to be performed before and after every measurement campaign				
	If required from techniques – internal optical adjustment	Radiometric calibration	Wavelength calibration using reference lines is only necessary if there is a large deviation, smaller uncertainties can be corrected during the fit	Wavelength calibration using reference lines is only necessary if there is a large deviation, smaller uncertainties can be corrected during the fit	Optical light reaching the detector needs to be sufficient to achieve desired signal-to-noise
Every measurement campaign	Check of optical windows and mirrors for dirt or damage – cleaning if necessary				Calibrations prior to, during, and after the campaign to identify potential changes in system performance
	Determination of ILS				
1 year	Check of all hygroscopic components				

28.8 Applications

The applications of spectrometers for remote sensing tasks are very broad; therefore, only a few applications are presented and these are the most typical.

28.8.1 Measurement of Gas Concentrations and Emissions by FTIR

FTIR spectrometers are used to determine the chemical composition of the atmosphere, exhausts, and gas releases by active absorption measurements, i.e., by means of a global on open paths. The chemical composition and temperature of the atmosphere, exhausts, and gas releases are determined by passive measurements also using natural light sources (e.g., the Sun) as well as via emission spectroscopy using temperature differences in the atmosphere, exhausts, or atmospheric radiation.

FTIR spectroscopy works for different weather conditions with the exception of fog, strong rain, or snow fall not influenced by turbulence.

The emission source strengths of (1) diffuse sources (industry, traffic, agriculture, waste disposals) and of (2) remote sources (smoke stacks, aircraft engines, flares, fires, volcanoes, mobile sources) are difficult to determine by single in-situ measurements. Remote sensing methods are necessary to quantify emission source strengths without any contact to the source. To determine emission source strengths of diffuse sources, inverse dispersion modeling is adapted to this objective [28.69–71]. The emission indices of compounds in aircraft engine exhausts are calculated with the simultaneously measured CO₂ concentration by stoichiometric calculation of total kerosene combustion [28.20].

Solar absorption spectrometry is not only applied for long-term observation of atmospheric composition in international networks [28.36, 37], but for the determination of diffuse emission source strengths as well [28.72–74]. Measurements of profiles are often validated by aircraft-based measurements through much of the column [28.75].

28.8.2 Measurement of Gas Concentrations and Emissions by DOAS

There are numerous applications of the DOAS techniques for the measurement of trace gas concentrations, ranging from satellite-based monitoring of the Earth over ground-based remote sensing stations to mobile in-situ measurements. The first satellite instrument using the DOAS retrieval was the Global Ozone Monitoring Experiment (GOME) [28.31] on the ESA remote sensing satellite ERS-2, mapping the global

distribution of O₃, NO₂, SO₂, BrO, OClO and H₂O since 1996. Several successor satellite instruments have been launched into space since then: Scanning Imaging Absorption Spectrometer for Atmospheric Cartography (SCIAMACHY) [28.76], GOME-2 [28.77], Ozone Monitoring Instrument (OMI) [28.78] and TROPospheric Monitoring Instrument (TROPOMI) [28.79] to name a few. Those instruments use scattered sunlight that has been traversing the Earth's atmosphere and the DOAS retrieval described in Sect. 28.3.2. DOAS derives the SCDs, which is an ensemble mean of the path distribution. In order to obtain a more comparable quantity that is independent from the viewing direction and solar zenith angle (SZA), the air mass factor (AMF) concept [28.80] is applied to convert the SCDs into vertical column densities (VCDs) or path-integrated mass concentration. This conversion requires the calculation of box air mass factors, which is the sensitivity of the measurement to the different layers, using radiative transfer simulations and additionally a profile shape of the trace gas under investigation. Those are typically taken from chemical transport model simulations. The AMF calculation is the main error source of satellite derived VCDs in addition to the DOAS fit error.

MAX-DOAS instruments are ideal for satellite validation, since they not only provide column measurements, but profile information as well, so that the main retrieval error cancels out in the comparison.

In order to study emission sources, top-down emission inventories of various trace gases can be produced by inverting chemical transport simulations. Common inversion techniques make use of adjoint models or the 4D-Var method [28.81]. Also, individual sources can be analyzed using inverse transport modeling, for example to estimate vertical profiles from SO₂ emissions from volcanic eruptions [28.82]. Ground-based DOAS measurements can be used for source estimation as well, e.g., when a MAX-DOAS instrument is mounted on a car for column measurements around a city, the total emissions of the encircled course can be determined in combination with information on wind speed and direction [28.55].

28.8.3 Measurement of Gas Concentrations and Emissions by Laser Spectrometers

Open-path laser spectrometers are widely used in field environments. Aircraft-based measurements of water using near-IR lasers [28.57, 83–85] have been made routinely for over a decade. Open-path measurements of methane (using a 1.65 μm VCSEL for

low-power applications) [28.86] and ammonia (9.06 μm QCL) [28.87] have been conducted for eddy covariance fluxes, where small changes in concentrations are correlated with high-frequency (10 Hz) updrafts and downdrafts. Long-path measurements and perimeter monitoring using telecommunication lasers and QCLs [28.88] are also common. Methane emission rates from landfills were estimated using open-path TDL measurements combined with dispersion models [28.89]. Volcanic emission investigations and flux determinations of volcanic gases were performed by TDL measurements in different configurations [28.90–93]. Mobile measurements with open-path sensors avoid power-hungry pumps and can be mounted on common passenger vehicles, avoiding expensive generators and custom vehicles [28.94]. Finally, drone-based sensors for methane show great potential in detecting methane emissions [28.95, 96].

28.8.4 Measurement of Gas Concentrations, Temperature and Wind by Microwave Spectrometers

The international Network for the Detection of Atmospheric Composition Change (NDACC) [28.97] includes more than 18 globally distributed microwave spectrom-

eters. They provide long-term measurements of vertical trace gas profiles in the stratosphere and mesosphere. This includes H_2O observed around 22 GHz [28.98], O_3 observed at either 110 or 142 GHz [28.99], as well as ClO around 278 GHz [28.100].

Measurements of the Doppler shift of ozone emission lines allow to derive profiles of horizontal winds in the upper stratosphere and lower mesosphere [28.101]. This is the only measurement technique that can provide continuous wind measurements at these altitudes. Another application for high-resolution microwave spectrometers is to resolve the weak emission lines of stratospheric oxygen on the wing of the saturated oxygen absorption band around 60 GHz. These are used to retrieve temperature profiles in the stratosphere [28.102].

The ground-based microwave radiometers described above can operate nearly continuously and under most weather conditions. This includes clouds, fog, and light rain, where optical and IR instruments will fail. They provide information on trace gas concentrations and dynamic processes on diurnal to multidecadal timescales that are relevant for different applications. This includes the validation of satellite observations or model predictions, as well as long term trend studies of the atmospheric composition.

28.9 Future Developments

Further developments include the determination of spectroscopic parameters or absorption cross sections of more atmospheric compounds so that the detection of these compounds in the atmosphere becomes possible. Also, miniaturization of spectrometers is under development so that smaller, lighter and cheaper instruments will be available [28.103].

For laser spectrometers, new advances in optical detection technologies offer new applications in trace gas detection. For example, frequency combs are now being demonstrated in field environments for methane detection at long distances [28.104], and chirped laser dispersion spectroscopy [28.105] also shows promise for high linearity over a wide range

of returned (backscattered) light. Optical heterodyne methods with a quantum cascade laser to derive vertical profiles from sunlight also show great promise for ground-based measurements [28.106]. Finally, laser-based measurements of line shapes to derive atmospheric pressure have also been accomplished on aircraft [28.107].

Newest application of FTIR is an unattended detection of gas releases or leakages from kilometers away by imaging spectroscopy [28.108–110] which has the potential of early warning prior to hazardous incidences. Chemical composition of gas clouds can be determined including retrieval algorithms of passively measured thermal emission spectra.

28.10 Further Readings

A thorough introduction into the history and physics of DOAS can be found in:

- U. Platt, J. Stutz: Differential Optical Absorption Spectroscopy – Principles and Application, first ed. (Springer, Heidelberg, Germany 2008).

A comprehensive review of the diverse sensors, applications and maintenance of FTIR and DOAS is given in

- EN: Luftqualität – Messungen in der bodennahen Atmosphäre mit FTIR-Spektroskopie (Air quality –

Atmospheric measurements near ground with FTIR spectroscopy), EN 15483:2008, DIN EN 15483, (European Committee for Standardization, Brussels November 2008).

- EN: Luftqualität – Messungen in der bodennahen Atmosphäre mit aktiver Differentieller Optischer Absorptionsspektroskopie (DOAS) – Immissionsmessungen und Messungen von diffusen Emissionen (Air quality – Atmospheric measurements near ground with active Differential Optical Absorption Spectroscopy (DOAS) – Ambient air and diffuse emission measurements), EN 16253:2013, DIN EN 16253, (European Committee for Standardization, Brussels July 2013).
- VDI: Fernmessverfahren. Messungen in der Atmosphäre nach dem Passiv-FTIR-Prinzip. Messen gasförmiger Emissionen und Immissionen (Remote sensing – Atmospheric measurements using passive FTIR spectroscopy – Emission and ambient air measurements), VDI 4211, (Verein Deutscher Ingenieure, Düsseldorf November 2018).

Klaus Schäfer

Atmospheric Physics Consultant
Garmisch-Partenkirchen, Germany
schaefer@atmosphericphysics.de

Klaus Schäfer is a Professor at Atmospheric Science College of the Chengdu University of Information Technology, China since 2016. He retired from the Karlsruhe Institute of Technology, Institute of Meteorology and Climate Research, Atmospheric Environmental Research in Garmisch-Partenkirchen on 03/2016. In 1988 he became Professor of atmospheric physics at the Academy of Sciences of GDR in Berlin. Research interests are air quality studies by remote sensing and in-situ.

Mark Wenig

Department of Physics, Meteorological
Institute Munich
Ludwig-Maximilians-University Munich
Munich, Germany
mark.wenig@lmu.de

Mark Wenig is a Professor at the Ludwig-Maximilians-University Munich, Germany. His research interests are on remote sensing of air pollutants with the aim to further the understanding of the anthropogenic impact on the environment, especially the climate system and the atmospheric composition. He attended the University of Heidelberg for his studies, where he received his PhD degree in environmental physics focusing on satellite retrieval algorithms to determine the global distribution of atmospheric pollutants. He continued to work with space-born spectroscopic measurement techniques at the NASA Goddard Space Flight Center. When he took up a professorship at City University of Hong Kong, he broadened his research area and developed different ground-based instrumental setups to analyze urban air quality.

Mark A. Zondlo

Civil and Environmental Engineering
Princeton University
Princeton, USA
mzondlo@princeton.edu

Mark A. Zondlo is an Associate Professor of Civil and Environmental Engineering at Princeton University. He leads the Atmospheric Chemistry and Composition Group that focuses on optical measurements of trace gases important to climate change and air quality. Zondlo received a B.A. in chemistry from Rice University (1994), a Ph.D. in physical and atmospheric chemistry from the University of Colorado (1999), and was an Advanced Study Program Postdoctoral Fellow at the National Center for Atmospheric Research from 1999–2002. Before joining the Princeton faculty in 2008, he was a Senior Research Scientist at Southwest Sciences, Inc., where he developed new laser-based instrumentation for the atmospheric sciences.

Axel Murk

Institute of Applied Physics
University of Bern
Bern, Switzerland
axel.murk@iap.unibe.ch

Axel Murk is leading the Microwave Physics Division at the Institute of Applied-Physics at the University of Bern. He received a PhD in Physics from the University of Bern in 1999, and a MSc in Physics from Technical University of Munich. His research interests include remote sensing of the atmosphere using ground-based or space-born microwave radiometers.

Konradin Weber

Laboratory for Environmental
Measurement Techniques
Duesseldorf University of Applied Sciences
Duesseldorf, Germany
konradin.weber@hs-duesseldorf.de

Konradin Weber is a Professor at the University of Applied Sciences (HSD) in Duesseldorf. He leads the Laboratory for Environmental Measurement Techniques at HSD. He got his PhD degree in Physics 1988 at the University of Marburg. He is involved since many years in atmospheric research of air pollutants in the troposphere, especially using different optical remote sensing techniques with application of FTIR, DOAS and TDL-based instruments. Recently he expanded his research to mobile measurements of air pollutants using light aircraft, measurement cars and measurement drones.

29. Passive Solar and Microwave Spectral Radiometers

Susanne Crewell , Manfred Wendisch , Ulrich Löhnert 

Radiation sensors operating from the ultraviolet to the microwave spectral range are widely used for passive remote sensing of a large variety of atmospheric properties (gases, aerosol particles, clouds). In general, radiometers measure radiant energy (in physical units of joule). The different types of radiometers are defined by instrument specifications, such as detector area, opening solid angle, spectral bandpass, and integration time. Remote-sensing techniques commonly make use of special spectral features to infer atmospheric parameters, which can be deduced from spectrally resolved measurements at a limited number of wavelengths. Here, we introduce two typical groups of passive remote-sensing instruments, which are frequently applied to retrieve aerosol parameters (sun photometers) and thermodynamic profiles, as well as liquid water paths (microwave radiometers). Sun photometers and microwave radiometers measure spectral radiances in the ultraviolet, the visible to near-infrared (photometer), and the microwave spectral ranges, respectively. Sun photometers detect spectral radiation in about 5–15 wavelength channels in different geometries (direct sun direction, zenith, nadir, fixed values of zenith distance or azimuth angle), from which the aerosol optical depth is derived, and further properties of the aerosol particle ensemble (such as size distribution, single scattering albedo, scattering phase function, index of refraction), as well as precipitable water vapor (or other path-integrated gas species) are derived. Microwave radiometers (also called microwave profilers) with several spectral channels along water vapor and oxygen emission features at frequencies < 100 GHz allow the retrieval of air temperature and humidity profiles with coarse vertical resolution. Both instruments, sun photometers and microwave radiometers, also provide information on the microphysical properties of clouds by either using spectral extinction (sun photometer) or the emission by cloud droplets

(microwave radiometer). The sun photometer is the standard instrument to measure aerosol optical depth, and the microwave radiometer is the most suitable device to observe the liquid water path of clouds. An advantage of these passive sensors is their simple operation, which requires only little maintenance and a low power supply, which makes them well suited for continuous network operation from the ground but also on research aircraft.

From the early days of the development of useful satellite-based remote-sensing observations in the 1960s, radiometers have been the backbone for Earth observations. Imaging radiometers operating from ultraviolet (UV) to microwave (MW) spectral ranges provide comprehensive information on the state of the atmosphere, including aerosol particle size distribution and microphysical characteristics, cloud optical and microphysical properties, as well as water vapor and temperature profiles. This chapter is dedicated to radiometers and the associated techniques used for remote sensing of the above-mentioned parameters and is not concerned with broadband radiation measurements (Chap. 12 *Radiation Sensors*). Only instruments

with a limited number of spectral bandpass filters are dealt with here, in contrast to spectrometers, which employ a large number of channels over a given wavelength band with high spectral resolution (Chap. 28 *Spectrometers*). Furthermore, this chapter focusses on instrumentation operated on the ground, while later chapters deal with radiation measurements from aircraft and satellites (Chap. 37 *Solar Radiation Sensors*, Chap. 39 *Microwave Radiometry*, and Chap. 42 *Imaging Techniques*).

Two examples are discussed in detail: sun photometers and microwave radiometers (MWRs). These instruments are easy to handle and suitable for long-term monitoring within larger observational networks.

29.1 Measurement Principles and Parameters

Solar spectral radiation measurements offer plenty of information on atmospheric constituents, such as gas concentrations (e.g., water vapor), or aerosol particles, and cloud properties. Sun photometers are a widespread instrument type to derive, in particular, aerosol properties. Different observation geometries of sun photometers include direct sun (looking into the direction of the sun for optical depth retrieval), as well as almucantar (keeping the zenith angle constant during observations) and principal plane (constant azimuth angle) constellations (for retrievals of aerosol particle size distribution, refractive index, shape of particles). Sun photometers are widely used in global networks, for example in the Aerosol Robotic Network (AERONET) [29.1], the Japanese SKYNET [29.2], or the Sun/sky-radiometer Observation Network (SONET) in China. Recently, polarization measurements were added to the sun photometer measurement program. The Global Atmosphere Watch–Precision Filter Radiometer (GAW-PFR) network was started in 1999; it conducts long-term aerosol optical depth (AOD) measurements at remote background sites. In 2015, in Germany (Lindenberg) AERONET photometers were modified to observe aerosol optical depth at night on an automatic and quasi continuous basis.

Ground-based MWRs measure atmospheric thermal emission by gases and hydrometeors, allowing the retrieval of air temperature and trace gas profiles, as well as the amount of liquid water in clouds. These measurements are useful in a variety of environmental and engineering applications, including meteorological observations and weather forecasting, communications, astronomy, radio-astronomy, geodesy and long-baseline interferometry, satellite validation, climate changes, air–sea interaction, and fundamental molecular physics.

Here, we focus on ground-based MWRs for deriving tropospheric air temperature and humidity profiles, and clouds, which, similarly to the sun photometers, become organized in networks, e.g., the microwave radiometer network (MWRnet) [29.3].

29.1.1 Measured Parameters

Sun photometers and MWRs measure spectral radiances in physical units of $\text{W m}^{-2} \text{sr}^{-1}$ per wavelength or per frequency/wavenumber unit. Sun photometers typically employ wavelength channels from the ultraviolet (340 nm) to the solar near-infrared (2000 nm) spectral ranges. In the microwave spectral range with wavelengths between 1 mm and 1 m (corresponding to frequencies of 0.3–300 GHz), the spectral location is typically given in terms of frequency. The measured radiances result either from the solar emission and subsequent scattering/absorption events within the atmosphere (sun photometer) or from thermal emission by atmospheric and surface constituents. Radiances measured by the sun photometer are calibrated either using reference standards (provided by accepted standards from, e.g., the National Institute for Standards and Technology) or by applying the so-called Langley plot method (Sect. 29.6.1). MWRs are calibrated to brightness temperatures (T_B in kelvin) using *Planck's law* (Table 29.1, (29.3)), which allows a direct conversion from spectral radiance to an equivalent brightness temperature T_B . Note, that the same nomenclature is used for infrared radiometers operating in the atmospheric window $\approx 10 \mu\text{m}$ wavelength. Here, the advantage of using T_B becomes evident by considering a cloud with no further atmospheric emission below it. As liquid water clouds can be treated as blackbodies in the infrared

Table 29.1 Measured parameters by spectral radiometers

Parameter	Description	Unit	Symbol
Spectral radiance (direct solar radiation, scattered skylight)	Radiance, as a function of wavelength and field of view (FOV)	$\text{W m}^{-2} \text{sr}^{-1} \text{nm}^{-1}$	I_λ
Brightness temperature	Radiances detected by microwave receivers in a limited frequency interval (bandwidth) and a certain polarization state, calibrated to <i>Planck</i> equivalent brightness temperatures	K	T_B

spectral range, the brightness temperature measured, T_B , directly corresponds to the cloud base temperature [29.4].

Sun photometers are usually adjusted into the direction of the sun to derive the AOD from atmospheric extinction of solar radiation. However, partly, these instruments scan the atmospheric hemisphere to measure scattered radiation from which several additional aerosol particle parameters besides AOD can be retrieved. MWRs typically detect the thermally emitted radiation in zenith direction, although elevation scanning is required to improve the vertical resolution of the retrieved temperature profiles [29.5]. Combined azimuth and elevation scanning by MWRs can be used to map the hemispheric environment in terms of water vapor and cloud liquid water [29.6, 7].

29.1.2 Principles of Measurements

In order to retrieve atmospheric parameters, spectral radiometers use different wavelength channels to measure a set of radiances I_λ (sun photometer) or brightness temperatures T_B (MWR). The basic target of sun photometer measurements is the total optical depth τ , which is a measure of the opacity of the atmosphere; τ is a function of wavelength λ and is derived as the vertical integral of the volume extinction coefficient σ_{ext} from the ground to the top of the atmosphere (TOA)

$$\tau(\lambda) = \int_0^{\text{TOA}} \sigma_{\text{ext}}(\lambda, z) dz; \quad (29.1)$$

σ_{ext} combines the extinction of radiation due to absorption and scattering by atmospheric gases, aerosol particles, and hydrometeors (clouds, precipitation). The total optical depth τ , as a function of λ , can be decomposed into the individual components. Retrieval algorithms (Sect. 29.1.3) exploit the wavelength-dependence to infer aerosol particle (Sect. 29.2 for the sun photometer) and atmospheric parameters (Table 29.3 for MWRs). The interaction between atmospheric radiation and gas molecules, as well as aerosol particles and hydrometeors (scattering/absorption/emission) is a distinct function of the ratio between the size of the interacting agent and the wavelength. While the measurement principle

of sun photometers and microwave radiometers can be described by similar physical principles, due to their different wavelength ranges, they can provide complementary information on atmospheric constituents.

The basic principle of the operation of a sun photometer is widely described in the literature, for example by [29.8]. Knowing the amount of incoming solar radiation at the TOA and measuring the direct solar radiation at the surface, the Bouguer–Lambert–Beer law quantifies the extinction of solar radiation when penetrating through the atmosphere as a function of the total optical depth τ . The total optical depth is determined by Rayleigh scattering on air molecules, as well as by absorption through specific atmospheric gas components, primarily water vapor, ozone, oxygen, and nitrogen dioxide. Furthermore, aerosol particles and hydrometeor extinction (scattering plus absorption) contribute to τ . Because it is difficult to point the photometer's opening solid angle precisely into the direction of the sun in cloudy conditions, sun photometers are preferably operated in cloud-free atmospheric conditions. Retrievals of cloud properties using sun photometer measurements during cloudy sky conditions are also carried out; however they mostly use sun photometer measurements at different observation geometries, other than into the direct sun. While the contribution of Rayleigh scattering can be approximated by common parameterizations, gaseous absorption and the aerosol particle extinction are highly variable. However, in the 940-nm water vapor absorption band, the total optical depth is dominated by water vapor and, thus, the columnar precipitable water vapor (PWV) can be derived from the total optical depth.

The aerosol particle optical depth τ_A can be retrieved by subtracting the contributions by gas and hydrometeor (in the case of clouds and/or precipitation) scattering and absorption. Exploiting the spectral dependence of τ_A can be used to invert the aerosol particle size distribution. The spectral slope of τ_A can be parameterized by the Ångström exponent α defined by

$$\frac{\tau_A(\lambda)}{\tau_A(\lambda_0)} = \left(\frac{\lambda}{\lambda_0} \right)^{-\alpha}. \quad (29.2)$$

The Ångström exponent α is inversely related to the average size of the aerosol particles: the smaller the

Table 29.2 Parameters retrieved from measurements by the sun photometer

Parameter	Description	Unit	Symbol
AOD	Aerosol optical depth at wavelength λ	–	τ_A
Ångström exponent	Wavelength dependence of τ	–	α
Volume particle size distribution	Differential particle volume per differential logarithmic size bin	$\mu\text{m}^3 \mu\text{m}^{-2}$	$dV/d \ln D_p$
Complex particle refractive index	Real and imaginary parts of particle refractive index, real part describing scattering, imaginary part the absorption properties	–	$n = n_{re} - i n_{im}$
Single scattering albedo	Ratio of particle scattering and extinction coefficient. The cosingle-scattering albedo is represented by $1 - \omega$	–	ω
Particle scattering phase function	Angular distribution of normalized differential scattering intensity	–	P
Precipitable water vapor	Column integrated amount of water vapor	kg m^{-2}	PWV

particles, the larger α . More detailed information on the size distribution of aerosol particles, their scattering phase function, and their refractive index can be derived by inversion of multiwavelength measurements in almucantar or principal plane mode together with τ [29.9–11]. Within AERONET, also the cloud optical depth is retrieved from zenith pointing measurements [29.12]. An overview of different possible retrieval products from sun photometer measurements is given in Table 29.2, along with the underlying measurement principles (Table 29.4).

In the MW frequency range, < 100 GHz, extinction is almost exclusively caused by absorption, since scattering at these frequencies plays a role for large precipitation particles only. Under cloud-free conditions, extinction is dominated by water vapor, i.e., the rotational water vapor absorption line at 22.235 GHz and continuum absorption, as well as oxygen absorption (Fig. 29.1). For the latter, the absorption in the center of the 60 GHz absorption complex is so dominant that a ground-based MWR receives radiation emitted

in its immediate neighborhood only and, thus, measures the temperature very close to the instrument. Frequency channels further away also receive radiation from higher atmospheric layers, the further the frequency channel is separated from the absorption complex center. Therefore, multiple measurements along the wing of the absorption band provide information on the vertical temperature profile.

The water vapor line at 22.235 GHz is much weaker than the oxygen complex, and its pressure broadening (≈ 3 MHz/Pa) provides approximate information on the vertical distribution of atmospheric moisture. To cover the relevant pressure range of the troposphere down to 1000 hPa, typically, seven channels are spaced along the wing of the line covering ≈ 7 GHz. This way, the channel at the outer wing of the line is hardly affected by line absorption and can be considered a window channel, i.e., a frequency channel that is only very weakly influenced by gaseous emission. Around 23.8 GHz, the water vapor extinction is roughly constant with the height, making measurements propor-

Fig. 29.1 Extinction coefficient in the MW spectral range for a cloudy atmosphere with liquid water content of 0.2 g m^{-3} at 900 hPa. The different contributions by water vapor (green dashed line), oxygen (red dotted line), and cloud water (blue dash-dotted line) are shown. Typical frequency bands used by state-of-the-art microwave radiometers are indicated by the thick lines (after [29.13] with permission from John Wiley and Sons)

Table 29.3 Parameters retrieved from measurements of brightness temperatures in different frequency channels for ground-based microwave radiometers

Parameter	Description	Unit	Symbol
Temperature profile	Vertically resolved atmospheric temperature	K	T
Precipitable water vapor	Column integrated amount of water vapor	kg m^{-2}	PWV
Humidity profile	Vertically resolved mixing ratio	kg kg^{-1}	q
Liquid water path	Column integrated amount of liquid water	kg m^{-2}	LWP

tional to PWV. Cloud liquid water extinction increases strongly with frequency, which allows us to simultaneously retrieve PWV and the liquid water path (LWP) by measuring at two wavelengths: one dominated by water vapor (often 23.8 GHz) and the other one dominated by cloud droplet emission in an atmospheric window, e.g., at 31.4 GHz, whereby a higher LWP accuracy can be achieved by using a 90 GHz channel [29.14]. An overview of the different atmospheric parameters, which are routinely derived from a set of measured brightness temperatures, is given in Table 29.3. Less established retrieval techniques to derive hydrometeor properties including drizzle [29.15], separation of cloud and rain water [29.16], and snow [29.17] exist. These techniques partly use different frequencies, observing geometries, and polarimetric measurements. Note that trace gas profiles observed from spectrometers are described in more detail in Chap. 28.

29.2 History

Hand-held sun photometers were introduced by *Fredrick E. Volz* in 1959 [29.19]. In 1957, he developed a simple photometer that measured AOD with a selenium detector and a green-transmitting 500-nm spectral filter. The photocurrent produced by the device was displayed on a small analog meter. *Volz* subsequently improved his instrument by adding filter channels and replacing the selenium cell with a silicon photodiode and amplifier. His photometers were used in various atmospheric haze studies and networks. Unfortunately, filter drift and the lack of calibrations contaminated the data from the networks. *Volz*'s photometers also served as models for *Glenn Shaw*, who developed hand-held and automated instruments and traveled to Mauna Loa many times to calibrate them [29.20].

Originally, sun photometers used narrow-bandpass filters (with a spectral full width at half maximum,

29.1.3 Siting Conditions

Both instruments (sun photometer and MWR) require an obstacle-free hemispheric view into the atmosphere, and, therefore, a position at an elevated location, e.g., a roof top, is recommended. The sun photometer needs to directly view the sun during daylight hours (unless no cloud observations are intended), in particular during calibration using so-called Langley plots (Sect. 29.6.1). If different observational geometries are considered (almucantar or principal plane), the complete hemisphere should be free of obstacles. In principle, a microwave radiometer can operate in zenith mode only and, thus, is less constrained to a specific location. However, the accuracy of brightness temperature measurements is improved when the so-called sky tipping method [29.18] exploiting elevation scans at principal plane geometry can be applied (Sect. 29.6.2). This is even improved if scans in two opposing directions, i.e., bilateral sky tipping calibrations, are performed to cancel out atmospheric inhomogeneity and instrument leveraging. Furthermore, elevation scanning adds information to the spectral information and can improve the accuracy of the temperature profile retrieval in the boundary layer.

With a typical weight of a few kilograms, a sun photometer is much lighter than an MWR, which weighs between 30 and 60 kg. For unattended continuous operation, a firm fixation to the ground is fundamental, which typically includes the addition of weights to the microwave stand to prevent damage due to very strong wind.

FWHM, of a few nm), but these filters are expensive, fragile, and subject to unpredictable failure. Therefore, light-emitting diodes (LEDs) have been introduced. LEDs as detectors have some disadvantages (their spectral FWHM is relatively large, in the range of a few tens of nm), on the other hand they are cheap and stable over time [29.21].

First MWR observations were intended for extraterrestrial applications, e.g., the sun and cosmic background radiation. During World War II *Robert H. Dicke* (1916–1997) developed an MWR consisting of an antenna connected to a crystal balanced mixer by a rectangular waveguide, which was able to detect a minimum power level of 10^{-16} W [29.22]. Using this radiometer [29.23] he measured the atmospheric absorption at three frequencies around the 22.235 GHz line and showed differences of $\approx 50\%$ to theoretical consider-

ations. It should also be noted that in parallel MWRs were developed in Russia; these, however, are difficult to trace in the open literature.

Early MWR measurements were aimed at a better understanding of microwave propagation in the atmosphere. The possibility to retrieve the atmospheric temperature profile from ground-based measurements along 60 GHz oxygen using a highly directive microwave antenna was first discussed by *Ed R. Westwater* in 1965 [29.24]. Later, he suggested the use of dual channel radiometers operating at ≈ 20 and 31 GHz to accurately derive PWV and LWP simultaneously [29.25].

29.3 Theory

In order to interpret sun photometer and microwave radiometer measurements, basic knowledge of atmospheric radiative transfer is required. The main ideas of radiative transfer and thermal emission are described, for example, by [29.29–31]. Their application to microwave radiometric remote sensing is outlined in [29.32, 33].

Thermal radiation, which is emitted by a blackbody, is described by *Planck's law* (29.3) in terms of spectral radiance, i.e., the emitted power per unit projected area, per unit solid angle, and per unit frequency ν (or wavelength λ), with h the *Planck* and k the *Boltzmann* constant. An ideal blackbody absorbs all incident radiation and re-emits all of the absorbed radiation as a function of its temperature and frequency (or wavelength). To indicate blackbody radiation the emitted spectral radiance is termed *brightness* and can be expressed either as a function of frequency B_ν or wavelength B_λ

$$B_\lambda(\lambda, T) = \frac{2hc^2}{\lambda^5} \frac{1}{\exp(hc/(\lambda kT)) - 1}, \quad (29.3a)$$

$$B_\nu(\nu, T) = \frac{2h\nu^3}{c^2} \frac{1}{\exp(h\nu/(kT)) - 1}. \quad (29.3b)$$

With an approximate blackbody temperature of ≈ 5780 K, the spectral radiance emitted by the sun has its maximum in the visible spectral range ≈ 500 nm. Sun photometers use this as a source and measure spectral radiance in typically less than 15 channels between 300 and 1100 nm wavelength.

The lower the temperature, the lower the emitted spectral radiance. With temperatures between 200 and 300 K, atmospheric constituents show an emission maximum in the thermal infrared. MW radiances

The potential for continuous monitoring of the troposphere using MWRs was quickly recognized, and *D.C. Hogg* [29.26] developed an automatic profiler for temperature, humidity, and wind combining a six-channel MWR for humidity and temperature with a wind profiler. With the technological developments in the last decades, in particular the use of microwave and millimeter-wave integrated circuit (MIMIC) technology, the size of microwave instruments decreased, while their stability increased. First commercial systems specifically designed for continuous and unattended operation have now been available for two decades [29.27, 28].

emitted by the atmosphere are seven orders of magnitude lower than those of solar radiation at TOA in the visible part of the spectrum. Nevertheless, current MWRs detect radiances with sufficient accuracy to retrieve atmospheric moisture, humidity, and temperature measured in typically less than 20 channels between 10 and 100 GHz.

Both sun photometer and MWRs basically measure voltages, and the calibration of these into radiances is one of the largest challenges for accurate measurements.

29.3.1 Sun Photometers

The basic principle of operation of a sun photometer is described, for example, by [29.8]. It is based on the Bouguer–Lambert–Beer law that formulates the exponential attenuation of direct solar radiation as it penetrates through the atmosphere

$$I_\lambda(\lambda, \theta) = I_{0,\lambda}(\lambda, \theta) \exp[-\tau(\lambda, \theta)m(\theta)], \quad (29.4)$$

where $I_\lambda(\lambda, \theta)$ is the radiance of the direct solar radiation measured at wavelength λ , and solar zenith angle θ , $I_{0,\lambda}(\lambda, \theta)$ is the radiance of the direct solar radiation incident at the TOA, τ is the total optical depth of the atmosphere defined by (29.1) at the given wavelength λ , and $m(\theta)$ is the relative optical airmass at the given solar zenith angle θ . In the following, the wavelength dependence of I_λ and τ will not be indicated explicitly.

A measure of the opacity of the atmosphere is τ , which gives the amount of attenuation of direct solar radiation at the given wavelength due to absorption and scattering by atmospheric gases and aerosol particles. It can be expanded into the individual components

that contribute to the extinction of solar radiation

$$\tau = \tau_A + \tau_R + \sum_i \tau_i, \quad (29.5)$$

where the subscript A represents aerosol particles (absorption plus scattering), R stands for *Rayleigh* scattering due to air molecules, and the subscript i indicates the various atmospheric gas components (primarily ozone, water vapor, and nitrogen dioxide) causing absorption of solar radiation.

The relative optical airmass, $m(\theta)$, is given as the slant path length for a given solar zenith angle, θ , relative to the slant path length in the vertical direction. When the sun is directly overhead, the relative optical airmass is equal to unity, and for most solar zenith angles ($\theta < 60^\circ$), the relative optical airmass can be expressed by

$$m(\theta) = \frac{1}{\cos \theta}. \quad (29.6)$$

However, for increasingly larger solar zenith angles ($\theta > 60^\circ$), when the sun gets closer to the horizon, the length of the slant path deviates from that approximated by (29.6), mainly due to the sphericity of the Earth's atmosphere and the effects of refraction. Various formulas and approximations have been developed to account for these effects [29.34]. Furthermore, the airmass depends on the vertical distribution of the scattering and absorbing components in the atmosphere, and for highest accuracies, the airmass for each component (aerosol particles, Rayleigh scattering, ozone, etc.) should be determined individually.

The instruments that measure direct solar radiation do not originally detect solar radiation but record a corresponding wavelength-dependent spectral voltage, V_λ . When this voltage is within the linear region of the given detector, it is directly proportional to the spectral radiance I_λ

$$V_\lambda(\theta) = CI_\lambda(\theta), \quad (29.7)$$

where C is a wavelength-dependent calibration constant characteristic to each detector. Using the above equations and incorporating the airmass factors for each attenuator, (29.7) can be rewritten as

$$V_\lambda(\theta) = V_{0,\lambda} \exp \left[-\tau_A m_A(\theta) - \tau_R m_R(\theta) - \sum_i \tau_i m_i(\theta) \right], \quad (29.8)$$

where $V_{0,\lambda}$ is the voltage that the instrument would read at the TOA at wavelength λ , and the calibration constant C has factored out. The spectral aerosol optical depth can then be obtained by rearranging

$$\tau_A = \frac{1}{m_A(\theta)} \left[\ln(V_{0,\lambda}) - \ln(V_\lambda(\theta)) - \tau_R m_R(\theta) - \sum_i \tau_i m_i(\theta) \right]. \quad (29.9)$$

When retrieving τ_A , the wavelength channels typically chosen for sun photometers are purposely located in regions of the spectrum where aerosol particles and Rayleigh scattering are dominant, and absorption by trace gases is of secondary importance. Most of the terms on the right-hand side of (29.8) can, therefore, be directly calculated or sufficiently estimated; V_λ is the measured signal, the Rayleigh optical depth τ_R can be accurately calculated [29.35], and the optical depths for the various atmospheric gases can be estimated using satellite or climatology data combined with radiative transfer calculations [29.36]; $V_{0,\lambda}$ represents the voltage that the instrument would read at the TOA; it is the one component on the right-hand side of (29.8) that needs to be determined through calibration (Sect. 29.6.1).

29.3.2 Microwave Radiometers

Microwave radiometers (MWRs) measure the thermal emission of atmospheric constituents along the path given by their antenna characteristics. Most microwave emitters show a lower emission compared to that of a blackbody at the same temperature, i.e., the so-called *graybody*. According to *Kirchhoff's* law, a graybody in thermodynamic equilibrium (at temperature T), which absorbs a fraction of incident energy α_ν (or α_λ) at a specified frequency (or wavelength) from a certain direction, will emit the amount $\alpha_\nu B_\nu(\nu, T)$ (or $\alpha_\lambda B_\lambda(\lambda, T)$) into the same direction. For a perfect blackbody, the absorptance α_ν is one for all $\nu \in [0, \infty]$. If a graybody is completely nonabsorbing at a distinct frequency, α_ν is zero, and, thus, in the case of a nonscattering medium, radiation will propagate without any interaction with the medium.

In order to model the microwave signal received by a MWR for a given atmospheric state, the radiative transfer equation (RTE) [29.32] is needed. For a nonscattering medium, it can be derived from the Bouguer–Lambert–Beer law (29.4) in its differential form by adding thermal emission $S = \sigma_a B_\nu ds$ as a source term along the infinitesimal path increment ds (29.10). Also, in a nonscattering atmosphere, the extinction coefficient

Table 29.4 Physical principles of spectral radiometer measurements and applications

Type of sensor	Measurement principle	Application
Sun photometer	Attenuation of direct solar radiation Wavelength dependence of τ_A Inversion of measurements for solar almuquantar, and principal plane geometries, and τ at multiple wavelengths Attenuation of direct solar radiation in 940 nm absorption band	Aerosol optical depth (AOD) Ångström exponent Aerosol microphysical aerosol particle properties (size distribution, refractive index, shape information, single scattering albedo, scattering phase function) Precipitable water vapor
Microwave radiometer (MWR)	Emission along oxygen absorption complex ≈ 60 GHz Emission along water vapor rotation line at 22.235 GHz Continuum emission of liquid water	Temperature profiling Water vapor profiling Liquid water path

σ_{ext} can be reduced to the absorption coefficient σ_a (in m^{-1}), so that we can write for the monochromatic case

$$\frac{dI_v}{ds} = \sigma_a (B_v - I_v). \quad (29.10)$$

Under the assumption of a plane-parallel horizontally homogeneous atmosphere, we may replace the path increment ds by $dz = ds \cos \theta_{\text{gb}}$ with θ_{gb} , the zenith angle of the ground-based observation. Integrating (29.10) the monochromatic radiance actually observed by a ground-based MWR in zenith mode can be described by

$$I_v = I_{v,\text{TOA}} e^{-\tau} + \int_0^{\text{TOA}} \sigma_a(z) B_v [T(z)] e^{-\tau_z} dz, \quad (29.11)$$

where the first term describes the contribution of the cosmic background ($I_{v,\text{TOA}}$) to the signal observed, which is attenuated within the atmosphere according to the total optical depth τ . The second term considers the thermal emission of the atmosphere at all heights z , which are also subject to attenuation

$$\tau_z = \int_0^z \sigma_a(z') dz'$$

on the way from its origin ($z' = z$) to the microwave antenna ($z' = 0$).

In order to simplify the units of (29.11) for measurement applications, *Planck's law* (29.3) can be solved for temperature. At low microwave frequencies and typical atmospheric temperatures, the radiance becomes nearly linearly related to temperature (*Rayleigh–Jeans approximation*). In the case of a gray emitter, T will no longer be equal to the physical temperature of the emitter. In this case, *Planck's law* is used to define an equivalent brightness temperature T_B , so that, applying the

Rayleigh–Jeans approximation, (29.11) can be rewritten to

$$T_B = T_{B,\text{COS}} e^{-\tau} + \int_0^{\text{TOA}} \sigma_a(z) T(z) e^{-\tau_z(z)} dz, \quad (29.12)$$

where $T_{B,\text{COS}}$ is the brightness temperature of the cosmic background radiation of 2.73 K.

Besides frequency, the absorption coefficient σ_a in (29.12) is a function of pressure, temperature, water vapor, and cloud liquid, which strongly varies with frequency (Fig. 29.1). The gaseous contribution can be calculated given the atmospheric state from widely used absorption models, e.g., [29.37, 38], however, improving these models is currently still an ongoing process. The absorption coefficient for liquid hydrometeors, such as cloud droplets, drizzle, or rain drops, which are assumed to be spherical, are calculated using Mie theory. It depends on the complex permittivity of liquid water, which is well known for temperatures $> 0^\circ\text{C}$. However, the refractive index of supercooled liquid water (i.e., liquid water at temperatures below freezing) is less certain, as laboratory data are extremely sparse, but new refractive index models have been developed recently that also take field measurements into account [29.39].

From (29.12), the dependence of the measured brightness temperatures on the vertical temperature profile is obvious, while other dependencies, e.g., towards humidity and liquid water are hidden in the absorption coefficient. Retrieval algorithms are needed to obtain atmospheric parameters from measurements of T_B as a function of frequency in selected bands (Table 29.4). In the case of boundary layer temperature profiles, additional information from measurements at multiple elevation angles can be exploited.

Retrieval algorithms are often developed as multivariate regression or neural network frameworks. Moderately nonlinear problems or composite profiling techniques using the synergy of different ground-based

Fig. 29.2a,b Normalized weighting functions for typical frequencies of ground-based microwave radiometers. **(a)** Temperature weighting functions for the center frequencies of typical V-band channels located on the left side of the 60 GHz absorption complex. **(b)** Water vapor density weighting functions at center frequencies of typical K-band channels (on the right side of the 22.235 GHz water vapor absorption line and window channel 31.4 GHz)

sensors (Chap. 47) can be solved within variational approaches that allow the uncertainty specification for each derived quantity. Regression-type algorithms are based on a large, representative data set of concurrent T_B and atmospheric variables, which are related to each other by means of a minimization algorithm (i.e., least-squares or neural network approach). One example is the use of radiosonde profiles measured in parallel to MWR measurements, e.g., [29.40]. Most of the time, such data are not available to cover the full range of atmospheric states, and, therefore, (29.12) is used to calculate brightness temperatures given a climatology of atmospheric profiles, e.g., from radiosondes or reanalysis, for the location of the radiometer. The synthetic data set of consistent T_B and atmospheric parameters is then used to derive the statistical relations.

In contrast, a variational algorithm finds a solution such that for each case, the measured brightness temperatures are sufficiently close to the ones simulated from the retrieved atmospheric state. In general, a large number of atmospheric states can satisfy each combination of T_B , so that physical constraints have to be applied, which will lead to a converged solution. Variational approaches use so-called weighting functions that describe at which altitudes the atmospheric parameters of interest contribute to which degree to the measured brightness temperature. For the standard atmosphere,

Fig. 29.2 illustrates the strong nonlinear function of the temperature weighting function along the oxygen absorption complex. The innermost channels only receive radiation from the lowest layers, while channels further away subsequently receive information also from higher layers. In general, very little information from the upper troposphere is contained in the measurements, which make them highly complementary to satellite observation where the opposite behavior occurs. For moisture, the 23.8 GHz channel weighting function is nearly constant with height, making T_B measurements an ideal proxy for PWV. Due to pressure broadening, frequency channels at frequencies further away from the line center receive higher contributions from the lower layers, while the innermost channels are sensitive to higher altitudes.

The smoothness of the weighting functions already indicate why MWRs only need a limited number of frequency channels along the absorption features. By calculating the number of degrees of freedom for signal following [29.41], it can be shown that typical zenith pointing temperature profilers contain only two independent pieces of information for temperature profiling, which can be increased up to four by adding elevation scans [29.42]. For humidity profiling, the information content increases for moister atmospheres, but the number of degrees of freedom for signal is generally below three.

29.4 Devices and Systems

Both sun photometers and MWRs are commercially available. In the past decade, much effort has been put into optimizing sensitivity and calibration accuracy, as well as unattended, reliable operations for network-suitable applications.

29.4.1 Sun Photometers

Sun photometers consist of a telescopic opening angle, a wavelength selective unit (interference filters, optical gratings) for spectral discrimination, and a detector unit producing an output voltage, which is processed further on. There are handheld instruments for easy application in the frame of field campaigns. Their disadvantage is related to issues of finding the precise sun position and keeping it constant for the time the data are taken. More sophisticated versions are installed in permanent ground-based networks (see example in Fig. 29.3). These instruments are calibrated regularly and follow standard measurement protocols. The data are centrally collected and inversion procedures are applied using unified software and analysis methods. Permanent sun photometers are installed such that they run automatically and that they additionally allow measurements in almucantar and principal plane geometries. Recently, some of the photometers have additionally been equipped with polarization measurement capabilities.

29.4.2 Microwave Radiometers

Microwave radiometers are usually total power instruments, i.e., they measure the signal power that is received by the antenna within the channel bandwidth

$\Delta\nu$ and over the integration time Δt . In the simplest configuration, an MWR consists of an antenna, an amplification chain, and a detection unit (Fig. 29.4). The recorded voltage is then converted to brightness temperatures using calibration information (Sect. 29.6.2). The measurements at the different frequency channels are taken either sequentially or synchronously, depending on the design of the radiometer.

The microwave antenna needs to be highly directive in order to treat the observation as a single (*pencil*) beam in which no horizontal inhomogeneities occur. The beam width of the antenna is commonly defined from its FWHM angular receiving characteristics and is typically on the order of a few degrees. For a given beam width, the diffraction limit causes the size of the antenna to become relatively large, e.g., to 0.5 m for < 10 GHz. Because retrieval algorithms combine channels with different frequencies, and each channel needs to see the same part of the atmosphere, radiometers employing a wide frequency range might need different antennas to match the beam size. The antenna is often connected to a scanning mechanism to adjust the azimuth and elevation angle, either for atmospheric scanning or to view calibration targets. Many designs use an offset parabolic mirror that focuses the microwave radiation onto a classical horn antenna connected to a waveguide. Here, corrugated feed horns provide symmetric beam patterns of a nearly Gaussian characteristic.

As pointed out before, microwave radiances are extremely low and, therefore, microwave radiometers need to amplify the signal received at the antenna by ≈ 80 dB. While lately low-noise amplifiers (LNA) have become available for frequencies up to ≈ 100 GHz, many microwave radiometers still employ the heterodyne technique, and only a few radiometers are based on direct detection techniques. In a heterodyne receiver (Fig. 29.3), the radio frequency (RF) is down converted to an intermediate frequency (IF) by a mixer using a frequency-stable local oscillator (LO). In principle, two side bands with $\nu_{\text{RF}} = \nu_{\text{LO}} \pm \nu_{\text{IF}}$ are converted to the IF. This has the advantage that signal amplification and detection can be performed at a lower frequency, where technology is widely established. Double-sideband measurements are advantageous when observations along a single symmetric absorption line are performed. In this case, the LO is set to the line center frequency, and contributions from equally distant frequencies on both sides of the line are combined into a single channel. This means that a single LO can be used for several frequency channels along the line and, thus, respectively, for pro-

Fig. 29.3 Photo of a sun photometer at the Jülich Observatory for Cloud Evolution (JOYCE) (photo © Birger Bohn)

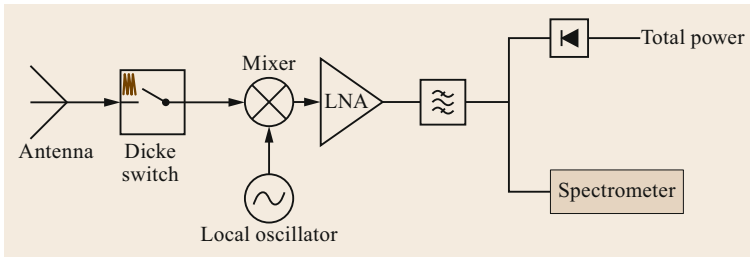

Fig. 29.4 Block diagram of a Dicke type microwave radiometer using the heterodyne principle. After the radio frequency has been down converted, the interim frequency is amplified and bandpass filtered. Afterwards, the signal can be split up and detected either within single-frequency channels or input into a spectrometer

filig. This technique is frequently applied to satellite microwave measurements or at the 183 GHz line for ground-based water vapor profiling. For window channels or along nonsymmetric lines, very low IF center frequencies have to be used to realize typical channel bandwidths of about a GHz or less. If only one frequency band will be received, a single sideband filter needs to be used. Within some radiometers, the LO is tuned, and different frequencies are measured sequentially.

Multichannel MWRs typically split the IF signal into the different channels by bandpass filters in a so-called filter bank approach. Each channel's signal is further amplified, detected, and finally converted to digital counts. For profiling of upper atmospheric gases, the pressure broadened line shape needs to be observed with a frequency resolution of ≈ 1 MHz. In this case, instead of a filter bank, back-end spectrometers are used (Chap. 28).

The sensitivity of a microwave radiometer is mainly determined by its system noise temperature T_{sys} , which is the sum of the receiver's internal noise contribution

and the atmospheric signal. The minimum T_B fluctuations that can be resolved by the radiometer depend on the bandwidth and integration time

$$\Delta T_B \approx \frac{T_{\text{sys}}}{\sqrt{\Delta\nu\Delta t}} \quad (29.13)$$

and are typically ≈ 0.1 K. Due to the high amplification required, microwave radiometers are very sensitive to temperature changes, and, therefore, a good thermal insulation is key. In order to avoid drifts most radiometers employ a gain adjustment by frequently observing a reference signal. This is classically achieved by a Dicke switch, which directs the view to a termination with well-known temperature (Fig. 29.4). However, also different designs that make use of noise injection from a well-characterized noise diode or observation of an external target are used. Absolute accuracy is mostly determined by the absolute calibration, which is either performed using liquid nitrogen or sky tipping [29.18].

Different commercial MWRs are available (Fig. 29.5). Radiometrics Inc. (radiometrics.com) offers the

Fig. 29.5a–c Examples of commercially available microwave profiling radiometers. (a) MP-Series profiler by Radiometrics Inc. (photo © Radiometrics Inc.), (b) HATPRO by Radiometer Physics GmbH (photo © Radiometer Physics GmbH), (c) MTP-5 by ATTEX (photo © ATTEX). Photos by permission

MP-Series Profiler [29.27, 43], which performs sequential measurements along the water vapor and oxygen absorption features for profiling (Fig. 29.1). Similar bands are covered by Radiometer Physics GmbH's (RPG; radiometer-physics.de) Humidity and Temperature Profiler (HATPRO, [29.28]), which uses direct-detection and parallel measurements of the different frequency channels. Both Radiometrics Inc. and RPG also offer dual channel radiometers for PWV and LWP measurements only. Optionally, RPG includes higher-frequency channels, like 90 GHz, to achieve higher LWP accuracy. The Russian company ATTEX (attex.net) offers the Microwave Temperature Profiler (MTP), which exploits elevation scanning at a single frequency along the oxygen complex to derive boundary-layer temperature profiles mainly for air pollution studies.

Operational instruments make use of a radome to shield the internal components of the microwave

radiometer (Fig. 29.4) from external disturbances (Fig. 29.5). The radome is made from microwave transparent material, which is often treated such that it repels rain drops. As liquid on the radome affects T_B measurements, a rain sensor helps to identify rainy situations. To keep the radome dry under light drizzle and to enable a quick recovery after a rain event a blower can be used. Radiometer observations are often combined with 2 m meteorological station data, whose temperature and humidity measurements can also serve as input to the retrieval algorithms, taking into account the different spatial representativeness of the point and radiometer measurements. Similarly, infrared radiometers mounted along the side can provide information on cloud occurrence and cloud base height. A global positioning system (GPS) receiver gives the exact time and can also be used to synchronize scans with satellite orbits for exact attenuation measurements.

29.5 Specifications

The retrieval accuracies of sun photometers and MWRs need to be carefully specified and communicated. In addition to instrument performance, these are limited by the physical principles of radiative transfer and remote sensing.

29.5.1 Sun Photometers

Procedures to determine measurement errors and inversion accuracy (depending on the product levels) have been extensively described for the AERONET [29.44] measurements [29.1]. AERONET also derives absorption properties, such as the imaginary refractive index and single-scattering albedo of aerosol particles from the sun photometer data, however, in this case, larger uncertainties have to be taken into account [29.45]. The degree of sphericity of aerosol particles can also be obtained [29.46]. Water vapor column measurements

by sun photometers have frequently been compared to those by other instruments, including MWRs showing an accuracy of $\approx 1 \text{ kg m}^{-2}$ [29.47].

29.5.2 Microwave Radiometers

In the last two decades, commercial MWRs have matured to robust instruments providing continuous and unattended operations. They can be operated at temporal resolutions down to a second and give accurate atmospheric observations under nearly all-weather conditions, except when rain contaminates the microwave window. Commercial MWR units are usually offered with azimuth and elevation-angle scanning capability. The absolute accuracy of well-calibrated microwave radiometers is $\approx 0.3\text{--}0.5 \text{ K}$ with an even lower noise level. Vendors typically include retrieval algorithms for a specific location. Their typical accuracies are given in Table 29.5.

Table 29.5 Specification of the accuracy of the sun photometer and microwave radiometer for different retrieval products

Retrieval product	Error	Limitations
Sun photometer		
AOD	≈ 0.02	Completely cloud-free conditions
Ångström exponent	≈ 0.1	Completely cloud-free conditions
Precipitable water vapor	$\approx 1 \text{ kg m}^{-2}$	Only during clear sky conditions
Microwave radiometer		
Precipitable water vapor	$0.5\text{--}1 \text{ kg m}^{-2}$	Not under precipitating conditions
Liquid water path	$\approx 20 \text{ g m}^{-2}$	Offsets can cause LWP < 0, these can be corrected for by using LWP variability
Temperature profile	$0.5\text{--}2.0 \text{ K}$	Accuracy decreases rapidly with distance from instrument, best performance < 500 m
Humidity profile	$0.2\text{--}1.5 \text{ g m}^{-3}$	Low resolution, typically only two degrees of freedom for signal

Profiles of liquid water content (LWC) are sometimes provided as an additional product by manufacturers. Because information on the vertical position of liquid water is only indirectly contained in the measurements via the temperature dependence of the liquid water absorption, [29.48] conclude that microwave ra-

diometer measurements alone do not contain enough information to retrieve LWC profiles. Additional constraints can be provided by simultaneous measurements of an infrared radiometer or ceilometer for cloud base height and cloud radar for cloud top and vertical structure.

29.6 Quality Control

Applying standardized, well-defined and regular calibrations is essential to obtain sufficiently quality-controlled data for passive radiometers. This will correct for the possible offsets and drifts that can occur within these systems.

29.6.1 Calibration of Sun Photometers

The *Langley* plot method is the primary technique used to determine the TOA calibration voltage constant, V_0 , for a given sun photometer. This method, originally developed in the early 1900s to obtain estimates of the solar constant [29.49], is also based on the Bouguer–Lambert–Beer attenuation law following the notation of [29.36]

$$V_{A\lambda}(\theta) = V_{0,\lambda}(\theta) \exp[-\tau_A(\theta)m_A(\theta)], \quad (29.14)$$

where

$$V_{A,\lambda}(\theta) = V_{\text{meas},\lambda}(\theta) \exp \left[\tau_R(\theta)m_R(\theta) + \sum_i \tau_i(\theta)m_i(\theta) \right], \quad (29.15)$$

is the measured voltage corrected for Rayleigh scattering and gas absorption, that is, the voltage that would be measured if aerosols were the only attenuating component, and $V_{0,\lambda}$ is the voltage the instrument would read at the top of the atmosphere at the time of the calibration.

Taking the natural logarithm of both sides of (29.14) yields the linear equation

$$\ln(V_{A,\lambda}(\theta)) = \ln(V_{0,\lambda}) - \tau_A m_A(\theta), \quad (29.16)$$

which states that for a given wavelength channel, a plot of the natural logarithm of a series of measurements, V_A , over a range of aerosol air mass values, m_A , will give a straight line with a slope that is equal to the aerosol optical depth, τ_A , and a y-intercept that is equal to $\ln(V_0)$. The *Langley* plot method takes advantage of this linear relationship and consists of measuring V_A

as the sun rises or sets (i.e., over a range of air mass values), plotting the $\ln(V_A)$ versus m_A , and then extrapolating the data to zero air mass (i.e., the y-intercept) to determine $\ln(V_0)$, from which the TOA-atmospheric calibration voltage constant, V_0 , can be obtained.

While theoretically straightforward, care must be taken while performing *Langley* plot calibrations to minimize various sources of error. The primary assumption of this technique is that the aerosol optical depth remains constant over the time span of the calibration measurements. For this reason, these calibrations are usually done at high-altitude locations, both to get above the majority of any aerosol particles in the atmosphere, and because the aerosol loading at higher altitudes is typically more temporally stable than that at lower altitudes. A discussion of various modifications and refinements to the *Langley* plot method have been suggested to better account for a variable atmosphere and to improve on the accuracy of these calibrations. A description of these techniques can be found in the literature [29.20, 50–52]. Practical information for obtaining high-quality AOD measurements within AERONET is given at https://aeronet.gsfc.nasa.gov/new_web/system_descriptions_calibration.html, Accessed 20 July 2021.

29.6.2 Microwave Radiometers

For accurate observations of brightness temperatures, signal calibration is of utmost importance. Classically, two blackbody calibration targets of well-known temperature and emissivity are used to derive the gain (receiver sensitivity to input signal change) and noise temperature (T_R , receiver offset), which are subsequently used to calculate brightness temperatures. In order to take system nonlinearities into account, an additional reference, such as a noise diode, is necessary. For absolute calibration, the full system, including the antenna and the scanning unit, needs to be characterized, which is realized either by the automatic sky tipping procedure or by external calibration involving a liquid-nitrogen (LN₂) cooled target. A thorough review concerning the uncertainties of both approaches is given in [29.18, 53].

Absolute calibration employs a warm (typically ambient temperature) and a cold (typically liquid nitrogen (LN₂) cooled) target, whose blackbody temperatures are known to a high accuracy. Assuming a linear detector, the two calibration parameters, i.e., gain and T_R , can be calculated from the voltages recorded with the radiometer pointing to the hot and the cold target, respectively. The temperatures of the targets are chosen such that the observed atmospheric brightness temperatures do not require a strong extrapolation from the calibration range. Nonlinearities can be taken into account by performing two additional measurements, adding a stable noise diode signal when pointing at the targets. From the four voltages measured, the noise diode temperature and the nonlinearity factor can be derived. The major challenge lies in the design of the calibration target and the exact characterization of its temperature. Here, avoiding reflections at the LN₂ interface, mixing oxygen into the LN₂, and the realization of a homogeneous temperature across the calibration target are important to obtain absolute accuracies < 1 K.

An alternative technique realizes the cold calibration point from scene observations, assuming a horizontally homogenous atmosphere. In a similar fashion to the *Langley* plot approach (29.16), atmospheric elevation scanning provides opacities for non-opaque frequency channels. These can be plotted as a function of airmass, and the opacity for an airmass factor of zero can be derived, which needs to correspond to the one of

the cosmic background. Typically, quality check thresholds are applied to the tipping curve in order to detect atmospheric inhomogeneities. Other systematic effects can be avoided by considering the antenna beam width and the Earth's curvature along the slant observation path.

For high-quality observations, the microwave window of the system must be clean of water/ice/dirt at all times. Continuous visual inspection via webcam is highly recommended to detect any disturbances, e.g., by birds, precipitation, or deterioration of the radome material. Communication technology is increasingly making use of higher microwave channels, which can lead to radio frequency interference (RFI) strongly disturbing individual or, in the case of broadband sources, even several channels. Therefore, quality control of brightness temperature time series for unphysical spikes, variability, and spectral inconsistency is necessary. In addition, procedures for checking the physical consistency of the retrieved products are also mandatory. Automatic quality control procedures have been developed by manufacturers as part of the data acquisition software. Also, within MWRnet, experienced operators have developed an online postprocessing tool that can be used to continuously monitor T_B time series against numerical weather prediction models. Last but not least, a regular visual inspection of the obtained T_B time series can often increase the data quality as well.

29.7 Maintenance

In addition to regular calibration, continuous maintenance procedures must be carried out in order to minimize the possibility of external and other instrumental factors deteriorating the radiometers' performance (Table 29.6).

29.7.1 Sun Photometers

NASA suggests a weekly procedure to maintain and service the sun photometers involved in AERONET (<https://aeronet.gsfc.nasa.gov/Operational/pictures/Checklist.html>, Accessed 10 July 2021). To verify system integrity, the following points should be accommodated: check battery connections, untangle zenith/azimuth cables, check sensor data cable, check enclosure box for leaks (remove water, repair leaks as necessary), and check rain detection. Heated rain detectors ensure that also snowfall is detected below freezing temperatures. Moreover, without active heat-

ing suitable measurement periods may be missed by formation of dew, in particular in the early morning.

Furthermore, the battery status and the solar panel connections, as well as the instrument clocks, need to be checked. An important point is to control the leveling procedures and automatic positioning of the sensor head. Instrument tracking and collimator obstructions require some attention. The ability of the instrument to track the sun and automatically scan the sky hemisphere (almucantar and principal plane) needs to be controlled. It is suggested that to remove the collimator (the double tubes on the sensor head) and to look through it toward the sun or a bright light to verify that there are no spider webs and other foreign matter. The collimator needs to be cleaned and obstructions need to be wiped away with soft cloth. However, the inlet optics should remain untouched to make sure that successive calibrations trace any drifts in sensitivity accurately.

Table 29.6 Maintenance of ground-based sun photometer and microwave radiometer systems

Maximum interval	Procedure
Sun photometer	
Daily	Check operation and data transfer
Weekly	Check wet sensor operation, collimator free from obstructions, sun-tracking, battery, and clock
Yearly	Calibration at least every 12 months
Microwave radiometer	
Daily	Automatic checking of the data for inconsistent values of brightness temperature as well as retrieved products to detect possible malfunctions.
Weekly	In spite of using different automatic quality controls, a visual inspection of the T_B time series is recommended in order to assure a complete quality control of data that can identify also nonmeteorological disturbances such as RFI, humans, birds, sun, moon or aircraft
Monthly	Pure water should be used to periodically clean the radome window of the MWR to prevent the reduction of the radome hydrophobic behavior
6-monthly	Absolute calibration using liquid nitrogen, exchange microwave window

29.7.2 Microwave Radiometers

Commercial microwave radiometers have been designed for continuous unmanned operation, and remote access allows data transfer and monitoring of instrument performance. Thus, daily automatic checking of the data quality is recommended to detect any malfunctions quickly (Table 29.6). This concerns continuous quality checks of the brightness temperatures measured for thresholds and spectral consistency, as well as the quality of retrieved products, e.g., by continuous comparisons with numerical weather prediction output or, if available, radiosonde ascents.

Although most commercial MWRs are equipped with rain sensors warning of the presence of rain, it is advisable to compare these data weekly to monthly with other measurements such as webcam, infrared camera, or rain gauge data. This is important to avoid flagging too many measurements as unusable, i.e., in the case of a too-sensitive or malfunctioning rain detector. However, also the opposite case can occur: e.g., after a heavy rain event has ended, the radome dries too

slowly, so that measurements are not yet useable. This can be due to the deterioration of the radome material or a malfunctioning blower/heater system. Also, non-meteorological signals from RFI, humans, birds, the sun, moon, or aircraft should be corrected for. Here, visual inspection of the time series is currently the best way to guarantee reliable data. Objective spectral consistency checks are currently still under development.

In order to guarantee that no artificial signals due to disturbances in the field of view or, particularly, on the microwave transparent radome, occur, the use of a webcam is strongly suggested. Environmental conditions (sunlight, precipitation, etc.) deteriorate the radome material of the microwave window, reducing its hydrophobic characteristic. Depending on the location, the window should be replaced about every 3–6 months. An absolute calibration with LN_2 is recommended every 6 months and can be combined with the exchange of the microwave window. In general, radiometer manufacturers suggest thorough system inspections by the company approximately every 2 years.

29.8 Application

Sun photometers and MWRs typically measure in continuous automated mode providing comprehensive information on the atmospheric state (Tables 29.2 and 29.3), which can be used for many applications. Figure 29.6 shows an example measurement from 26.06.2018 at the Jülich Observatory for Cloud Evolution (JOYCE) [29.54, 55]. The LWP from the microwave radiometer indicates the presence of stratiform clouds starting shortly past midnight and lasting until noon. These clouds strongly influence the thermody-

namic stability. First, the typical nighttime surface-based inversion weakens slowly. Further, the transition from stable to well-mixed conditions only happens around noon, when the cloud layer disappears. The transition to neutral conditions in the boundary layer is rather abrupt and within 1 h the conditions at the surface even change from neutral to superadiabatic. AOD and PWV observations by the sun photometer only become available after cloud disappearance, as a free view of the sun is necessary. At first, only isolated measurements

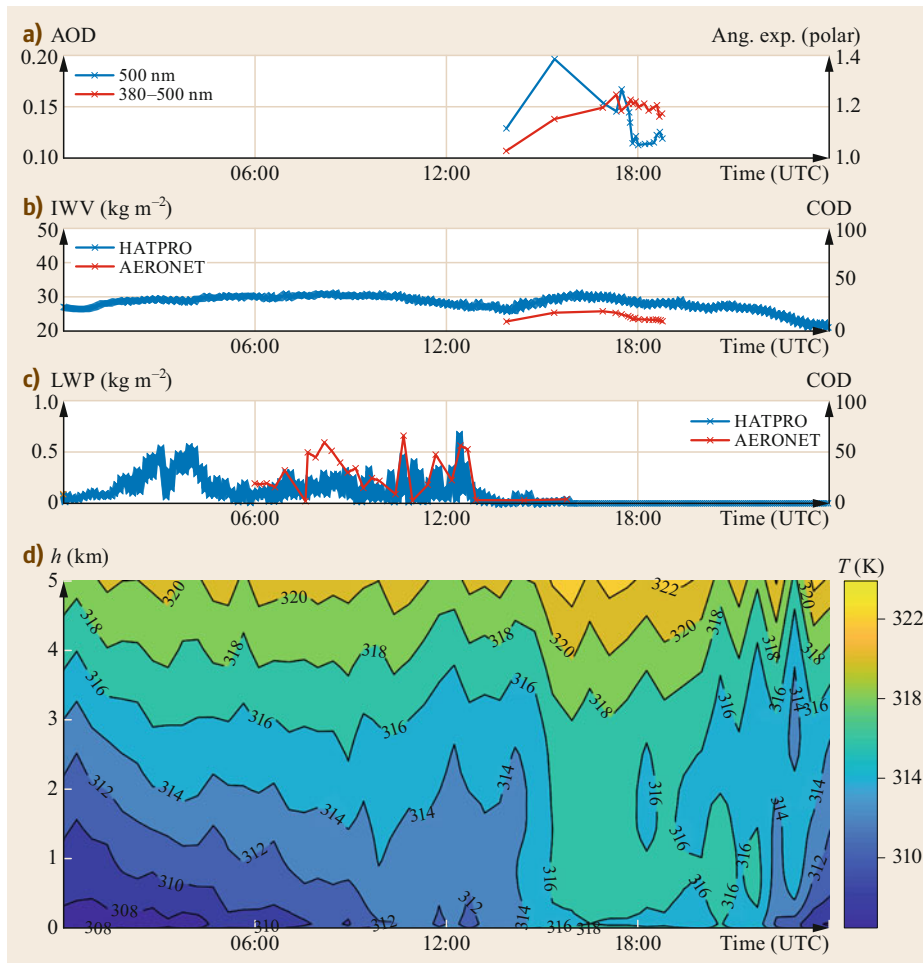

Fig. 29.6a–d
Time series of different measurement quantities on 25.06.2018 at JOYCE: (a) aerosol optical depth at 500 nm (blue) and Ångström exponent between 380 and 500 nm (red), (b) precipitable water vapor from microwave radiometer (blue) and sun photometer (red), (c) liquid water path (blue), and cloud optical depth (red), (d) time-height series of potential temperatures from microwave radiometer HATPRO. COD refers to the cloud optical depth

are available, as some isolated low LWP values still indicate broken cloud conditions, but they become more frequent in the 2–3 h before sunset. Close to sunset an AOD at 500 nm of 0.12 and an Ångström exponent (between 380 and 500 nm) indicate rather typical conditions at JOYCE, which is located in an agricultural area and sometimes under the influence of plumes originating from the cities of Düsseldorf or Cologne. Immediately after sunset a surface-based inversion develops again due to long-wave cooling.

When PWV from both the sun photometer and the microwave radiometer are available, their temporal behavior agrees rather well, however, a systematic offset occurs, which is a bit higher than that identified by [29.47]. Biases between different PWV data sets are frequently found, and the identification of reference measurements is an ongoing challenge for the

community, i.e., as carried out in the Global Climate Observing System (GCOS) Reference Upper Air Network (GRUAN, Chap. 63). Under overcast conditions, the sun photometer turns into zenith staring, the so-called cloud mode of AERONET, and a cloud optical depth retrieval is performed, which shows some correlation with microwave radiometer derived liquid water path. The latter is available with 1 second temporal resolution, while for the sun photometer, the frequency of a valid retrieval is much lower, i.e., 15 min.

The example shows the synopsis of sun photometer and microwave radiometer measurements to capture the atmospheric state with respect to atmospheric stability, aerosol burden, PWV, and clouds. This information is of particular interest for air quality applications and can be enriched by using more details on the aerosol composition, e.g., fine and coarse mode occurrence.

29.9 Future Developments

Within Europe, AERONET is already, and will continue to be, integrated into the ACTRIS (Aerosols, Clouds, and Trace Gases Research Infrastructure) project (<https://www.actris.eu>). The strategic aim of ACTRIS is to secure long-term coordinated aerosol, cloud, and trace gas observations. Within this framework, calibration activities, software upgrades, and new station setups (including new instrument purchases) will be increasingly coordinated. Data analysis will be harmonized in workshops and other meeting activities. These future developments on a European level are closely linked with international projects worldwide.

In France, there are new instrumental developments for mobile photometry, in particular for airborne observations and also for marine applications on board ships. First successful tests have been reported for ship-borne observations. This development opens the path to future automatic marine observations. Another new development is lunar photometry. Furthermore, several low-cost photometer versions are under development, which will enable us to obtain more data on aerosol optical depth.

In the past decades, MWRs have matured into commercially available systems that are able to provide autonomous estimates of temperature and humidity profiles, as well as liquid water paths in nearly all weather conditions. In the United States (US), the Climate Research Facility of the US Department of Energy's Atmospheric Radiation Measurement (ARM) Program operates a network of ground-based MWRs, which provides long-term measurements with a focus on LWP in different climate zones [29.56].

In Europe, different COST (European Cooperation in Science and Technology) actions (EG-CLIMET (European Ground-Based Observations of Essential Variables for Climate and Operational Meteorology) and

TOPROF (Towards Operational Ground Based Profiling with Ceilometers, Doppler Lidars and Microwave Radiometers for Improving Weather Forecasts) [29.57]) have fostered the development of the MWRnet advocating joint standards for operation and processing of microwave radiometer data. First attempts have been made to assimilate MWR profiles of temperature and humidity into numerical weather prediction models [29.58] where benefits in accumulated precipitation forecasts up to 12–18 h, in particular for larger accumulations, have been found. Also, the potential for directly assimilating microwave radiometer brightness temperatures into numerical weather prediction models is currently being explored, which has become possible by the development of the forward operator RTTOV-gb [29.59]. This is of special interest as microwave radiometers provide continuous information on the temperature profile in the boundary layer, which is difficult to assess from satellites. For data assimilation, but also to obtain accurate retrievals of thermodynamic profiles and clouds, stringent quality assurance and accurate uncertainty characterization are of high importance, and efforts to harmonize on the European scale are underway within the European research infrastructure ACTRIS. Within ACTRIS and funded by Deutsche Forschungsgemeinschaft (DFG), a center for MWR calibration and quality assurance is currently installed at JOYCE.

This article has presented standard instrumentation, however, special developments like small-scale networks, tomography, or higher-frequency radiometers for use under low water vapor conditions are explored as well. This is not restricted to the meteorological community as microwave radiometry is also a valuable tool for astronomy, geodesy, and communication studies.

29.10 Further Readings

Radiative transfer theory is explained in detail by:

Susanne Crewell

Institute for Geophysics and Meteorology
University of Cologne
Cologne, Germany
susanne.crewell@uni-koeln.de

Susanne Crewell is a Professor for Meteorology at the University of Cologne (Germany). She received her PhD at the University of Bremen in 1993. She has been active in the field of microwave remote sensing, including instrument development for more than two decades, covering ground-based, airborne, and satellite measurements for different applications emphasizing a better understanding of atmospheric water cycle processes.

Manfred Wendisch

Physics and Earth Sciences
University of Leipzig
Leipzig, Germany
m.wendisch@uni-leipzig.de

Manfred Wendisch is a Professor at the University of Leipzig (Germany) and Director of the Leipzig Institute for Meteorology. He is involved in airborne field observations, studying the influence of clouds on the atmospheric radiative energy budget with a focus on cirrus and Arctic mixed-phase clouds, as well as on subtropical trade wind cumuli.

Ulrich Löhnert

Institute for Geophysics and Meteorology
University of Cologne
Cologne, Germany
ulrich.loehnert@uni-koeln.de

Ulrich Löhnert is a Professor at the University of Cologne (Germany). His research focuses on the use of ground-based atmospheric remote sensing for a better understanding of the physical processes within the atmospheric boundary layer as well as for improving weather forecast models. For this, he leads JOYCE – the Jülich Observatory for Cloud Evolution (www.joyce.cloud).

Weather Rad

30. Weather Radar

Jörg E.E. Seltmann

Of all ground-based instruments measuring the atmosphere, weather radar is the only one that can deliver volumetric data over large areas at a high spatiotemporal resolution. Born as a byproduct of military development during the Second World War, weather radar has evolved from analog *intensity only* radar over Doppler radar to present-day digital multiparameter radar with a wide use in both research and operational atmospheric measurement.

Being a very intricate active and indirect remote-sensing device, weather radar relies on a plethora of theoretical assumptions and simplifications. Interferences from nonmeteorological targets (*clutter*), unwanted radiation sources, as well as technical limitations and compromises add to the overall error of a radar. The radar receiver measures only a few parameters describing the returned electromagnetic wave. A variety of observables is then being derived via dedicated signal processing. Some of them may directly be related to useful local meteorological information, such as rain rate or radial wind speed.

Radar data are not confined to point measurements but yield areal precipitation fields over wide areas, covering whole countries, if networked. At a (range-dependent) high resolution, spatial structures allow us to detect characteristic meteorological features, such as the vertical extent of convection, wind shear, hook echoes, tornado vortex signatures, and many more.

On a temporal scale, radar observation is quasi continuous at a high temporal resolution of a few minutes, typically. Thus, the rain rate may be integrated to yield hourly or daily precipitation sums. Cell displacement and evolution may be tracked and extrapolated permitting categorical, as well as quantitative nowcasting in automated procedures.

All this makes weather radar the most versatile, powerful, and complex of all instruments probing the atmosphere.

Weather radar, through volume scanning with high areal coverage in the order of 100 000 km² and with a typical resolution of presently 1°, 250 m, provides information about the spatial distribution of precipitation over large areas, even in inaccessible regions. The precipitation amount can be quantified locally, areally, and vertically integrated. The hydrometeor type, such as rain, drizzle, snow or hail, can be classified and separated to some extent from unwanted targets, called clutter. Observation over time enables monitoring, tracking, and extrapolation of the temporal development of convection and precipitation fields (*nowcasting*). Information on areal wind fields and on small-scale wind phenomena, such as gusts, downbursts, mesocyclones, and even tornadoes, may be gained using standard Doppler radar.

Severe weather alerts and warnings, including natural hazards, such as flash floods or tornadoes, depend heavily on automated radar data processing.

Thus, weather radar represents an indispensable tool not only in the daily work of meteorologists and hydrologists, but also for media, fire fighters, emergency management and services, water authorities, local event organizers, farmers, and, very importantly, aviation, including military. Lately, radar data have even become available to individual users through weather apps on smartphones.

Radar reflectivity and wind data are routinely assimilated into numerical hydrological and weather forecast models. Radar climatology and hindcast is used by experts reporting to court or insurance companies.

30.1 Measurement Principles and Parameters

Weather radar is an active (having a transmitter of its own) and commonly monostatic (transmitter and receiver in the same place) remote-sensing instrument. Unlike optical or IR devices (see Chaps. 13, 24–27, 40), radar works reliably even under unfavorable weather conditions, as microwaves exhibit low absorption. This chapter is about ground-based scanning weather radar; for airborne, millimeter and high frequency radars, or radar wind profiler see Chaps. 31–33, 39.

A typical weather radar sends out a train of short ($\approx 1 \mu\text{s}$) microwave pulses at a pulse repetition frequency typically between 200 and 2000 Hz. Each pulse travels out at the speed of light to meet some rain droplets (or any kind of refraction discontinuities), which backscatter an *echo* that is collected by the radar antenna. The

incoming signal is eventually fed to the radar receiver and is digitized at some point, measuring the exact return time to yield the exact target distance. Together with the known antenna azimuth and elevation there are three coordinates to define the position of the measuring volume in space. Unlike air traffic control and military radar, a weather radar does not only detect and range the target, but it also infers its qualitative and quantitative properties measuring the absolute magnitude of received power.

Tables 30.1 and 30.2 summarize some of the most important technical and measurable parameters of a weather radar. For a detailed description of observables see Sect. 30.3.4. From these relatively few observables, a wealth of meteorologically relevant products may be calculated, such as rain rate and rain accumu-

Table 30.1 Important technical radar parameters

Parameter	Symbol	Unit	Typical value
Number of elevations	n_{el}	–	10–20
Antenna azimuth rate	ω_{az}	rpm	0.1–10 rpm
Antenna size	\varnothing	m	1–8 m
Antenna beam width	θ	deg	1°
Wavelength	λ	cm	3, 5, 10 cm
Pulse width (pulse duration)	τ	μs	1 μs (64 with pulse compression)
Pulse repetition time (interpulse period)	PRT	ms	1 ms
Pulse repetition frequency $\text{PRF} = \text{PRT}^{-1}$	PRF	Hz	200–2500 Hz
Pulse peak power	P_t	W; dBm	10 kW–1 MW
Pulse energy	τP_t	Ws = J	1 J
Average transmitted power $P_{ave} = f P_t$	P_{ave}	W; dBm	10–1000 W
Duty cycle $f = \tau \text{PRT}^{-1} = P_{ave} P_t^{-1}$	f	1; dB	10 ⁻³ ; –30 dB
Received power	P_r	W; dBm	10 ⁻¹² W = 1 pW
Dynamic range		dB	100 dB
Sensitivity	MDS	dBm	–110 dBm
Calibration constant	C	$\text{mm}^6 \text{m}^{-3} \text{mW}^{-1} \text{m}^{-2}$	7 $\text{mm}^6 \text{m}^{-3} \text{mW}^{-1} \text{m}^{-2}$
Calibration reflectivity	Z_0	dBZ	–40 dBZ

Table 30.2 Some radar observables

Parameter	Symbol	Description	Unit
Equivalent reflectivity factor	$z; Z, Z_H, Z_V$	Sum of D_i^6 per unit volume for Rayleigh spheres of equivalent radar cross section	$\text{mm}^6 \text{m}^{-3}$; dBZ
Mean radial velocity	V, V_H, V_V	Weighted mean of Doppler spectrum	deg, rad, m s^{-1}
Spectral width	W, W_H, W_V	Width of Doppler spectrum	deg, rad, m s^{-1}
Differential reflectivity	ZDR	Ratio of copolar reflectivities	dB
Differential (propagation) phase	PHIDP	Phase difference between H and V $\text{PHIDP} = \text{PHIHH} - \text{PHIVV}$	deg
Specific differential phase	KDP	PHIDP per km $\text{KDP} = \Delta\text{PHIDP}/\Delta r$	deg km^{-1}
Depolarization ratio	LDR, CDR	Linear or circular depolarization ratio (crosspolar over copolar)	dB
Copolar correlation	RHO_{co}	Correlation between copolar time series, e.g., $\text{RHO}_{\text{Hr}}, \text{RHO}_{\text{Hv}}$	
Co-crosspolar correlations	$\text{RHO}_{\text{H}}, \text{RHO}_{\text{V}}$	Correlations between copolar and crosspolar time series	

lation, vertically integrated liquid water and ice, echo top height, radial wind fields, vector wind fields and wind profiles, hydrometeor classification, detection and warnings of severe weather, hail, gusts, wind shear, mesocyclones, and tornadoes, see Sect. 30.8.

The volume coverage, high update rate, high representativity, and good resolution are a weather radar's unquestioned strengths. This uniqueness may render verification difficult. Resolution is still better than satellite or numerical weather prediction (NWP) resolution and is usually considered satisfactory, even though for

some features (e.g., TVS, Sect. 30.8.3) a higher resolution might be desirable. Most target parameters are measured indirectly, calling for inversion techniques and models introducing uncertainties larger than the absolute measurement errors. Sometimes, but not always, not being able to measure close to the ground due to beam elevation and Earth curvature may be a disadvantage. Weather radar is complex and expensive causing high initial, operation, and maintenance effort and cost.

30.2 History

Isidor Isaac Rabi (1898–1988), Nobel laureate in physics and one of the leaders in the development of both radar and the atomic bomb, emphasized that the technological advance that contributed most to victory in World War II was not the bomb but microwave radar [30.1].

Radar is based on the theoretical foundation of electromagnetic wave propagation given in 1864/65 by the Scotsman *James Clerk Maxwell* (1831–1879) and experimentally proven some 20 years later (1885–88) by the German *Heinrich Rudolph Hertz* (1857–1894). The Russian *Alexander Stepanovich Popov* (1859–1906) and the Italian *Guglielmo Marconi* (1874–1937) both worked on radio telegraphic transmission by radio waves. In 1904, the German engineer *Christian Hülsmeier* (1881–1957) was the first to make use of electromagnetic waves to remotely detect ships (on the Rhine river in Cologne) by what might today be called a monostatic pulse radar and to patent this *telemobiloskop* (remote motion viewer) in Germany [30.2] and in Great Britain, and a trigonometric method for ranging shortly after. Note that there were no narrowband – let alone microwave – wave sources, no real directional antennas, no frequency filters, no detection or amplifi-

cation tubes, and no measuring of wave travel speed. At the time, the German navy failed to recognize the importance of Hülsmeier's invention, as did the US navy with the bistatic experiment of *Albert H. Taylor* (1879–1961) and *Leo C. Young* (1891–1981) from the US Naval Research Laboratory on the Potomac river in 1922 and their proposal of a *burglary prevention* for navy ports, but its capability was eventually recognized by air forces trying to detect long-range large bombers. At the beginning of the 1930s, Germany, France, Great Britain, Italy, Japan, The Netherlands, the Soviet Union, and USA were all investigating the topic.

“Britain started radar research for aircraft detection in 1935” [30.3], and the Scotsman *Robert Wattson Watt* (1892–1973), a descendent of James Watt and “the inventor of British radar” [30.3], patented the detection and location of aircraft by radio waves that same year, resulting in the construction of the *Chain Home* line of early warning radars (operating at 30 MHz!) starting from 1937 (operational September 1938, continuous operation since Easter 1939), and its German counterpart, the *Kammhuberlinie*, stretching more than 1000 km between Denmark and France.

In Germany, *Rudolf Kühnhold* (1903–1992) was able to range ships in 1934 using something that today

is known as a traveling wave tube, and he presented the first fully functional *Funkmess* device in 1935 [30.4]. “At the beginning of World War II, Germany had progressed farther in the development of radar than any other country”, and “radar was installed on a German pocket battleship as early as 1936” [30.3]. Germany also pioneered the PPI presentation (invented by *Hans E. Hollmann* (1899–1960) and first used it, even remotely, on *Jagdschloß FuG 404*, [30.5]) and the use of shorter wavelength (375 and 560 MHz) radar. In 1942, Telefunken built the passive *Kleinheidelsberg* radar eavesdropping on the British Chain Home [30.6], and Gema built the world’s first phased array radar *FuMG 41/42 Mammuth* in 1944 or 1945 with an azimuth coverage of $2 \times 100^\circ$, a range of 325 km, and a resolution of 300 m [30.7].

Driven by the contest of the belligerent nations, a variety of radar equipment was hastily developed during WW II, and ironically, the US American SCR 270 detected the Japanese bomber attack approaching Pearl Harbour in 1941 but was not believed [30.3].

One decisive step was the development of the high-frequency cavity magnetron that is usually attributed to *John T. Randall* (1905–1984) and *Henry Boot* (1917–1983) of the University of Birmingham, UK, in 1939/40 [30.8]. This invention was shared with MIT Radiation Lab (RL) in the USA, where over 100 radar systems were developed by the end of WW II. After the war, developments were completed by the victorious allies, and the civil use of radar, in the beginning mostly converted military, extended to atmospheric remote sensing. The superheterodyne receiver had been developed as early as WW I.

Even during WW II, weather echoes were sometimes seen to interfere with (to *clutter*) echoes from aircraft. In Great Britain, the first 10 cm-radar was deployed and operated by the General Electric Company GEC in July 1940, and it has been concluded [30.9] that the “first detection of precipitation on radar” was probably accomplished by this radar. In [30.10] a photograph is presented of “thunderstorm conditions” in MIT’s vicinity, detected with a 10 cm-radar on 14 July 1942. While a nuisance in military use, it soon became obvious that radar may be used to guide airplanes around severe weather.

The theoretical foundations to describe the backscattering of electromagnetic waves by small spherical particles had been given by *Lord Rayleigh* (*John W. Strutt*, (1842–1919)) in 1871 [30.11], and for spheres of arbitrary size by *Gustav Mie* (1868–1957) in 1908 [30.12]. Comprehensive basic theoretical work was done by *John Walter Ryde* (1898–1961) and his wife *Dorothy* in Great Britain, also of GEC, between 1946 and 1948 [30.13], in order to determine the effect of weather on military radar, including handwork computation on the re-

lation of radar return and rain rate, i.e., the first *Z/R*-relation [30.9]. In the 1950s, more theoretical concepts evolved, such as signal detection in noise, the matched filter, and Doppler filtering. *Hooper* and *Kippax* from Telecommunications Research Establishment were later able to prove the wavelength and range dependencies of radar echoes, and *J.R. Probert-Jones* derived what is now known as the Probert-Jones factor in the radar equation in 1962 [30.14].

In the USA, radar meteorology can be tracked back to 1941/1942 at MIT RL. MIT also investigated clear air and *angel* echoes, as well as ground and sea clutter and ducting, fluctuations caused by turbulence, and variable polarization, and offered tuition as well. The Army Air Forces conducted the AW-MET-8 project in late 1945 to “investigate the use of airborne radar in meteorology . . .” [30.15].

A weather radar program was initiated as early as 1945 by *J.O. Fletcher* and *E.J. Istvan*, who ordered specification of “three weather radars: a wind finding radar, a storm detection radar, and a cloud base and top detection radar”. The U.S. Air Force (USAF) Weather Service CPS-9 X-band radar of 1954 is considered to be the first specifically designed weather radar [30.16]. In 1953, the Severe Local Storms Forecast Unit (SELS) was created conducting the National Severe Local Storms Research Project later that decade, renamed *National Severe Storms Project NSSP* in 1960, and *National Severe Storms Laboratory NSSL*, in 1964 [30.17].

In Canada, the *Stormy Weather Group* around *J.S. Marshall* and *W.M. Palmer* was set up in 1943, from 1945 at Montreal’s McGill University, who created the famous Marshall–Palmer *Z/R* relationship [30.18].

In postwar Germany, Italy, and Japan radar development had to be stopped, but the Berlin weather radar of 1957 boasts an interesting first-day success story [30.19].

In Japan, the first operational weather radar was established in 1954. A network of typhoon warning radars was initiated soon after, and by the beginning of the 1980s, all radar data output was digital and collected in realtime by the Japan Meteorological Agency [30.20].

In the Soviet Union, the dual-wavelength meteorological radar MRL-5 was designed in the 1960s and is being used to date in different upgraded versions in several parts of the world [30.21].

While MTI (moving target indicator) radars making use of the Doppler effect were developed during the war to suppress stationary targets, the first meteorological application of pulsed Doppler radar and the first weather observation by continuous wave Doppler radar seem to have been described only in 1953 and 1957 [30.22]. Full operational Doppler processing became feasible with computerization in the eighties.

In the 1950s, the US Weather Bureau started replacing weather adapted war radars by specifically designed WSR-57 S-band weather radars creating the first dedicated national weather radar network [30.17]. In the 1960s, electronically steered phased arrays made their reappearance, and in the 1970s, the advance of digital technology enabled data processing in radar. In the 1970s and early 80s, a couple of dual polarization research weather radars were deployed around the world (Colorado State University/University of Chicago-Illinois (CSU-CHILL), Chilbolton, Deutsches Zentrum für Luft- und Raumfahrt (DLR)) [30.23].

Computer control had started to replace the hand-wheel of early days, facilitating operator access and even automated operation without operator involvement. While cathode ray tubes as the first ever radar screens may occasionally still be met, computerization soon led to the development of digital data processing, including product generation, presentation, output, and archiving. This was a tremendous step ahead, even though in the beginning, signal processors were hardwired and wire wrapped, programs hardcoded, projection was through lookup tables (precalculated by a program aptly called *iworm*), presentation based on sixel graphics on VT 100, and archiving on 10.5" tapes.

Around the 1990s, increasing computing power and disk memory provided resources for more challenging techniques, such as realtime Fourier transforms, product calculation and projection on the fly, and storage on disk and configurable templates. Internal and external networking facilitated automated and remote monitoring and messaging and data exchange. National radar networks were equipped with Doppler capability. Solid-state technology, as well as integrated microwave circuitry, enabled digital receivers and solid-state transmitters.

Also in the 1990s, the US WSR-57 radar network was replaced by WSR-88D (D stands for Doppler capability) and called next generation radar (NEXRAD), and radar networks evolved in Europe and many countries around the world as well. International collaboration and exchange even induced harmonization and

supernetworking of national networks, in Europe starting with several COST (European Cooperation in the Field of Scientific and Technical Research) actions, the GORN (Liaison Group on Radar Networking) group and its followup EUMETNET (European Meteorological Network) OPERA (Operational Programme for the Exchange of Weather Radar Information) programs. The OPERA Data Center ODC (*Odyssey*) [30.24] has been collecting radar data from major parts of Europe creating a large-scale pan-European composite covering most of Europe every 15 min. To date, over 120 radars contribute to the OPERA composite. OPERA has also developed the OPERA Data Information Model ODIM for use with WMO (World Meteorological Organization) BUFR (binary universal form for the representation of meteorological data) and HDF5 (hierarchical data format) formats and has recently entered phase V (2019–2023).

With the dawn of the new millennium, the current type of commercial dual-pol radars became available. A *bolt-on* antenna-mounted dual-pol upgrade of an analog Doppler-radar was tested at Hohenpeissenberg Observatory in 2005 using a commercial digital receiver mounted *piggyback* over the antenna elevation shoulder.

With the availability of fast processors and converters digitization has extended into formerly analog receiver parts. Solid-state techniques have been developed to replace electron tubes, and analog as well as rotating parts of a radar by solid-state modulators or transmitters, and – so far in research – electronically steered antennas. Today, networked mass storage media and telecommunications enable archiving of huge data amounts and broadcasting even to cell phone apps.

By now, weather radar has greatly contributed to our understanding of atmospheric processes, to nowcasting, hazard warning, and aviation safety, and radar principles have been adopted by similar sounding technologies, such as lidar, sodar, and sonar. While the weather-radar community is constantly growing, it keeps gathering at the now biannual series of the American Meteorological Society (since 1947) and European (since 2000) conferences on weather radar.

30.3 Theory

As a ground-based remote-sensing instrument, weather radar is sounding the atmosphere indirectly: meteorological phenomena and quantities are targeted, sending out electromagnetic waves to interact with precipitation at a large range of distances. This interaction occurs by way of scattering, and the energy scattered back towards the radar carries characteristic information on the location and properties of the respective scattering tar-

gets. As absorption is largely negligible at microwave frequencies, and scattering is a weak effect, the atmosphere is well transparent to the radar even under cloudy and rainy conditions.

Weather radars are commonly designed as monostatic systems, using the same antenna for transmission and reception. Furthermore, the antenna is usually permanently rotating while stepping through several dis-

crete elevation angles in order to scan the atmosphere. Target location is readily determined in radar-centered polar coordinates.

Using a pencil-beam antenna, the pointing direction of the antenna yields two angles (azimuth and elevation). Distance is derived measuring the round trip time of the echo from a specific range gate, knowing the propagation speed c of electromagnetic radiation to be $c_{\text{vac}} = 299\,792\,458\text{ m s}^{-1}$ in vacuum. In order to measure propagation time, some marker is needed to match transmitted and received radiation. A simple continuous sine wave does not carry any distinguishing information to discriminate the time difference between transmission and echo arrival of a certain target. The easiest marker is to start/stop the radiation in the form of a pulse whose rising (or falling) edge may serve as a marker. Frequency or phase coding represent further options that are also feasible with continuous-wave (CW) radars.

A predefined number of echo pulses may be collected at each range gate to form one batch or time series as a basis for signal processing. More often, however, these batches are synchronized with the antenna movement. For example, one batch is collected between azimuths of 0.5° and 1.5° and is assigned to a position of 1° east of north. This is tolerable, as the antenna azimuth rate is slow compared to the pulse repetition frequency.

Electromagnetic waves are characterized by only a few parameters, such as amplitude, phase, or polarization. These are the parameters that need to be decoded within the receiver and the digital signal processor (DSP). However, they are not the aim of the indirect measurement. The target properties *coded* in the received radiation may be retrieved from intensity, and Doppler and polarization properties of the echo, as well as from the spatiotemporal behavior (e.g., texture) of these parameters. Retrieval calls for model assumptions about the target and the measurement. The desired information may still be altered by propagation effects on its way back to the receiving antenna.

The choice of radar wavelength depends on technical and logistic aspects: short wavelengths (X-band (9.4 GHz, $\lambda = 3.2\text{ cm}$)) are stronger attenuated in heavy rain, and, therefore, longer wavelengths (S-band (3 GHz, $\lambda = 10\text{ cm}$)) are preferred in the (sub)tropics and wherever high-range coverage is desired (USA *tornado alley*). Longer wavelengths also offer larger unambiguous velocities (Sect. 30.3.2). On the other hand, X-band antennas are smaller, so higher directivity and gain may be obtained at lower cost. Short wavelength is, therefore, preferred for short range (regional catchment coverage, sewerage plants) and mountainous areas, or as gap fillers in networks of larger radars. Large parts of

Europe prefer the intermediate C-band (5.6 GHz, $\lambda = 5.4\text{ cm}$), which also offers better frequency protection.

From conventional and Doppler radar, echo strength (reflectivity factor) and Doppler radial velocity are obtained. Adding geometrical and textural characteristics (height extent, echo structure) and physical knowledge (e.g., on coherency and homogeneity), information may indirectly be derived on severe convection, hail, wind profiles, or ground clutter. To better capture and parameterize the physical properties of scatterers and to discriminate between them, more radar observables are necessary, which can be provided by multiparameter (dual wavelength, dual polarization) radars. Multiparameter multiradar observations are employed to describe the full precipitation process from hydrometeor formation to precipitation.

30.3.1 Radar Basics

Weather radar is a pulse radar with a limited unambiguous range. The radar beam propagates through the atmosphere and is bent due to refraction. An *echo* is returned due to scattering by raindrops, etc. The main observable is the radar reflectivity factor. It is related to the properties of the scatterers and is expressed in logarithmic units of dBZ.

Pulse Radar

A short microwave pulse of pulse width (PW) τ is sent out at a pulse repetition frequency PRF, i.e., at a pulse repetition time $\text{PRT} = \text{PRF}^{-1}$, and the radar *listens* to the incoming echo during $\text{PRT} - \tau$ until the next pulse is sent out. The antenna is switched to the transmitter during τ and to the receiver during $\text{PRT} - \tau$ by the T/R-switch (Sect. 30.4.1). This is called time multiplexing and allows for a monostatic setup avoiding crosstalk. Short pulses offer high resolution but call for large bandwidth ($B = \tau^{-1}$) as the time-bandwidth product equals 1.

Range and Cross-range Resolution. Targets are range resolvable if their echoes do not overlap: $t_1 - t_2 > \tau$, i.e., the minimum distance that can be resolved is

$$\Delta r = \frac{c\tau}{2} = \frac{c}{2B}. \quad (30.1)$$

For instance, with $\tau = 1\text{ }\mu\text{s}$, $\Delta r = 150\text{ m}$. This range resolution is not to be confused with the sampling resolution (Sect. 30.4.4), which may be higher (oversampling) or (rarely) lower (undersampling). Range resolution may be increased applying pulse compression techniques (Sect. 30.4.4).

The cross range (= azimuth) resolution depends on the antenna beam width (very often 1°), i.e., on the an-

Fig. 30.1 Illustration of range aliasing: echoes of the previous pulse are folded into the unambiguous range R_u (image © J. Seltmann, used by permission)

tenna size and wavelength, and on the number of pulses that are integrated and assigned to a specific azimuth direction (angle syncing, see Sect. 30.4.4). Crossbeam resolution in linear units degrades progressively with increasing range and is thus poor at a distance, as compared to range resolution.

Unambiguous Range and Range Folding. The return time of the echo is measured relative to the pulse that has been sent out last. If the echo originates from a previous pulse, the range assignment becomes ambiguous or *folded*, as illustrated by Fig. 30.1. The maximum unambiguous range R_u is, therefore, determined by a two-way return time smaller than PRT, i.e.,

$$R_u = \frac{c\text{PRT}}{2} = \frac{c}{2\text{PRF}}. \quad (30.2)$$

Thus, a PRF of 1000 Hz corresponds to $R_u = 150$ km. A target at $R = 185$ km appears *folded* at 35 km. Range-folded echoes are called second (third, multiple)-trip echoes or second (third, multiple)-time around echoes. If standalone, they may be recognized by their compressed shape due to the intercept theorem, their weak power (because of wrong range correction, see Sect. 30.6.3), and their incoherency (if incoherent pulses are sent by a magnetron or on purpose, see Sect. 30.6.3). If a second-trip echo overlaps a first-trip echo, its reflectivity adds to the first trip reflectivity, which is consequently overestimated, and its radial velocity estimate may be biased and noisy. Unambiguous ranges between 50 and 250 km are common; the US WSR-88D (NEXRAD) even ranges to 460 km in surveillance scans.

Beam Propagation

Radiation propagation follows Fermat's extremum principle that extremizes the optical path through the atmosphere described by the refractive index $n := c_{\text{vac}}/c_{\text{medium}}$. Under ITU standard conditions, $n = 1.000315$ is very close to unity, giving rise to the definition of refractivity $N = (n - 1) \times 10^6$. In a homogeneous medium $n = \text{const.}$, resulting in propagation along a straight line. In a layered atmosphere,

$$N = \frac{77.6}{T} \left(p + 4810 \frac{e}{T} \right), \quad (30.3)$$

where p is the barometric pressure in hPa (= mbar), e in hPa is the water vapor pressure (important for microwaves), and T in K is the absolute temperature. As the variables p , e , and T usually decrease with height (p , e even rapidly), so does N (c_{medium} increases with height), and the radar beam is bent downward by refraction.

In an exponential model, the refractivity height profile in the lowest kilometers of a standard atmosphere is

$$N(h_{\text{asl}}) = N_0 \exp \left(\frac{-h_{\text{asl}}}{h_{\text{scale}}} \right), \quad (30.4)$$

where h_{asl} is measured above sea level, $h_{\text{scale}} = 7.35$ km is the global average scale height, and $N_0 = 315$ is the average atmospheric refractivity at sea level (values according to [30.25]).

In a linear approximation, $dN/dh \approx \text{const.}$ ($\approx -40 \text{ km}^{-1}$) in the relevant height range so that beam curvature is also constant. Then, the radius of the Earth R_E may be replaced by an effective radius kR_E , where $k = 1/(1 + R_E dn/dh) \approx 4/3$. Over a fictitious Earth surface with radius kR_E , the radar beam would be a straight line. This *four-thirds Earth radius* holds under standard refraction. A nonstandard refractivity profile leads to anomalous beam propagation called *anaprop*. *Subrefraction* occurs if the gradient dN/dh is weaker than the standard or even positive, so that the radar beam is bent less or even upward. If dN/dh is more negative than -40 km^{-1} , as under temperature inversion (nocturnal cooling), the beam curvature is stronger than the standard. This is called *superrefraction*; Fig. 30.2 shows an example. The radar beam may even be trapped within an inversion layer creating an atmospheric dielectric wave guide (like in a glass fiber), which is called *ducting* or *trapping* and occurs when $dN/dh \leq -157 \text{ km}^{-1}$. Anaprop conditions are particularly common if warm air masses are advected over cold water or landmasses.

Scattering and Reflectivity

For many purposes, the energy sent out by one pulse may be considered to be contained in a truncated cone

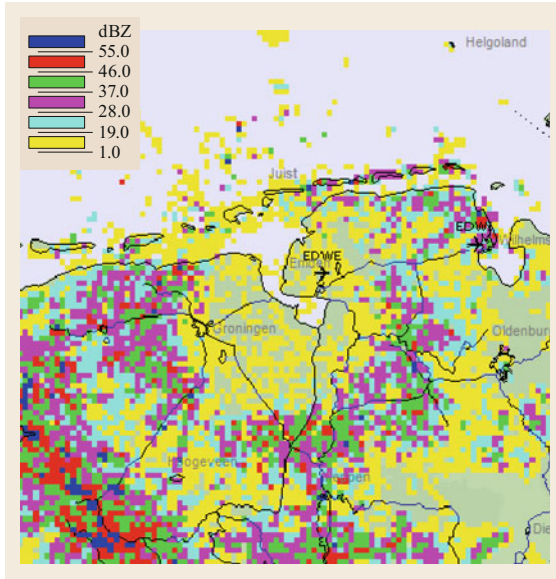

Fig. 30.2 Example of a pronounced anaprop situation at the Emden radar, Germany. There is no precipitation in this case (after [30.26], © DWD)

of length $c\tau$. The total energy scattered back by any drops contained within this pulse volume ΔV – usually a very large number of drops with an unknown drop-size distribution (DSD) – will be measured; ΔV should be large enough to be statistically representative and small enough so that the scattering particles can be approximately considered to fill the beam completely and homogeneously. In reality, ΔV is given by the range-dependent beam broadening. Therefore, it is useful to take to quantities normalized to unit volume (intensive quantities).

For a monostatic radar, the characteristic target parameter is the radar backscattering cross section σ_b , which depends on wavelength λ , refractive index n , and particle diameter D . As there are very many targets in the measuring volume of a weather radar, each individual backscattering cross section $\sigma_{b,i}$ contributes to the sum of all scatterers in a unit volume. This sum is called the reflectivity $\eta = \sum \sigma_{b,i}$.

Assuming spherical scatterers, the scattering process is described by Mie theory [30.12]. A few non-spherical symmetric shapes may be calculated as well, e.g., rotational ellipsoids [30.27] or Chebyshev particles [30.28]. Most scatterers, however, exhibit a complicated backscatter that cannot be solved analytically. Numerical methods have been developed, such as the EBCM (extended boundary condition method), also called the T-matrix method, for rotation-symmetric particles of arbitrary size [30.29], layered multiphase particles [30.30], and tumbling particles [30.31], or the discrete dipole approximation of [30.32].

Table 30.3 Radar backscattering cross sections σ_b of typical targets

Target	Typical σ_b (m^2)
A 380, B26	100
Light aircraft	3
Human being	1
Stealth plane	0.1
Bird	0.01
Raindrop $D = 1$ mm	10^{-11}

The radar backscattering cross sections of different targets comprise many orders of magnitude (cf. Table 30.3). If the sphere is large compared to the wavelength, $D \gg \lambda$ (e.g., $D > 10\lambda$ or $D > \pi\lambda$), the backscattering cross section approaches the geometrical cross section, where $\sigma_b = \pi D^2/4$. This is referred to as the geometric region.

The range where target size is of the order of the wavelength $D \approx \lambda$ ($\pi D \approx \lambda$) is the Mie or resonance region with the full Mie theory applicable. The backscattering cross section $\sigma_b(D)$ is not a monotonous function of D in the Mie region.

Often (but not always), however, the scattering particles can – in addition to being spherical – be considered small compared to the wavelength, $D \ll \lambda$ (e.g., $D < 0.1\lambda$ or $\pi D < \lambda$). This condition is more critical with shorter wavelengths (X-band) but is notwithstanding usually assumed. In this case the Rayleigh approximation applies and

$$\sigma_b = \pi^5 |K|^2 D^6 \lambda^{-4}, \quad (30.5)$$

where $K = (m^2 - 1)/(m^2 + 2)$, and $m = n - jk$ is the complex index of refraction with $N \approx 9$, $k = 0.63 - 1.47$ ($20 - 0^\circ\text{C}$, $\lambda = 10$ cm) in liquid water, and $n \approx 1.78$, $k = 2.4 \times 10^{-3}$ to 5.5×10^{-4} ($0 - 20^\circ\text{C}$) in ice, so that the factors $|K|^2 \approx 0.93$ (water), 0.197 (ice), differ by 7 dB (see Sect. 30.3.1, subsection *Calculation in Decibels*, for decibel and Sect. 30.6 for bright band).

In the case of rain or clouds, billions of individual point targets are assumed to be spherical and small. Integrating over all scatterers in a unit volume to calculate reflectivity yields

$$\eta = \sum \sigma_{b,i} = \pi^5 |K|^2 \lambda^{-4} \sum D_i^6, \quad (30.6)$$

where D_i is the diameter of the i -th droplet, and the sum is over the unit volume. As the radar wavelength is fixed, the important feature here is not the dependence of $\sigma_{b,i}$ on λ^{-4} (which accounts for the blue sky), but the proportionality to D_i^6 . It states that *a million droplets are needed to produce the same reflectivity as one single drop only ten times as large!* The factor $\sum D_i^6$ (sum over unit volume) is determined by the DSD $n_j(D_j)$ (where j

Table 30.4 Correspondence reflectivity – rain intensity

Z (dBZ)	Presumable target

40	Rain, graupel
50	Hail, rain
60	Hail

numbers size classes) and is called the (radar-)reflectivity factor

$$z = \sum D_i^6 \quad (\text{mm}^6 \text{m}^{-3}, \text{ sum over unit volume}). \tag{30.7}$$

The reflectivity factor is the most important observable of a weather radar and the only one of a classical intensity-only radar. It is correlated with precipitation activity so that a radar image represents something like a weather chart, cf. Figs. 30.13, 30.17, and 30.22. As, unlike η , the reflectivity factor is independent of wavelength, z values are comparable between X, C, and S-band radars. However, in linear units of $\text{mm}^6 \text{m}^{-3}$, the values of z are cumbersome, easily stretching over 12 orders of magnitude. This is why radar meteorologists invented the unit of dBZ (see below). Often z is used to refer to linear units, and Z indicates log units of dBZ. Whenever the drop-size distribution is known, (e.g., from disdrometer measurement), Z may be calculated.

In the real world it is difficult to know if the Rayleigh condition is met for real targets with unknown distribution of composition, number, size, shape, orientation, and velocity. Therefore, the echo power measured by the radar is related to an *effective* reflectivity factor z_e ; one that would result in the same radar return if the Rayleigh condition were fulfilled. Table 30.4 gives some typical observed values.

The Radar Equation

What parameters determine the echo power P_r received by the radar? The radar equation anatomizes the dependence of received power P_r on radar and target properties.

If the radar were an isotropic source of radiation transmitting the pulse power P_t into space, the total inner surface of any sphere concentric around the radar would receive exactly this power, due to conservation of energy, irrespective of the radius of the sphere. As the sphere’s surface $4\pi r^2$ increases with distance r from the radar, the irradiance or power density decreases propor-

tionately: $P_t/(4\pi r^2)$. This decrease is sometimes called the spreading loss or free-space path attenuation.

A real radar, however, is built to radiate as much energy as possible into a preferred direction at the cost of all other directions. The energy is no longer evenly distributed on the imaginary sphere’s inner surface, but the irradiance in forward direction is increased by a factor G called the antenna gain. A rain drop at distance r is, thus, irradiated by $P_t G/(4\pi r^2)$, scattering a (very) small portion of the incident power into all directions. From a distance, the raindrop may itself be seen as a point source of radiation sending the power $P_t G \sigma(\theta, \varphi)/(4\pi r^2)$ into the direction of θ, φ . In the usual monostatic configuration, the portion $\sigma(\theta = 180^\circ, \varphi = 0^\circ) = \sigma_b$ goes back to the radar antenna and is called the radar backscattering cross section, as it must have the dimension of an area, according to the equation.

The resulting irradiance at the receiving antenna decreases with $4\pi r^2$ again and, thus, amounts to $P_t G \sigma_b/(4\pi r^2)^2$. The power received by the effective area $A_e = G \lambda^2/(4\pi)$ [30.33] of the radar antenna is therefore

$$P_r = \frac{P_t G^2 \lambda^2}{4\pi} \frac{\sigma_b}{(4\pi r^2)^2} = \frac{P_t G^2 \sigma_b \lambda^2}{(4\pi)^3 r^4}. \tag{30.8}$$

This is the radar equation for a point target located in the middle of the radar beam (where the gain is G). Note the proportionalities to the target property σ_b and to the fourth power of the distance r .

However, there may be billions or trillions of distributed point targets (rain drops) in one radar sample volume, which is defined by the pulse length and beam cross sections at a given distance. Under a geometric beam approximation, the sample volume is a truncated cone (frustum) of volume

$$V = \pi r \frac{\theta_0}{2} \frac{r \Phi_0}{2} \frac{c\tau}{2}, \tag{30.9}$$

where r is the distance to the radar, θ_0 and Φ_0 are the horizontal and vertical beam widths in rad (typically, $\theta_0 \approx \Phi_0$ for a weather radar), and $c\tau$ is the pulse length and receives a factor of 1/2 for the leading edge of the radar volume to go out and come back in order to arrive simultaneously with the trailing edge. As a figure to remember, the diameter of a 1° beam is about 1 km at a distance of 57 km. With a raindrop density of 100 drops per 1 m^3 , one sample volume may contain 10^9 – 10^{12} droplets.

Provided that the sample volume is completely and homogeneously filled and evenly illuminated by the radar, the backscattering cross sections $\sigma_{b,i}$ of all point targets (numbered by i) contribute linearly to the total backscatter, yielding a total backscattering cross section

of

$$\begin{aligned} \sigma_{\text{tot}} &= \sum \sigma_i \quad (\text{sum over } V) \\ &= V \sum \sigma_i \quad (\text{sum over unit volume}). \end{aligned} \quad (30.10)$$

In reality, the sample volume is not homogeneously irradiated, as there is no radar beam but an antenna diagram (Sect. 30.4.2). The decrease of gain within the 3-dB beam width may, in a first approximation, be described by a Gaussian, leading to an average over the beam width or shape factor of $1/2 \ln(2) \approx 72\%$ [30.34]

$$V = \frac{\pi}{16 \ln(2)} r^2 \theta_0 \Phi_0 c \tau. \quad (30.11)$$

As σ_{tot} is an extensive quantity, it is convenient to normalize to the unit volume, making use of the (radar-) reflectivity $\eta = \sum \sigma_{b,i} = \sigma_{\text{tot}}/V$, where the sum is over the unit volume and is measured in units of m^2/m^3 or cm^{-1} . Letting $\theta_0 = \Phi_0$ for a circular beam,

$$\sigma_{\text{tot}} = \frac{\pi}{16 \ln(2)} r^2 \theta_0^2 c \tau \sum \sigma_{b,i} \quad (30.12)$$

$$\begin{aligned} P_r &= \frac{1}{1024 \ln(2) \pi^2 r^2} P_t G^2 \lambda^2 \theta_0^2 c \tau \sum \sigma_{b,i} \\ P_r &= \frac{\pi^3}{1024 \ln(2) \lambda^2 r^2} P_t G^2 \theta_0^2 c \tau |K|^2 z_e \end{aligned} \quad (30.13)$$

This is the radar equation for distributed (volume) targets. Note that for volume targets, P_r (dBm) is proportional to r^{-2} : $P_r \propto z_e \lambda^{-2} r^{-2}$, so that $z_e = CP_r r^2$ or, in logarithmic form,

$$Z_e = 10 \log_{10} P_r + 20 \log_{10}(r) + 10 \log_{10}(C). \quad (30.14)$$

C ($\text{mm}^6 \text{m}^{-3} \text{mW}^{-1} \text{m}^{-2}$) or ($\times 10^{-15} \text{mm mW}^{-1}$) is called the radar constant and contains all coefficients and parameters that are not functions of r or Z_e . The system-specific radar constant is determined during calibration (Sect. 30.6.1). Once C is known, a target's Z_e may be determined measuring its range and return power.

As droplets within the sample volume move around, successive radar pulses produce identical echoes only if $\text{PRT} \rightarrow 0$. Hydrometeors need to reshuffle for the radar to obtain statistically independent samples. The time needed to decorrelate (e.g., to 0.01) is called the decorrelation time or time to independence and decreases with decreasing wavelength and increasing turbulence. Experimentally, $t_{0.01}$ (ms) $\approx 2.5\lambda$ (cm) in the range of 3.5–30 ms [30.33]. In reality, this condition is not met because under operational conditions the dwell time is

too short. Instead, more pulses are collected at higher PRF, and independence is increased by averaging over azimuth and range.

Calculation in Decibels

There are a couple of variables in radar science that span a very large dynamic range. The radar reflectivity factor for small particles increases with D^6 and easily spans more than ten orders of magnitude. The received power of a radar is up to 18 orders smaller than its transmit power. In cases like these, it is convenient to take the logarithm in order to avoid writing many digits. Thus, it is considered more convenient to write $-30 \text{ dB}\sigma$ and $+90 \text{ dBZ}$, instead of 0.001 cm^2 and $10^9 \text{ mm}^6 \text{m}^{-3}$.

The unit of decibels is defined as a logarithmic power ratio $10 \log_{10} P_1/P_0$. A power ratio of 1 results in 0 dB.

Calculation in dB follows the laws of exponentiation and logarithm, e.g., $\log_{10} 10^{a-b} = \log_{10}(10^a/10^b) = a - b$. Keeping in mind that $\log_{10} 10 = 1$, $\log_{10} 2 \approx 0.3$ and $\log_{10} \pi \approx 0.5$, it turns out that a factor of 2, 3, 10, 100 corresponds to 3, 5, 10, 20 dB. Then, it is easy to estimate the following useful examples (Table 30.5).

Thus, *decibel* is a dimensionless power ratio. However, it may be agreed upon to refer this ratio to a given absolute value x , which is subsequently indicated in the unit of dBx. For instance, the unit of dBm refers to $P_0 = 1 \text{ mW}$ by convention, so that $0 \text{ dBm} = 1 \text{ mW}$, and $33 \text{ dBm} = 2 \text{ W}$. Table 30.6 shows a couple of examples.

It should be kept in mind that any power calculation, such as averaging or Fourier transformation, must be performed on linear values; e.g., Z (dBZ) must not

Table 30.5 Useful dB values

Factor of	Write as	dB
0.1	10^{-1}	-10
0.5	$1/2$	$0 - 3 = -3$
1	10^0	0
2	$10 \log 2$	3
3	$10 \log 3$	5
4	2×2	$3 + 3 = 6$
5	$10/2$	$10 - 3 = 7$
10	10^1	10
250	$10^3/4$	$30 - 6 = 24$

Table 30.6 Some absolute logarithmic quantities

Log unit	Refers to	Typical value
dBZ	$z = 1 \text{ mm}^6 \text{m}^{-3}$	-31.5 to +95 dBZ
dBm	$P = 1 \text{ mW}$	84 dBm = 250 kW
dBi	$G = 1$ (isotropic radiator)	45 dBi
dBσ	$\sigma = 1 \text{ cm}^2$	-30 to +80 dBσ
dBsm	$\sigma = 1 \text{ m}^2$	-40 to +20 dBsm
dBRR	$RR = 1 \text{ mm h}^{-1}$	-1 to +2.5 dBRR

be averaged. (Even though it has been pointed out that interpolation in log units may produce smaller errors.)

30.3.2 Doppler Radar Principles

Doppler radar is based on the Doppler effect that is well known in daily life (the siren of a passing police car) and science (the Hubble effect). The movement of a precipitating cloud is such that there is no relativistic effect but only a linear radial Doppler effect. It describes the change of frequency in dependence of a moving light (or sound) source's velocity by

$$f' = f_0 \left(1 \mp \frac{V_r}{c} \right), \quad (30.15)$$

where f' is the observed frequency and f_0 is the transmitted frequency, c its wave propagation velocity, and V_r the velocity of the moving source relative to the observer; V_r is counted as negative (positive) if directed towards (away from) the radar and creates a positive (negative) Doppler shift. In a monostatic radar, the effect occurs twice as the target acts as a moving receiver and as a moving backscatterer at the same time, so the Doppler frequency shift f_{DOP} becomes

$$f_{\text{DOP}} = \frac{-2V_r}{\lambda} = -2V_r \frac{f_0}{c}. \quad (30.16)$$

The Doppler shift is, thus, 62.5, 36.4, or 20.0 Hz for every 1 m s^{-1} of radial velocity at X-band, C-band, or S-band, respectively. It must be kept in mind that only the radial wind component V_r can thus be measured, and nothing can be said about the magnitude and direction of the real wind vector \mathbf{V} , even if the subscript r is sometimes dropped.

Each droplet k within the radar volume contributes to the echo according to its radar backscattering cross section σ_k and Doppler frequency $f_{\text{DOP},k}$, the whole ensemble giving rise to the Doppler power spectrum $S(f_k)$. The individual contributions are conveniently described as complex pointers or vectors $\mathbf{a}_k = a_k \exp(-j\omega_{\text{DOP},k}t)$, using the echo amplitude a_k and angular frequency $\omega_{\text{DOP},k} = 2\pi f_{\text{DOP},k}$ of each droplet. As all droplets in the radar volume are illuminated by a coherent wave, their contributions add coherently (vectorially) to $\mathbf{A} = \sum \mathbf{a}_k = \sum a_k \exp(-j\omega_{\text{DOP},k}t)$, which, in turn, represents a complex number $\mathbf{A}_i = a_i \exp(-j\omega_{\text{DOP},i}t)$. Here, k counts the droplets in the radar volume and i the irradiating pulses. Each pulse i returns a complex echo at every range bin. The index of the range bin is usually suppressed, where appropriate.

Phase Measurement

According to the above formula, the frequency shift between transmitted and received waves is in the or-

der of 1 kHz (often less) at meteorological velocities and is, thus, very small compared to the radar transmit frequency f (e.g., 5 GHz), which makes it difficult to calculate the frequency difference. The phase shift $\Delta\phi$ due to target displacement between two consecutive pulses is measured instead and divided by PRT to obtain the target radial velocity. Thus, the (double) target interpulse displacement is measured in units (as a fraction $\Delta\lambda$) of the transmitted wavelength λ modulo integer multiples of λ or as $\Delta\phi$ in radians modulo 2π . Division by the pulse repetition time PRT (or multiplication by PRF) yields the mean target velocity

$$v(\Delta\lambda) = \frac{\Delta\lambda \text{PRF}}{2}, \quad (30.17)$$

$$v(\Delta\phi) = \frac{\Delta\phi \lambda \text{PRF}}{4\pi}. \quad (30.18)$$

Mathematically, if the transmitted phase is ϕ_0 , and the distance to target is r , then the distance traveled by the wave is $2r$ or, measured in wavelengths, $2r\lambda^{-1}$, or $2\pi 2r\lambda^{-1}$ if measured in radians, so that the phase of the echo wave incident at the radar is $\phi_0 + 4\pi r\lambda^{-1}$. Its derivative with respect to time t is

$$\frac{d\phi}{dt} = \frac{4\pi}{\lambda} \frac{dr}{dt}, \quad (30.19)$$

where $d\phi/dt = 2\pi f_{\text{DOP}} (= \omega_{\text{DOP}}$, the angular Doppler frequency), and $dr/dt = -V_r$, the radial target velocity (counted negative if approaching), so that $f_{\text{DOP}} = -2V_r/\lambda$, as before. The differential quotient $d\phi/dt$ is approximated by the difference quotient $\Delta\phi/\Delta t$, where Δt is the time difference between pulses, i.e., PRT, and $\Delta\phi$ is the respective pulse-to-pulse phase difference. In order to compare the phases of consecutive pulses, their phase must be corrected for the initial transmit phase ϕ_0 if the latter is not constant (as in a magnetron system, see Sect. 30.4.1, or in a whitening procedure, see Sect. 30.6.3).

The Doppler Dilemma

Due to Nyquist's sampling theorem ([30.35] or Chap. 2), f_{DOP} has to be sampled twice (by different radar pulses) in order to be recovered correctly. If the pulse repetition frequency is PRF, then $|f_{\text{DOP}}|$ may not be larger than $\text{PRF}/2$, yielding

$$V_{r,\text{max}} = \pm \text{PRF} \frac{\lambda}{4}. \quad (30.20)$$

Thus, the maximum unambiguous Doppler velocity that can be measured by a radar depends on its wavelength λ and pulse repetition frequency PRF.

Table 30.7 Product of unambiguous velocity and unambiguous range

Band	λ (cm)	$V_{r,\max}R_{\max}$ (km m s ⁻¹)
X	3	1125
C	5	1875
S	10	3750

The range $[-V_{r,\max}, +V_{r,\max}]$ of unambiguous velocities is also called the Nyquist interval $[-V_N, +V_N]$ and is expressed in either absolute velocities (m s⁻¹), in phase units (deg or rad), or normalized to $[-1, +1]$. Velocities lower than $-V_N$ or higher than $+V_N$ will appear aliased or *folded* into the unambiguous interval. That is, $V_r = V_N + \partial V$ will be erroneously interpreted as $-V_N + \partial V$, which is $2V_N$ away from the real value V_r , see Fig 30.16 for an example. Combined with (30.2) this yields

$$V_{r,\max}R_{\max} = \pm\lambda \frac{c}{8}. \quad (30.21)$$

The equation shows that there is a tradeoff between $V_{r,\max}$ and R_{\max} , each one can only be extended at the cost of the other. This is called the Doppler dilemma. Obviously, an S-band radar is capable of simultaneously measuring larger unambiguous velocities and ranges than an X-band radar. This is shown in Table 30.7. Methods exist to extend the unambiguous range (Sect. 30.6.3).

Complex Signals in Time and Frequency Domains

For each single pulse, echoes are returned from targets along the propagation path. The return time defines the target distance. In modern computerized radars, the incoming echo is digitized at certain range gates (range bins). This is done for every single transmitted pulse, yielding a time series of returned pulse signals at each range gate. For an operational radar, the length of the time series is defined by the time on the target (dwell time), which is a function of antenna beam width and angular (usually azimuth) rate.

In an intensity-only radar, the measured time series is just a real time series representing the echo intensity, and nothing is known about phase. In a Doppler radar, the echo phase complements each measurement to form a complex number in either Cartesian, trigonometric, or exponential representation. A dual-polarization radar measures two complex time series, one for each polarization. All meteorological information is contained in and must be derived from these signals in either the time or the frequency (spectral) domain using filters, correlations, and Fourier transforms for every single range gate. This is performed in realtime by a digital signal processor DSP (Sect. 30.4.4).

The echo amplitude A_i and phase ϕ_i of the i -th pulse at a certain range bin (the range index is dropped) are considered as a complex signal in the exponential notation

$$A_i = A_i \exp -j\phi_i, \quad (30.22)$$

which may be equally well described in its algebraic form

$$A_i = I_i + jQ_i, \quad (30.23)$$

where $I_i = A_i \cos \phi_i$ and $Q_i = A_i \sin \phi_i$ constitute the Cartesian components. These are the (real) signals measured in a radar, possibly for each polarization, after I/Q demodulation by an analog or digital quadrature detector. The pulse (or time) index i runs from the first usable pulse to the last one in a batch, so that A_i forms a time series. Note that a time series is obtained at each (raw) range bin, whose index has been dropped for simplicity. The time series may be processed either in the time domain or in the frequency domain; the equivalency is guaranteed by the Wiener–Khinchin theorem, which states that the autocorrelation function $R(t)$ and the power spectrum $S(f)$ of a signal form a pair of Fourier transforms cf. Chap. 2.

The Doppler spectrum is commonly modelled to consist of three parts: a Gaussian weather spectrum of width W around the mean velocity V and a narrow clutter spectrum centered at zero velocity, above a white noise floor; S , C , and N are the powers (the areas under the respective curves) of the Gaussian weather spectrum, the (Gaussian) clutter spectrum and the white noise; S , V , and W are the zeroth, first and second moments of the Doppler spectrum in a mathematical sense.

Time-domain or Pulse-pair Processing (PPP)

Time-domain processing is based on correlation calculation. As per definition, the autocorrelation of the filtered (superscript “f”; cf. Sect. 30.6.3) or unfiltered complex radar time series $A_i^{(f)}$ is

$$R_l^{(f)} = \frac{1}{n-l} \sum_{i=1}^{n-l} A_i^{(f)*} A_{i+l}^{(f)}, \quad (30.24)$$

where n is the number of available pulses (the length of the time series), l is the lag index, and the asterisk (*) denotes the complex conjugate. Commonly, unfiltered R_0 is denoted T_0 , and (f) is omitted for filtered autocorrelations, so that R_0 , R_1 , and R_2 are understood to be filtered; T_0 and R_0 are real numbers, all other R_l are complex.

The desired information – weather echo power S , mean radial velocity V , and spectral width W – is concentrated in the first lags ($l = 0, 1, 2$) of R_l and extracted during signal processing, cf. Sect. 30.4.4.

Table 30.8 Autocorrelations and moments

	Formula	Physical model
T_0	$\frac{1}{n} \sum_{i=1}^n A_i^* A_i$	$\frac{S+C+N}{2\pi}$
R_0	$\frac{1}{n} \sum_{i=1}^n A_i^{(f)*} A_i^{(f)}$	$\frac{S+N}{2\pi}$
R_1	$\frac{1}{n-1} \sum_{i=1}^{n-1} A_i^{(f)*} A_{i+1}^{(f)}$	$\frac{S}{2\pi} \exp\left(j\pi V - \frac{(\pi W)^2}{2}\right)$
R_2	$\frac{1}{n-2} \sum_{i=1}^{n-2} A_i^{(f)*} A_{i+2}^{(f)}$	$\frac{S}{2\pi} \exp(j2\pi V - 2(\pi W)^2)$

Table 30.8 gives an overview of this. The mean velocity V and spectral width W are normalized to $V_N = [-1, +1]$.

Frequency-domain Processing.

The discrete Fourier transform (DFT) of a periodic signal x_n is

$$X_k = \sum_{n=0}^{N-1} x_n \exp -\frac{2\pi jkn}{N}, \quad (30.25)$$

and the inverse DFT is

$$x_n = \frac{1}{N} \sum_{k=0}^{N-1} X_k \exp \frac{2\pi jkn}{N}.$$

As the radar signal A_i is *not* periodic, it must be made periodic by tapering it with a periodic window, which, on the downside, produces unwanted sidelobes and a higher variance (reducing the effective number of independent samples). This is why several windows, such as rectangular, von Hann, Hamming, and Blackman, have been designed for tradeoff. A rectangular window exhibits a narrow pulse response but high sidelobes masking weak targets, while a Blackman window shows a broad pulse response but very low sidelobes, which can only be exploited in very low-phase noise systems. In a magnetron radar, a Hamming window is usually considered appropriate.

A fast Fourier transform (FFT) requires a power-of-two number of samples, which cannot be guaranteed under a free-running antenna with dynamic angle synchronization DAS (Sect. 30.4.4). As a workaround, the number N of samples available within one batch (ray) may be split into two overlapping groups of 2^n pulses each, where $2^n < N$. FFT is performed on each group separately, and the results are averaged. Once the Fourier spectrum has been obtained, adaptive clutter filtering is performed (Sect. 30.6.3).

The Doppler moments may then be directly derived from the spectrum (e.g., adding up the spectral components to find the filtered and unfiltered powers and finding the strongest Fourier component to determine the mean velocity). Often, however, the spectrum

is converted back to the time domain via an inverse Fourier transform to make use of the autocorrelation processing.

In the end, T_0 , R_0 , R_1 , and R_2 are available. Time-domain processing is faster and less intensive, as all correlations may be calculated incrementally simply by adding each new pulse, and only few lags need to be calculated. It can also work with lower SNR. Doppler filtering (Sect. 30.6.3), however, as well as scientific analysis, is more efficient in the frequency domain.

It may be noted that the assumption of a Gaussian weather spectrum is appropriate if one mean velocity and one spectral width is calculated for the whole Doppler spectrum by the above standard algorithms. If, however, there is a high enough spectral resolution, which is the case for a long underlying time series (e.g., 1024 pulses), then several modes may be detected, and their corresponding mean velocities and spectral width calculated in order to discriminate between different groups of hydrometeors within the radar detection volume.

The physical moments and parameters that may be calculated from Doppler measurements are integrated into Sect. 30.3.4.

30.3.3 The Multiparameter Approach

As there is only one radar observable in a reflectivity-only radar, and three in a Doppler radar, it is desirable to measure more independent observables in order to describe the distributions of size, shape, aggregate state, and velocity of the ensemble of scattering particles. Polarization or frequency diversity radars are promising candidates.

Compared to dual polarization, dual frequency has received considerably less attention so far, except for the Russian MRL-5, which features two nested parabolic antennas. The COST-75 study [30.36] opted against dual-wavelength radars mainly because of beam matching challenges. Existing dual-frequency radars mostly operate at higher frequencies (Ku-W-band) [30.37]. Measuring the frequency-differential reflectivity, also called differential frequency ratio (DFR), which is defined as the difference of radar reflectivity factors between the respective frequency bands, it is expected that hail may be detected making use of the resonances of the radar backscattering cross section in the Mie region.

Dual-Polarization Principles

Besides wavelength, amplitude, and phase, polarization of an electromagnetic wave is one more parameter that may be measured to gain additional information. Polarization is defined as the direction of the electric field vector – if there is any predominant direction. The

most general polarization state would be elliptical, with circular and linear polarization as special cases. The instantaneous polarization state is usually described as a vector in an arbitrary orthogonal basis $\{e_1, e_2\}$, most often circular (left/right-handed $\{e_l, e_r\}$) or linear (horizontal/vertical $\{e_h, e_v\}$).

Any action on the polarization state is then described by a left matrix multiplication, e.g.,

$$\begin{bmatrix} E_h^r \\ E_v^r \end{bmatrix} = \begin{pmatrix} S_{hh} & S_{hv} \\ S_{vh} & S_{vv} \end{pmatrix} \begin{bmatrix} E_h^t \\ E_v^t \end{bmatrix} \frac{\exp(-2jkr)}{2r} \quad (30.26)$$

represents the transformation of the transmitted wave (superscript t) into the received wave (superscript r) due to backscattering only. The complex 2-D vectors are called Jones vectors and characterize the electric field vector orthogonal to the direction of propagation (so that the third field component is zero). The complex elements (*scattering amplitudes*) of the backscattering matrix \mathbf{S} are directly connected to the scattering-related polarization observables (Sect. 30.3.4). The Jones formalism is applicable to fully polarized transversal waves. Partially polarized waves are described by the 4-D Stokes formalism combining 4-D Stokes vectors by Mueller matrices. The Stokes–Mueller formalism may be represented by the Poincaré sphere [30.38] but is related to intensity only (no phase information).

Classical and Doppler radars are not *unpolarized*; rather, their polarization can neither be altered during transmission nor differentiated while receiving. The polarization of such a radar is usually chosen horizontally to maximize the return of large, oblate raindrops.

Fully polarization-agile weather radar systems (e.g., CSU-CHILL, Chilbolton, DLR) are mostly research systems whose full capabilities (to measure the full covariance matrix in different polarization bases) cannot be adequately valued here, see [30.38] instead for a thorough theoretical discussion of polarization and its measurement. They are capable of changing the polarization state on a pulse to pulse basis, e.g., alternating between horizontal and vertical polarization, making use of a fast polarization switch. This mode is called the alternate or switched mode.

Operational dual-polarization weather radars usually invoke a linear polarization base (i.e., horizontally and vertically) in the so-called hybrid (or STAR, or SIDPOL©) configuration. STAR stands for simultaneous transmit and receive of *H* and *V*, (*not* transmitting and receiving at the same time). Transmitting equal power in *H* and *V* simultaneously results in transmitting at 45° (vector addition). Two transmitters may (rarely) be used to produce *H* and *V*, or a power splitter (*magic tee*) may be applied. Phase measurement accuracy (correlation) is higher with hybrid mode because *H*

Table 30.9 Pros and cons of switched and hybrid dual-pol modes

Switched mode	Hybrid mode
Full polarization matrix measurable	No cross-polar measurements
Vulnerable ferrite switch	Robust power divider
Expensive	Cheaper
Full power available	Half power each channel
Only every second pulse coherent	Pulses less decorrelated

and *V* measurements are obtained simultaneously for each pulse, while in alternate mode, only every other pulse is to be used. The hybrid mode is easy and robust to set up using a splitter, while pulse-to-pulse ferrite switches are prone to failure. While halving the transmit power by splitting into *H* and *V* does not pose a real problem (at least in magnetron and klystron systems), no cross-polar measurement can be performed in hybrid mode, and there is a small error in the copolar measurement due to the depolarized component of the other (cross polar) channel. Therefore, some radars may be able to switch off one (usually the vertical) channel temporarily so as to enable measurement of the cross polar components. These are still much weaker than copolar backscatter and are, therefore, difficult to measure because of low SNR and possible crosstalk in antenna and receiver. In Europe, only the MetOffice seems to operate their radars using both hybrid and LDR mode operationally. Table 30.9 summarizes advantages and drawbacks of both approaches.

30.3.4 Radar Observables

Based on the echo time series available (intensity only, Doppler, dual pol), the following observables or *moments* may be calculated.

The Reflectivity Factor

An intensity-only weather radar measures just the received power P_r , commonly in logarithmic units. It may also calculate a clutter correction CCOR from the amplitude fluctuation, see Sect. 30.6.3. Based on (30.14) the effective reflectivity factor Z_e (dBZ) is calculated as

$$Z_e = 10 \log P_r + 20 \log r + ar + Z_0(+CCOR), \quad (30.27)$$

where the prefix C or U is commonly added to indicated the corrected or uncorrected moment, so that:

- UZ is the uncorrected (unfiltered and without adding CCOR) reflectivity.
- CZ (CCOR added) is the (clutter and, if required, second-trip) corrected reflectivity.

- r (km) is the target range, and $20 \log r$ is the r^2 range correction (Sect. 30.6.3).
- a (dB km⁻¹) is the two-way specific gas attenuation (Sect. 30.6.3).
- Z_0 (dBZ) is the calibration reflectivity determined during calibration (Sect. 30.6.1).
- P_r is the pulse-averaged (linear) received power (including clutter) after subtraction of (measured) noise and biases.
- In the case of a Doppler radar, $P_r = (T_0 - N)N^{-1}$ is calculated from the unfiltered unlagged autocorrelation and the noise measurement.
- CCOR is the clutter correction (Sect. 30.6.3).

If applicable, the reflectivity factor is calculated separately for both polarizations (e.g., h and v) and denoted Z_h and Z_v , with the above prefixes.

Doppler Moments

Many more parameters can be derived using a Doppler radar. Note that all of these are obtained twice in a dual-pol radar.

Mean Radial Velocity V . For a symmetric Doppler spectrum V may be calculated from formula (Table 30.8)

$$V = \frac{\lambda \arg(R_1)}{4\pi\tau} \quad (30.28)$$

R_1 is the complex autocorrelation (30.24) at lag $l = 1$, whose argument is the phase difference between the two pulses. In the case of a magnetron system, the phases of the individual pulses must first be corrected for the transmitted initial phase sampled from the burst pulse prior to correlating in order to be comparable; V may be calculated from filtered and unfiltered time series and, in a dual-pol radar, for both polarizations yielding V_h , V_v , UV_h , and UV_v ; V may be output by DSP in absolute units of m s⁻¹ or normalized to the Nyquist intervals $[-V_N, +V_N]$, $[1, +1]$, respectively.

Spectrum Width W . In a Gaussian model, this parameter is the spectral width of the Doppler spectrum. It is indicative of shear, turbulence, or a radial component of the fall velocity distribution and subject to broadening effects, such as system (particularly magnetron) phase instability and antenna rotation. As a side note, the spectral width of clutter also depends on phase stability and antenna speed, and, in addition, on natural fluctuations, such as moving leaves. This broadening influences the clutter filter width to be chosen (Sect. 30.6.3).

In signal processing, an effective spectral width will be estimated, as real spectra are sometimes not Gaus-

sian or even not monomodal. There are two algorithms to estimate the Doppler spectrum width. The faster one,

$$W = \frac{\sqrt{2 \ln(R_0)/|R_1|^{-1}}}{\pi} \quad (30.29)$$

uses only R_0 and R_1 and requires a Gaussian spectrum and large SNR (e.g., SNR > 10 dB), as clarified by (30.32), when SNR/(SNR + 1) → 1.

The more accurate one,

$$W = \frac{\sqrt{\frac{2}{3} \ln(|R_1|)/|R_2|^{-1}}}{\pi} \quad (30.30)$$

makes use of R_0 , R_1 , and R_2 and can work with lower SNR (e.g., SNR > 0 dB);

W may be calculated from corrected and uncorrected time series and, in the case of a dual-pol radar, for both polarizations yielding W_h , W_v , UW_h , and UW_v . The output format may be normalized to [0–1] or absolute m s⁻¹.

Signal Quality Index SQI . The power normalized amplitude of lag 1 autocorrelation is called the signal quality index

$$SQI = \frac{|R_1|}{R_0} \quad (30.31)$$

where R_0, R_1 are the autocorrelations at lag 0 and lag 1 of the filtered time series according to Table 30.8. Its value is zero for white noise and one for a single spectral line. In the Gaussian model,

$$SQI = \frac{SNR}{SNR + 1} \exp\left(-\frac{(\pi W)^2}{2}\right) \quad (30.32)$$

SQI may, thus, be considered as an indicator of the Doppler signal quality, and $SQI < SQI_{thr}$ may be used as a threshold criterion thereof. In a digital receiver of a magnetron (or of a pulse coded klystron) radar second or third-trip SQI may also be calculated cohering to the phase of the previous or earlier pulses, see Sect. 30.6.3.

Clutter Phase Alignment CPA . CPA is the absolute value of the complex (vectorial) addition of the A_i time series, normalized to the sum of A_i magnitudes,

$$CPA = \frac{|\sum A_i|}{\sum |A_i|} \quad (30.33)$$

CPA is an indicator of the phase variability within (over N samples of) the received complex time series. The echo phase is constant for stationary targets but

changes deterministically in weather echo, if the mean velocity is not zero, and randomly for noise. Thus, CPA ranges between 0 and 1 and is low if the resulting vector is *short* due to rapid phase shifts, and approaches 1 (e.g., CPA > 0.95) if all A_i point to the same direction, indicating no Doppler shift as an evidence of a stationary target (ground clutter). Azimuthal super resolution may be used to capture the maximum CPA under strong reflectivity gradients, but the reliability of CPA decreases if N is too small.

Amplitude STD. The normalized standard deviation STD of the received signal amplitude $|A_i|$

$$\text{STD} = \sqrt{1 - \frac{\sum |A_i|^2}{\sum |A_i|^2}} \quad (30.34)$$

is a stability indicator. Low STD is indicative of stable signals with low amplitude variance. On the contrary, interference from pulsed foreign transmitters exhibits high STD. A typical value for noise would be STD \approx 0.5. This property may be applied to detect pulsed RF interference, cf. Sect. 30.6.3.

Signal-to-noise Ratio SNR. This standard parameter is calculated as

$$\text{SNR} = 10 \log \frac{T_0 - N}{N}, \quad (30.35)$$

where the total power is T_0 (Table 30.8) in a Doppler radar and the average of squared unfiltered amplitudes (linearized log samples) in an intensity-only radar. The noise power N is determined from noise measurement (Sect. 30.6.1). SNR is typically used for quality control and can easily be converted to the received power simply adding the minimum detectable signal (MDS) in dBm that is determined during calibration. The power estimate can then be related to an external reference, such as the sun to monitor the receiver calibration.

Clutter Correction CCOR. Clutter correction CCOR is defined as

$$\text{CCOR} = 10 \log \frac{S}{C+S} = 10 \log \frac{1}{\text{CSR} + 1}, \quad (30.36)$$

where the antilogarithm is related to the clutter-signal ratio CSR = CS^{-1} but is calculated differently in intensity-only, analog and digital Doppler radar, see Sect. 30.6.3.

When SNR is large enough,

$$\text{CCOR} = 10 \log \frac{R_0}{T_0} \quad (30.37)$$

(cf. Table 30.8) approaches (30.36). Using T_0 , R_0 , R_1 , and additionally R_2 , signal and clutter powers may be

calculated independently by

$$C = \frac{T_0 - R_0}{2\pi}, \quad (30.38)$$

$$S = \frac{|R_1|}{2\pi} \exp \frac{\pi^2 W^2}{2}, \quad (30.39)$$

even with low SNR.

Note that CCOR is *negative* by definition, as it will be *added* in (30.27). The calculated CCOR is usually tested against a predefined threshold CCOR_{thr}, cf. Sect. 30.6.4.

Weather Signal Power WSP. This parameter (sometimes called SIG or SIGPOW) estimates the SNR of the weather signal in dB after clutter correction. WSP may be calculated from T_0 , R_0 , R_1 alone by

$$\text{WSP} = 10 \log \frac{T_0 - N}{N} + 10 \log \frac{R_0}{T_0}, \quad (30.40)$$

which represents the total SNR plus CCOR by (30.35) and (30.37). If R_2 is available,

$$\text{WSP} = 10 \log \frac{S}{R_0/2\pi - S}, \quad (30.41)$$

with S as before (30.39).

WSP is mainly used for thresholding; the pertaining threshold is WSP_{thr} (Sect. 30.6.4).

Polarization Observables

Several observables may be derived from the complex copolar and cross-polar dual-pol time series. First, all moments known from a Doppler radar may be obtained in h and v versions: Z_h/Z_v , UZ_h/UZ_v , V_h/V_v , W_h/W_v , SQI_h/SQI_v , and $CCOR_h/CCOR_v$. Second, several ratios, differences, and correlations may be formed:

Differential Reflectivity ZDR. Differential reflectivity is the ratio z_{hh} over z_{vv} of horizontal over vertical copolar reflectivity factors measured in $\text{mm}^6 \text{mm}^{-3}$ (noise subtracted) – or their dBZ difference

$$\text{ZDR} = 10 \log_{10} \left(\frac{z_{hh}}{z_{vv}} \right) = Z_h - Z_v \quad (\text{dB}). \quad (30.42)$$

Intuitively, ZDR describes the shape or axis ratio of the scattering targets, so that for spheres (raindrops smaller than 0.3 mm) ZDR = 0, while for oblate particles (large drops falling against air drag) ZDR = 0–6 dB. This may be used as a measure of drop size in quantitative precipitation estimation QPE and hydrometeor classification HMC. Depending on temperature (measurement height), ZDR larger than 1 may also be indicative of

supercooled water drops in strong storm updrafts. Prolate (aligned ice) particles exhibit negative ZDR. ZDR is around 0 in hail, because falling hail is usually not aligned. Thus, ZDR may be used to differentiate between hail and large raindrops. Small reflectivity combined with larger ZDR may indicate insects.

Although ZDR may be calculated from both filtered and unfiltered reflectivities, it is preferred to use uncorrected input to avoid clutter filter artifacts. ZDR must be calibrated for any offset and will be biased by differential attenuation.

ZDR may also be calculated using the autocorrelations at first lags

$$\text{ZDR}_1 = 10 \log_{10} \left(\frac{|R_{1h}|}{|R_{1v}|} \right). \quad (30.43)$$

A differential Doppler velocity is sometimes calculated according to

$$\text{DDV} = V_h - V_v. \quad (30.44)$$

It may be used as an indicator in bird watching [30.39].

Depolarization Ratio LDR. Not all of the energy is scattered back at the same polarization as it was transmitted. Some part may be depolarized into the cross-polar channel. The depolarization ratio relates this cross-polar received power to the copolar received power. For example, transmitting horizontally in a linear polarization base, the cross-polar reflectivity factor Z_{vh} measured in the vertical channel is related to the copolar reflectivity factor Z_{hh} . (By convention, the first index refers to the receive channel, the second one to the transmit channel.) Hence, the *linear depolarization ratio* is

$$\text{LDR}_{vh} = 10 \log_{10} \left(\frac{z_{vh}}{z_{hh}} \right) = Z_{vh} - Z_{hh} \quad (\text{dB}) \quad (30.45)$$

and is, thus, negative by definition. LDR depends on the shape, orientation, and fall behavior of particles and is, therefore, used to identify particles that are rotated against the plane of polarization, e.g., the melting layer (*bright band*) or wet hail/graupel, tumbling asymmetric melting particles exhibiting high copolar and cross-polar reflectivities, as well as ground clutter and non-met echoes. LDR may be calculated from filtered or unfiltered reflectivities and must be calibrated for any offsets, usually by pointing at the sun. LDR cannot be measured under the hybrid (STAR) setup as no cross-polar channel is available.

Under a circular polarization base transmitting, say, lefthanded circular (LHC) and receiving both LHC (copolar) and RHC (cross polar), the *circular depolarization ratio* is defined as

$$\text{CDR}_{rl} = 10 \log_{10} \left(\frac{z_{rl}}{z_{ll}} \right) = Z_{rl} - Z_{ll} \quad (\text{dB}). \quad (30.46)$$

Compared to ZDR and LDR, CDR can be measured more easily and depends only weakly on the orientation of scatterers. CDR is mainly conducive of their shape and phase composition and is, therefore, used to study ice microphysics and hail size. On the other hand, CDR is prone to corruption due to differential attenuation and phase shift to a degree of turning positive, particularly behind strong precipitation [30.40].

Both LDR and CDR tend to $-\infty$ for spheres, but very low values are limited by the radar overall crosstalk, mainly caused by the antenna assembly including the feed. As depolarization will also occur in forward scattering, the polarization purity of the incident wave may be affected when passing through a depolarizing medium.

Copolar Cross Correlation RHOHV. The copolar cross correlation is the correlation between the copolar complex time series, usually horizontal $A_{hh,i}$ and vertical $A_{vv,i}$, or between the corresponding elements of the backscattering matrix \mathbf{S} . Its absolute value at lag zero is designed RHOHV,

$$\begin{aligned} \text{RHOHV} &= |\rho_{hv}(0)|, \\ \rho_{hv}(0) &= \frac{\sum S_{vv} S_{hh}^*}{\sqrt{\sum S_{vv}^2 \sum S_{hh}^2}} = |\rho_{hv}(0)| \exp j\delta. \end{aligned} \quad (30.47)$$

RHOHV is very close to 1 (e.g., 0.99) with spherical and uniformly falling particles and decreases in unevenly falling nonspherical particles, such as hail, graupel, or melting snow. Clutter may be expected to the range below 0.6. RHOHV is, therefore, used to discriminate between different hydrometeors. Figure 30.10 shows an example of a *bright band*. As RHOHV is phase sensitive, it is best calculated from the unfiltered time series to avoid filter phase errors. The phase angle δ in (30.47) is the differential backscattering phase. In the absence of propagation effects it describes the phase change upon (non-Rayleigh) scattering.

If the full polarization measurement is available, or if the radar is in LDR mode, the cocrosspolar cross correlation coefficient RHOH (or RHOV, if V is transmitted) may be computed similarly to RHOHV, even

though these correlations have so far rarely been used in routine operation. For example,

$$\text{RHOH} = |\rho_h(0)|, \quad \rho_h(0) = \frac{\sum S_{vh} S_{hh}^*}{\sqrt{\sum S_{vh}^2 \sum S_{hh}^2}}. \quad (30.48)$$

Differential Phase PHIDP. While all of the above observables describe target properties within the respective range bin, there are a number of cumulative parameters representative of the two-way propagation path. For example, oblate and prolate raindrops lead to different attenuations of the H and V polarized waves. This is called *differential attenuation* but cannot be measured directly using a monostatic radar. Also, the microwaves experience a phase shift on their way through the atmosphere, which may be different for H and V waves [30.41]. The differential phase PHIDP is the integral (cumulative with range) two-way phase shift between H and V returns measured in units of deg or rad, including the intrinsic differential propagation phase φ_{DP} , the differential backscattering phase, and any measurement errors

$$\text{PHIDP} = \Phi_{hh} - \Phi_{vv}. \quad (30.49)$$

PHIDP can be calculated from the hybrid or from the alternating mode. It is usually smoothed over some distance and must be corrected for system offset $\text{PHIDP}_{\text{offset}}$, mainly introduced by different H and V path lengths.

PHIDP is a reliable indicator of oblate or prolate scatterers and, therefore, of heavy rain with large drops,

as large drops are increasingly oblate. Intuitively, the horizontally polarized wave travels slower than the V component. PHIDP is a monotonically increasing function of range in rain and finds a major application in rainfall attenuation correction (Sect. 30.6.3). Also, PHIDP of meteorological echoes exhibits a smooth structure, whereas clutter or clear air echoes show a noisy pattern. This feature is commonly used to separate clutter and weather echoes.

The one-way local slope (range derivative) of PHIDP is called the *specific differential propagation phase*

$$\text{KDP} = \frac{1}{2} \frac{d\text{PHIDP}}{dr}, \quad (30.50)$$

and describes the differential phase shift per unit range, and as such may be very susceptible to the noisiness of PHIDP. Measures have to be taken to smooth, unfold, and interpolate PHIDP. Practically, it must be calculated as a difference quotient over a certain range, e.g., $\Delta r = 5$ (or 10) km to smooth PHIDP. Its unit is deg km^{-1} or rad km^{-1} with typical values of $0\text{--}8^\circ \text{ km}^{-1}$ in rain (in the C-band). KDP is a function of target size, shape, and orientation. Statistically isotropic (randomly oriented) targets result in $\text{KDP} \approx 0$. KDP is positive (negative) for oblate (prolate) targets, e.g., large raindrops (conical graupel). Any system phase offset cancels in KDP and it does not depend on calibration and transmit power errors or beam blockage errors. KDP is used to parameterize rain-rate relations (Sect. 30.8.3) and to correct for attenuation effects (Sect. 30.6.3). All differential polarization parameters LDR, CDR, PHIDP, and KDP are immune to errors in absolute calibration.

30.4 Radar Systems

As was mentioned above, most radars, particularly pulse radars, measure the return time of the echo as well as the antenna pointing direction in order to locate a target. A weather radar additionally measures at least echo intensity (reflectivity factor Z).

Doppler radar offers additional phase measurement; this calls for coherency. Depending on the transmitter type (see Sect. 30.4.1), the system may be fully coherent (e.g., klystron, travelling wave tube (TWT), solid-state power amplifier) or coherent on receive (magnetron). In an analog receiver (Sect. 30.4.3), coherency cannot be achieved in the logarithmic channel LOG, because the logarithm introduces phase distortions. This is why an additional linear channel LIN is needed.

A dual-pol radar is able to discern at least two orthogonal polarizations on reception, and it may be able to transmit two different (orthogonal) polarization states. Polarization diversity refers to the measurement of polarization variables at fixed transmit polarization, while polarization agility means a radar's ability to change the transmitted polarization state on a pulse-to-pulse basis. Dual-polarization, thus, adds differences and correlations between at least two polarization states. Weather radars may, therefore, be classified to be intensity-only (classical, conventional), Doppler, and multiparameter (dual-pol, dual-frequency). Most principles, components, and features used in a classical radar are also used in the more complex ones and are well described in the standard tutorials, e.g., [30.42] or [30.43].

Dual-frequency radars are too rare to be treated in extenso here, suffice it to point out that two transmitters are needed as well as matched receivers, and two antennas either collocated side by side, or the smaller one (X-band) inset into the larger one (S-band) (as e.g., MRL5, [30.21]).

The introductory remarks to Sect. 30.3.3 define some of the main components of a radar, most of which are represented in more detail in Fig. 30.5. A transmitter creates the high-power microwave waveform that is radiated into the atmosphere by the antenna. The antenna movement and position are controlled by the servo. Usually a weather radar is monostatic in that it uses the same antenna to collect the energy backscattered by the target. This is why a duplexer switches the antenna to the transmitter or to the receiver, accordingly. During transmit, the duplexer in conjunction with the T/R-limiter protects the receiver from the high-power transmit pulse. The received energy is amplified and sent to a superheterodyne receiver, as is common at radio frequencies to demodulate the high frequency. The receiver output signal is digitized and fed to a digital signal processor, DSP. The DSP calculates the parameters of interest and outputs them to a realtime display and to the host computer.

The host computer calculates special radar products and/or distributes the data and status messages via an external network. Via an internal network and the radar control unit RCU, it is also in control of the whole radar, including servo, DSP, and BITE. This is the built-in test equipment capable of automatically checking most radar components and supplementary devices. In the case of power failure, computer, and sometimes even transmitter, operation is temporarily maintained by an uninterruptible power supply UPS and possibly by an emergency generator.

30.4.1 Transmitters

The transmitter (TX) consists of either a high-power oscillator like a magnetron or a power amplifier, such as a klystron, a travelling wave tube (TWT), or a solid-state power amplifier (SSPA). Oscillator and amplifier tubes need a high voltage supply. High-voltage components are enclosed in a safe enclosure called a hotbox. Key parameters of the transmitter are efficiency, peak power, pulse length(s) PW, duty cycle (maximum PRF depending on PW), coherency, (phase) noise, long time stability, and maintainability, and size/weight may be an issue in mobile radars.

Power Amplifiers

Klystrons, TWT, and SSPA are high-power amplifiers magnifying precision low-power signals that contain

the desired waveform (frequency, phase, PRF, pulse coding . . .), e.g., supplied by the DSP. Therefore, radars applying power amplifiers inherently turn out to be coherent.

Klystrons are efficient and stable. Their size and weight and their need for high voltage (around 90 kV) usually do not pose a problem in ground-based systems. The klystron bandwidth increases with output power, while the TWT bandwidth decreases. Amplifier tubes are rugged and tolerant towards heat, overpower, antenna mismatch, and the environment.

Solid-state power amplifiers consist of many low-power amplifier modules. Even if a few elements fail, the transmitter as a whole continues working. Redundant elements increase the failure resistance and render entire backup transmitters (as with the US terminal Doppler weather radar, TDWR) unnecessary. SSPA offer high reliability and a long life (millions of hours) and are easy to maintain; modules are sometimes hot swappable. They dispense with a high-voltage power supply, thus decreasing noise and increasing safety. Their efficiency is even better than that of tube transmitters.

With the advent of GaN monolithic microwave-integrated circuits (MMICs) capable of 100 W each, the limited peak power of early (GaAs) SSPA is no longer a real issue. SSPA with 12 kW peak power are available, which achieve a sensitivity comparable to a conventional 500 kW magnetron transmitter. As solid-state modules feature low peak power, they are well suited for flexible waveforms of long pulses (pulse compression). Long (e.g., 64 μ s), low-power frequency or phase-coded waveforms are transmitted to obtain independent samples, and both the required sensitivity and range resolution. SSPA are still costly, but radars with solid-state transmitters are already being operated at X and C-bands.

Solid-state amplifier modules feature a relatively wide bandwidth and easily lend themselves to frequency agility, as well as to being arranged in an active array permitting electronic beam steering.

Magnetrons

The magnetron is a high-power self-oscillator that bursts into free oscillation with an unpredictable phase each time high voltage is applied. Its pulses are, therefore, not coherent, but may be cohered-on-receive (COR, Sect. 30.4.3). Active pulse coding is not feasible. A changing thermal regime, external or due to a changing load, primarily after a cold start, causes a frequency drift in a magnetron. Its waveform is not flexible and must be provided by a modulator.

The classical modulator consists of a pulse forming network (PFN) and a thyratron. The PFN consists of at least one set of condensers and coils immersed in oil for

high-voltage isolation that buffer energy and, thus, define the pulse width. If there are several sets for several pulse widths, they must be de-energized for switching, which takes a couple of seconds. The thyatron is a high-voltage switch that is sparked by the system trigger. Once the thyatron opens, it cannot be closed until the charge buffered in the PFN has completely discharged into a transformer that provides the necessary high-voltage pulse (25–40 kV) to the magnetron.

A more recent type of modulator is the solid-state modulator (SSM) based on field-effect transistors (FET) or insulated gate bipolar transistors (IGBT). The storage capacitors of an IGBT SSM are charged at ca. 800 V. When triggered, a one-shot oscillator gates the IGBT switch array, which, in turn, enables discharge of the capacitor energy into a pulse transformer, similarly to a thyatron, and the magnetron fires. The resulting pulse characteristics are, thus, defined by the modulator setting and the tuning of the magnetron.

More Devices in the Transmit Path

To transport the high-power high-frequency pulse from the transmitter to the antenna using a *thick cable* will not do. Due to the skin effect, all energy is transported in a thin surface layer (the *skin*) of the conductor. The skin becomes thinner, as the effect becomes more pronounced with higher frequency. No energy would be transported in the center of such cable at microwave frequencies. That is why only a conducting skin is needed and is built in the form of a hollow, often rectangular tube, called *waveguide*. The cross dimension of a waveguide is in the order of the wavelength.

The wave guide must be dehydrated in order to avoid arcing. Electrically, the wave guide must be impedance matched so that no energy is reflected back. This is achieved using a *double-stub tuner* to minimize the voltage standing wave ratio (VSWR), which is usually checked by RF sensors measuring the transmitted and reflected pulse powers at the *bidirectional coupler's* forward and reverse ports. VSWR should be close to 1. Usually, waveguide RF harmonic and bandpass filters will be necessary to suppress out of band transmission.

The transmit RF pulse is routed to the antenna through azimuth and elevation *rotary joints*. In a monostatic system, the *duplexer* or transmit–receive switch alternately switches the antenna onto transmitter or receiver. While formerly branched or balanced duplexers, nowadays mostly ferrite circulators are in use. They feature insertion losses of ≈ 0.3 dB and isolation of ≈ 20 dB.

In the case of a dual-pol radar, there may be two transmitters, or the transmit pulse may be split by a *power divider* in the transmitter cabinet. In this case, there are two circulators in the cabinet, two waveguides and dou-

ble rotary joints for azimuth and elevation in the pedestal, one for each polarization channel, and the received signal comes back the same way. The preferred setup, however, is to route the RF through single azimuth and elevation rotary joints to the antenna, as in a single-polarization radar. The power divider or ferrite switch and two circulators are then placed on the antenna. There may also be a *waveguide switch* to bypass the power divider and transmit only H (or rarely V) to enable measurement of the cross-polar component of the return signal in order to calculate LDR. As there is only one waveguide below the power divider in this case, the dual-pol receiver must be placed on the antenna as well. This configuration is called antenna-mounted receiver (AMR) or receiver-over-elevation (gear) (ROE); a schematic is shown in Fig. 30.3. It features smaller waveguide losses, and there is no need for double rotary joints (for h, v) that might cause additional imbalance. However, air conditioning and maintenance may be more demanding than in the traditional setup.

30.4.2 Antenna, Pedestal, and Radome

The antenna facilitates radiation transition from waveguide to free space or vice versa. In weather radar, reflector antennas are the most common, consisting of a parabolic *dish* with a feed in its focus. If applicable, a four-port orthomode transducer (OMT) serves as a polarization duplexer, combining orthogonal polarizations h, v for transmission through one feed. Weather radar antennas are highly focussed into a main beam (*pencil beam*) in order to facilitate high resolution sampling of the atmosphere. In reality, there is no strictly bounded geometric beam, but a 3-D radiation pattern $P(\theta, \varphi)$ (W sr^{-1}) and a normalized pattern: $P_{\text{norm}}(\theta, \varphi) = P(\theta, \varphi)P_{\text{max}}^{-1}(\theta = 0, \varphi = 0)$ that resembles the (Mie) scattering function of a scattering sphere and indicates the antenna sensitivity in every direction in space. The integral over all angles θ, φ is the total radiated power P_{tot} . As can be seen from Fig. 30.4, this pattern shows a strong forward lobe that is considered Gaussian and is taken to represent the radar beam, which is most often defined in terms of the half-power beam width (HPBW), i.e., within the -3 dB points off maximum, and is typically of the order of 1° . The first minima occur around 2.5° on both sides and define the first null beam width (FNBW), while sidelobes should be down 40 dB from the main beam maximum. The feed design is critical to sidelobe performance and polarization purity. Sidelobes are also affected by the strut design (Fig. 30.4), as center-fed antennas require struts to keep the feed in focus.

$P_{\text{max}}(\theta = 0, \varphi = 0)$ relative to isotropic radiation $P_{\text{tot}}/(4\pi)$ is the antenna gain G usually expressed in

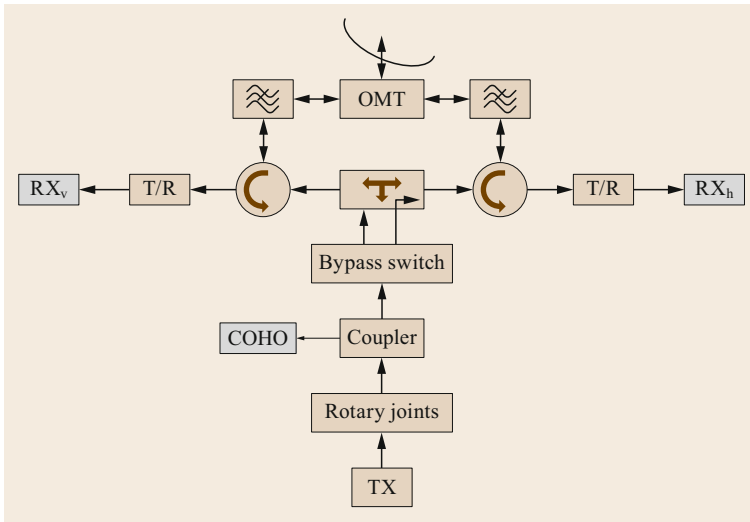

Fig. 30.3 Transmitter schematics with transmitter (TX), splitter, circulators, and antenna with orthomode transducer (OMT) in a dual-pol hybrid mode setup with an antenna-mounted receiver. Receivers (RX_h, RX_v) are also indicated (image © J. Seltmann, used with permission)

Fig. 30.4 Detail from measured 3-D antenna diagram showing the main lobe and part of the side lobes. Sidelobe deterioration due to feed supports is clearly visible (*diagonals*). Image © M. Frech, DWD, modified from [30.44]

logarithmic units of dBi (Table 30.6) and is used in the radar equation (30.8). Gain values of 40–45 dBi are common in weather radar. Antenna gain, beam width, and the number of sidelobes depend on the ratio of antenna diameter D to wavelength λ , so that larger and more expensive antennas are needed for higher resolution (smaller beam width) and for higher wavelengths. As a rule of thumb, the beam width BW (rad) is

$$BW = 1.22 \frac{\lambda}{D}. \quad (30.51)$$

Weather radar antennas used to be parabolic dishes, which may be center or offset fed or of some special

design, such as the Cassegrain or Gregory type. Early antenna dishes used to be deep-drawn from solid metal, then cut for transport, and flanged for reassembly. Nowadays, paraboloids consist of compound materials, such as carbon graphite. Larger antennas are sometimes made from metal grids.

Phased array antennas, although they have been in military use since WW II and have been under testing in research weather radar for a while, have long been deemed an investment that does not pay in weather radar [30.36] and are only recently being reconsidered as an option for (operational) weather radar to answer the increased demand for rapid scanning. Further

research is needed in order to achieve the same performance as a standard radar using a parabolic dish. While earlier issues of power and focusing seem to have been solved, 360° round view and polarization purity, beam shaping, and sidelobe control pose the major challenges presently. Multiple beam designs so far suffer from insufficient beam isolation and sensitivity. Electronically steerable antennas may also help suppress antenna sidelobes [30.45]. Antenna characteristics are decisive for the overall performance of a system and have to be carefully specified (Sect. 30.5), particularly in a dual polarization radar.

The antenna is mounted on a *pedestal* and should be well balanced by counterweights and have its balance point close to the axes in order to keep accelerating moments low. High-precision servo amplifiers, motors, and gears are required to rotate and position the antenna in azimuth and elevation. The motion must be appropriately damped to avoid oscillating overshooting on the one hand, as well as asymptotic positioning on the other hand. Lubrication (depending on wear) must be supplied manually or by an automated pumping system. There should be hardware and software breakers to limit elevation e.g., at 0° or -2° and possibly at 90° (depending on the design). The actual antenna position is read by angle encoders (*syncros*). If safety sector blanking (TX is turned off for safety reasons) is required, encoders must be safety approved (fault-tolerant and redundant). The pedestal must be stable and level (this should be specified); inclinometers and a vibration sensor may be provided to check that the pedestal is upright.

Waveguides have to be routed through the stationary pedestal, the rotating azimuth gear, and the up-and-down swinging elevation gear to the antenna dish. This is effected by special *rotary joints*, which must exhibit isotropy, low insertion loss (< 0.1 dB), and low VSWR. Depending on the receiver/DSP setup, it may include a (fiber) optical data channel using an optical rotary joint. The azimuth rotary joint is usually supplemented by a slip ring to transfer power supply and signals. Rotating parts must exhibit isotropic characteristics (not a function of direction); isotropy should also be specified.

With most operational weather radars, the antenna and any collocated system parts (e.g., an antenna-mounted receiver) are protected from severe environmental conditions by a *radome*, mainly to alleviate the wind load (deformation). The radome is usually a self-supporting or air-inflated geodesic sphere panelized for ease of transport. However, due to absorption and anisotropy, the radome interferes with the antenna radiation [30.46]. Particularly with dual polarization, identical RF performance for both horizontal

and vertical polarizations is essential. Therefore, special construction types (“orange peel”, quasi random, ...) made of sandwich panels with hydrophobic coatings as well as electrically seamless, impedance-matched *stealth* radomes are offered by manufacturers. To reduce snow load and icing and absorption thereby, and to climatize AMR, the radome interior may be heated.

30.4.3 Receivers

The radio frequency (RF) signal (*echo*) received by the antenna is coupled into the waveguide(s) by the antenna feed (separately for H and V, in the case of a dual-pol radar). It is then circulated (Sect. 30.4.1) to the receiving channel(s) and coupled out (usually by a waveguide to a type *N* adaptor) after passing the T/R limiter (see below).

Classically, the receiver used to be mounted in a receiver cabinet (e.g., 19" rack) next to the transmitter cabinet, way down from the antenna tower. As a consequence, the RF signal had to pass waveguides and rotary joints twice. In the wake of miniaturization and digitalization, antenna-mounted receivers (AMR, also called receiver over elevation (gear), ROE) have become a preferred setup.

During transmit time, the duplexer protects the sensitive receiver from the high-power burst pulse. Its isolation of ca. 20 dB is, however, by far not sufficient, and further receiver protection is needed, also against damaging high power by way of duplexer failure, mismatch of VSWR, abnormal operation (arcing), or external transmitters. *Receiver protectors* (RP) need to feature minimum insertion loss (e.g., 0.3 dB) and a maximum receive power (lower protection limit) around 10 dBm, and low waveform distortion. They may be active switches (e.g., all solid state), or passive, self-activating (T/R tubes). While each one has its own advantages and disadvantages, a T/R tube is often the optimum overall tradeoff, as it is robust and protective even out of band or under radar failure. This is why T/R limiters are the preferred choice in weather radar.

Superheterodyne Receivers

A radar receiver, much as any current radio receiver, is a superheterodyne receiver that provides high sensitivity and frequency selectivity and easily meets nearly all performance requirements. After passing an initial low-noise amplifier (LNA) and an RF bandpass filter, the incoming RF is downconverted by multiplicative mixing with the signal of an internal high-frequency oscillator (called stable local oscillator (STALO)) that keeps a constant difference from the transmitter frequency. The mixing product of received RF and STALO frequencies contains the sum and difference and higher-

order frequencies and is, therefore, filtered to keep only the difference frequency, which serves as an intermediate frequency (IF, often 30 or 60 MHz in a radar) and contains all necessary information but is much easier to process than RF. In a dual-pol system, the STALO signal is split to mix independently with the incoming H and V RF signals.

The STALO must exhibit low noise, low phase noise, and high stability, as it sets the reference frequency. Current STALOs will consist of a quartz oscillator and a digital synthesizer. Downconverters are also designed to suppress the image frequency (image rejection mixers; the image frequency is the RF mirrored by the STALO frequency so that incoming signals at image frequency are downconverted to the same IF).

Because in a magnetron system frequency keeps drifting depending on the duty cycle, the transmitter burst pulse is sampled and fed to an automatic frequency control (AFC) controlling the STALO to keep the IF stable. The AFC may be analog (typically via SMA) or digital (typically via RS-232) and may be hard to set manually. AFC is not necessary in a klystron system. Furthermore, shifting the STALO frequency by AFC introduces small phase errors, so that a magnetron radar's coherency is slightly inferior to that of a klystron or solid-state transmitter.

So far, this has to be analog technology, even today. Depending on the type of radar, the following stages may be digital or analog. In both cases, the receiver setup depends on the type of radar (intensity-only, Doppler, dual polarization/dual frequency) and on the type of transmitter (fully coherent or not).

Coherent Receivers

In a classical, non-Doppler weather radar only the echo intensity z is measured, the phase information is lost. A Doppler radar needs to keep track of the transmitted and echo phases in addition to the amplitude. In a fully coherent (amplifying, e.g., klystron) system, the transmit phase is a-priori known because it is coupled to the injected small signal (e.g., from STALO). It is either constant or actively modulated and may, thus, be used for a phase reference.

A magnetron, however, is a free oscillator, and the phase of each burst pulse must be measured in order to later correct (cohere) the echo phase. This is sometimes called *coherent on receive* (COR). To this end, in an analog COR system, the phase of an appropriately attenuated RF burst sample is also downconverted to IF and injected into another, highly coherent oscillator (COHO) that is phaselocked to the current pulse over its echo return time and started anew with the next burst pulse. This reference phase is routed to the quadrature detector together with the amplified echo IF.

Analog and Digital Receivers

With the advent of fast processors and analog digital converters (ADC) with a wide dynamic range, digitization has extended far into the formerly all-analog receiver.

Dynamic Range. The dynamic range of radar signals is tremendous: 12 orders of reflectivity magnitude are easily obtained for realistic drop size ranges, plus 5 orders for range dependence (recall that $P_r \approx D^6 r^{-2}$, Sect. 30.3.1). As it is difficult to build a linear receiver with that large a dynamic range, a logarithmic analog receiver (LOG) is used instead, which, however, introduces phase distortions. Therefore, there needs to be an additional linear receiver (LIN) in an analog Doppler radar.

The dynamic range of a digital receiver is largely determined by the ADC's number of bits, as the least significant (LSB) and the highest bits set the low and high limits of the converter range. One additional bit increases the voltage range by a factor of 2 and the power range by a factor of 4 (6 dB). Currently, 16-bit high-speed IFD are standard. An ideal 16-bit (12-bit) ADC yields a dynamic range of 98 dB (74 dB). As this is not quite sufficient in radar application, the dynamic range of each channel may be extended in current digital receivers by splitting the input signal and using two or more ADCs with different attenuation in parallel. This is sometimes called *stacked ADC* architecture.

Analog Receivers. In an analog receiver, the signal is first passed to a filter that is optimally adapted to the transmitted waveform and, thus, maximizes the signal-to-noise ratio. For a simple rectangular pulse of length τ , this is a bandpass filter of band width $B = \tau^{-1}$. There have to be several physical filter banks if there are several pulse widths. Depending on the type of radar, the resulting narrowband IF is then fed into a logarithmic (LOG) amplifier (in an intensity-only radar) or split into a LOG and a linear (LIN) channel (in a Doppler-radar). The LIN channel provides true-phase signals for Doppler processing and must, therefore, maintain symmetry in both amplitude and phase over a certain limited range (e.g., 30–40 dB). In order to keep the current signal within this linear range, a gain control is needed, which may be based on range time (sensitivity time control, STC), the intensity of the previous batch/ray (automatic gain control, AGC), or on the instantaneous power (instantaneous AGC, IAGC) and must not distort amplitude or phase characteristics. The IF is then input to a quadrature detector, which is additionally fed the COHO reference phase and its replica shifted by 90° to produce the I and Q signals (30.23). In a fully coherent (klystron) system, this is the signal of a coher-

ent oscillator (COHO), the same one that is amplified by the klystron. In an analog COR (magnetron) system, the COHO is phase locked to every single transmitted pulse using the analog burst sample. This phase locking and its stability is a limiting factor in COR systems. While in an analog magnetron system the burst phase is thus corrected for, its value is not known. In a digital receiver, the phase is measured digitally and stored for further advanced processing (Sect. 30.6.3).

Digital Receivers. In a digital receiver, the echo phase (and amplitude) is directly digitally sampled from the echo IF and corrected for the transmitted phase. The burst IF is sampled as well in order to determine the transmit power and PW, and its phase is used to digitally cohere the incoming radar signal in a digital COR system. Unlike with an analog COHO, it is easy to digitally store the transmit phase over several pulses and cohere to or correct for previous pulses (multiple-trip echoes, Sect. 30.6.3.).

In a digital receiver, most analog IF components (such as matched bandpass filters, COHO, LOG and LIN amplifiers, including AGC, quadrature phase detector, and analog AFC) are redundant or replaced by controllable digital modules: IF bandpass, IQ calculation, measurement of and correction for transmitter phase and amplitude (the latter was not feasible earlier), and measurement of burst frequency and output for AFC of STALO. Essentially, a digital receiver needs only STALO and downconverters, and, in the case of a magnetron, AFC. After downconversion, the IF is directly digitized. This also renders maintenance simpler, as there are fewer spare parts, which in addition are easy to replace. Also, a digital receiver is well suited to transform an intensity-only radar into a Doppler radar, possibly even with some dual-pol functionality.

The IF digitizers (IFD) are located exactly where there are the LOG (and LIN) amplifiers in an analog radar, traditionally in the receiver cabinet under the antenna or on the back of the antenna dish in an antenna-mounted receiver AMR. The IFD ingests analog IF (typically 30 or 60 MHz) and outputs digital I/Q data.

There are one or two IFDs for one or two polarizations and, in the case of a magnetron transmitter, also for the burst sample. The IFDs usually come with the signal processor (DSP) due to their tight internal connection, while hooking the IFDs to an analog signal of adequate power level is pretty simple. IFDs connect to DSP (in a narrow sense) via a fiber optics link that allows for about 100m distance if routed through an optical rotary joint. However, an antenna-mounted receiver greatly facilitates the connection between IFDs and DSP, even though there are systems that bring the waveguide (H, or both H and V) down the rotary joints.

While an analog LIN receiver hardly exceeds a dynamic range of 40dB and depends on sensitive bias control (AGC), present-day digital linear receivers feature almost the same dynamic range as earlier analog logarithmic receivers without sensitive circuitry. In an analog receiver, the signal IF must be switched to the appropriately matched filter depending on the pulse width, while in a digital receiver, the corresponding filters may be digitally controlled. The matched filter is realized digitally either in the IFD or in the DSP, e.g., as a decimating complex digital FIR filter. The digital phase lock provides a better coherency as a function of range than an analog COHO, thus enabling distant second-trip handling.

A digital receiver is stable, robust, and long-lived and provides monitoring and control algorithms (e.g., COHO and burst-sample gate adjustment) that improve overall performance, which, together with simpler troubleshooting and replacement, provide better maintainability and availability compared to an analog receiver.

30.4.4 Signal Processing

Signal processing in radar refers to the creation and processing of the scalar (X_i) or complex time series (A_i) in order to calculate certain observables (moments) for each range bin. This is performed by the digital signal processor DSP, the main steps being:

- Data ingest and filtering.
- Processing of X_i and/or A_i time series for each raw range bin. Time (= azimuthally) averaged power \bar{X} and/or lag 0, 1, and 2 autocorrelations both Doppler filtered and unfiltered for each polarization, as well as cross correlations are obtained and range averaged. Full spectra may also be calculated and output.
- Calculation of observables or *moments* (Sect. 30.3.4) from (averaged) correlations and subsequent quality screening by thresholding.
- Conversion of all data to the required output format, e.g., 8 bit or 16 bit integer or 32 bit float, and output to the radar host computer.

In a wider sense, the DSP also performs a couple of auxiliary processes: The DSP usually provides the radar master clock, trigger and several slave triggers, pulse width switch, AFC and possibly AGC, signal output to klystron, depending on the radar system. Modern DSPs are even capable of direct digital waveform synthesis (DDS) with frequency or phase pulse modulation for digital output to state-of-the-art transmitters. All configuration parameters necessary to the DSP are uploaded from the radar host computer.

Digital weather radar signal processors may be proprietary but there is a clear tendency worldwide towards open source (Linux-based) systems. Algorithms are pipelined and lend themselves to parallel bin processing allowing near-realtime performance on a nonrealtime operating system.

Data Ingest

The DSP is hooked to the radar receiver output channels and ingests its data in a first step. Depending on the receiver type, the LOG, I , and Q video channels of the analog LOG and LIN receivers are acquired and digitized and sampled into range gates, or the digitized IF of a digital receiver is acquired, separately for H and V, in a dual-pol radar.

In this case, the DSP receives digitized (sampled) IF data together with the necessary meta data, such as antenna position (azimuth and elevation), angle syncing flag, sampled burst IF, AFC status, etc. for each pulse.

A modern DSP receives and digitally bandpass filters (e.g., by an FIR-matched filter) the IF time series if this has not been performed in the IFD already. The digital matched filter must be adapted to the pulse width and may usually be designed interactively by a skillful user. Time samples are then assigned to the correct range gates (raw bins). For each raw range bin, the appropriate number of pulse returns is stored, forming the time series X_i or $A_i = A_i^{\text{raw}} - \bar{A}_{\text{noise}} = I_i + jQ_i$ after noise subtraction to give the time-series zero mean. The appropriate number of pulses in each range bin is determined according to an angle syncing flag set for each pulse if either the required number of pulses has been collected (e.g., 32 or 1024 pulses) or a synchronizing condition has been met. A common syncing condition is the dynamic angle syncing DAS, synchronizing on the antenna position, usually spaced every 1° . From the digital receiver of a COR system, the DSP also receives the magnetron burst sample IF signal. Data acquisition needs to take place in near realtime in order to avoid losses. Sometimes the I/Q data stream may be tapped via a high-speed connection for storage or third-party processing.

Pulse Processing

In a second step, range-gate-based time series are processed in the time or frequency domains including Doppler or statistical filtering, possibly staggered PRT, and multiple-trip handling (Sect. 30.6.3), to obtain spectra or, commonly, autocorrelations. As this is performed on each individual raw range bin, the range index is usually dropped.

Realtime pulse processing for thousands of range bins is computationally demanding, even today. Whereas accumulation of T_0 , R_0 , R_1 , and R_2 can be

performed while collecting the pulses, DFT/FFT processing needs to wait for a time series (batch) to be complete.

Log Processing. The analog signal of an intensity-only logarithmic receiver is digitized by the DSP. In order to perform any linear processing, such as adding and averaging, the A/D log power readings P_i of a single pulse i must be linearized according to

$$X_i = 10^{\frac{SP_i}{10}}, \quad (30.52)$$

where S is the slope of the calibration curve, and relogarithmized for calibration and output. Unlike a Doppler measurement, the LOG time series is real, not complex, because no phase is retained. Therefore, LOG processing takes place in the time domain. The time series is then split: one branch is highpass filtered (Sect. 30.6.3), while the other one is not. The filtered, as well as the unfiltered, scalar amplitudes X_i^f and X_i are each squared and time averaged, yielding the filtered and unfiltered power estimates \bar{X}^f and \bar{X} .

The measured noise \bar{X}_N is subtracted, and the result quality checked against the (linearized) noise threshold. Any bias (X_{offset}) is then corrected, and the result is applied as P_r in (30.27), so that

$$Z_c = 10 \log_{10}(\bar{X} - \bar{X}_N) - 10 \log_{10}(X_{\text{offset}}) + Z_0 + 20 \log_{10}(r) + ar + \text{CCOR}. \quad (30.53)$$

Doppler Processing. Pulse processing of a coherent time series A_i may take place in the time or frequency domains, or both, in order to extract the correlation and spectral moments described in Sects. 30.3.2 and 30.3.4. Prior to this, some special processing and corrections (Sect. 30.6.3) must also be performed at this stage if selected, viz. pulse compression, second-trip and staggered PRT velocity unfoldings, and clutter filtering.

Burst Sample Processing: In a digital COR (magnetron) system, the DSP also receives and analyzes IF samples of the magnetron burst. The burst amplitude is used in order to monitor and automatically correct pulse-to-pulse power variability. The burst phase is applied to cohere the echo phase for coherent processing.

This phase correction may be performed to an accuracy of about 1° independently of range (while an analog COHO tends to drift with range time). The difference between burst sample and STALO frequencies is calculated, D/A-converted if necessary, and uplinked via IFD to control the STALO/AFC. In a fully coherent (klystron) system, the DSP commonly provides the waveform (pulse width, frequency/phase control) that is input to the power amplifier.

Pulse-pair Processing (PPP): time-domain processing calculates the desired lags of the complex autocorrelation following its definition (30.24), adding up complex products of (conjugate complex) amplitudes of the current pulse i with the complex amplitude of the same ($l = 0$), the previous ($l = 1$), or the antepenultimate ($l = 2$) pulse. Consequently, for each moment, only one pair of pulses has to be kept in memory at any time; hence the name of pulse-pair processing (PPP). With PPP, the accumulation of T_0 , R_0 , R_1 , and R_2 can be efficiently performed while collecting the pulses.

Fourier Transform Processing: frequency-domain processing is launched by Fourier transforming the A_i time series into the corresponding Doppler spectrum for each raw range bin. A discrete Fourier transform (DFT) or a fast Fourier transform (FFT; forcing a power of two number of pulses for computational efficiency) may be applied.

After clutter filtering and second-trip processing in the frequency domain, the spectra are commonly retransformed to the time domain for ease of pulse-pair autocorrelation processing.

Pulse Compression. Range resolution and/or sensitivity may be increased by transmitting wideband waveforms to boost the time-bandwidth product τB using pulse compression. For example, in linear intrapulse frequency modulation between low and high frequencies f_1 and f_2 , $B = \Delta f = f_2 - f_1$. Frequency changes may also be digitally coded (Barker, Costas, and Frank codes).

Bandwidth can also be increased using phase coding where a long pulse of duration τ is divided into N short subpulses (*chips*) of duration τ/N . The phase of each subpulse is set to either 0 or 180° (0 or π , + or -), following some binary phase code, such as a Barker code [30.47]. Phases may also be a multivalued function, e.g., of the SZ(8/64) code [30.48] designed to minimize range sidelobes; N defines the compression ratio. The new bandwidth will be $B = N\tau^{-1}$, the compressed pulse width $\tau N^{-1} = B^{-1}$, and the pulse energy increased N times. Thus, pulse compression benefits from the energy of a long pulse and the resolution of a short pulse at the same time.

Range Averaging. As a last substep, the correlation data is range sampled, if so required. The raw range bins (e.g., spaced every 25 m) are sampled or averaged to form larger output bins, e.g., 1 km long. The optional clutter microsuppression CMS (Sect. 30.6.3) is applied at this stage as well.

Moment Estimation

In a next step, physical moments as well as parameters of interest for QA/QC are calculated from the correla-

tions according to their definitions in Sect. 30.3.4. They are then usually passed to a correction stage including (Sect. 30.6.3) range and (both gas and precipitation) attenuation corrections, velocity unfolding by dual PRF, and spectral width correction. Some QC algorithms usually follow (Sect. 30.6.4), including thresholding and flagging for various interferences, and a speckle remover.

Data Output and Recording

The output of an operational DSP to the host computer consists of the calculated moments on a ray basis and is called preprocessed base data or level II data. For research purposes, data may be tapped for offline processing and storage as soon as they are digitized, even on the IF level (I/Q data). This may be useful to test new pulse-processing algorithms. Even Fourier spectra may be recorded and displayed. Some processors offer data output to a realtime display (time series, spectra, A-scope, etc.).

30.4.5 IT Structure

In the digital age, radar is no longer controlled by manual switches and cranks but by computers, and it delivers digital data to computers instead of analog signals to a cathode ray tube. In fact, a modern radar is largely a computer of its own, called the radar control unit RCU; its console is the closest one can get to control the radar manually.

Thus, radar operation may be attended by an operator or may be fully automatic and remote controlled even for a whole network. In continuous operation, the RCU is slave to a host computer that runs the radar control software. It stores all necessary data and parametrization in templates and sends them to the RCU according to a configurable scheduler.

Within the radar, many components and sensors are networked using IP addresses and optical, ethernet, USB, and wireless communications. Their data are fed to the BITE system (Sect. 30.4.6). The RCU also collects BITE and other internal messages and status information and passes them on to the host computer. The host distributes the data to the operator, a user help desk, or some archive, according to selectable severity levels. This greatly facilitates troubleshooting. The system can take predefined action automatically, e.g., restart certain processes or devices, or shutdown in case of emergency.

The host computer also collects the data produced by the DSP. Under normal operation, the DSP processes the bin-based I/Q time series and outputs processed rays of tagged *moments* (Sects. 30.3.4 and 30.4.4) over the appropriate range. The host computer ingests these rays and packs them into sweeps at a given elevation or

Table 30.10 Data rates at different stages of radar processing

Data stream	1980s: Analog Z-only radar	1990s: Analog Doppler radar	Present: Digital dual-pol radar
Bit resolution	8	8; 16	8; 16; 32 float
Number output moments	1	4	50
One ray (kB)	0.256	0.512	> 20
One sweep (kB)	92.160	368	3200
Sweeps per update interval	21	26	13
One volume (MB)	2	9.5	75
Volume update rate (min)	15	15	5
GB per day	0.185	0.912	21

at a fixed azimuth (PPI or RHI, Sect. 30.8.1) that are subsequently sent to product generation by either the host computer itself (nowadays often called *legacy* production) or by centralized processing.

All processing has to be performed in near real-time so that no incoming data is being lost. In internal processing, the number of available pulses N is determined by PRF, the azimuthal sampling resolution, and the antenna azimuth rate ω_{az} , e.g., 55 pulses at realistic values of 1° resolution, $\omega_{az} = 3$ rpm, and PRF = 1000 Hz. This number (maybe reduced by a few filter stabilizing pulses) is identical for each raw range bin. Depending on computing power, the DSP may perform pulse processing (Sect. 30.4.4) on a limited number of raw range bins, e.g., 2048 bins. Raw bin data are often averaged to e.g., 1 km, yielding output rays of 256 range bins at a range of 256 km. This range resolution has a large impact on data rate; increasing the output range resolution from 1 km to 250 m (50 m) increases the data rate by a factor of 4 (20). The number of output moments is another influential parameter that multiplies the data rate in proportion. While operational azimuth resolution is commonly 1° over one full revolution of 360° (one sweep), oversampling is possible and easily increases the data amount by a factor of 10. Lastly, the volume definition and update rate determine the number of sweeps with a recent tendency of faster update at the cost of fewer elevations.

Table 30.10 gives an example of the approximate data throughput for one single radar under operational conditions in the past and presently. Data may vary largely.

30.4.6 Auxiliary Components

There are a couple of auxiliary components and devices that are necessary to successfully operate and maintain a radar. A weather radar has a variety of monitoring and test devices that are jointly referred to as built-in test equipment (BITE). The BITE checks and measures around 250 system states and parameters such as voltages, currents, and temperatures that are collected by the RCU and forwarded to the host computer message

system. BITE messages are used to continuously monitor the radar state, to check the proper operation, and diagnose system failures.

Depending on the type of radar, more test and safety equipment is necessary or desirable to perform calibration and maintenance, such as power meters, attenuable and phase shiftable test signal generators, interface devices, spectrum and network analyzers, in addition to standard tool kits and user utilities. A test signal generator (TSG) is usually built into the radar and may be controlled through RS 232 for remote access or automated test procedures, even under operation.

For safety purposes, there is a system-wide interlock circuit including radome hatch and *hotbox* contactors to prevent radome or hotbox access under operation, as well as emergency switches and labels marking radioactivity and radiation according to regulations.

As a provision for the case of power failure, an uninterrupted power supply (UPS) is commonly provided to keep the system alive and accessible. At least computers are not to be switched off in an uncontrolled manner. Sometimes, the whole system, including the transmitter, may be run on UPS for a couple of minutes until an emergency generator engages or power returns.

Air conditioning is necessary for a couple of reasons: the transmitter needs to be cooled, and the receiver is to be kept at a stable (preferably low) temperature in order to avoid drift. This is true even under favorable climatic conditions. Often, the radome is also climatized to keep a snow cap and icing away and to create bearable working conditions.

30.4.7 Siting, Radar Infrastructure, and Regulations

An unfavorable radar site can create many and uncorrectable problems. An unobstructed view is one obvious condition that usually calls for an elevated position with no higher mountains situated nearby. Buildings, towers, bridges, and wind parks should be far enough away, which may be difficult to achieve in flat terrain. In a radar network, high areal coverage and near equal radar distances should be aimed for.

Infrastructure is another issue to be considered, as it must be able to accommodate the radar size, weight, and wind load and to provide the operating requirements and environmental conditions (temperature, humidity classes for normal, emergency, and stopped operation) defined by the radar manufacturer. What will be the necessary height and stability of the radar tower? Vibration under strong winds and tilting due to solar irradiation may become a problem. Accordingly, a concrete tower and/or guying may be considered. Safety considerations should be kept in mind as well, such as protection against falling ice and against vandalism. Is an escape exit mandatory?

A certain site development may be necessary. Must a road be built and maintained, or supply of telecommunications, power (e.g., 10 kW, 3×18 A, possibly UPS/generator), sanitary facilities, water, and sewerage? Can those requirements be met at the site under consideration, particularly if situated in a nature sanctuary or if the radar operator is not the land owner?

Laws on radio and telecommunications, safety, and construction will be applicable. What authorizations must be obtained under the operator's specific legislation? In Europe, a radar station must be compliant with the EC machinery directive and CE conformity, and national technical inspection certificates, local building regulations, and governmental priority regulations. As radar emits strong radiation, a radiation permit must be obtained from the respective authorities that limits transmit and out-of-band power and bandwidth, and sets safety distances and possibly certain angular sectors that must – safe against any failure – be blanked. Moreover, a radar usually contains radioactive substances (T/R limiter, Sect. 30.4.3), which must also be authorized and sometimes notified to local disaster management and firefighters. In addition, radars supplying data to air traffic require an EC test report with regard to the implementation of the European regulations on interoperability defined in regulation (EC) No. 549/2004, Article 2. The procurement process itself must comply with applicable laws. All permits granted, may citizens' initiatives overthrow radar construction plans?

Operators usually establish additional safety instructions of their own, e.g., decide on authorized staff or a two person rule. On the other hand, little-thought-of regulations may seriously degrade data quality (four lightning poles around the radar) and coverage (priority construction of obstacles) or even preclude deployment (frequency allocation).

The following list gives some specific regulations that apply in Germany:

- Location permit (Federal Emission Protection Law) by the Federal Radio Authority (BNetzA)

- Permit as per the Radiation Protection Regulation (StrlSchV)
- Permit according to the X-Ray Protection Regulation (RöV)
- Technical inspection certificates (TÜV)
- Lighting protection and potential equalization according to DIN V VDE 0185 or its equal
- Procurement regulation (UfAB).

30.4.8 Radar Networks

The main reason to combine individual weather radars to form a network is the complete coverage of a certain area, often a nation's whole territory. Most networks are, therefore, operated and their data shared by national or federal authorities, even though operation may be outsourced, or local networks may be operated by research groups and syndicates. NEXRAD data, although not completely covering the contiguous USA, is used by the US National Weather Service (NWS), Federal Aviation Administration (FAA), and the Department of Defense (DoD), the media, and private institutions.

A network may, depending on its density, mitigate some of the problems in single radars, such as data gaps due to radar maintenance and failure, incomplete elevation coverage including the *cone of silence*, beam blockage, beam elevation over the Earth surface and beam overshoot, cross-beam resolution increasing with range, or thresholding due to poor data quality. It, thus, enhances the detection of low-altitude and small-scale phenomena and facilitates object-based automated algorithms. Moreover, multiple overlap enables calculation of dual and multiple Doppler wind vectors (Sect. 30.8.3).

Functionally, the network may be considered to represent one measuring instrument with the individual radars as sensors sending their data to some central facility via telecommunication, preferably with guaranteed bandwidth, as timely transmission and data supply is crucial. The central facility collects and processes all the data in near real time and distributes them to users. It may also remotely control each radar sending predefined parameter templates. In a centralized network, it is easier to maintain data homogeneity using identical and well-documented scanning and processing. Data quality may automatically be assessed and error statistics derived by identical algorithms.

The US NEXRAD system is run by operators who adjust offsets, select a scan pattern according to the weather situation, etc. Germany operates a network of fully automated, identical weather radars running at identical scan strategies (Fig. 30.6).

30.5 Specifications

Radar manufacturers report a very wide span in the depth of customer specifications. Some customers may just specify “the best possible radar for their money”, others may take a more thorough approach. In the USA, for instance, extended joint experiments were conducted over several years to establish the capabilities and requirements of Doppler (JDOP experiment 1976–1978) and dual-polarization (JPOLE, 2000–2004) techniques. Germany affords the Hohenpeissenberg re-

search radar to evaluate upcoming new features prior to final operational specification.

Besides the general type of radar (X, C, or S-band, klystron/magnetron, dual-pol, AMR), internal and remote network capabilities and functionalities, control and access structure (e.g., reboot performance, remote version inquiry and upload/upgrade), data output formats, interfaces, maximum maintenance intervals and line replaceable units (LRU), including LRU interfaces,

Table 30.11 Overall specification

Wavelength	3.2–10.7 cm
Continuous operation	24/7/365
Availability excluding maintenance	98%
MTBF	E.g., 6 months
Maintenance interval and downtime	E.g., 9 months and 6 h down
Internal and external time synchronization	E.g., NTP
AMR	Dual-pol splitter and IFD or DSP above elevation gear
Product generation	(specify products, Sect. 30.8)
Local product storage	E.g., 14-day ring buffer. Fault logging
Fault logging	Selectable transmission and storage
Min and max operation temperatures	–40 to +50 °C outdoors, 0 to 40 °C transmitter and receiver
Power supply: mains voltage and frequency, number of phases	110/115/120/127/230/240/400 V AC 50/60 Hz + 5 Hz, 3 phases evenly loaded
Documentation requirements	Operations, maintenance, and SW manuals in native language, up to date, including safety instructions, digital (PDF) and print (3×)
Range coverage	60–460 km
System overall coherency	E.g., 1° to 180 km
Clutter suppression	E.g., 40 or 50 dB
Safety appliances and precautions	Emergency interlocks and latches; selective system protection (fuses, circuit breakers); warning and danger signs; safety directions; and interference immunity

Table 30.12 Antenna and radome specification

Antenna type	Parabolic (center-fed; offset; Cassegrain etc.) Electronically steered (planar phased array, <i>crow nest</i>)
Angular ranges	Elevation 0–90°, azimuth 0–360° cont.
Azimuth/elevation rotation rate	0.1–3–10 rpm (0.6–18–60° s ⁻¹)
Max azimuth/elevation acceleration	E.g., 15° s ⁻²
Safe sector blanking	Radiation safety, e.g., for close buildings (even in the case of system failure!)
Feed	Single or dual-pol corrugated horn. OMT
Diameter	0.7–8.5 m and larger
Gain	45 dBi
Beam width horiz. and vert.	0.5° or 1° both
Sidelobe suppression	–25 to –35 dB
Pointing error and dual pol beam squint	0.05°
Polarization crosstalk	–35 dB
Radome construction type	Orange peel; quasi random panel; air-inflated structure; hydrophobic coating
Radome diameter	4–12 m and more
Maximum wind speed	250 km h ⁻¹
Maximum snow/ice load	250 kg m ⁻²
Dry radome oneway transmission loss; delta ZDR; differential attenuation	< 0.2 dB; < 0.005 dB; < 0.005 dB

Table 30.13 Transmitter specification

Transmitter type	Magnetron, klystron, TWT, SSPA
Frequency	X, C, or S-band, rarely X+S-band
Pulse power	0.1–1 MW
Pulse widths	0.2–4.5 μ s, often switchable; 64 μ s with pulse coding
PRF	200–4000 Hz
Max. duty cycle	E.g., 30 dB
Safety sector blanking	Yes/no
Polarization base and setup	Single (mostly linear); dual pol H/V (pulse-to-pulse or hybrid); LHC/RHC; arbitrary

Table 30.14 Receiver specification

Type	Analog or digital Intensity-only (LOG) or coherent/COR LIN Optional dual-pol dual channel
IF	30 MHz, 60 MHz
IF bandwidth	0.2–5 MHz depending on pw
MDS	E.g., –114 dBm
Dynamic range	90 dB
Noise figure	E.g., 2 dB
Image rejection	E.g., 56 dB

and expected lifetimes (maybe expenditure estimation), as well as safety and emergency appliances should also be specified according to technical and legal conditions. Some special construction features may be dictated by existing infrastructure.

All radar data and messages must be time stamped (if appropriate, on a pulse-to-pulse basis) based on synchronized (e.g., by ntp daemon) time (master clock) and logged and flagged according to severity. Ray data must be tagged with start and stop timestamps, angles (az and el start and stop) and mean antenna velocity, housekeeping information, and metadata, such as radar settings and DSP parameters.

Tables 30.11–30.15 are just examples and are not intended to be a complete or consistent real specification.

An uncertainty estimation (according to the laws of error propagation) may be stipulated for certain observables. Alternatively or additionally, measurable ranges and error limits may be specified (Table 30.16).

Overall signal detection capabilities, such as minimum sensitivity and a minimum large signal detection at various ranges may also be benchmarked (Table 30.17).

For the sake of clarity in testing, the operation parameters should be given with these specs, e.g., $PW = 0.8 \mu$ s, $\omega_{az} = 18^\circ \text{ s}^{-1}$, $PRF = 600 \text{ Hz}$, range averaged to 1 km. Note that double pulse width PW will increase MDS by 3 dB. If MDS can be lowered by a factor of 4 (6 dB), the same target can still be detected at double range.

Procedures and utilities to prove compliance with specs during acceptance tests, including test software, may or may not be left to the tenderer. Depending on the buyer's legislature and procurement regulations it may be necessary to define acceptance procedures as early as the call for tender. Special scan definitions may be devised to test overall performance under certain ranges and stress combinations of interrelated parameters.

When specifying a new radar network, it appears useful to include identity of all systems at some end-point, as manufacturers will beta-test and systems will evolve over the production process. Unlike in a first

Table 30.15 DSP specification

Signal Processor	Options/typical values (examples)
Maximum number of range bins per ray	E.g., 4000
Minimum sampling resolution	E.g., 25 m
Basic processing modes	PPP, FFT, dual pol, pulse compression, phase coding/random phase processing
IIR Clutter filter depth and halfwidth	30–60 dB; 5–25% V_N
Meteorological moments (depending on transmitter/receiver setup)	$Z_h, Z_v, V_h, V_v, W_h, W_v$ ZDR, LDR, PHIDP, KDP, RHOV
Quality moments and thresholds	LOG, SNR, SQI, WSP, CPA, CCOR
Correction algorithms	Range averaging, CMS, Doppler filter, GMAP, CMD, thresholding, velocity unfolding, attenuation and second-trip correction
Define adjustable offsets to account for any power and phase imbalances	$\Delta ZDR, \Delta LDR, \Delta PHI$ and $\Delta PHIDP$
Ray header information	Operation mode, # of pulses used; time + Az and El start/stop and rate; AFC and sector blanking status; burst av. power, STD, frequency, etc.
Storage capability of raw I/Q data	E.g., 4 TB

procurement, in a replacement, usually not all radar components are specified at the same time, particularly in a network. Often, it is deemed appropriate to change just one module, such as software or signal processors, or to replace an analog receiver by a digital one. While modular system architecture is current state of the art, module interfaces must be specified precisely to every relevant detail. Also, it may be necessary to specify communication structure and interfaces so that they conform to the customers IT and SW. SW source codes and/or special licenses may be required.

Keeping in mind legal requirements and specification of infrastructure (Sect. 30.4.7), specifying a weather radar is sufficiently complex, and it is highly recommendable to profit from the know-how of an experienced weather radar operator.

30.6 Quality Control

Weather radar data quality plays a major role in data interpretation and sales processes. European weather services supplying data to air traffic control and airports even have to be ISO certified according to ISO 9001 to fulfill the requirements of Single European Sky (SLS), including the process of radar data acquisition. Therefore, quality assessment QA and quality control QC are important throughout the data acquisition chain, starting with proper specifications (30.5), accurate calibration, appropriate parametrization, and monitoring (Sect. 30.6.1).

Radar data quality is greatly influenced by interferences and nonmeteorological targets and also by the degree to which underlying model assumptions are fulfilled (Sect. 30.6.2). Some of the shortcomings can, at least in principle, be overcome (Sect. 30.6.3), others can only be detected (Sect. 30.6.4), or are not accessible at all.

30.6.1 Calibration, Parametrization, and Monitoring

There are about 5000 tuneable parameters in a radar to optimize its performance. Some of them – such as trigger timing, transmit frequency adjustment, and receiver calibration – harmonize the proper functioning of the system. Some of them optimize performance to some specific purpose, such as pulse repetition frequency, which defines an unambiguous range versus unambiguous velocity (Sect. 30.3.2), calling for either a compromise or targeted optimization, e.g., special parametrization in research radars.

Table 30.16 Accuracies and measurement ranges

Observable	Range	Max error
Z	−32 to 96 dBZ	±1 dB
V	±32 or ±48 m s ^{−1}	±0.5 m s ^{−1}
ZDR	±6 dB	±0.1 dB
RHOHV	0 to > 0.995	±0.005
LDR	< −35 dB	±1 dB
PHIDP	±180°	±0.5°

Table 30.17 Detection benchmarks

Large signal detection	$Z_e = +64$ dBZ	4 km
MDS	$Z_e = -45$ dBZ	1 km
MDS	$Z_e = -25$ dBZ	10 km
MDS	$Z_e = -5$ dBZ	100 km
MDS, long pulse	$Z_e = +7$ dBZ	250 km
Point target detection	$\sigma = 4$ cm ²	100 km
Rainfall of 0.01 mm hr ^{−1}	−10 dBZ _e	50 km

Calibration

A full system end-to-end calibration includes the transmitter, antenna, receiver, and DSP, and is astonishingly difficult to perform. Although calibration with a sphere of known backscatter cross section suspended at some height and distance may seem straightforward, keeping the sphere motionless in the center of the radar beam poses a major problem. In most cases, radar calibration refers to the calibration of the receiver making use of independent transmitter and system measurements.

Receiver Calibration. Receiver calibration may be performed manually or by automated utilities injecting a TSG signal of known power into the antenna coupler and stepping through the calibration curve (to detect nonlinearities, otherwise a two-point calibration will suffice). On a log/log scale there will be a linear part of the calibration curve that defines the dynamic range between noise and saturation roll-off.

During receiver calibration the calibration reflectivity $Z_0 = 10 \log(Cr_0^2 P_0)$ is determined from (30.14) at $r_0 = 1$ km, where P_0 is the intercept of the calibration curve with the noise level; Z_0 is, thus, the minimum detectable reflectivity factor at range $r_0 = 1$ km. Some typical values are: $C = 6.8 \times 10^6$ mm⁶ m^{−3} mW^{−1} km^{−2}, $P_0 = 3 \times 10^{-11}$ mW = −105 dBm, and $Z_0 = -37$ dBZ [30.49].

Once linearity and dynamic range have been established, calibration may even be checked *on the fly*, placing a TSG signal at some distant range bin during normal operation or by monitoring the sun whose position and solar constant are very well known. Sun

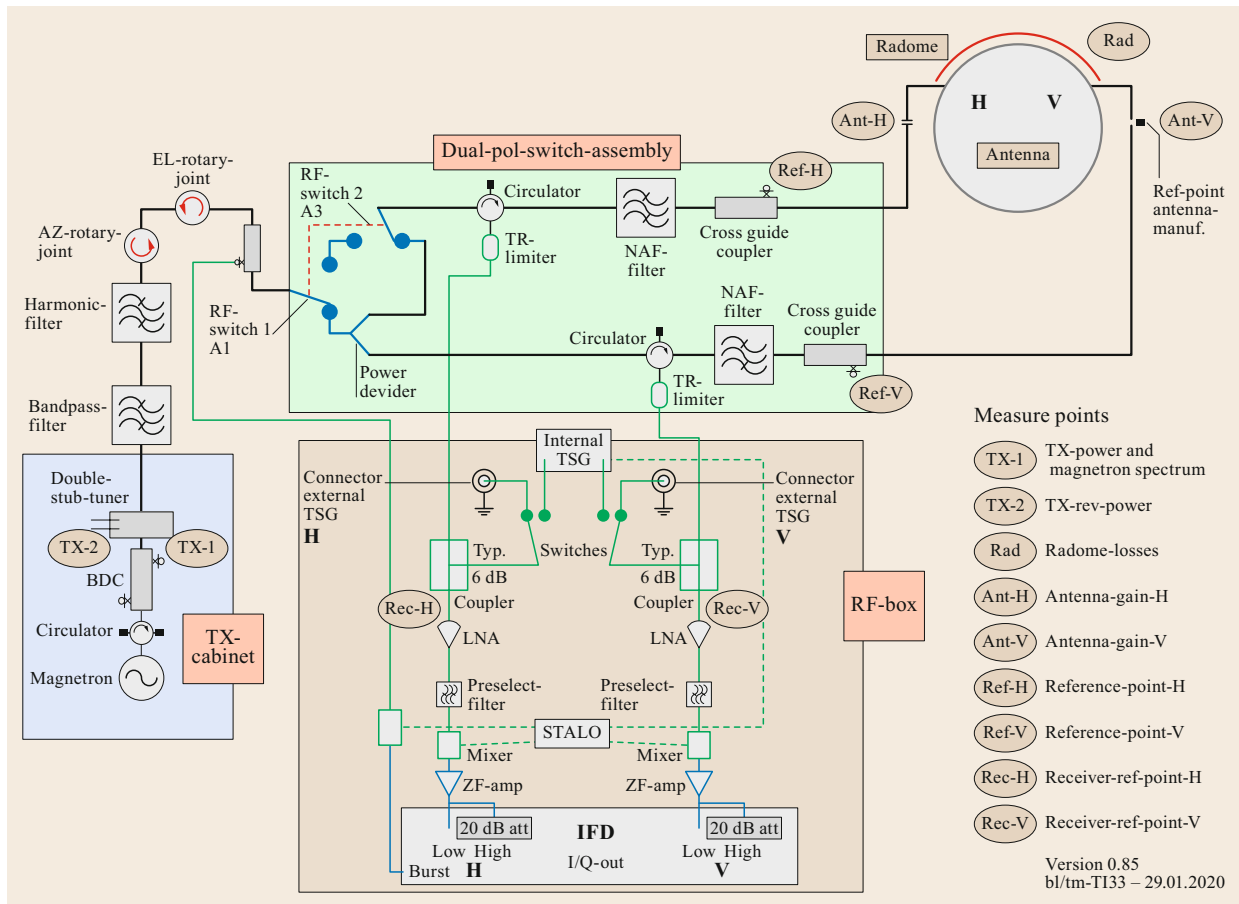

Fig. 30.5 A typical hardware calibration diagram of polarimetric weather radar, indicating all relevant elements to be considered and characterized in the transmit and receive paths (image © T. Mammen, DWD)

calibration can be performed by tracking the sun (interrupting operation) or fitting occasional hits during volume scanning over a day.

Noise Sample. In order to estimate the noise floor of the calibration curve, a noise measurement is performed to determine the current noise power plus any biases in receiver and ADC. The noise value is determined by pointing the antenna away from the ground and taking a certain number of samples at a distance sufficient to ensure that no thermal noise or target is present. (The rare chance of hitting aircraft may be handled by an outlier check.) Noise samples are taken not only during calibration but are repeated periodically (e.g., every hour) during regular operation to check for any drift.

Losses. Care must be taken to account for any power losses, such as waveguide, cable, and coupler insertion losses. Some fraction L_t of the energy (factor < 1) is lost between the transmitter (where P_t is specified) and

antenna feed (radiated power), as L_r is lost between antenna and receiver input (where P_r is measured). Losses of spectral components in the limited bandwidth receiver filter (dependent on the pulse width), as well as any amplifier gains G_r must also be accounted for. Figure 30.5 gives the idea of this. These losses will appear as constant linear factors or summands in the linear or logarithmic form of the radar equation and are commonly integrated into the radar constant.

ZDR Calibration. ZDR is calculated as $Z_h - Z_v$ according to (30.42), where imbalances between the horizontal and vertical channels in the transmit, antenna, and receiver parts may occur and produce a bias in ZDR. In order to get rid of any system imbalances, an end-to-end ZDR calibration is best carried out on symmetric targets that do not generate intrinsic differences between H and V, e.g., raindrops appearing circular when seen from below. Therefore, it is common practice to observe falling rain by pointing the antenna vertically and

rotating over a full circle in the azimuth [30.50]. ZDR calibration methods, including an *engineering method* for WSR88D (not capable of 90° elevation) are summarized in [30.51].

Parametrization

Once a radar is ready to run it needs to be configured so that it can operate in a predefined state. Some of the necessary parameters are static, site or type specific. Most of them are variable and define the operational properties of the radar (*scan definition*), such as the sequence of antenna elevations, the azimuth rate, the polarization state, PRF, thresholds, etc. Configuration parameter sets are combined into templates that are stored in the host computer and uploaded to the RCU and DSP according to a configurable scheduler.

Scanning of a radar (of operational radar, at least, and even more so of networked operational radars) is a trade-off between dense volume coverage, accuracy, and fast update rate. For some applications, slow scanning is required for higher accuracy, while rapid surveying can be faster. Applications related to air traffic, severe convection, and vertical profiles need extended height coverage even close to the radar. Early investigations showed that the quality of (Z-only) precipitation estimation dropped if updated after 6 min or slower. The same has proved true for cell tracking, cf. Fig. 30.22. Thus, the selection of scan parameters depends on priority tasks.

Unlike earlier radars, current systems are capable of pointing vertically in order to measure time–height profiles over the radar. High elevations close the *cone of silence* above a radar site, but the radar beam will soon be beyond any weather phenomena taking place in the lowest layers of the atmosphere only, particularly in winter. Relatively, lower elevation leads to more information, but ground proximity is still limited by the Earth's curvature and orography.

In routine 24/7 operation of a radar, parameters may be different for different sweeps according to a predefined time schedule describing the scan strategy or volume coverage pattern (VCP). While with earlier patterns it was deemed necessary to cover a dense volume (e.g., 18 elevations in 10 min), rapid update has been given priority in recent years at the cost of thinned-out volume coverage. The so-called *Swiss scan* [30.52] to speed up volume coverage using two interleaved *half volumes* of 10 elevations each within 5 min is a famous example.

In a network, radar parametrization may be strictly identical for all radars at all times (e.g., in the German radar network) or dependent on season, orography, and climate region (in very large networks, e.g., USA), or may be adapted to the prevailing weather conditions (*adaptive scanning*) by an operator or automatically.

NEXRAD operators may currently choose from 13 different VCPs [30.53].

DWD has been running identical volume scans at every radar consisting of 10 elevations, plus a prioritized terrain-following sweep optimized for precipitation measurement, plus a 90° vertical scan, every 5 min since 2013 [30.54], as is shown in Fig. 30.6. DWD is presently experimenting with a lowest (0.5°) sweep every minute. Faster update rates will only be available with future electronic scanning and beam steering.

Monitoring

Besides calibration, parametrization, and regular maintenance, it is good practice to monitor proper radar operation, data quality, and data availability for timely detection of any problems in order to keep availability and data quality high. The notion of monitoring refers to the observation, characterization, and tracking over time of parameters, status, availability, and any undue alteration thereof. Thus, monitoring helps achieve and maintain specified conditions and performance.

Firstly, it is desirable to detect any problems as early as possible in order to keep the duration of any radar failure or of degraded data quality at a minimum. This is particularly true for radars operated in remote areas with low accessibility. Continuous monitoring of all elements of a radar system is necessary to achieve an in-time detection of a radar system component failure.

There are also some elements in a radar system that tend to creepingly degrade with time, such as a TR-limiter. Such degradation does not cause instantaneous failure but may affect data quality. If it is possible to detect trends or unusual changes of radar parameters early enough, preventive maintenance may be scheduled, so that an actual system failure can be avoided. The BITE system supplies continuous information that may be monitored and analyzed.

Secondly, based on user requirements, radar data are subject to high-quality standards concerning absolute accuracy and associated uncertainty. The latter is mainly determined by the sampling strategy (e.g., acquiring a sufficient number of pulses) and must be optimized/traded off in a proper design of a scan definition. Observed variations in the measurements (e.g., related to the scatter of ZDR) beyond what can be expected theoretically may indicate a hardware issue and should be monitored.

The absolute accuracy of a radar moment is determined by all components of its transmit and receive chains, which are typically characterized during calibration. Obviously, any changes in the transmit path (e.g., transmit losses due to a wet radome or a degrading circulator) will affect the absolute accuracy of all radar moments that rely on the received power measurement.

Fig. 30.6 Current scan sequence at DWD. The pattern starts at hh:mm with a coarsely terrain-following lowest sweep optimized for QPE. It continues with a sweep at an elevation of 5.5°, moving downwards by 1°-steps to cover the lower atmosphere without gaps in such way that at hh:mm +2.5 there is another lowest sweep at 0.5°. The volume finishes upward with elevations at 8, 12, 17, and 25°. A vertical scan is added for calibration of ZDR and as a meteorological profiler scan, so that the complete volume is finished before hh:mm +5. Values for numbers 1 to 10 (and PRECIP and 90°) in given order: elevation (°), azimuth rate (° s⁻¹), dual PRF ratio, PRF1 (Hz) : PRF2 (Hz) (image © P. Tracksdorf, DWD)

All components of the radar that may affect data quality need to be identified and monitored.

However, the uncertainty of engineering measuring techniques is too large when it comes to quantifying all relevant elements in the transmit and receive paths within an accuracy of 1 dB for Z, or 0.1 dB for ZDR. Therefore, integral end-to-end assessments of the system performance have to be considered. An end-to-end radar system monitoring may be performed including well characterized targets or reference measurements, so that all elements of the radar equation are taken into account.

Data-based monitoring approaches have been established, where well-characterized targets or reference measurements are used to quantify the accuracy of radar moments and to detect issues in the radar hardware. For instance, the sun may be used to monitor the pointing accuracy of a weather radar [30.55] as well as its power and ZDR calibration [30.56, 57], as the sun's position and radiation properties are well known. Receiver calibration may also be monitored with the radar operating and placing a test signal at some remote range bin, where there is no weather. The noise level is monitored periodically during operation; weather permitting, the same is feasible for 90° ZDR calibration. A digital receiver provides data to monitor the transmit pulse

power and frequency. Single radar end-to-end monitoring may be performed using external devices, such as rain gauges, disdrometers, or another radar. Radar-radar comparisons may be performed in the overlapping areas of a radar network to check consistency. However, due to different radar positions, beam propagations, and beam heights/widths, a pointwise comparison is difficult, and a statistical evaluation is necessary instead.

Beyond the technical and observed parameters of a radar itself, system load, network performance, data completeness (a check for missing rays), data transmission (a check for missing sweeps), and product generation (check timely production) are usually also monitored in order to ensure high data availability.

30.6.2 Error Sources

The accuracy of radar interpretation largely depends on the underlying model assumptions, as given in Sects. 30.3 and 30.8. Some of them are readily met under normal conditions, while others are known to be critical, if only under extreme weather conditions. On the other hand, there are interferences from external error sources, such as nonmeteorological targets and active emitters.

Model Assumptions

There are several assumptions underlying the radar equation (30.13) and its constituents, such as antenna properties:

- No unknown losses, misadjustments, or undiscovered malfunctions are assumed to occur in the radar system; the radar is considered to run according to specifications and parametrization.
- A geometric radar beam is usually assumed to hit the target at a certain direction, while in reality, there is an antenna pattern transmitting and receiving via both the main lobe and sidelobes. The assumption relies on a more rapid decrease of the main lobe flanks than a possible gradient in off-beam reflectivity. If this is not the case, measurement and interpretation may go grossly wrong, as strong echoes will be collected over the side lobes or flanks of the main lobe and projected into the direction of the main beam.
- Beam propagation is assumed to occur in standard atmosphere and to follow a $4R_E/3$ curvature. Anaprop and multipath scattering are sometimes detected but not usually corrected for.
- Increasing beam broadening and increasing beam height with increasing range make measurements essentially incomparable.
- In routine operation, at least in single-polarization radars, target droplets are commonly assumed to consist of water, using a K^2 -factor of 0.93 in the radar equation. If real measurement occurs in ice, K^2 should be 0.176, i.e., 7 dB less, and reflectivity is overestimated by this amount.
- Moreover, targets are considered to be Rayleigh scatterers, i.e., small spheres. Liquid droplets may be considered spherical, if small, but large drops are oblate, ice crystals are symmetric, hail and graupel and nonmeteorological scatterers are irregular, canting, tumbling and often large. In the latter respect, a larger wavelength (S-band) can help at a cost.
- Also, complete and homogeneous beam filling is assumed, while in reality, overshooting and large reflectivity gradients (such as hail shafts, bright band, wind turbines) may occur.
- In a real radar, several parameters will deviate from their specification, such as the transmit power, pulse form, phase stability, polarization purity, and antenna squint.
- Signal-processing assumptions, such as a monomodal Doppler spectrum, will not always be fulfilled.
- Range and/or velocity folding may go unrecognized.
- Radar parametrization and scan strategy introduce sampling gaps and a cone of silence.

Even with a perfect measurement, some more assumptions are related to data interpretation:

- Classical QPE relies on an average Z/R -relation, which is based on an average drop-size distribution (e.g., Marshall–Palmer) with a very large spread.
- Some interpretations of Doppler radial wind depend on the assumptions of wind field homogeneity, continuity, and, maybe, horizontality.
- Some correction procedures may themselves turn out to introduce new errors, such as Doppler filtering, thresholding, dual-PRF unfolding, or range correction in the second trip, or the comparison of radar volume measurement to gauge-point measurements.
- The vertical reflectivity profile VRP may not be an error in itself but commonly causes errors in QPE because the (maybe correct) radar measurement from aloft is extrapolated to the ground not taking into account drop-sorting effects due to size/velocity distribution, or evaporation (virga), or the *bright band*.
- The bright band appears as a height region of enhanced reflectivity caused by the melting layer just below the zero isotherm. It is caused by melting particles, e.g., snow flakes or graupel, which due to their water cover appear to be large solid raindrops (remember K^2 in (30.5) and (30.13) is 7 dB larger for water than for ice). The bright band is more conspicuous at higher antenna elevations than close to the ground.

External Error Sources and Interferences

There are more things between heaven and earth than are dreamt of in pure rain. Besides precipitation and other meteorological phenomena, other targets are also seen by a weather radar, such as (Fig. 30.7) mountains, buildings, ships, wind parks, birds, and chaff (anaprop was mentioned before). Sometimes, a careless radar setup may produce additional errors, such as obstacles in the antenna near-field.

Any unwanted echoes are collectively called clutter. Clutter affects not only reflectivity, but also biases Doppler wind [30.58] and dual pol moments.

Clear air echoes from insects or turbulent fluctuations in the refractive index [30.59–61] may be considered clutter or may be used as wind tracers. External interference is caused by active emitters, such as the sun and foreign narrow or broadband transmitters, such as other radars, WiFi, or (thermal) noise. Figure 30.7 allegorizes most of these error sources. Many error sources may to some degree be corrected for, as is shown below.

Fig. 30.7 Graphic depiction of external error sources in a weather radar (image © N. Rathmann, DWD, inspired by M. Peura, FMI)

30.6.3 Correction Algorithms

Some correction algorithms may be run in realtime on the DSP, where maximum radar information but limited external information is available. The following algorithms are commonly applied to the moment estimates of Sect. 30.3.4. External postprocessing/QC has all possible weather and technical information available, but maybe not all of the radar internals. This is presented in Sect. 30.6.4 together with DSP thresholding algorithms.

Range and Noise Correction

According to the radar equation (30.13) the received power decreases with the square of the distance. This must be corrected for in the calculation of the reflectivity factor by a term of $-20 \log(r)$. For example, 40 dB must be added for a volume target 100 km away. This may seem simple, but will only be correct if applied to a target at range r .

If, for instance, the signal contains system noise (which does *not* depend on range–time), the noise will nonetheless be corrected by $\sim r^2$ together with the signal, causing the noise to increase with range. Even though this may be detected, the data will be useless and must be excluded from causing problems. Therefore, noise is measured periodically – often at the beginning of every scan – and subtracted from the signal in the radar equation. If in reality the target is *not* located at range r , e.g., originating from second or higher trips (Sect. 30.3.1), range correction goes wrong, and second-trip echoes are represented too weakly and in the wrong place, if no specific measures are taken (see Sect. 30.6.3, *Second-trip Unfolding – Range Dealiasing*).

Attenuation and Beam Blockage

In addition, the received power has been attenuated by atmospheric gases, depending on wavelength and distance, and by precipitation. Part of the radar beam may be blocked by obstacles.

Atmospheric *gas attenuation* is taken into account as a tunable parameter in the radar equation. A two-way attenuation of $a = 0.016 \text{ dB km}^{-1}$ is considered standard at the C-band and is applied as the $-ar$ -term in (30.27). Even though the radar wavelength is chosen not to be attenuated even by large precipitation fields, the radiation field may be noticeably damped by strong rain or hail.

Attenuation by precipitation is usually not corrected for in classical radar. In dual-pol radars, the dependence of PHIDP on attenuation by large drops allows for an attenuation correction of the horizontal and differential reflectivities. Attenuation losses by heavy rain are intuitively assumed to be proportional to K_{DP} (Sect. 30.3.4), $A_h(r) = \alpha K_{DP}(r)$ and may be corrected for, e.g.,

$$\begin{aligned} {}^A Z_h(r) &= {}^U Z_h(r) + 2 \int_0^r A_h(r'; \alpha) dr' \\ &= {}^U Z_h(r) + \alpha \Delta \text{IDP}, \end{aligned} \quad (30.54)$$

where A_h is the attenuation factor in dB km^{-1} , K_{DP} in deg km^{-1} is approximated as $\Delta \phi_{DP}/2\Delta r$, the left superscripts indicate uncorrected (U) and attenuation corrected (A) reflectivity factors Z_h in dBZ, and the parameter α is around 0.08 in the C-band. The same reasoning holds for differential reflectivity

$$\begin{aligned} {}^A Z_{DR}(r) &= {}^U Z_{DR}(r) + 2 \int_0^r A_{dp}(r'; \beta) dr' \\ &= {}^U Z_{DR}(r) + \beta \Delta \text{PHIDP}, \end{aligned} \quad (30.55)$$

based on the effect of differential attenuation $A_{dp}(r) = \beta K_{DP}(r)$ with a parameter β 0.02 in the C-band. The crux of the matter lies in the parameters α and β , see [30.38] for details. PHIDP must be unfolded and possibly interpolated first.

Shadowing/beam blockage is best avoided by choosing an appropriate radar site with free round view. Methods have been proposed to correct precipitation measurements from intensity-only radars [30.62] and to take beam blockage into account in dual polarization radars [30.63].

Clutter Correction

The main starting point for the treatment of stationary clutter is that clutter does not move or is in some way more stable than weather echoes. In olden times, one or several measurement sweeps were taken when there was no precipitation. Any remaining echo was considered clutter and stored in a so-called static clutter map, which was used to flag suspicious range bins later with precipitation present. Because of varying propagation conditions, it is difficult to set the sensitivity of the clutter map so that no clutter goes unrecognized and not more weather echo is flagged than necessary. Better results are achieved using a dynamic clutter map, e.g., based on radial velocity output. Anyway, the clutter can only be recognized; the weather echo is lost and cannot be restored. Nowadays, dynamic clutter maps based on more sophisticated approaches are used to decide on adaptive filtering (see CMD below).

Realtime clutter suppression started with analog filters called moving target indicator (MTI) which essentially subtract the previous pulse or, in a more sophisticated way, subtract not only the most recent pulse but also a few earlier pulses with corresponding weights a_i . In recursive filters, filtered pulses (weighted b_i) are fed back as well resulting in an infinite impulse response (IIR) filter. The same technique is applied in digital filters, cf. (30.56) below.

Statistical Clutter Filters. In a radar without Doppler capability, a recursive (IIR, e.g., third order) highpass filter called a *statistical filter* may be applied to the fluctuating LOG *amplitude* time series following [30.64]. Low amplitude variance due to stable returns from clutter is filtered out. Therefore, unlike Doppler processing, samples should be taken at low PRF in order to not be correlated. In principle, CCOR (30.36) is calculated as the difference of filtered and unfiltered powers (averaged squares of amplitudes) but includes some subtleties, such as a correction factor due to Poisson statistics and a gamma-bias correction depending on the estimated CSR. Statistical filters are the only clutter filters available in intensity-only radars and

are less effective than Doppler filters. Notwithstanding, they are sometimes also used in Doppler radars as a makeshift, e.g., with staggered PRT where filters requiring equally spaced samples cannot be used. In this case, the amplitude time series is calculated from IQ as $A_i = \sqrt{I_i^2 + Q_i^2}$. Statistical filters may improve reflectivity measurements but, of course, cannot correct Doppler and dual-pol moments.

Doppler Clutter Filters. In a Doppler radar, clutter filtering is achieved by applying either time series IIR or frequency-domain (*Fourier*) filters, usually in a second channel parallel to an unfiltered one. CCOR is then calculated as the difference in the reflectivity factor between the two. For time-series (IIR) filters with fixed coefficients, CCOR is limited by the fixed filter depth. In an analog Doppler radar, CCOR is transferred to the LOG receiver channel for application in the logarithmic radar equation (30.53).

Doppler clutter filters rely on zero radial clutter velocity or a sufficiently narrow clutter spectrum around zero velocity. These spectral components are filtered out by a digital high-pass filter, which may be implemented in the time or spectral domains. In fact, the superior performance of its clutter filters is one of the main reasons to choose FFT processing.

Time-domain Doppler filters are usually implemented as recursive or infinite impulse-response (IIR) filters, e.g., a Chebyshev filter of order $n = 4$,

$$A_k^f = \sum_{i=0}^n a_i A_{k-i} - b_i A_{k-i}^f, \quad (30.56)$$

where $b_0 = 0$. The choice of coefficients determines the width and depth of the filter. In modern signal processors, predefined filters are available but may also be customized using graphical tools and downloaded to the DSP. Clutter filters of different depth/width may be set depending on range and elevation (the more aggressive filters at closer range and lower elevation). An example of effective clutter correction is shown in Fig. 30.8.

Besides being an effective means of clutter removal, there are some drawbacks to IIR filters. Due to the theoretically infinite impulse response, any perturbations (strong gradients, changing PRF) practically propagate over many pulses, possibly into subsequent rays. This effect can largely be mitigated by a filter delay that lets the filters stabilize at the beginning of each new ray, possibly after reinitializing (zeroing), by skipping the closest (say, three) pulses without using them.

Filters must also be reset if PRF changes, e.g., with staggered PRF (Sect. 30.6.3), or if AGC (Sect. 30.4.3) is applied. This loss of pulses may be critical with a fast

Fig. 30.8a,b The effect of successful quantitative clutter filtering. (a) Cutout of a PPI of UZ over the Karwendel mountains, BY, Germany. The DWD Hohenpeissenberg radar is located to the left (red cross). (b) Cross section of CZ (green) plotted over UZ (blue) along the black line in (a). CCOR is indicated in red (right scale), mountains are filtered by up to 40 dB, precipitation is left unchanged (after [30.65], © J. Seltmann, DWD)

rotating antenna. Furthermore, as the filter coefficients are fixed, so are its stopband depth and width. Therefore, a clutter peak stronger or wider than the filter will be attenuated but not completely removed. On the other hand, weather echoes around zero velocity (with no or only weak clutter present) may be attenuated as well, losing signal power in Z with a chance of SQI falling below the threshold (Sect. 30.6.4) and losing Doppler moments, too.

Frequency-domain Clutter Filter. The Fourier transform of such IIR time-domain filter is a spectral highpass filter with a notch around zero velocity. If the Doppler Fourier spectrum $S_i = |FFT(A_j)|^2$ is available, a highpass notch filter (laxly called a Fourier filter) may be designed in an even more effective way. The idea is to remove and subsequently interpolate a certain uneven number $2k - 1$ of spectral components around zero velocity

$$S_i^f = S_{-k-1} + (S_{-k-1} + S_{k+1}) \frac{k+i+1}{2(k+1)},$$

$$i = -k \text{ to } +k. \quad (30.57)$$

This makes the filter adaptive (no predefined filter depth) and particularly effective removing the clutter

signal while reconstructing the weather signal, even if it overlaps with the weather. Interpolation may be linear as in (30.57) or use an (iterative) Gaussian model. The Gaussian model adaptive processing GMAP [30.66] fits a Gaussian to the three central spectral taps of the clutter spectrum (centered around zero) and removes all taps under this curve. The remaining weather spectrum is then fitted to another Gaussian. This procedure is repeated until the resulting power and mean velocity of the signal stabilize within 0.2 dB and $0.005 V_N$. Finally, the optimum tapering window is decided upon based on CSR.

Clutter-mitigation Decision System CMD. IIR clutter filters and even adaptive spectral filters still remove weather power when the weather spectrum is narrow, and its mean V is close to zero. Therefore, the clutter-mitigation decision system CMD [30.67] applied by NEXRAD identifies clutter prior to filtering. To this end, CPA (Sect. 30.3.4) plus three internal parameters are calculated:

- The texture reflectivity TDBZ of a range bin is defined as the mean of squared differences between reflectivities on both sides of that bin.
- The SPIN parameter tells how often the reflectivity gradient changes sign in a certain neighborhood of a bin, normalized by the number of neighbors used.
- Clutter ratio narrow (CRN) is computed dividing the power contribution of the three spectral lines centered at $V = 0$ by the power of four adjacent lines (two on each side).

CMD is then calculated in a fuzzy logic from weighted membership functions of TDBZ, SPIN and CPA, and CMD. The decision flow is IF SNR > 3 dB THEN IF CRN > 6 dB THEN IF CMD > 0.5 THEN set clutter flag and apply clutter filter. An excellent skill of CMD has been reported [30.67]. An update to CMD is described in [30.68], including two dual-pol membership functions based on the standard deviation of ZDR and PHIDP.

An internal dynamic clutter map may be created within the DSP based on CMD or CPA alone. Doppler filtering is only applied to range bins that are flagged as clutter. This works also for PPP (except for CRN) rendering IIR filtering, in a sense, adaptive. If the parameters mentioned above are output as additional moments by the DSP, CMD may even be performed a posteriori in a centralized QC (Sect. 30.6.4).

Clutter Microsuppression CMS. CMS excludes raw range bins exceeding a predefined clutter/signal ratio estimated by $(T_0 - R_0)/R_0$ from range averaging auto-correlations, i.e., at a very early processing stage. This

improves subclutter visibility in the presence of strong, isolated clutter targets.

Unfolding, Dealiasing

Range or velocity folding (aliasing) or both may occur due to the Doppler dilemma (Sect. 30.3.2). There are several techniques to recognize and even correct them.

Second-trip Unfolding – Range Dealiasing. In order to resolve the range ambiguity, i.e., to differentiate between first and second (or higher)-trip echoes in a pulse radar, pulses must in some way be *labeled* to be distinguishable. To this end, phase coding or alternate dual-pol mode are feasible under the appropriate hardware setups.

COR (magnetron) systems offer a simple approach to range unfolding as they perform, so to say, an involuntary random phase coding. Second trips are not coherent to the first trip and appear as white noise in the (first trip) Doppler spectrum, as a traditional receiver is phase locked to the most recent pulse. On the other hand, the random magnetron phase of each pulse is measured. It may be stored in a digital receiver and be used to rotate each A_i vector (using matrix multiplication) to cohere to the second trip; the first trip will now turn incoherent and show up as white noise in the (second-trip) Doppler spectrum. The coherent second trip (and its coherent clutter) may now be removed from the spectrum by an adaptive whitening filter, leaving the first trip as white noise, which will now be recovered to the first trip. This way, both signals may be retrieved. Comprising Fourier transforms, matrix multiplications, autocorrelations, and filtering, second-trip processing imposes a substantial computational load on the DSP. In fully coherent radars, the method will only work when coding the transmitter phase on a pulse-to-pulse basis.

Velocity Unfolding. As unambiguous velocity and velocity folding depend on PRF, different folded velocities will show up under different pulse repetition times. For instance, if the real radial velocity is $V = +20 \text{ m s}^{-1}$, then at $\text{PRF} = 800 \text{ Hz}$ ($V_{\text{max}} = 10.6 \text{ m s}^{-1}$) the radar detects $V'_{800} = -1.2 \text{ m s}^{-1}$, while at $\text{PRF} = 1200 \text{ Hz}$ ($V_{\text{max}} = 16 \text{ m s}^{-1}$) $V'_{1200} = -12 \text{ m s}^{-1}$. This may be exploited to detect and correct for velocity folding.

One method called staggered or dual PRF alternates transmit PRF between adjacent rays (consecutive batches), i.e., one high PRF_h and one low PRF_l , so that the measured velocities are $V'_{1/h} = \theta_{1/h} \lambda \text{PRF}_{1/h} / 4$, resulting in an enlarged unambiguous velocity, $V_{\text{max}} = \lambda / 4 (\text{PRT}_h - \text{PRT}_l)$. With a stagger ratio of $\text{PRF}_h : \text{PRF}_l = 4 : 3$ (3 : 2), an extended unambiguous $V_{\text{max}} = 3V_{\text{max};h}$ ($2V_{\text{max};h}$) is obtained. In the above example

of 1200/800 Hz an unambiguous velocity of $V_{\text{max}} = 32 \text{ m s}^{-1}$ results. The method assumes that the radial velocity is constant over adjacent azimuthal rays. If this is not the case, e.g., with small-scale clutter targets or at the edge of a precipitation field, staggered PRF unfolding will go wrong. As PRF is changing between rays, clutter filters need to stabilize at the beginning of each ray. This filter delay is configurable but diminishes the effective number of available pulses (the length of the time series). Still more serious, the filter notches at the center of the original, narrower Nyquist intervals of $\pm V_{\text{max};l}$ and $\pm V_{\text{max};h}$ now appear several times in the extended interval $\pm V_{\text{max}}$ (four times at a 3 : 2 ratio, three of them unwanted).

The same principle may be applied to changing pulse repetition time pulsewise within one ray (batch), which is referred to as staggered (dual, triple, ...) or random PRT [30.69, 70]. As IIR filters and FFT processing assume equidistant pulses, neither of them may be used under staggered PRT; statistical clutter filter may be applied instead.

Spectral Width Correction. A rotating antenna causes the Doppler spectrum width to broaden. A formula has been proposed for the variance σ_r^2 ($\text{m}^2 \text{ s}^{-2}$)

$$\sigma_r^2 = 0.017 \left(\frac{\omega_{\text{az}} \lambda}{\theta} \right)^2, \quad (30.58)$$

where ω_{az} is the antenna azimuth rate in deg s^{-1} , θ the horizontal beamwidth in deg, and λ the radar wavelength in m. The spectrum width W calculated by (30.29) or (30.30) may be corrected for this spectral widening.

30.6.4 Thresholding and Postprocessing

Quality control occurs throughout the data generation chain. Quality checks may be performed as a last step within DSP before data are output, but also by means of postprocessing or as an entrance test to follow-up meteorological algorithms (Sect. 30.8.)

Thresholding

The validity and quality of individual moments measured in certain range bins may be checked by screening against nonmeteorological values of some adequate parameters. Output moments are subjected to a logical combination of configurable thresholds usually stored in a binary bit mask. Different threshold combinations may be applied to different moments. Range bins and moments that do not pass these tests are flagged as invalid. For instance, radar measurements are usually discarded if the signal-to-noise ratio SNR is consid-

Table 30.18 Common thresholds

Threshold	Typical value	Typically applied to
CMS	35 dB	R_i^f
CPA	0.95	Filter yes/no?, CMD
CMD	0.5	Clutter filter yes/no?
$CCOR_{thr}$	-25 dB	CZ, V, W
LOG (NOISE)	1 dB	SNR, UZ, CZ, ZDR
STD_{thr}	0.5	RF interference
SQI_{thr}	0.5	V, W
$SQI2_{thr}$	0.3	Second trip
$RHOHV_{thr}$	0.8 rain, 0.5 clutter	CZ
WSP_{thr}	10 dB	W

ered too low, the clutter correction $CCOR$ too high, the spectrum width too wide, etc. Setting thresholds too stringent will result in a loss of sensitivity, setting them too loose may pass interference/noise. Table 30.18 shows the most commonly used thresholds.

Noise Power Threshold, LOG . The SNR parameter is tested against the noise threshold in order to suppress data with an SNR lower than the selected threshold. The noise threshold is usually set visually so that no noise is visible, commonly around 0.5–1 dB above the noise floor measured during the noise sample, thus defining the system MDS. Averaging in time (i.e., a longer time series) or range allows lower LOG values. LOG should be set high enough to eliminate noise and low enough not to lose sensitivity. Low-reflectivity range bins above the noise threshold will be considered as valid *no rain* bins.

Clutter-correction Threshold, $CCOR_{thr}$. The $CCOR$ parameter is the clutter correction obtained from LOG , IIR, or FFT filtering. A threshold $CCOR_{thr}$ may be used to reject data where very strong clutter is present, i.e., $|CCOR|$ is large, as it may not be desirable to trust corrections that are very much (e.g., by a factor 100) larger than the weather signal.

Recalling that $CCOR$ is negative, setting a threshold $CCOR_{thr}$ means that more negative corrections (with a larger absolute value) will be rejected. As $CCOR_{thr}$ approaches zero *less* corrections will pass.

$CCOR_{thr}$ should be chosen to eliminate the strongest clutter targets but leave headroom to filter and correct for the weaker ones. The measured $CCOR$ and the pertaining threshold $CCOR_{thr}$ depend on system coherency and the clutter filter chosen. To optimize $CCOR_{thr}$ watching a realtime reflectivity PPI, the absolute value of the threshold should be increased starting from a value close to zero (thresholding nearly all clutter), until the number and size of clutter targets no longer increase. The threshold absolute value should be set approximately 5 dB lower (closer to zero).

Signal-quality Index Threshold, SQI_{thr} . As SQI (Sect. 30.3.4) is a measure of coherency, noncoherent echoes, such as the sun, foreign transmitters, or second-trip echoes may effectively be thresholded. An SQI threshold is usually applied to Doppler data V and W at values around 0.5. A second, lower threshold may be used to screen against second trip. If second-trip processing is available, the time series may be cohered to the previous pulses, so that second or even third-trip signal quality may be calculated for the previous pulses. Storing and applying the phase information of the respective pulses in a digital receiver, $SQI2$ (and $SQI3$) may be calculated to be coherent with the second and third-trip echoes.

SQI_{thr} should be set to the lowest value eliminating noise in the velocity display. A higher value will pass less valid range bins. Averaging fewer pulses or range bins will force a higher value of SQI_{thr} .

RF Interference. Frequency assignment has become an increasing issue as more and more radiation sources fill the ether. There may be authoritative regulations, but many RLAN devices are not compliant to dynamic frequency selection (DFS) requirements. External RF emitters within the receiver bandwidth of the radar, such as the sun, or radio links, or other radars, will cause artifacts in the data. The interfering radiating source may be broadband or narrowband, continuous or pulsed, local or moving. A cw interferer, such as the sun will cause a spike of typically 1° width in the data and its intensity will increase with range because it is wrongly r^2 -corrected. Pulsed interferers (e.g., radio links) are not synchronized with the radar pulses, so that the standard deviation STD (30.34) of a pulsed interferer will be high, and no well-defined distance can be made out. The pattern of a moving pulsed interferer (aircraft, a neighboring radar reflected from a mountain) may be complicated. In any case, an external source will not be coherent, so that a low SQI is measured. These properties may be used to detect and flag external RF.

Speckle Handling. Range bins left isolated after thresholding are called speckles. Valid (= not thresholded so far) but isolated range bins are considered to be of nonmeteorological origin and may be flagged or removed by a speckle filter. Likewise and independently, isolated invalid (= thresholded earlier) bins may be recovered by interpolation, depending on the number of valid neighbors. Speckle handling may be performed on a 1-D or 2-D (or even 3-D) basis, the notions of *isolated* and of *neighbors* (their number) must be defined accordingly in order to decide on the speckle property of each bin.

Fig. 30.9 Demonstration of the handling of speckle bins #11, #12, #13, #14 after range averaging and thresholding

In Fig. 30.9, a so-far valid bin is defined as speckle if surrounded by less than three valid neighbors. Bin #14 is, hence, flagged invalid. Thresholded bins #11 and #13 are considered isolated, as they have three or more valid neighbors that are consequently used as interpolation boundaries. Bin #12 is not a speckle and left unchanged (valid). Speckle removal may be applied for any output parameters. As a consequence, some earlier thresholds might be relaxed iteratively/in retrospect to increase sensitivity. Interpolation should be used with caution. A 2-D speckle remover will lag the quasi real-time output by 1° while waiting for the subsequent ray.

Postprocessing Quality Control

Fixed thresholds have long been used within DSPs to output only valid data for the sake of computational effectiveness. However, the results of threshold tests and classifications (such as CMD, second trip, RF interference) may be also stored and output as additional moments (sensor map) by the DSP. With fast processors and broadband data transmission, it is presently possible to calculate and output virtually all parameters and moments. Knowing for each output range bin what thresholds were not passed offers greater flexibility in choosing different threshold values and combinations for different applications and complex offline user quality control.

For example, a clutter-detection algorithm similar to CMD has been realized in the form of a centralized postprocessing QC [30.71] using fuzzy logic classification plus the texture of PHIDP to detect stationary and variable clutter (birds, insects, chaff, etc.) and to recover data that should not have been filtered, replacing them with uncorrected data.

Some more corrections and quality checks are possible outside the DSP when volume radar data and external information, such as model or satellite data are available.

Vertical Reflectivity Profile (VRP). Growth, melting (bright band!), riming, evaporation, coagulation, break up, and drop sorting due to size-dependent fall velocity are the main reasons for a vertical profile of reflectivity to exist and to be highly variable in space and time. Depending on the elevation angle and distance, the radar beam often measures rain at close range, and snow of lower reflectivity at greater distance/height. Crossing the bright band inbetween gives rise to a ring/layer of increased reflectivity in a PPI/RHI (Sect. 30.8.1). VRP has been considered the main problem in radar precipitation estimation [30.72]. Therefore, VRP correction aims at extrapolating radar measurements at height to yield precipitation fields at the ground, and several approaches have been proposed. Mean climatological profiles may be derived from several years of radar volume data, possibly differentiated by location, season, or weather type. Updated profiles may be obtained averaging local volume radar data at ranges where many elevations scan the volume, or from radiosonde or vertically pointing radar [30.73, 74]. As RHOHV and LDR have proved to be good indicators, polarimetric weather radars offer new ways of bright-band detection [30.75].

Quality Products. QC is continued when products are being generated from base data (sweeps collected ray by ray from DSP). A literature review of radar QC techniques is given in [30.76]. In DWD, a quality index field [30.77] is produced that contains flags of several data contaminations for every range bin. Simple algorithms are used to detect gross errors/corrupt data sets (no transmitter, no noise sample ...) as well as artefacts, such as spikes (sun/external emitters, beam blockage) and rings (sidelobes), clutter remnants and speckles. Similar approaches have been proposed [30.78] or realized [30.71] for polarimetric and Doppler moments.

30.7 Maintenance

Weather radar is an instrument designed to operate 24/7 with a low downtime and a very high availability, usually above 95% including, or 98% excluding maintenance. In order to meet the high quality standards and availability requirements, careful maintenance is imperative. (Unless the radar operator chooses to maximize availability reducing downtime due to maintenance.) Maintenance may be split into two categories, preventive and corrective.

Corrective maintenance becomes necessary in the case of failure. Waveguides have been seen sparking, antenna gears broken, magnetrons dead, electronics gone faulty, radomes damaged by lightning stroke, and whole radar towers unbolted. Obviously, serious breakdowns can easily thwart high availability, especially if broken parts have to be brought from overseas or are no longer available at all. This calls for stocks of spare parts, logistics and prevention.

The BITE and message systems facilitate active or on-demand distribution of selected information. Automated messages containing predefined status reports may be sent to configurable addresses, e.g., a user help desk or a technician on duty, by the radar host computer. Remote access to modern radars allows us to read out, check and control system functions and processes, such as BITE messages, scan definition and scheduler, log-files, product generation and data distribution, etc. In the case of failure, an operator may assess and possibly evaluate any problems at home and take correct spare parts to the repair site. This greatly reduces downtime.

Preventive maintenance is performed to avoid unforeseeable failures. It includes definition and stock-keeping (regional, national, or continental) of line replaceable units (LRU) as well as maintenance plans; maintenance contracts may be bought if technical service cannot be provided by the operator and is to be outsourced. Likewise, a midlife refurbishment may be negotiated with the manufacturer, or a service life extension program (SLEP, as is presently planned in NEXRAD) may be initiated.

Maintenance plans have to be thought of. If, for instance, a complete maintenance takes more than one working day, then monthly maintenance does not fit an overall availability requirement of 97%. Maintenance intervals may be stretched using solid-state, optical, and digital units instead of analog and mechanical ones, defining LRUs that are fast to replace, and by making use of automated and/or remote BITE, monitoring, calibration, validation, and messaging techniques. Rou-

time maintenance intervals have increased from earlier monthly to presently 6 or 9 months.

Many preventive maintenance tests are quite cumbersome and need to be performed more often with an analog radar, even though there may be special maintenance utilities with graphic frontends to facilitate (remote) maintenance, such as asscopes, spectrum presentation, AFC checks, calibration tools, sun trackers etc. Some maintenance checks turn out to be more easy or even unnecessary or become automated in digital parts of the radar. As digital devices and solid-state parts are very reliable and easily manageable, very low MTTR (mean time to repair, e.g., 1 h) and fairly high MTBF (mean time between failure, e.g., 50 000 h) may be expected under nonextreme operation conditions.

The following example of a maintenance checklist is neither complete nor consistent. Checks with an asterisk* lend themselves to automated monitoring (depending on the radar type), whereas a caret^ refers to high-maintenance analog components that are not present in a digital receiver. Some checks have to be performed twice on a dual-pol system:

- Overall system: check safety switches and indicators; air conditioning; leak tightness of waveguides; screws and cables; voltages*; BITE* and log messages*; USV*. Clean flies, air filters, lubrication, slip rings, radome etc.
- Antenna/radome: check motors, servos, gears, lubrication; 2-D levelling of pedestal; antenna pointing* (e.g., sun position*); servo velocities* and accelerations*; slippings/brushes; antenna safety breakers; radome water tightness and hydrophobicity; obstruction lights.
- Transmitter: Check transmit power*, stability*, frequency* and bandwidth; klystron current*, waveform*, RF input level*; PW*, PRF*, duty cycle*; VSWR*; trigger*; thyatron and burst pulse gates; any waveguide switches*; safety sector blanking
- Receiver: check T/R limiter dead time; COHO window^, frequency^ and phase locking^; AFC locking; burst sample gate^; oscillator and AFC outputs; noise figure*; gain*, MDS and dynamic range; known intensity and velocity target*, e.g., sun power*

Continuous radar monitoring (Sect. 30.6.1) presents another way to prevent failure, enable timely corrections (e.g., of biases), and ensure the required data quality.

30.8 Applications

Weather radar data are used in many fields. In atmospheric research, an operating scientist may still sit in front of the radar watching a realtime display. External users will be supplied with standard or tailored radar products. Increasingly, radar data are evaluated by computer algorithms and are integrated into complex automated procedures.

30.8.1 Radar Products and Presentations

Prior to the advent of digital signal processing, the analog video signals coming from the receiver were just displayed on a cathode ray tube (CRT). From DSPs hooked to analog receivers, the LOG, I and Q , and maybe AGC signals are still tee'd off for check on an oscilloscope. For digital receivers, there are no real baseband videos but they may be generated by the DSP for visual inspection. In an analog receiver, analog signals may still be viewed on a realtime display prior to digitization as in the past on a CRT. A-scope (intensity, etc., over range), plan position indicator (PPI), and range–height indicator (RHI) are typical presentations of this type but may also be generated on a digital base.

A PPI is one of the oldest and still one of the most common presentations of radar data. It shows the radar echoes in two-dimensional radar-centered polar coordinates (range, azimuth) with a brightness or color-coded intensity, or any other measured parameter.

An RHI is obtained by vertical antenna scanning at a fixed azimuth. It is well suited to investigate the inner structure of thunderstorms. For instance, an automated

or operator-induced RHI may be performed through the strongest echo in an operational azimuth scan. As there is a fixed volume scan schedule in most operational weather radars, a pseudo or soft-RHI may be produced from the volume data with a much coarser resolution and with some distortion due to the time delay between elevations. Figure 30.10 shows an example of a real (hardware) RHI. Note that due to the presentation scales the vertical is largely exaggerated.

For data presentation, radar data may be referred to GIS-based digital maps, warped to Google Earth®, or provided with vector under- and overlays. While radar data are intrinsically measured in radar-centered polar coordinates (range, azimuth, elevation), many radar products are projected to some geographic grid based on an earth-centered (e.g., stereographic projection) or geodetic datum (e.g., WGS 84 flat map). There are several issues with sampling in this type of projection, as the data density is large close to the radar and scarce at a distance, depending on the range bin and pixel size. For example, at near range, the range bin closest to the Cartesian pixel center may be chosen to represent the pixel, or the maximum or mean value, and range bins flagged for interference (Sect. 30.6.4) may be excluded.

Many more products may be generated from volume data. For instance, a CAPPI (constant altitude PPI) is a horizontal cut at a certain height. Obviously, a cut in a strict sense would just produce concentric rings, as measurement occurs on cones of constant elevation. To close gaps between different elevations, data are usually *zigzag*-sampled from a layer around the nominal CAPPI

Fig. 30.10 Range–height indicator RHI of RHOHV through summer noon precipitation. The bright band and ground clutter are clearly discernible, illustrating RHOHV to be a potent hydrometeor discriminator (image © J. Seltmann, DWD)

Fig. 30.11 Echo-top product indicating the height of the 10 dBZ isoreflectivity surface (in km). Rings are due to discrete elevation sampling (image © DWD)

height. The layer thickness depends on the elevation spacing as a tradeoff between the desired accuracy versus data completeness. A thicker layer produces more data less accurately located and more visible rings. Figure 30.16 shows an operational product containing 12 CAPPs at heights between 1 and 12 km.

An echo-top product (Fig. 30.11) is a color-coded height indication of a certain iso-reflectivity level, e.g., the maximum height where 18 dBZ are encountered. Visible rings occur due to the *elevation jump*, as before. Special considerations lead to more specific products, such as a top-down maximum projection, or the lowest *clean* (= not thresholded) voxel bottom-up.

A 2.5-D presentation is a very useful tool to locate severe convection or hail shafts. It may be created using a ground view (e.g., a low CAPPI or a maximum projection top-down) together with two maximum projections west–east and south–north through the data cube, as shown in Fig. 30.12.

A maximum projection makes sense only with reflectivity, while for radial wind data, two real cross sections E–W and S–N through the radar would be appropriate.

The aforementioned *legacy products* may all be (and traditionally are) generated by the radar software on site. In a weather radar network or compound, product generation may be centralized. This is particularly true for products based on several radars.

Multiradar Products

While research facilities sometimes run their own radars for research purposes, the national weather services in many countries operate networks of weather radars, often covering all of their country's territory. Water management facilities and national and supranational associations generate composites (mosaics) over certain regions, such as catchment areas, individual countries (Fig. 30.13), or (part of) Europe.

Not only may the individual radars be mosaicked, thereby making up for beam blockage or attenuation and reducing the effect of beam broadening as a positive side-effect, but due to some overlap the data volume may be densified in space and time, closing elevation gaps and possibly filling each other's cone of silence, resulting in faster updates and information condensation for meteorologists and vertically sampling algorithms. Echo top, maximum-column reflectivity, or vertically integrated liquid water content (Sect. 30.8.3) are examples of products that will profit from multiradar data. Thus, products of networked radars are more robust than single-radar products. However, even with identical calibration, two radars may not see the same thing. Differences of several dB have been reported.

If several radar data sets are being composited, in addition to the projection considerations above, it must now be decided how to handle overlapping areas.

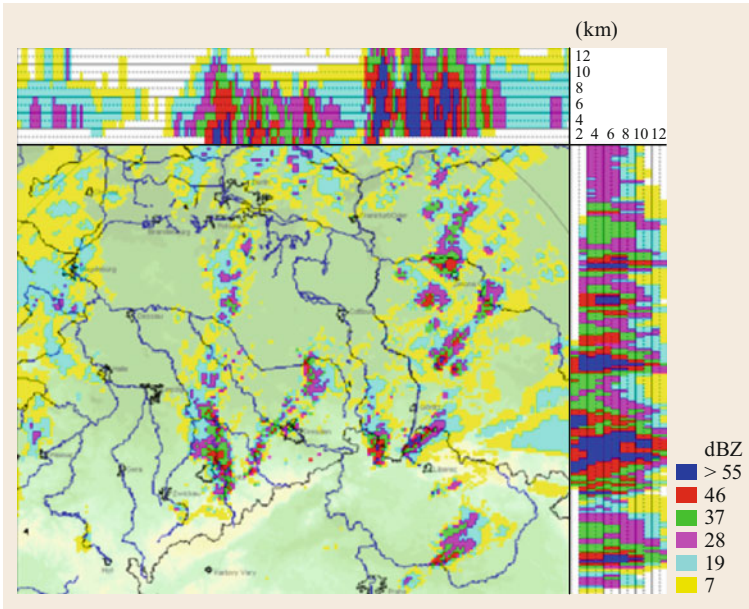

Fig. 30.12 2.5-D product showing a severe weather case that was to cause damage in Saxony, Germany, on 14 May 2007, here as seen by the Dresden radar at 16:41 UTC. The vertical maximum projections S→N and W→E show several high-reaching cells that may easily be located in the ground projection (image © DWD)

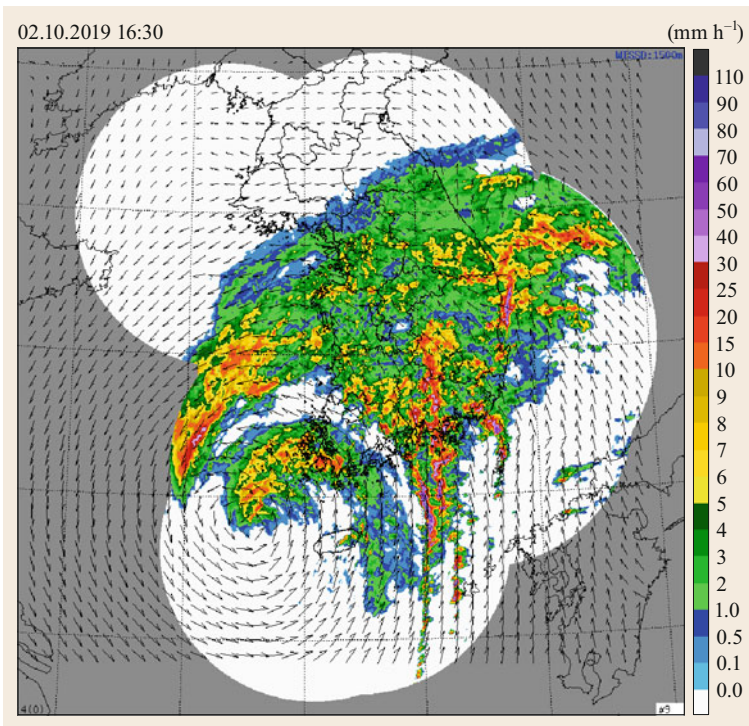

Fig. 30.13 Korea nationwide mosaic of rain rate estimation during typhoon Mitag, the 18th tropical storm in 2019 and the 7th to hit Korea, causing 9 casualties due to drowning and landslides (image © Korea Meteorological Administration)

Again, minimum, maximum, average, or closest-to-ground values may be chosen, or the decision may be based on some quality information that comes along with the data, choosing the higher quality [30.77]. This impacts pixel origin and availability and, hence, any climatological interpretation.

Several countries (Canada, Denmark, Germany, and Switzerland) are conducting a common project *NinJo* [30.79] to help process and display meteorological data, combining data of several sources (*layers*), such as synoptic observations, aerological soundings, lightning, satellite, and radar data into a common

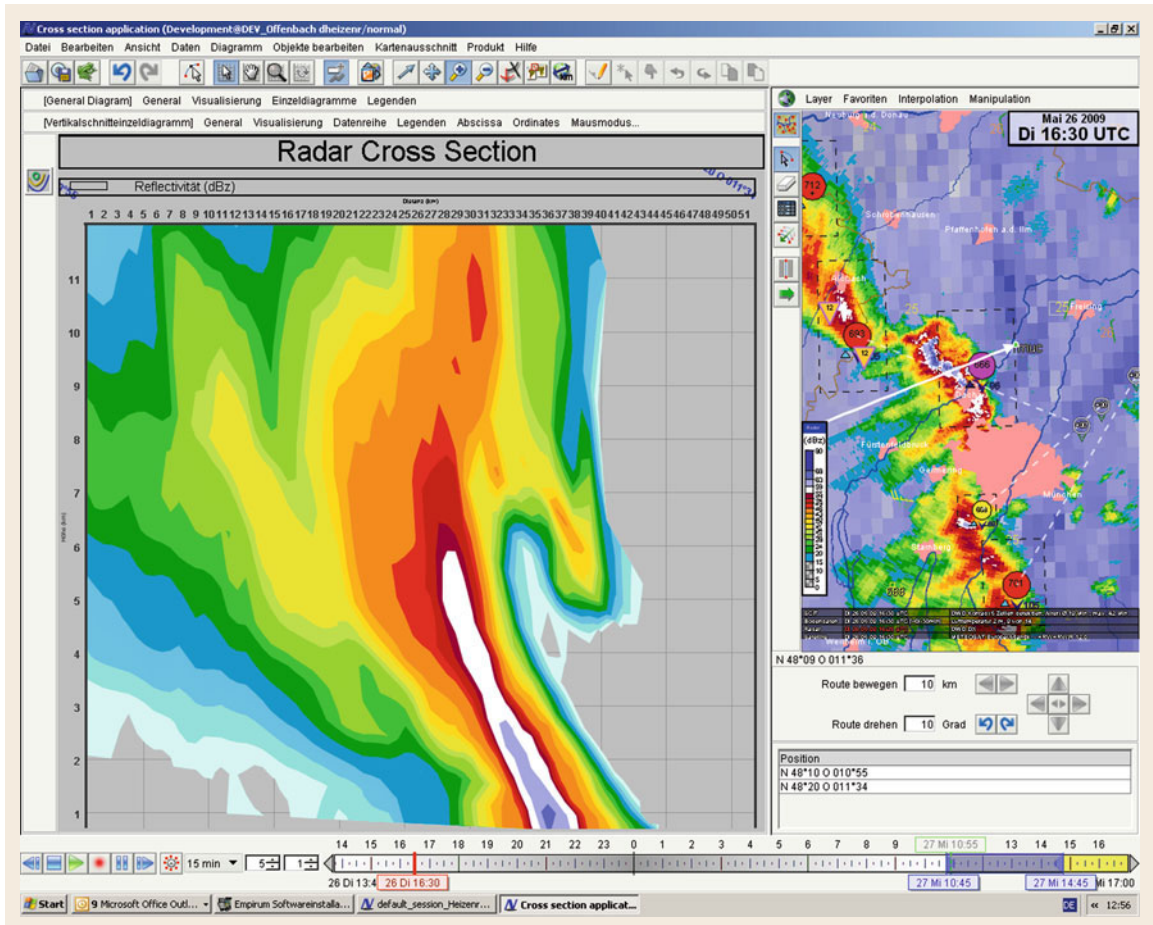

Fig. 30.14 Interactive cross section (indicated by a *white arrow, right*) through a squall line, NinJo presentation (image © DWD)

database. This allows interactive presentations, such as arbitrary cross sections through a thunderstorm, as shown in Fig. 30.14, or along a flight path.

30.8.2 Interpretation of Weather-Radar Products

The easiest way to use weather radar is visual image interpretation. Widespread precipitation, its areal distribution and patterns, including strong local gradients, are readily detected. Specific features typical of certain meteorological phenomena can sometimes be seen, as well checking the local data structure for high-resolution (e.g., 250 m, 5 min) products. For instance, echoes about 57 dBZ and above are usually associated with a high chance of hail even in a single PPI, and the more so if extending high (Fig. 30.12). Hook echoes (Fig. 30.17) are considered typical of mesocyclones with a high risk of tornado, a so-called hail spike is sometimes visible behind strong hail, and conver-

gence/divergence or velocity dipoles may be detected in radial wind patterns. The same is true with 3-D data: hailshafts or overhanging precipitation may be detected from vertical cross sections or projections, the vertical extension of precipitation may be read from echo top presentations, and jet streams may be seen in velocity PPIs at medium elevation. Observation over time will help in nowcasting storm movement and development. Time–height presentations may help investigation into the vertical structure of precipitation, e.g., the detection of a descending *bright band* (Fig. 30.15).

Negative differential propagation phase and negative ZDR may betray cloud regions where ice crystals are aligned by electric fields, even when there is no lightning [30.81, 82]. In combination with satellite images radar also helps monitor tropical cyclones (Fig. 30.13) and issue hurricane landfall warnings.

The following considerations may help to interpret Doppler radial wind products: velocity folding is easiest recognized by abrupt color jumps between $+V_N$

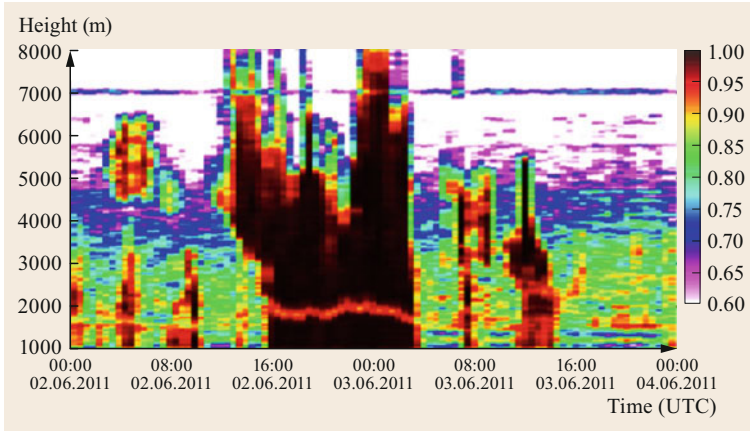

Fig. 30.15 Time series of vertical scans with a bright band descending over time clearly visible in RHOHV. Hohenpeissenberg radar, 02–04 June 2011 (after [30.80], © M. Frech, DWD)

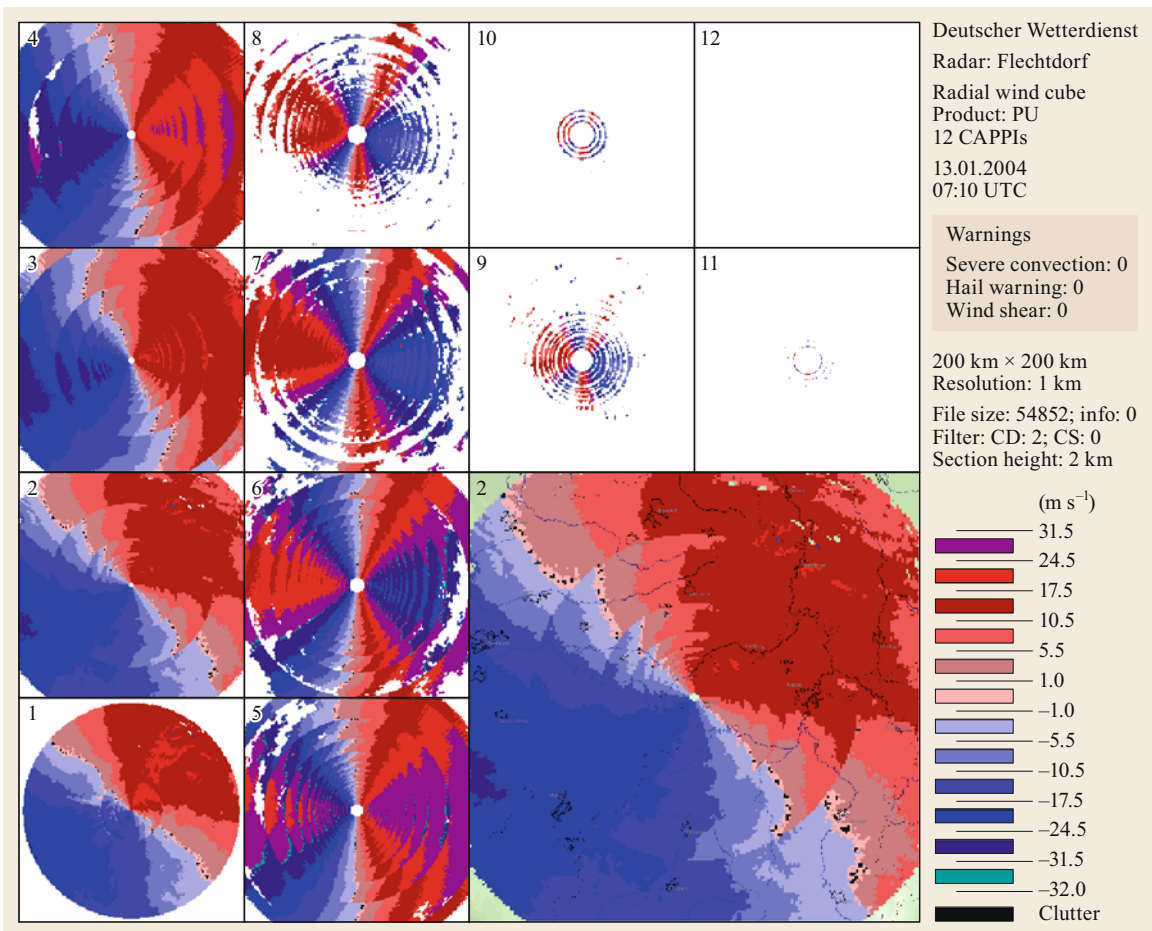

Fig. 30.16 Radar product with CAPPIs at several altitudes, small numbers indicate heights in km. The wind is veering clockwise from SW at 1 km to W at 5 km (advection of warm air). A slight divergence seems to occur at midaltitudes. Folding occurs starting from 4 km upwards. Elevation jumps are visible due to the CAPPI sampling process (image © DWD)

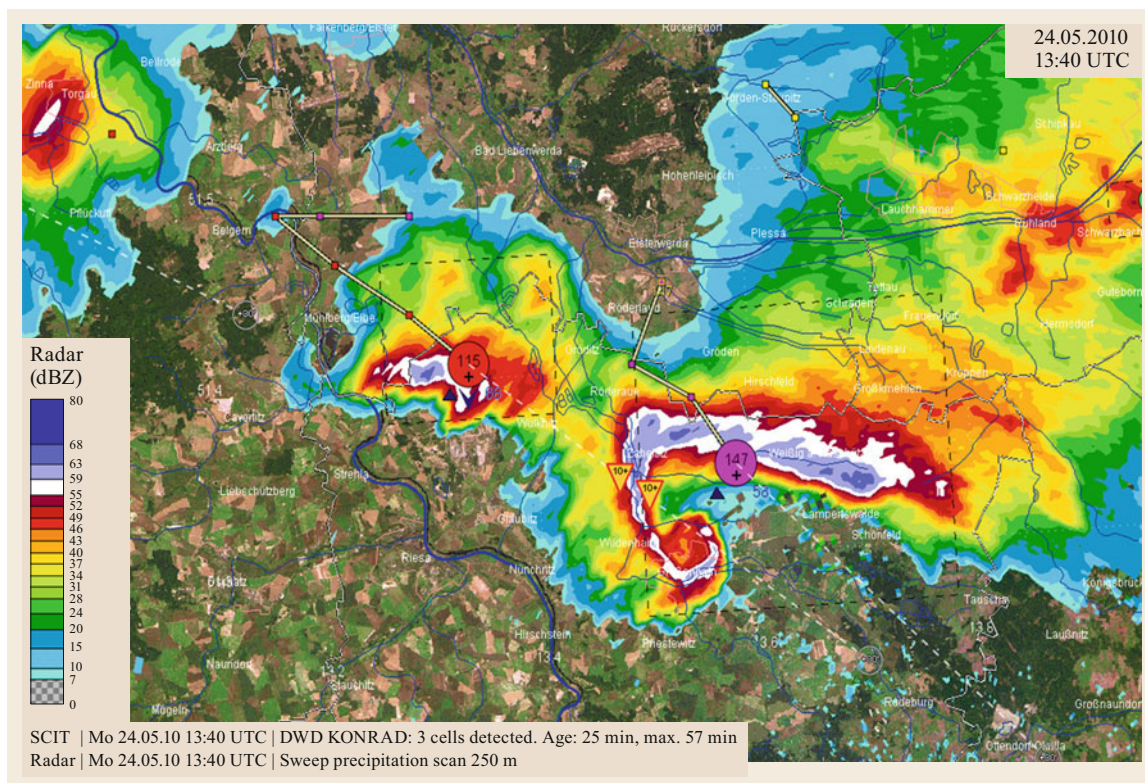

Fig. 30.17 A hook echo is indicative of a supercell that may potentially produce a tornado, exemplified here by the disastrous Grossenhain tornado (F3) of 24 May 2010 in Germany (image © 2018, NinJo-Consortium/DWD)

and $-V_N$ in continuous precipitation fields (red and blue in Fig. 30.16). Searching for the (central) zero isodop (the line of zero radial velocity) and moving against or with the wind (maybe crossing another – folded – zero isodop), the real radial velocity may be estimated. On the (unfolded) zero isodop, the real wind vector is a tangent to any circle around the radar. This helps recognize regions of convergence or divergence. Also, looking at the elevation of a PPI, something can be said about the vertical wind profile, e.g., vertical wind velocity or directional shear (veering). Even a low-level jet may be detected this way (velocity first increasing, then decreasing again with height/slant distance). Warm air advection is accompanied by a clockwise rotation with height (Northern Hemisphere), whereas cold fronts may be detectable by a cyclonic wind jump. Azimuthally closely spaced pixels of opposite wind direction (called a dipole) indicate rotation, as in a mesocyclone (Fig. 30.21).

The temporal development of some radar objects may occur very rapidly. This is not only true for the movement of tornadoes. *Normal* thunderstorms can develop from nonexistent to a full-grown hailstorm within less than 10 min (Fig. 30.18).

30.8.3 Automated Weather Radar Algorithms

While visual interpretation may be intelligent and complex, there are strong reasons even besides the cutdown of human resources to automatically derive interesting features, such as rain accumulation over a catchment area or weather warnings. For example, difficult situations may arise for a meteorologist if large-area networks have to be monitored in critical situations. Some characteristics may not be accessible to the human eye at all or can only be estimated roughly. Lately, a weather radar's increased ability to detect and possibly warn of short-lived local weather hazards has become one of its most important applications. Integrations, thresholding, BOOLEAN decision trees, or fuzzy logic, as well as image processing, are typical automated algorithms. Products from integrated data of several networked radars facilitate faster update, denser data, and greater robustness than single-radar products and may help with beam blockage, beam broadening, and the cone of silence. Verification may turn out to be difficult if no observation is available.

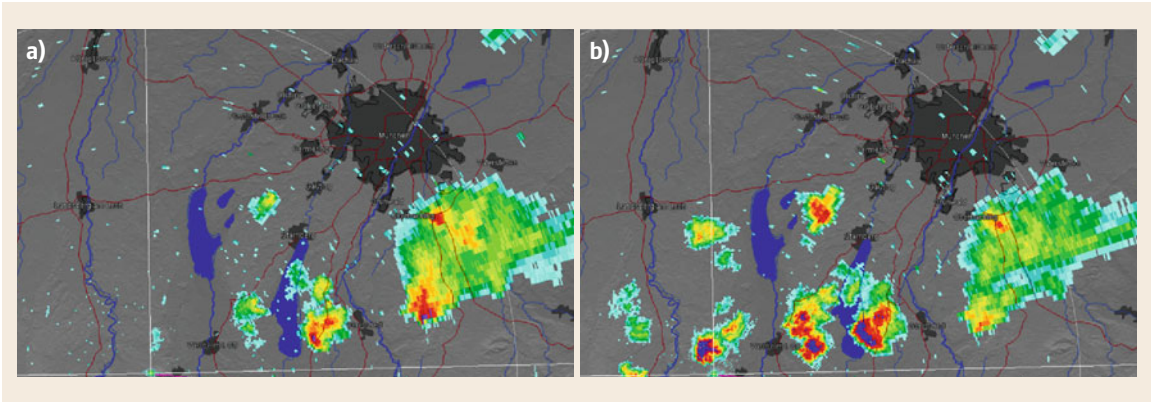

Fig. 30.18a,b Extremely rapid development of several convective cells over the lakes Ammersee and Starnberger See, close to Munich, Germany, detected by Hohenpeissenberg radar on 1 August 2018, at 18:57 (a) and 19:04 UTC (b). Within 7 min, at least two additional convective cells, one of them with a high probability of hail ($Z \geq 55$ dBZ), appear out of nowhere (image © J. Seltmann, DWD)

Quantitative Precipitation Estimation

Radar quantitative precipitation estimation QPE and quantitative precipitation forecast QPF have long received high priority consideration in most national hydromet authorities and by WMO [30.83].

One of the earliest and simplest methods to estimate precipitation intensity is the conversion of the measured echo strength (reflectivity factor z) into rain rate R by a so-called Z/R -relation. Its empirical determination is straightforward, if Z and R are observed, plotted, and fitted to an analytical function. The same may be effected semi-empirically if the raindrop size distribution is measured by a disdrometer and z and R are calculated integrating over the observed size spectra according to

$$z = \int_0^{\infty} N(D)D^6 dD \tag{30.59}$$

$$R = \frac{\pi}{6} \int_0^{\infty} N(D)D^3 v(D) dD \approx \frac{\pi}{6} \int_0^{\infty} N(D)D^{3.7} dD . \tag{30.60}$$

In an attempt to reduce the coincidence mismatch in space and time between individual samples of rain gauge and radar, pairs of z_i and R_i showing equal cumulative probabilities (CDFs): $\int p(z) dz = \int p(R) dR$ (pairs of equal CDF percentiles) are matched in the probability matching method [30.84], where the integrals run from 0 to z_i and R_i , respectively. In [30.85], it was proposed to confine radar data to a spatiotemporal window about the gauges in the window PMM (WPMM).

Marshall et al. [30.86] fitted their data to $z = aR^b$, resulting in a straight line in a log-log plot and in the

Marshall–Palmer relation

$$z = 200R^{1.6} , \tag{30.61}$$

which is the most famous among hundreds of Z/R -relations derived locally, climatologically, and for specific weather conditions (stratiform, convective, northern, tropical ...). Ambiguities arise trying to express the strongly nonlinear and multiparameter relation between z and R by only one measured parameter. As this type of Z/R -relation usually overestimates high rain rates, a partwise linear approach has been proposed [30.87, 88].

With the advent of dual-polarization radar, more observables are available to parameterize the highly nonlinear relationship. Again, many individual relations have been proposed; many of them of the type $cZ^a ZDR^b$, $cZ^a 10^{0.1bZDR}$, or $cKDP^a ZDR^b$.

As an example, the following prototype NEXRAD algorithm (tuned for Oklahoma) was published [30.38]

$$\left. \begin{aligned} R(z) &= 0.017Z^{0.714} , \\ R(K_{dp}) &= 45.3|KDP|^{0.786} \text{sign}(KDP) \\ R &= \frac{R(z)}{0.4 + 5.05(ZDR - 1)^{1.17}} \\ &\quad \text{if } R(z) < 6 \text{ mm h}^{-1} , \\ R &= \frac{R(KDP)}{0.4 + 3.48(ZDR - 1)^{1.72}} \\ &\quad \text{if } 6 < R(z) < 50 \text{ mm h}^{-1} , \\ R &= R(KDP) \\ &\quad \text{if } R(z) > 50 \text{ mm h}^{-1} . \end{aligned} \right\} \tag{30.62}$$

It has been established that ZDR needs to be accurate within 0.1 dB for light rain and 0.2 dB for heavy

rain in order to perform better than a nonpolarimetric estimator [30.51]. Moreover, polarimetric target classification (see Sect. 30.8.3, *Hydrometeor Classification HMC*) can help select the correct QPE regime and avoid biases in precipitation estimation due to snow, bright band, and non-met targets.

Once fields of rain rate have been obtained from radar data, they are usually validated against or adjusted to *ground truth*. There are many different ways to accomplish gauge adjustment, such as a constant average factor derived from a comparison of radar and gauge average areal precipitations, updated Z/R -relations, kriging including co-kriging and external-drift kriging, as well as a geostatistical merging procedure, which are all described in [30.89].

Vertically Integrated Products: VIL, VILD, VII

Using 3-D volume measurements, vertically integrated liquid water (VIL) or ice (VII) content in a vertical column over a certain area are easily obtained by adding and possibly interpolating measurements at different radar elevations within the column after conversion to rain amount. VIL yields the mass of water over 1 m^2 and is typical between 0 and 100 kg m^{-2} . Following [30.90],

$$\text{VIL} = \sum 3.44 \times 10^{-6} \left(\frac{Z_i + Z_{i+1}}{2} \right)^{\frac{4}{7}} \Delta h, \quad (30.63)$$

where the layer mean reflectivity (the round bracket) is capped at 56 dBZ to screen against ice. If possible, the bright band should be removed from the Z profile. High values are typical of heavy rain or hail. Convective events typically exhibit $\text{VIL} > 10 \text{ kg m}^{-2}$ [30.91]. VIL is used to estimate storm potential and, thus, serves as a warning indicator of storm severity.

VIL density (VILD) is defined as VIL normalized by its column depth at each grid point. For precipitation reaching the ground, the echo-top height h_{ET} may be used

$$\text{VILD} = \text{VIL} h_{\text{ET}}^{-1} \quad (\text{g m}^{-3}). \quad (30.64)$$

The 18 dBZ echo top is applied in [30.92]. VILD is considered to be more useful than a VIL-of-the-day threshold to assess storm severity.

Similarly, an estimate of vertically integrated ice VII may be derived from the VRP $Z(h)$ within the ice growth layer determined by sounding or model analysis. VII may be used as an indicator of initiating convective storms, cell growth, and electrical activity, of storm severity and potential for hail, and of increasing/decreasing updraft intensity. One formula is given

in [30.93] and [30.94]

$$\text{VII} = 10^3 \pi \rho_i N_0^{\frac{3}{7}} \left(\frac{5.28 \times 10^{-18}}{720} \right)^{\frac{4}{7}} \int_{H(-10^\circ)}^{H(-40^\circ)} Z(h) dh, \quad (30.65)$$

with the ice density $\rho_i = 917 \text{ kg m}^{-3}$ and the parameter $N_0 = 4 \times 10^6 \text{ m}^{-4}$; the integration here is performed between the -10 and -40°C isotherms.

Hail Detection

Due to its high potential for damage, hail has always received special attention in the interpretation of weather radar. Several criteria and algorithms have been developed even for intensity-only radars using characteristics such as high-reaching strong echoes and strong horizontal gradients (Fig. 30.12), *hail spike*, and special polarization signatures:

- In the CAPPI method, a reflectivity threshold is defined at a certain height, e.g., $Z_{\text{thr}} = 55 \text{ dBZ}$ at a height of $H = 0.8, 1.5$ or 2 km .
- In the ZMAX-method, the maximum reflectivity in a vertical column is checked, e.g., $Z_{\text{max}} = 55 \text{ dBZ}$.
- In the VIL method, the vertically integrated liquid water content VIL is used as a hail indicator, e.g., $25\text{--}35 \text{ kg m}^{-2}$ and $50\text{--}60 \text{ kg m}^{-2}$ in cold and warm air masses, respectively.
- In the VIL density method, VILD is used instead, e.g., $\text{VILD}_{\text{thr}} = 3.5 \text{ g m}^{-3}$.
- The Waldvogel method [30.95] checks for a certain reflectivity at a certain height above freezing level, e.g., $H_{45\text{dBZ}} \geq H_{0^\circ} + 1.4 \text{ km}$.
- The severe hail index SHI is calculated using a Z/\dot{E} relation (instead of Z/R in VIL). In this sense, SHI is complementary to VIL, making use only of higher reflectivities and leaving out lower ones.

$$\text{SHI} = 0.1 \int_{H_0}^{H_T} W_T(H_T) \dot{E} dH \quad (\text{J m}^{-1} \text{ s}^{-1}) \quad (30.66)$$

$$\dot{E} = 5 \times 10^{-6} \times 10^{0.084Z} W(Z) \quad (\text{J m}^{-2} \text{ s}^{-1}) \quad (30.67)$$

[30.96], where H_T is the storm cell top height, \dot{E} is the kinetic energy flux of hail, and $W(Z)$ is a weight function that increases linearly from 0 to 1 between certain reflectivity limits, e.g., between 40 and 50 dBZ. The vertical integration is further weighted by temperature, excluding heights below the freezing level at 0°C and increasing to 1 around the -20°C height obtained by sounding or NWP. SHI is primarily used in the following methods.

- The POSH method estimates the probability of severe hail. An SHI warning threshold WT was empirically found in [30.96] as a function of the melting layer height $H_{0^\circ\text{C}}$ (km) above radar: $WT = \max\{20; 57.5H_{0^\circ\text{C}} - 121\}$ ($\text{J m}^{-1} \text{s}^{-1}$). POSH (%) is then calculated as

$$\text{POSH} = \min \left\{ \max \left\{ 0; 29 \ln \frac{\text{SHI}}{\text{WT}} + 50 \right\}; 100 \right\}, \quad (30.68)$$

so that there is a 50% chance of severe hail if SHI meets the warning threshold. POSH is used to describe the probability of 1.9 cm (3/4", the former US weather service's NWS severe hail criterion) diameter hail; 70% POSH is also considered equivalent to a 50% probability of 1" (2.54 cm) hail.

- Maximum estimated size of hail (MESH) in cm. This parameter is calculated from SHI as

$$\text{MESH} = \sqrt{\text{SHI}} \times 2.54 \text{ cm} \quad (30.69)$$

and is used to estimate the maximum expected hailstone size as well as areal hail distribution [30.96].

- The hail signal according to [30.97] is based on Z_h and ZDR

$$\text{HDR} = Z_h - \begin{cases} 27 \\ 19\text{ZDR} + 27 \\ 60 \end{cases} \cdot \begin{cases} \text{ZDR} < 0 \text{ dB} \\ 0 \text{ dB} \leq \text{ZDR} \leq 1.74 \text{ dB} \\ \text{ZDR} > 1.74 \text{ dB} \end{cases}. \quad (30.70)$$

- Fuzzy logic hydrometeor classifiers usually feature a hail class of their own.

Hydrometeor Classification HMC

Differentiation of targets within the radar volume according to their aggregate state has been one of the main goals in radar observation and one of the main reasons for deploying multiparameter radars. Interestingly, some estimation is possible even with Z-only radars using empirical intensity and/or height extension thresholds and possibly external (temperature) information (see the description of hail detection above).

As dual-pol observables (Sect. 30.3.4) depend on phase, shape, orientation, and the number distributions of the targets, the former are well suited to classify different types of hydrometeors and nonmeteorological targets. Several techniques have been proposed [30.38],

such as a Boolean decision logic [30.98], statistical decision theory, or neural networks. Fuzzy logic is commonly considered one of the most promising approaches; [30.99, 100], and different types of membership functions, such as triangular, trapezoidal, ramp, or beta functions have been used. Classification categories may be just a few, or more than a dozen. Hydrometeor classification at radar beam height may then be extrapolated to the ground. Figure 30.19 shows an example.

Wind Products

While interpreting radial wind patterns may give the meteorologist a clue to the mesoscale wind regime, there are also automated procedures to derive wind vector fields or profiles or to detect shear, mesocyclones, or even tornado signatures.

Velocity Azimuth Display (VAD) and Volume Velocity Processing (VVP)

Assuming a horizontally homogeneous horizontal wind field over the radar site [30.101], the radar measurement over a circle at constant radius (height) may be fitted to a sine over the azimuth. Its amplitude yields the wind speed, and the argument of the minimum is the wind direction. VAD may be performed at several heights over one conical elevation scan with increasing circle diameter, or at constant circle diameter over several elevations. The method fails if the homogeneity assumption is violated, leading to an insufficient number or a large spread of measuring points. The VVP technique [30.102] uses volume data in a multidimensional regression.

Uniform Wind Method UW. As the above-mentioned sine over azimuth is theoretically defined by two values, the homogeneity condition may be relaxed. In the uniform wind (UW) technique, homogeneity is stipulated only over certain areas of, e.g., $20 \text{ km} \times 20 \text{ km}$. A sine is then fitted in each of these areas, resulting in a coarse wind field estimate as shown in Fig. 30.20.

Dual Doppler. While one radar is capable of measuring only one – the radial – component of the wind vector field, suitably positioning two or more radars offers the possibility to measure two different radial components. The latter will be orthogonal only on a circle (sphere) through both radars, but useful wind fields can be constructed as long as the components are not near collinear.

If more than two radars overlap in a network, a multiple-Doppler technique may be applied to increase areal coverage and data quality. The distance between radars must not be too large because of beam elevation and beam broadening (decreasing resolution).

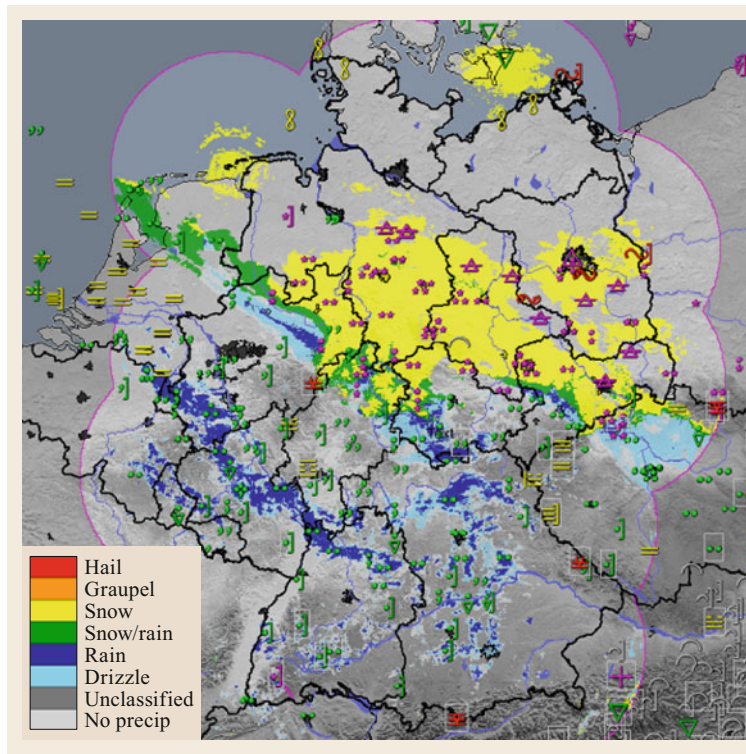

Fig. 30.19 DWD final product of hydrometeor type estimation at 2 m AGL, preoperational state. Polarimetric fuzzy logic classification of radar measurement aloft has been extrapolated to the ground using model and ground temperature information. NinJo presentation of German composite overlaid with ground observations (image © DWD)

Multistatic Doppler. More than one wind component may also be cost-efficiently measured by deploying additional receivers around a transmitting radar in a so-called bistatic or multistatic configuration [30.103]. Strict synchronization between transmitter and receivers is necessary.

Mesocyclone Detection and Tornadoes. Automated mesocyclone detection relies on the existence of a cyclonic rotation dipole in high-resolution polar radial wind data [30.104]. In order to estimate the risk of a tornado once a mesocyclone has been detected, the mesocyclonic rotation is scrutinized to find a *tornado vortex signature* (TVS), which is defined as a three-dimensional circulation with its base at 0.5° elevation or below 600 m above radar [30.105]. It indicates a region where the rotational shear is further intensified, representing the transition to a tornado, as shown in Fig. 30.21. The detection of a TVS may initiate a tornado warning.

Multitemporal and Tracking Products, Nowcast, and Forecast

The notion of nowcasting refers to a very short mesoscale forecast (2 h) using extrapolation methods (e.g., *optical flow*). In addition to quantitative extrapolation of precipitation fields, tracking and extrapolation of convective cell motion, including potential cell development, has

gained particular focus. Radar data also help in nowcasting the potential for icing through supercooled large drops in air traffic, and freezing in road traffic.

VIL Track. A VIL track is accumulated over some span of time, say 3 h, each pixel representing the sum or the maximum VIL over this span of time. VIL tracks are another way to visually track storm cell movements over time, see Fig. 30.22.

MESH tracks are calculated similarly from the maximum values of MESH and simultaneously show history and trends in the motion and development of a storm, particularly its hail core, as well as regions of large hail fall, over a certain period of time.

The operational DWD nowcasting product CONRAD (convection development in operational radar products) [30.107] detects, analyzes, and evaluates cell cores with respect to echo strength, areal extension, and direction of past movement. This is extrapolated, and warnings are given for heavy rain, hail, and wind gusts.

Assimilation into NWP Models

Radar data may be assimilated into high-resolution numerical weather prediction (NWP) models, thus forcing the model into realistic initial conditions. Especially cloud-resolving models may benefit, as those models are designed to simulate severe weather conditions

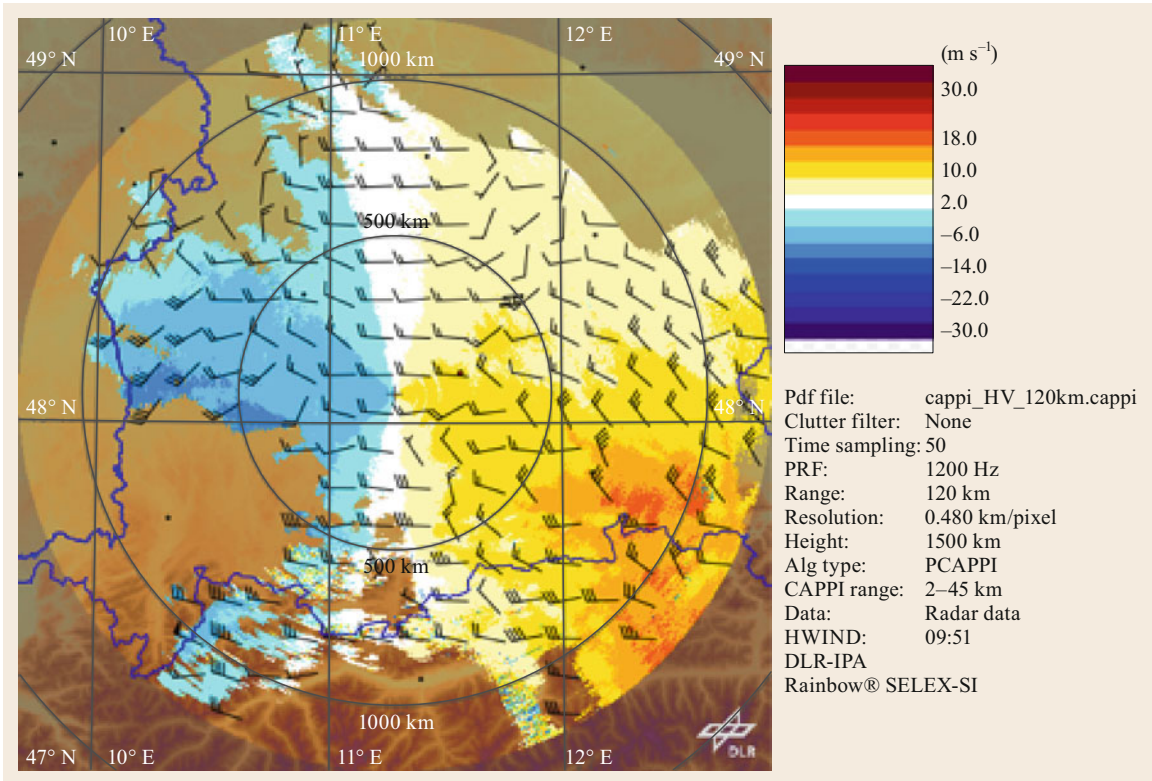

Fig. 30.20 CAPPI at 2 km ASL of radial wind, overlaid with wind barbs according to the UW method. DLR POLDIRAD, Germany, on 15 February 2013 at 09:51 UTC (image © DLR, reprinted with permission)

in near-realtime. Several approaches have been developed to assimilate different kinds of radar observations and related products. Latent heat nudging, as well as variational approaches 3-D-Var and 4-D-Var are used and have been demonstrated to improve short-range forecast scores. A survey is given in [30.108]. High-quality radar wind and precipitation fields including error statistics are needed to improve initial conditions for NWP models [30.109]. In any case, the model has to provide information comparable to the radar observation. Some of the following approaches are already running successfully in operational applications.

The simplest approach is assimilation of 2-D composites of derived precipitation rates using the so-called

latent heat nudging (LHN) approach [30.110, 111]. The model state will instantaneously respond by simulating a precipitation rate very close to the observation. LHN is

Fig. 30.21 Rotation structure of a mesocyclone (Glas-huette, Germany, 13 May 2015 at 19:15 UTC) as detected by the Feldberg radar at an elevation of 1.5° after subtraction of the cell displacement velocity. The dipole is slightly rotated due to convergence. There is a marked TVS signal according to Mitchell (pixel pairs and velocities indicated). The mesocyclone was detected 15 min prior to the occurrence as per ESWD entry (modified from [30.106], © T. Hengstebeck, DWD) ▶

Fig. 30.22 VIL track composite product showing trails of several eastwards moving convective cells with high columnar water contents. Cell splittings and a right mover are visible. Fast movement produces discontinuous tracks, depending on the volume update rate (image © 2018, NinJo-Consortium/DWD)

operational at the United Kingdom Met Office (UKMO) and Consortium for Small-Scale Modelling (COSMO) consortia; Canada decided on implementation recently.

In order to assimilate 3-D radar reflectivity, a model forward operator is required to calculate a radar equivalent model parameter. This provided, reflectivity can be applied in any kind of variational assimilation methods or in ensemble-based methods. At Meteo France, reflectivity is assimilated indirectly within a 3-D-Var scheme, whereas UKMO uses reflectivity directly in 4-D-Var. 3-D radar radial wind is operationally assimilated at UK Metoffice and at Meteo France. Given the radar location, radial velocity can easily be obtained within the model. However, aliasing turned out to cause problems.

Vertical profiles of horizontal radar wind (e.g., VAD) have also long been assimilated into global models. The benefit of this suffers from quality issues of the VAD approach. First approaches have been developed and tested to assimilate 3-D polarimetric parameters and refractivity (see below).

Special Applications

Refractivity and Moisture Fields. A method was proposed in [30.112] to estimate the refractivity and, hence, the near-ground moisture fields using the principle explained in Sect. 30.3.2. The phase of the incoming echo from many fixed ground targets is monitored. Knowing that such a target is not moving, and assuming that the radar frequencies and phases are known, any phase changes are attributed to changes in refractiv-

ity along the radar path and may be used as a proxy to mesoscale air humidity patterns. The method is relative (measuring only phase changes) but may be coupled to absolute refractivities determined independently. It is limited by phase aliasing and by the curvature of Earth.

Bird Observation. Weather radar has also been used by ornithologists and entomologists using Doppler data [30.113], the differential Doppler velocity $DDV = V_h - V_v$ [30.39], and polarimetric data [30.114].

Radar Statistics and Climatology. Weather radar data are, in principle, well suited for climatology studies because they cover weather phenomena from micro to macro scale with a spatiotemporal resolution exceeding the demands of climatology. However, due to frequent changes in radar hardware, calibration, parametrization, and maintenance state, as well as differences (including availability) between network radars, the homogeneity and duration of radar time series used to be insufficient. Lately, with digital hardware becoming more stable, demanding less frequent repair and maintenance, and with quality standards for maintenance, unified calibration, parametrization, and scan strategies being agreed upon, reliability and availability have been increasing. First cautious steps have already been taken to climatologically exploit radar data [30.115] using statistics of severe convection, hail, or mesocyclones. Radar statistics may also be used for correction of beam blocking and beam height [30.62, 116].

30.9 Future Developments

Over the past three or four decades, the use of weather radar data has tremendously increased worldwide and will continue to do so. Radar has been revolutionized by solid-state technology, miniaturization, digitization, computerization, and networking. This process is still ongoing and, in turn, facilitates elimination of moving mechanics, sensitive analog electronics, and critical high voltage, leaving an all-digital all-solid-state fast scanning radar on today's horizon.

30.9.1 Rapid Update

The need to catch and understand rapidly developing phenomena, or tornadoes and microbursts, and to produce timely warning, has produced a demand on data update rate that cannot yet be fully satisfied. Speeding-up antenna rotation meets its limits, even though experiments are underway to combine 5 min volumes with lowest sweeps every minute using a standard mechanical parabolic antenna. Weather adaptive scanning may be an option to save scan time and gain more information from high priority targets and regions, e.g., taking RHIs through convective storms. The main effort, however, is concentrated on electronic scanning and adaptive waveform selection.

30.9.2 Electronic Scanning

Only recently are electronically steered antennas being tested and evaluated for operational meteorological purposes. When the remaining difficulties are overcome, large and heavy rotating paraboloids, and even all mechanically rotating parts, will eventually be replaced, which will allow fast and flexible scanning and system stability. Under benefit–cost considerations, mechanical rotation in the azimuth of a vertically scanning plane phased array will likely be a first step.

30.9.3 Denser Networks

Densification of existing networks using more network radars or smaller (e.g., X-band) radars will close network coverage gaps and improve radar overlap, as well as boundary layer coverage due to the lower radar beam. A gap-filling network of short-range radars offers many of the advantages of a dense network if data fusion models are available. Gap-filler radars will start to be deployed near metropolitan areas and airports or in fast reacting drainage systems using low-power solid-state transmitters. Solid-state technology may also open the way to multifrequency radar.

30.9.4 Radar Allocation

Unfortunately, in heavily populated countries, such as within the European Union, siting new radars is becoming an increasing problem due to the lack of unused areas fulfilling the requirements of unobstructed sight and of radiation regulations, and possible movements against electromog. Frequency allocation may turn out to be next to impossible in the future. Some upcoming technologies (e.g., pulse compression) result in wider bandwidth waveforms, increasing problems with frequency allocation and (wideband) external jammers.

30.9.5 Data Processing

Nowadays, DSPs are ready to handle SSPAs, pulse coding and pulse compression, and adaptive waveforms. Open-source processing is becoming more widespread in radar signal processing, too. What was an exclusive domain of commercial DSPs, even pulse processing, will increasingly be handled by common PCs.

With increasing transmission rates and bandwidths available, near-realtime distribution of undreamt-of data amounts is close at hand. In radar networks, this will further increase centralized processing, exploiting the benefits of multiradar data-based object-oriented processing and quality control instead of product generation at the radar site. Instead of waiting for complete data volumes, sweepwise dissemination will enable processing of intervolumetric products (a new product with each new sweep), so that the product update rate will be increased beyond the radar volume update rate. More raw and base data, as well as complex and comfortable archives, will be available for research, climatology, and hindsight expertise.

30.9.6 Homogeneous Data

Faster updates, denser data, and improved quality monitoring will produce more homogeneous data. Radar climatology will become more meaningful, as continuous and quality controlled data become available from standardized and homogeneous radar networks. This process is being worked upon by WMO, Eumetnet, and national authorities.

On the one hand, hardware, software, and data processing chains, including scan strategy, will be harmonized within national networks and beyond. On the other hand, there is a tendency to adapt scanning according to geographic and climatic environment, particularly in large countries, such as Russia or the USA, and to the imminent weather situation.

30.9.7 Internationalization

International data exchange is still on the rise, promoting standardization of data models and formats (HDF5), as well as radar data centers. Multinational supernetworks, such as OPERA, are evolving to harmonize future national development and are supplying support to emerging nations.

30.9.8 Fully-Integrated Observing Systems

However, the future of radar will not be confined to the development of radar technology and specialized processing alone. It is believed that future weather radars will be embedded into integrated observing systems merging data from sources facilitating as manifold

a description of the atmosphere/hydrosphere system as possible. Likewise, quality control and processing of radar data will be in synergy with complex analysis and processing techniques, such as complex interpretation schemes as input into a seamless 4-D data assimilation in combined numerical models.

As all these processes continue, they will, on the one hand, further push the cutting edge in radar meteorology. On the other hand, an increasing number of high technology radars will level the gap between frontline development and (sometimes older) operational systems to very high average standards. Above all, with increasing data availability and quality, radar remote sensing will continue to contribute to man's understanding of the atmosphere and play an important role in the preservation of life and property.

Jörg E.E. Seltmann is a physicist and senior radar scientist at the German Meteorological service (DWD). He has conducted and supervised several radar projects and was responsible for the system design and technological innovation of the current German weather radar network, including the introduction of the dual-polarization technique. He led DWD's research unit on radar meteorology and precipitation process at the Hohenpeissenberg Observatory up to 2020 and is teaching radar meteorology at Augsburg University.

Radar Wind

31. Radar Wind Profiler

Volker Lehmann, William Brown 

Radar wind profilers (RWPs) are meteorological radars that are used to determine the vertical profile of the wind vector in the atmosphere. RWPs typically use wavelengths ranging from about 20 cm to about 6 m. The scattering processes that occur at such wavelengths give these instruments a unique ability to obtain detectable echoes in both the optically clear, as well as in the particle-laden, atmosphere (i.e. in the presence of clouds, fog, or precipitation). The height coverage of RWPs varies, mainly due to the wavelength dependence of the clear air scattering process: boundary-layer RWPs (which operate at frequencies of around 1 GHz) typically probe the lowest 3–5 km of the atmosphere, while (markedly larger) systems in the 50 MHz band can provide data on the atmospheric region up to about 20 km above the ground.

Gravity causes the atmosphere to stratify in a distinct manner that is reflected in significant vertical variations in atmospheric variables. One such variable is the wind—the velocity vector that describes the motion of the air [31.1]. Structures such as jet streams (both low-level jets and those near the tropopause) as well as shear

zones at frontal boundaries are prominent examples of the rich three-dimensional (3-D) flow structure of the Earth's atmosphere. Quantitative knowledge of the vertical profile of the wind vector is crucial for various reasons, but most obviously for weather forecasting and aviation.

31.1 Measurement Principles and Parameters

A radar wind profiler (RWP) is essentially a coherent radar that operates at long wavelengths ranging from about 20 cm to about 6 m. Electromagnetic waves in this range are scattered at fluctuations in the refractive index of particle-free *clear air*, which are almost omnipresent due to the turbulent state of the atmosphere. This clear-air scattering allows a RWP to obtain measurable echoes even when there are no hydrometeors in the radar resolution volume.

The fundamental radar measurables are the amplitude and phase (relative to the transmitted signal) of the signal received at the output port of the antenna. During signal processing, important properties such as the reflected power and Doppler information are extracted from the demodulated receiver signal in a range-resolving fashion. It should be noted that even these fundamental radar variables are obtained through often rather complex mathematical operations. It is therefore useful to structure the data obtained by a RWP into hierarchical data levels that correspond to the various stages of processing. At each stage, a particular algorithm implemented by a software module converts the data from a lower to a higher data level. The ultimate aim of signal processing is to convert the received electrical signals into meteorological quantities.

RWP architectures fall into two broad categories: Doppler systems that use a single receiving antenna and spaced-antenna systems that use multiple receiving antennas. Doppler systems steer the radar beam in various near-zenith directions. The Doppler shift arising from the movement of the atmospheric medium in each of these line-of-sight directions can then be measured directly. An explicit wind vector retrieval operation is then performed to transform the radial Doppler shifts into a 2-D or even 3-D wind vector. In contrast, spaced-antenna systems use an arrangement

of three or more horizontally spaced and vertically directed receiving antennas to measure the diffraction pattern due to atmospheric scattering. This diffraction pattern shifts due to the horizontal drift of the scatterers, allowing the movement of the atmospheric medium to be inferred from a cross-correlation analysis of the signals obtained by the different antennas. The vertical component is derived directly through the Doppler method.

The main variable determined by a RWP is the vertical profile of the horizontal wind vector, i.e., the wind speed and direction as a function of altitude. These quantities can be estimated in a fully automated way under almost all meteorological conditions. The radar hardware as well as the signal and data processing algorithms needed for this task can nowadays be regarded as mature.

Measurement of the vertical wind component is more difficult. Since cloudy air is a complex multiphase, multivelocity, and multitemperature physical system [31.2, 3], there is generally a need to distinguish between the velocity of the gaseous phase (wind in the strictest sense) and the velocity of liquid and solid water particles with respect to the surrounding air. While the horizontal displacement of the rather small water particles is usually dictated by the horizontal wind, the terminal velocity of the hydrometeors needs to be taken into account when estimating the vertical wind. Especially at shorter wavelengths, such as in the 1 GHz band and even in the 400 MHz band, Doppler measurements obtained with a vertically directed beam often reflect an unknown combination of the vertical wind and the terminal speed of the hydrometeors, unless the particle scattering can be unambiguously separated from the clear air scattering component.

RWP signals contain more information than just the Doppler shift, so enabling quantities other than the wind

Table 31.1 Signals measured by RWP and important derived properties

Variable	Description	Unit	Symbol
RX time series	Time series of the demodulated receiver voltage	arb. u.	$I/Q(t)$
Doppler spectrum	Power spectrum of the I/Q time series	arb. u.	$S(f)$
Signal power	Zeroth moment of the signal component in the power spectrum	arb. u.	P_s
Mean Doppler frequency	First moment of the signal component in the power spectrum	Hz	f_D
Spectral width	Second moment of the signal component in the power spectrum	Hz	σ

Table 31.2 Meteorological quantities that can be extracted from RWP data

Variable	Description	Unit	Symbol
Radial wind velocity	Atmospheric motion along the line of sight of the antenna beam	m s^{-1}	v_r
Horizontal wind vector	Horizontal components (u, v) of the 3-D wind vector (u, v, w)	m s^{-1}	\mathbf{v}_h
Vertical wind	Vertical component w of the 3-D wind vector (u, v, w)	m s^{-1}	w

to be determined. For instance, atmospheric properties such as the structure constant of the refractive index C_n^2 [31.4] can be derived, although the extraction of such parameters requires a tailored data analysis using specialized algorithms to account for the complexity of the measurement process. It is therefore difficult to fully automate algorithms for these quantities as they can usually be only be applied for a limited range of atmospheric conditions.

31.2 History

This section provides a brief overview of the main phases in the evolution of RWP. More comprehensive historical overviews of the development of clear-air radars or RWPs are given in [31.5–7].

31.2.1 Puzzling Radar Echoes from the Clear Air

The story of radar-based wind profiling began in 1939, when *Albert Wiley Friend* (1910–1972) published a letter in the *Bulletin of the American Meteorological Society* [31.8] that described a radio wave propagation experiment in which he related reflections from the troposphere to temperature inversions and the associated changes in the dielectric constant of the atmosphere. He even went as far as suggesting a monitoring of these discontinuities in between profile measurements obtained with radiosondes. Such echoes were later called *angels* by the radar community [31.9], which directed considerable effort into understanding this intriguing phenomenon. The autobiography of *David Atlas* (1924–2015) gives an interesting personal account of that period of research [31.10]. By the end of the 1960s, it was theoretically and experimentally established that dot echoes from clear air originate from point targets such as insects and birds, whereas diffuse echoes are caused by sharp gradients in the refractive index. The theoretical foundations for radar wind profiling were laid by *Valerian Tatarskii* (born 1929), who utilized a combination of Maxwell’s electromagnetic theory and statistical turbulence theory [31.11]. The state of knowledge at that time is summarized in [31.12].

31.2.2 Jicamarca and Follow-On Research

Another decisive development was triggered by incoherent radar scattering investigations of the upper atmosphere. Radio observatories with large and powerful radar systems such as Jicamarca [31.13] and Arecibo [31.14] were founded for this purpose in the

Obviously, the site at which a RWP is installed must have an electrical power supply as well as data transmission infrastructure and should be accessible for maintenance. Furthermore, such RWPs should preferably be sited at locations that minimize potential problems with ground or sea clutter, external electromagnetic interference, corrosion, and lightning damage. As with all radars, a proper license for radio spectrum use is a prerequisite for legal operation.

early 1960s. It is interesting to note that the breakthrough experiment performed at the Jicamarca Observatory under the direction of *Ronald Woodmann* (born 1934) was the consequence of pure curiosity-driven research: when the USA and Peru quarreled about fishing grounds off the coast of Peru, American funding was withheld for a period, freeing the Jicamarca group to look more closely at radar echoes from the neutral atmosphere using unconventional processing methods [31.7]. New findings from this research were published in 1974 in a seminal paper by *Woodman* and *Guillen* [31.15]. These results spurred comprehensive follow-on research, including the construction of specialized radars for sounding the upper atmosphere (mesosphere-stratosphere-troposphere (MST) radars) [31.16]. The findings were reviewed in early 1980 [31.17] with a focus on the resulting theoretical understanding of the clear-air returns and some aspects of the capabilities of the hardware and signal processing used. The paper also listed a variety of atmospheric phenomena that the new technique could be employed to observe. Considering operational applications, it was concluded that “large pulsed radars can provide continuous vector wind measurements throughout the troposphere under all weather conditions”.

31.2.3 Development of RWP for Meteorology

The potential of the MST radar technique was brought to the attention of the meteorological community [31.18], which led to the development and testing of prototypes of dedicated wind-profiling Doppler radars [31.19]. Soon after, the *Colorado Wind-Profiling Network*, an experimental network of five radars, was constructed as a means to evaluate the long-term viability of the method [31.20]. At about the same time, small boundary-layer radars probing with higher frequencies (around 1 GHz) were developed for wind profiling [31.21, 22]; these were subsequently commercialized through technology transfer to the private sector.

31.2.4 Operational Use of RWP Networks

The first truly operational network, initially termed the Wind Profiler Demonstration Network (WPDN) and later denoted the NOAA National Profiler Network, was completed in May 1992 [31.23–25]. This network was routinely operated until the NOAA announced that it would be decommissioned in 2014, mainly due to management issues and funding difficulties within

the NWS. In Europe, the first demonstration of radar wind profiler networking, the COST WIND Initiative for a Network Demonstration in Europe (CWINDE) project [31.26], was organized in early 1997 as part of COST Action 76. Other operational networks followed, in particular the outstanding WINDAS network of the Japanese Meteorological Administration [31.27] and the network of the Australian Bureau of Meteorology [31.28, 29].

31.3 Theory

The aim of RWP instrument theory is to derive sufficiently accurate but tractable functional relationships between the properties of the atmosphere and the signal received by a RWP [31.30]. This theory incorporates scattering physics to describe the interaction of the (artificially generated) wave with the atmosphere, the reception of the scattered wave, its transformation into a measurable function (receiver voltage), and finally the extraction of the desired atmospheric information from this signal using adequate mathematical signal processing methods.

31.3.1 Scattering Processes for RWP

The fundamental physical process for scattering is the interaction of an electromagnetic wave with the discrete electric charges in matter, that is protons and electrons. Those charges are set in oscillatory (accelerated) motion by the wave which leads to secondary radiation that superposes with the incident field. This fundamental microscopic process manifests itself in macroscopic effects such as diffraction, refraction, reflection, scattering, changes in propagation speed, polarization, and absorption [31.31], depending on the properties of the medium. It is impossible to describe these macroscopic effects at an elementary (microscopic) level for any practical problem, even with the aid of modern computers [31.32, 33], so macroscopic electrodynamics is used instead, and the electromagnetic properties of matter are described using bulk parameters [31.34, 35].

The atmosphere below the thermosphere can be assumed to be an electrically neutral continuum, i.e., a dielectric gas mixture, although short-lived ionization can occur in meteor trails or lightning channels. Furthermore, a suspension of a broad range of liquid and solid particulates (hydrometeors and aerosols) may be embedded in this continuum. Airborne objects such as insects, birds, and airplanes must also be considered. The following idealized scattering models can be formulated:

- Scattering at refractive index inhomogeneities in particle-free air
- Scattering at particle ensembles in an otherwise homogeneous medium
- Scattering at plasma in lightning channels
- Echoes from airborne objects
- Echoes from the ground surrounding the RWP (through antenna sidelobes).

Instrument theory for RWP is typically restricted to scattering at inhomogeneities in the refractive index of air. Since the atmosphere is almost permanently in a turbulent state, the link between electrodynamics and turbulence theory is key. For the idealized case of exclusive clear air scattering, the theory that maps the atmospheric properties of interest (implicitly contained in the field of refractive-index fluctuations) to the signal measured by the RWP is relatively well developed [31.36].

The very nature of turbulence makes theoretical analysis an extremely challenging task, as our understanding of turbulence and refractive-index structure at the meter and submeter scales in the free atmosphere is still very limited. Numerical simulations of realistic turbulent flows are increasingly being used in lieu of high-resolution in-situ measurements to investigate various aspects of RWP measurements in unprecedented detail [31.37–40].

The second atmospheric scattering process relevant for RWPs is scattering at small particles, such as hydrometeors. While the Rayleigh approximation can be used for simplification because the particle diameter is always much smaller than the wavelength, this approximation assumes that the particles are randomly positioned, which is open to debate. Thus, there is also the possibility of coherent scattering effects from non-randomly positioned particles [31.31, 41–43].

Often, both scattering processes act in tandem, and separating the simultaneous contributions from particulate scattering and clear-air scattering poses a practical problem if the data are to be used to extract

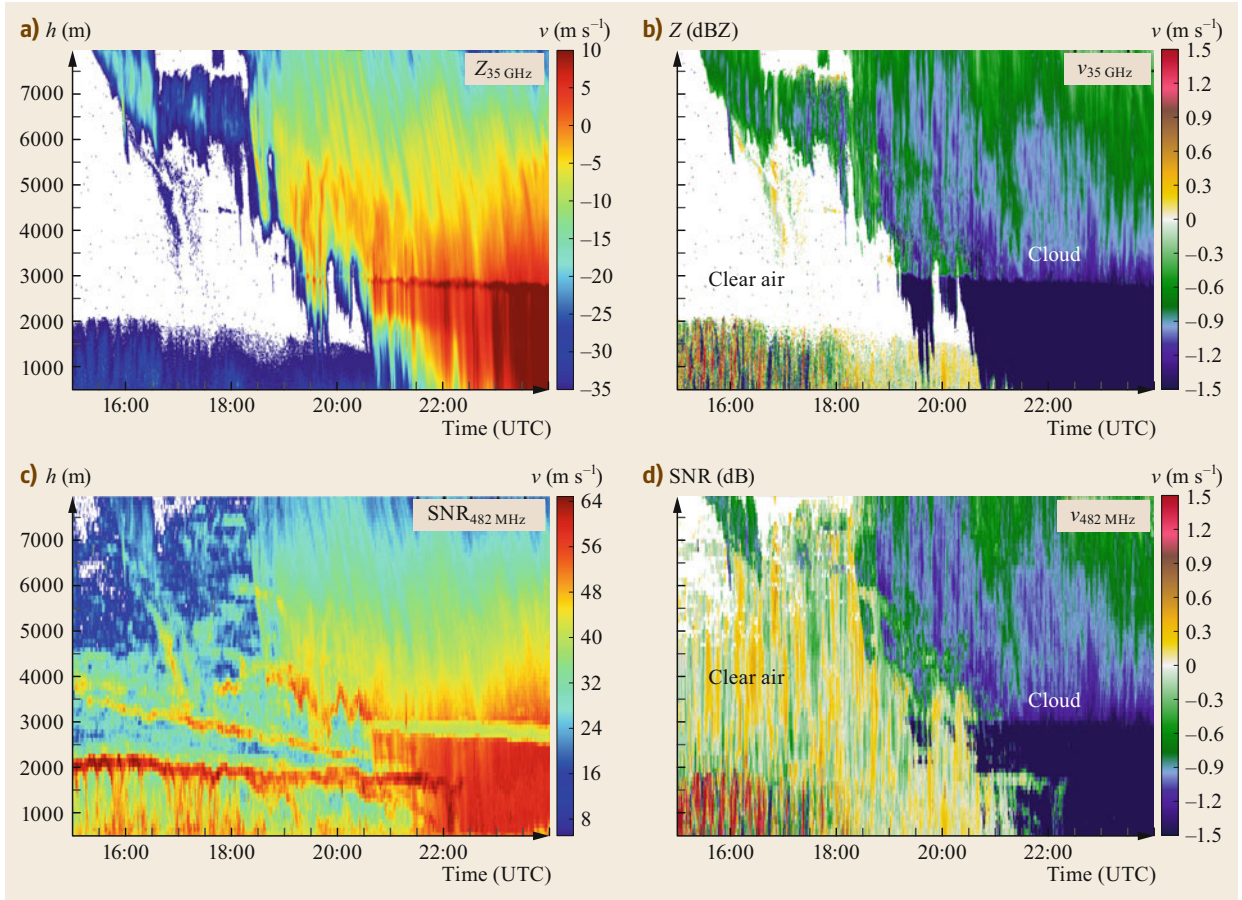

Fig. 31.1a–d Cloud radar reflectivity (a), RWP SNR (c), cloud radar velocity (b) and RWP velocity (d) at Lindenberg (Germany) on 17 June 2015, illustrating simultaneous clear-air and particle scattering. When the particle return dominates (i.e., there is high reflectivity in the 35 GHz cloud radar), the clear-air signal in the RWP is dominated by falling particles (after [31.44] © Authors Creative Commons Attribution 4.0 License)

information other than the estimated horizontal wind components [31.44–54]. An example of this so-called Bragg–Rayleigh ambiguity is shown in Fig. 31.1.

All remaining scattering or echoing mechanisms are considered to be clutter: unwanted echoes. This includes scattering at plasma in lightning channels [31.55–58], scattering by airplanes [31.19, 20] and birds [31.24, 59], as well as ground clutter echoes received through the ubiquitous sidelobes of finite-aperture antennas [31.15, 60–64].

31.3.2 Clear-Air Scattering

There is a considerable amount of literature on clear-air scattering [31.4, 30, 31, 36, 65–67], and this topic continues to attract new research [31.36, 68–70]. Due to its unique relevance to RWP systems, an overview of the theory of clear-air scattering is provided below.

The macroscopic polarization properties of air are described through a material parameter, the relative permittivity ϵ . By using different expressions for the atomic polarizability of dry air (nonpolar gases) and water vapor (a polar gas), ignoring carbon dioxide, and noting that by definition the relative permittivity is related to the refractive index via $n^2 = \epsilon$, it can be shown [31.71] that

$$(n-1)_{\text{Air}} = \frac{k_1 p}{z_a T} + \frac{k_2 e}{z_w T} + \frac{k_3 e}{z_w T^2}, \quad (31.1)$$

where e is the partial pressure of water vapor and the parameters k_i relate to the molecular polarization. z_a and z_w are corrections to the ideal state equation for gases. In radar meteorology, it is common to use the refractivity N [31.66], defined as $N = (n-1)10^6$. Using the

constants given by [31.66],

$$N = c_1 \frac{p}{T} + c_2 \frac{e}{T} + c_3 \frac{e}{T^2}, \quad (31.2)$$

with

$$c_1 = 0.776 \frac{\text{K}}{\text{Pa}}, \quad c_2 = 0.716 \frac{\text{K}}{\text{Pa}}$$

and $c_3 = 3.7 \times 10^3 \frac{\text{K}^2}{\text{Pa}}.$

The ubiquitous variations in temperature, humidity, and pressure in the turbulent atmosphere result in variations in the refractive index of the atmospheric medium [31.4, 66], which in turn cause the macroscopic scattering of electromagnetic waves propagating through the atmosphere.

The first step when analyzing the scattering problem is to utilize the macroscopic Maxwell equations. If we only consider a harmonic time dependence of the fields by separating a factor $e^{i\omega t}$ from the electric and magnetic field vectors $\mathbf{E}(\mathbf{r}, t)$ and $\mathbf{H}(\mathbf{r}, t)$, respectively [31.72], we obtain the vector Helmholtz equation

$$\Delta \mathbf{E}(\mathbf{r}) + \epsilon_0 \mu_0 \omega^2 \epsilon(\mathbf{r}) \mathbf{E}(\mathbf{r}) = -\nabla[\mathbf{E}(\mathbf{r}) \cdot \nabla \ln(\epsilon(\mathbf{r}))], \quad (31.3)$$

which implicitly assumes that the phenomenon under consideration is monochromatic. This is a good approximation whenever the medium varies over a much longer timescale than the propagation time of the wave. The permittivity of the atmosphere fluctuates around a value of 1, so

$$\epsilon(\mathbf{r}, t) = \langle \epsilon(\mathbf{r}, t) \rangle + \epsilon'(\mathbf{r}, t) = 1 + \epsilon'(\mathbf{r}, t). \quad (31.4)$$

The ansatz for the total electric field is written $\mathbf{E} = \mathbf{E}_0 + \mathbf{E}_s$, where \mathbf{E}_0 is the solution of the homogeneous version of (31.3), i.e., the field in the absence of permittivity fluctuations. For single scattering, all products of the two small quantities \mathbf{E}_s and ϵ' are neglected (Born approximation), which leads to an equation for the scattered electric field \mathbf{E}_s ,

$$\Delta \mathbf{E}_s(\mathbf{r}) + \epsilon_0 \mu_0 \omega^2 \mathbf{E}_s(\mathbf{r}) = \epsilon_0 \mu_0 \omega^2 \epsilon'(\mathbf{r}) \mathbf{E}_0(\mathbf{r}) - \nabla[\mathbf{E}_0(\mathbf{r}) \cdot \nabla \ln(\epsilon'(\mathbf{r}))] \quad (31.5)$$

The solution to this equation when there are no additional boundary conditions for \mathbf{E}_s (except for the radiation condition) in the far field is known to be [31.4, 69]

$$\mathbf{E}_s(\mathbf{r}) = \frac{k^2}{4\pi} \iiint_V \frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|} \epsilon'(\mathbf{r}') [\mathbf{o} \times [\mathbf{E}_0(\mathbf{r}') \times \mathbf{o}]] d^3 \mathbf{r}'. \quad (31.6)$$

The unit vector $\mathbf{o} = (\mathbf{r} - \mathbf{r}')/|\mathbf{r} - \mathbf{r}'|$ is directed from the variable scattering point to the observation point. Equation (31.6) is fairly general because it only assumes that the observation point lies in the far field of the scatterer.

For any concrete problem, the exact scattering geometry (e.g., the location of the transmitting and receiving antenna) and the incident field $\mathbf{E}_0(\mathbf{r})$ must be specified. To obtain closed-form expressions, it is customary to simplify the treatment by assuming that the transmitted electromagnetic pulse has a Gaussian shape and that the antenna radiation pattern (the beam geometry) is also Gaussian [31.36, 69]. This model for \mathbf{E}_0 together with the term $e^{ik|\mathbf{r}-\mathbf{r}'|}/|\mathbf{r}-\mathbf{r}'|$ essentially defines the instrument sampling function. A comprehensive theoretical analysis of the measurement process for clear-air Doppler radars based on explicit formulations for the instrument sampling function is presented in [31.36]. Two levels of approximation are used to simplify this instrumental sampling function analytically. These are obtained by expanding $|\mathbf{r} - \mathbf{r}'|$ in a Taylor series and retaining terms up to first order (i.e., linear; this is known as the Fraunhofer approximation) or up to second order (i.e., quadratic; this is termed the Fresnel approximation).

The Fraunhofer diffraction or small-volume scattering approximation assumes that the phase fronts of the incident wave are planar over the scattering volume. In this case, (31.6) simplifies to

$$\mathbf{E}_s(\mathbf{r}, t) = \mathbf{E}_0 \frac{k^2}{4\pi} \frac{e^{ikr}}{r} \iiint_V \epsilon'(\mathbf{r}', t) e^{-i2k\mathbf{r}' \cdot \mathbf{r}} d^3 \mathbf{r}', \quad (31.7)$$

which explicitly allows for a refractive index variation with a timescale that is much longer than the propagation time of the wave. Equation (31.7) shows that the field of permittivity fluctuations is sampled at twice the wavenumber k of the incident electromagnetic wave. Therefore, refractive index fluctuations at the half-wavelength scale play a prominent role in clear-air backscattering. This is essentially a condition for constructive interference, which leads to detectable backscattered signal levels.

Current radar theory builds upon the Fresnel approximation, which is applicable under much weaker assumptions and includes additional relevant effects [31.36, 65, 69]. However, the Fresnel approximation leads to the same final radar equation as the traditional Fraunhofer approximation if the refractive index perturbations are statistically isotropic at the Bragg wavenumber [31.36].

It is convenient to choose a coordinate system with the origin centered on the scattering area (Fig. 31.2). Assume that the scattering region is illuminated by

Fig. 31.2 Geometry of the general scattering problem

a monochromatic and linearly polarized plane wave of normalized (to unity) amplitude

$$E(\mathbf{r}, t) = e_i e^{i(\mathbf{k}\mathbf{r} - \omega t)}, \quad \text{where } k = \omega \sqrt{\mu_0 \epsilon_0}. \quad (31.8)$$

In this case, at a sufficiently large distance R from the scattering area, the scattered wave can be formally written as

$$E_s(\mathbf{r}, t) = f(\mathbf{o}, \mathbf{i}) \frac{e^{i\mathbf{k}\mathbf{R}}}{R}. \quad (31.9)$$

This equation introduces the *scattering amplitude* $f(\mathbf{o}, \mathbf{i})$, a parameter that is commonly used in the theory of scattering processes [31.73] and ignores the harmonic time dependence. It describes the amplitude, phase, and polarization of the scattered wave in the far field. In radar meteorology, the cross-section is defined as “the area intercepting that amount of (incident) power, which, if scattered isotropically, would return to the receiver an amount of power equal to that actually received” [31.74], see also [31.31, 66]. Mathematically, this can be expressed as [31.73]

$$\sigma(\mathbf{o}, \mathbf{i}) = \lim_{R \rightarrow \infty} \frac{4\pi R^2 S_s(\mathbf{o}, R)}{S_i(\mathbf{i})}, \quad (31.10)$$

where $S_s(R)$ is the scattered power flux density at a distance R in direction \mathbf{o} from the scatterer and S_i is the incident power flux density. The Poynting vector $\mathbf{S} = \mathbf{E} \times \mathbf{H}^*$ for an electromagnetic wave progressing in unit direction \mathbf{n} is

$$\mathbf{S} = \frac{|\mathbf{E}|^2}{\sqrt{\eta}} \mathbf{n}, \quad (31.11)$$

where $\eta = \sqrt{\mu_0 / (\epsilon \epsilon_0)}$ is the wave impedance. Upon inserting (31.11) and (31.9) into (31.10) and noting that E_i has an amplitude of unity by definition, we obtain

$$\sigma(\mathbf{o}, \mathbf{i}) = 4\pi |f(\mathbf{o}, \mathbf{i})|^2. \quad (31.12)$$

For distributed targets, the volume reflectivity η is defined as the radar cross-section per unit volume

$$\eta = \frac{d\sigma}{dV}. \quad (31.13)$$

By definition, the backscattering cross-section is given by

$$\sigma_b = \sigma(-\mathbf{i}, \mathbf{i}) = 4\pi |f(-\mathbf{i}, \mathbf{i})|^2. \quad (31.14)$$

The field of fluctuations in the dielectric number ϵ' is a random function, meaning that the scattering amplitude is also a random function [31.66, 73],

$$\sigma_b = \frac{k^4}{4\pi} \iiint_V \iiint_V \langle \epsilon'(\mathbf{r}'_1) \epsilon'(\mathbf{r}'_2) \rangle e^{i2\mathbf{k}\mathbf{i}(\mathbf{r}'_1 - \mathbf{r}'_2)} d^3\mathbf{r}'_1 d^3\mathbf{r}'_2. \quad (31.15)$$

The function $B_\epsilon = \langle \epsilon'(\mathbf{r}_1) \epsilon'(\mathbf{r}_2) \rangle$ is the correlation function for dielectric fluctuations. If we introduce the new coordinates [31.75] $\boldsymbol{\sigma} = 1/2(\mathbf{r}_1 + \mathbf{r}_2)$ and $\boldsymbol{\delta} = (\mathbf{r}_1 - \mathbf{r}_2)$, then

$$\sigma_b = \frac{k^4}{4\pi} \iiint_V \iiint_V B_\epsilon(\boldsymbol{\sigma}, \boldsymbol{\delta}) e^{i2\mathbf{k}\mathbf{i}\boldsymbol{\delta}} d^3\boldsymbol{\delta} d^3\boldsymbol{\sigma}. \quad (31.16)$$

The last integral can be interpreted as a Fourier transformation of B_ϵ with respect to $\boldsymbol{\delta}$. According to statistical turbulence theory, this gives the variance spectrum Φ of ϵ [31.76]. Thus,

$$\sigma_b = 2\pi^2 k^4 \iiint_V \Phi_\epsilon(\boldsymbol{\sigma}, 2\mathbf{k}\mathbf{i}) d^3\boldsymbol{\sigma} \quad (31.17)$$

and

$$\eta_b = 2\pi^2 k^4 \Phi_\epsilon(\boldsymbol{\sigma}, 2\mathbf{k}\mathbf{i}). \quad (31.18)$$

The volume reflectivity is directly proportional to the 3-D spectrum of refractivity for the wavenumber corresponding to half the radar wavelength. The sampling of Φ at just one wavenumber is the Bragg condition, which is required for constructive interference. Note that the variance spectrum is sampled at wavevector $2ki$. Obviously, there is a dependence of the volume reflectivity on the direction of the incident wave in case of an anisotropic variance spectrum of the permittivity at the wavenumber $2k$. This phenomenon is indeed observed with radars in the 50 MHz band and is termed *aspect sensitivity*. It is very difficult to derive the statistical properties of a stratified and therefore anisotropic medium, so heuristic models are commonly used [31.77].

For locally isotropic fluctuations in the dielectric number (i.e., in the inertial subrange), (31.18) reduces to

$$\eta_b = 8\pi^2 k^4 \Phi_n(\sigma, 2k). \quad (31.19)$$

If the corresponding variance spectrum for the refractive index is used, $\Phi_\epsilon = 4\Phi_n$ [31.31].

Kolmogorov's statistical theory predicts that the 3-D variance spectrum in the inertial range has a typical wavenumber dependence of $k^{-11/3}$ and can therefore be written as

$$\Phi_n(\sigma, k) = 0.0330 C_n^2(\sigma) k^{-11/3}, \quad (31.20)$$

where C_n^2 is the structure parameter for the refractive index [31.76]. Thus, we finally arrive at

$$\eta_b = 0.3787 C_n^2(\sigma) \lambda^{-1/3}, \quad (31.21)$$

an important equation that is used in radar meteorology to determine the volume reflectivity caused by fluctuations in the refractive index (see for example [31.75, 78–80] and references cited therein).

Such a scattering process is often termed *Bragg scattering*. It is clearly the most relevant scattering model for RWPs [31.31, 80].

31.3.3 Signal Processing

The RWP antenna receives the backscattered electromagnetic wave and converts it into a measurable electrical signal S at the antenna output port, where

$$S(\mathbf{r}, t) = \iint_F \mathbf{E}_s(\mathbf{r} + \boldsymbol{\rho}, t) f_A(\boldsymbol{\rho}) d^2 \boldsymbol{\rho}. \quad (31.22)$$

Here, f includes the antenna radiation pattern [31.81].

The voltage at the output port of the antenna $S(\mathbf{r}_0, t) = S(t)$ is the physical carrier of all of the information about the atmosphere that is made available by the scattering process. The purpose of signal processing is therefore to convert the measured electrical signal into meteorological parameters [31.82].

In signal analysis, it is useful to find a mathematical representation of the signal that facilitates physical interpretation. The signal is typically transformed into another representation (e.g., from the time domain to the frequency domain) in order to study the same piece of information from a different perspective [31.83]. It is important to pick an appropriate new representation for subsequent signal processing tasks such as detection, classification, and estimation. The representation is well adapted to the problem if only a few coefficients reveal the information contained in the signal. This is called a sparse representation [31.84]. A typical radar echo is sparse in the frequency domain; hence the prominent role of the Doppler spectrum. The suppression or filtering of unwanted echoes is also more efficient if a sparse representation of the clutter signal component can be found.

RWP signal processing was initially developed for an idealized setting where the receiver signal was assumed to consist of only the atmospheric signal of interest and the ubiquitous thermal noise of the receiver electronics. The idealized properties of the receiver signal at the antenna output port of a pulsed single-frequency RWP are [31.85]:

- $S(t)$ is a continuous real-valued random voltage signal
- $S(t)$ is narrowband, with the information contained in the slowly varying signal envelope [31.86]
- $S(t)$ has a large dynamic range, with strong signal power for some clutter echoes and extremely low power signals typically occurring at the uppermost range gates.

The detection of weak signals in noise or—equivalently—optimization of the SNR requires a matched filter approach [31.66, 87].

Demodulation, Range Gating, and A/D Conversion

The narrowband RWP signal at the output port of the low-noise amplifier can be written

$$S_{rx}(t) = A(t) \cos[\omega_c t + \Phi(t)]. \quad (31.23)$$

Information about the scattering process is contained in the amplitude and phase modulation of the received signal $S_{rx}(t)$. A demodulation step is first

Fig. 31.3 Simplified schematic of range-time sampling for two successive pulses

performed to remove the carrier frequency ω_c while retaining the modulation information contained in the instantaneous amplitude $A(t)$ and the instantaneous phase $\Phi(t)$. This yields the complex baseband signal

$$\tilde{S}(t) = I(t) + iQ(t), \quad (31.24)$$

where the real part $I(t)$ is called the in-phase component and the imaginary part $Q(t)$ is termed the quadrature-phase component of the signal [31.86]. The implementation details of this demodulation depend on the particular receiver architecture of the RWP.

RWPs transmit a series of short electromagnetic pulses. The backscattered signal is sampled during the time interval ΔT between successive pulses. Knowledge of the propagation speed of the wave group (i.e., the speed of light) allows the radial distance of the measurement to be determined, as illustrated in Fig. 31.3. The maximum distance that can be determined unambiguously (known as the maximum unambiguous range h_{\max}) is of course limited by the pulse separation or interpulse period ΔT , with $h_{\max} = c\Delta T/2$.

The vertical resolution is determined by the pulse width τ , with $\Delta r = c\tau/2$. It is customary to perform range sampling with a frequency of at least $1/\tau$. Note that it is not possible to increase the vertical resolution by range sampling more densely [31.87].

Range gating is usually done during A/D conversion. If the range sampling frequency is given by $1/\Delta t$

and N_h is an integer that denotes the number of range gates with $\Delta T > N_h\Delta t$, then the signal $\tilde{S}(t)$ is obtained at the discrete grid

$$\begin{aligned} \tilde{S}[j, n] &= \tilde{S}(t_0 + j\Delta t + n\Delta T), \\ j &= 0, \dots, N_h - 1, \quad n = 0, \dots, N_T - 1. \end{aligned} \quad (31.25)$$

For each range gate j at height $c/2j\Delta t$, a discrete (complex) time series of the signal is obtained with a sampling interval of ΔT . This can be written in a simplified notation as

$$S[n] = S_I[n] + iS_Q[n], \quad n = 0, \dots, N_T - 1. \quad (31.26)$$

The Digitized Raw Signal

The theoretical basis for RWP signal processing is the mathematical model of stationary Gaussian random processes. Specifically, the model for the digitized and range-gated RWP signal is

$$S[n] = I[n]e^{i\omega n\Delta T} + N[n], \quad (31.27)$$

where $I[n] \propto \mathcal{N}(0, \mathbf{R}_I)$ and $N[n] \propto \mathcal{N}(0, \mathbf{R}_N)$ are independent, complex, zero-mean, Gaussian random vectors that describe the atmospheric signal and the receiver noise, respectively [31.88], ΔT is the sampling interval of the sequence and ω is the mean Doppler frequency. Furthermore, $I[n]$ is narrowband compared to the receiver bandwidth and $|\omega| \leq \pi/\Delta t$ (the Nyquist criterion).

Since $S[n]$ results from the demodulation of a real-valued, zero-mean, stationary Gaussian random process, the resulting complex random process is also stationary, has a mean of zero, and is proper; that is, the sequence has vanishing pseudo-covariance $E(S[p]S[q]) = 0$ [31.89]. The underlying random process of the realization $S[n]$ is completely characterized by its covariance matrix \mathbf{R} , where [31.85]

$$\begin{aligned} (\mathbf{R})_{p,q} &= \text{Cov}(S[p], S[q]) \\ &= \sigma_I^2 \boldsymbol{\varrho}[p-q] e^{i\omega(p-q)\Delta T} + \sigma_N^2 \delta_{p-q,0}, \end{aligned} \quad (31.28)$$

The autocorrelation sequence $\boldsymbol{\varrho}$ is typically assumed to be Gaussian as well, and therefore corresponds to a Gaussian signal peak in the power spectrum. If the spectral width of the signal is σ_v , then [31.88, 90]

$$\boldsymbol{\varrho}[n] = e^{-2\pi^2 \sigma_v^2 n^2 \Delta T^2}. \quad (31.29)$$

This Gaussian correlation model must not be confused with the characterization of the random process as Gaussian, which encompasses a much wider class of signals. To completely describe such a random process, it is sufficient to consider either the autocovariance function or—according to the Wiener–Khinchine theorem—the power spectrum. In radar meteorology, the latter is usually referred to as the Doppler spectrum.

This signal model provides the theoretical justification for why only the first three moments of the Doppler spectrum are usually estimated. Note that stationarity must be assumed over typical dwell times of $O(1 \text{ min})$.

Real-world effects such as clutter or radiofrequency interference make it necessary to extend the simple model (31.27) by adding an additional clutter component with potentially very diverse properties, i.e.,

$$S[n] = I[n]e^{i\omega n \Delta T} + N[n] + C[n]. \quad (31.30)$$

Furthermore, atmospheric scattering is of course not limited to only clear-air echoes. This modifies the general properties of the signal as follows:

- $S(t)$ becomes multicomponent due to the possibility of simultaneously acting atmospheric scattering mechanisms, internal (electronic) noise, and external (artificial) effects
- $S(t)$ can be nonstationary due to the transient nature of bird, airplane, or lightning echoes.

Strictly speaking, only the clear-air scattering mechanism is of interest in radar wind profiling. However, from a practical point of view, it has become customary to include the scattering at hydrometeors as a non-

clutter component too, provided that the particles can be considered tracers for wind measurements. Multiple signal components from different scattering processes or other effects need to be separated and classified using additional information provided a priori. The presence of several independent stationary signal components will give rise to a Doppler spectrum with multiple signal peaks, which will necessitate more sophisticated target classification.

While the receiver signal is intrinsically nonstationary due to the impulsive character of the transmitted signal (a pulse) and the inhomogeneous vertical structure of the atmosphere, this property changes significantly during range gate sampling. The assumption of stationarity is usually valid for atmospheric scattering, ground clutter, and noise. However, intermittent clutter introduces nonstationarity at the level of the range-gated I/Q data. This nonstationary signal character requires the application of nonstationary signal analysis to obtain the problem-adapted (sparse) signal representation required for efficient filtering [31.91].

Time Domain Processing: Digital Filtering

Digital time-domain processing includes all the operations applied to the signal \mathbf{S} before a Doppler spectrum is estimated. This includes coherent integration, which essentially allows the data rate to be reduced at the expense of the analyzable Nyquist interval and introduces unwanted digital filtering [31.92], as well as specially designed linear FIR (finite impulse response) [31.93] and sophisticated nonlinear (clutter) filtering algorithms [31.85, 91, 94]. An example of a coherently integrated time series is shown in Fig. 31.4.

Frequency Domain Processing: Spectral Estimation

For a stationary Gaussian random process, the power or Doppler spectrum provides a sparse representation. A modified periodogram is typically used as a classical nonparametric estimator of the power spectrum [31.95, 96] since it does not need any further information a priori and produces reasonable results for a large class of relevant processes, including ground clutter and simple types of radio-frequency interference (RFI). It can easily be implemented using a discrete Fourier transform (DFT).

The (leakage) bias of the periodogram estimate is reduced through data tapering [31.97]. Welch's overlapped segment averaging [31.96, 98] is a popular method for reducing the variance of the estimate due to its ease of implementation. This is known as spectral or incoherent averaging [31.20]. Other methods such as multitaper estimators can also be applied [31.99].

Fig. 31.4a,b Example of a coherently integrated I/Q time series obtained from a 482 MHz RWP at 08:24:59 UTC on 1 Dec. 1999 (Beam East, height 3035 m): **(a)** real component, **(b)** imaginary component (after [31.70] with permission)

The Doppler spectrum is usually given as a function of velocity rather than frequency. Interconversion between the frequency shift f and the radial velocity v_r is achieved using the well-known relation $f = 2v_r/\lambda$, where λ denotes the radar wavelength.

An example of a Doppler spectrum is shown in Fig. 31.5.

Signal Detection, Classification, and Moment Estimation

To discriminate between the noise and the signal, an objective noise level is estimated using the method proposed by *Hildebrand and Sekhon* [31.100]. The next step is the identification of the signal peak caused by the atmospheric return. A simple method that selects the signal peak with the highest power density as the atmospheric signal works very well for single-peak spectra and is furthermore robust [31.20, 101]. A number of multiplex algorithms have been proposed for more complex situations, including rather simple ground-clutter algorithms and more sophisticated techniques [31.93, 102, 103]. Unfortunately, only a few of these algorithms have been comprehensively validated [31.104–106]; most methods remain experimental.

Since the power spectrum of the atmospheric signal is often assumed to be Gaussian in form, the first three moments (power, mean frequency, and frequency spread) are sufficient to describe the signal [31.15]. They are well defined even when the assumption that the power spectrum is Gaussian is violated [31.62]. For spectra with sufficient frequency resolution, it may therefore be useful to estimate higher-order moments.

Fig. 31.5 Example of an incoherently averaged Doppler spectrum obtained from a 482 MHz RWP at 08:24:59 UTC on 1 Dec. 1999 (Beam East, height 3035 m). The clear-air echo peak is visible at about -18 Hz, whereas an unusually strong ground-clutter peak is centered around 0 Hz. The signal contribution from the noise is spread evenly across the Nyquist frequency range. The spectral density of the noise level has been normalized to zero as the radar was not calibrated (after [31.70] with permission)

Small SNR values are typical of RWPs, at least for the uppermost range gates. Consequently, one is faced with a statistical detection task that leads to a binary decision problem with two hypotheses (H_0 : no atmo-

spheric signal is present; H_1 : an atmospheric signal is present). A simple but powerful method known as consensus averaging is often used to discriminate between (false) Doppler estimates caused by random noise peaks and (correct) estimates that are due to stationary atmospheric returns. The technique essentially provides a homogeneous (nonlinear) estimator for the Doppler velocity that includes outlier suppression [31.20, 90, 107].

31.3.4 Wind Vector Estimation: Doppler Beam Swinging

In so-called Doppler systems, the frequency shift of the scattered waves is used to measure the motion of the scattering medium directly. However, the velocity can only be determined along the line of sight or radial direction of the antenna beam. Most RWPs use a simple method known as Doppler beam swinging (DBS) to determine the wind vector [31.108–110]. Three linearly independent beam directions are required to transform the measured line-of-sight radial velocities into the wind vector using additional assumptions concerning the wind field. Measurements are usually taken in more than three directions to minimize errors.

For a given azimuth α and zenith angle ϕ , the beam direction can be described mathematically by a unit vector $\mathbf{e} = (\sin \alpha \sin \phi, \cos \alpha \sin \phi, \cos \phi)^T$. The wind vector \mathbf{v} is retrieved from projections of \mathbf{v} onto a set of different beam vectors $\{\mathbf{e}_k\}_{k=1}^N$, which defines the spatial sampling. These projections are described by the inner product of the wind vector and the beam unit vectors.

For a stationary and horizontally homogeneous wind field, i.e., $\mathbf{v}(x, y, z, t) \approx \mathbf{v}(z)$, and for N beams, the N inner products can be expressed as a linear system of equations

$$\mathbf{A}\mathbf{v} = \mathbf{V}_r, \quad (31.31)$$

where $\mathbf{v} = (uvw)^T$ and $\mathbf{V}_r = (V_{r1} V_{r2} V_{r3} \dots V_{rn})^T$.

The rows of matrix \mathbf{A} consist of the beam unit vectors, i.e.,

$$\mathbf{A} = \begin{pmatrix} \sin(\alpha_1) \sin(\phi) & \cos(\alpha_1) \sin(\phi) & \cos(\phi) \\ \sin(\alpha_2) \sin(\phi) & \cos(\alpha_2) \sin(\phi) & \cos(\phi) \\ \sin(\alpha_3) \sin(\phi) & \cos(\alpha_3) \sin(\phi) & \cos(\phi) \\ \dots & \dots & \dots \\ \sin(\alpha_n) \sin(\phi) & \cos(\alpha_n) \sin(\phi) & \cos(\phi) \end{pmatrix}. \quad (31.32)$$

System (31.31) is obviously an overdetermined set of equations. If the azimuth angles α_i (with $i = 1, \dots, n$) and the elevation angle ϕ are chosen properly, \mathbf{A} is a matrix with full column rank: $\text{rank}(\mathbf{A}) = 3$. The solution is unique and exact when it does exist; otherwise,

an approximate solution that minimizes $\|\mathbf{V}_r - \mathbf{A}\mathbf{v}\|_2^2$ can be obtained using the method of least squares,

$$\mathbf{v} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{V}_r = \mathbf{A}^+ \mathbf{V}_r, \quad (31.33)$$

where \mathbf{A}^+ denotes the Moore–Penrose pseudoinverse of \mathbf{A} . However, this solution tends to worsen the condition of the matrix, i.e., $\text{cond}(\mathbf{A}^T \mathbf{A}) = (\text{cond}(\mathbf{A}))^2$. It may be ill conditioned or even numerically singular, i.e., small errors in the (measured) data may produce large errors in the solution. It is therefore useful to employ the singular value decomposition (SVD) of matrix \mathbf{A} , namely $\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{V}^T$, where \mathbf{U} is an orthogonal matrix, \mathbf{V} is a 3×3 orthogonal matrix, and \mathbf{D} is a diagonal matrix whose elements σ_i are called the singular values of \mathbf{A} . The least squares solution can then be expressed as

$$\mathbf{v} = \mathbf{A}^+ \mathbf{V}_r = \mathbf{V}\mathbf{D}^{-1}\mathbf{U}^T \mathbf{V}_r. \quad (31.34)$$

This method provides stable numerical solutions in the general case and can therefore be implemented in operational Doppler systems, whether they utilize radar or lidar [31.111]. Obviously, an explicit solution of (31.31) would provide more insight into error propagation and possibly also the optimal sampling conditions. Such an explicit solution can be obtained for a symmetric VAD-like sampling scenario; see [31.112].

With preassigned equispaced azimuth angles $\alpha_k = 2\pi k/N$, $k = 0, \dots, N-1$ and a constant zenith angle ϕ , the explicit solution for the wind vector is obtained as

$$\mathbf{v} = \begin{pmatrix} u \\ v \\ w \end{pmatrix} = \begin{pmatrix} \frac{2}{N \sin \phi} \sum_{k=0}^{N-1} \sin \alpha_k V_k \\ \frac{2}{N \sin \phi} \sum_{k=0}^{N-1} \cos \alpha_k V_k \\ \frac{1}{N \cos \phi} \sum_{k=0}^{N-1} V_k \end{pmatrix}. \quad (31.35)$$

Assuming a Gaussian error model for the radial wind $\Delta V \propto \mathcal{N}(\boldsymbol{\beta}, \boldsymbol{\Sigma})$, where $\mathcal{N}(\boldsymbol{\beta}, \boldsymbol{\Sigma})$ is the N -dimensional normal distribution with expectation vector $\boldsymbol{\beta}$ and variance matrix $\boldsymbol{\Sigma}$, and that the components β are constant ($\beta_i = \beta$ for $i = 0, \dots, N-1$) and $\boldsymbol{\Sigma} = \text{diag}(\sigma^2, \dots, \sigma^2)$, error propagation yields

$$E(\Delta \mathbf{v}) = \frac{\beta}{\cos \phi} \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}. \quad (31.36)$$

A constant bias in the radial wind estimates only affects the estimation of the vertical wind component; the horizontal wind vector components remain free from bias. This is due to the symmetry of the sampling, which leads to the cancellation of any existing bias in the radial winds.

The RMS error can be estimated as

$$E \begin{pmatrix} (\Delta u)^2 \\ (\Delta v)^2 \\ (\Delta w)^2 \end{pmatrix} = \begin{pmatrix} \frac{2\sigma^2}{N \sin^2 \phi} \\ \frac{2\sigma^2}{N \sin^2 \phi} \\ \frac{\sigma^2}{N \cos^2 \phi} \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ \frac{\beta^2}{\cos^2 \phi} \end{pmatrix}. \quad (31.37)$$

In the presence of wind field inhomogeneities, the RMS error in the wind retrieval is reduced by increasing the number of off-vertical beams used in the Doppler beam-swinging technique. Note, however, that for the vertical wind component, increasing N only reduces the random error.

The assumption of a horizontally homogeneous and stationary wind field appears to be fairly restrictive, but the goal is not to determine the instantaneous wind vector in an arbitrary turbulent wind field but rather the mean (horizontal) wind vector over an averaging time of $O(10\text{--}30 \text{ min})$. For the average wind field, horizontal homogeneity must be assumed over the area encompassed by the beams (typically $O(1\text{--}10 \text{ km})$ for Doppler radar profilers), and stationarity must be assumed to hold during the averaging time. In the vertical direction, the wind field is assumed to be piecewise constant within layers that are approximately as thick as the radial resolution of the RWP, namely $O(100 \text{ m})$. An experiment with a volume-imaging multisignal radar wind profiler in a convective boundary layer indicated that the assumptions inherent in the DBS retrieval method can indeed be valid for a wind field that is averaged over 10 min [31.113].

However, deviations from these assumptions can easily lead to wind retrieval errors of $O(1 \text{ m s}^{-1})$. Wind retrievals are particularly error-prone during strong gravity-wave activity [31.109], patchy precipitation [31.114], and of course over complex terrain [31.115]. Errors can also occur in convective boundary layers if they are not horizontally homogeneous in the statistical sense. While the assumptions of statistical (local) homogeneity and quasi-steadiness are applied quite often in boundary-layer meteorology [31.116], it is clear that violations will occur when larger-scale (coherent) structures are present [31.117]. More work is required to quantitatively appraise the effects of this nonhomogeneity and nonstationarity on wind retrieval for various types of convective boundary layers.

31.3.5 Wind Vector Estimation: Spaced-Antenna Systems

Spaced-antenna (SA) wind profilers address the homogeneity problem by using multiple receiving antennas with overlapping sampling volumes. SA profilers only transmit pulses vertically, i.e., there is no steering, in contrast to DBS profilers. The backscattered signal is

then sampled by receivers on multiple closely spaced receiving antennas (Figs. 31.6 and 31.7).

As the atmosphere moves overhead, so does the backscattered signal at the ground. The time series of signals received by the spaced antennas are slightly temporally displaced in a manner that can be related to the motion of the atmosphere. As can be surmised by tracing the rays in Fig. 31.7, the velocity of the diffraction pattern at the ground is twice that of the atmosphere. Historically, SA techniques have primarily been used to observe the upper atmosphere [31.118, 121], although they are now used in some tropospheric and boundary-layer radar systems [31.28, 122, 123]. SA radars sample the drift of backscattered signals over the ground to derive wind velocities, so this method is sometimes called *spaced antenna drift*.

A variety of techniques are used to analyze the backscattered signals and thus determine the wind velocity. Many techniques use cross-correlation analysis, in which the time series of signals from the receivers are cross-correlated. Ideally, the sampling volumes of the receiving antennas overlap, so there is a significant degree of correlation between the time series from the receivers. The temporal difference between the time series obtained from a pair of neighboring receivers is determined by examining the cross-correlation function for a sequence of time offsets (or *lags*),

$$\rho(\varepsilon_{ij}, \eta_{ij}, \tau) = \frac{\langle E_i(t) E_j^*(t + \tau) \rangle}{\sqrt{\langle E_i(t) E_i^*(t) \rangle \langle E_j(t) E_j^*(t) \rangle}}, \quad (31.38)$$

where ε_{ij} and η_{ij} indicate the eastward and northward spacing of a pair of receivers (i, j) and τ indicates the time lag.

The cross-correlation function (31.38) shows a peak at the time lag corresponding to the average temporal difference between the time series of the neighboring receivers. Note that, as it moves, the atmosphere is continually changing (due to turbulence for instance), so there is never perfect cross-correlation.

The distance vector between the neighboring antennas is divided by the displacement time to obtain the component of motion along that vector. The *apparent* velocity can be determined by considering multiple pairs (at least three nonorthogonal pairs) of neighboring antennas and their cross-correlation functions. Note that this is denoted the apparent velocity because it is distorted by changes in the atmosphere as it moves. The more the atmosphere evolves, the more the received signals become temporally decorrelated. The effect of this decorrelation is that the cross-correlation functions become biased towards shorter time lags, which in turn means that the apparent velocity is always an overesti-

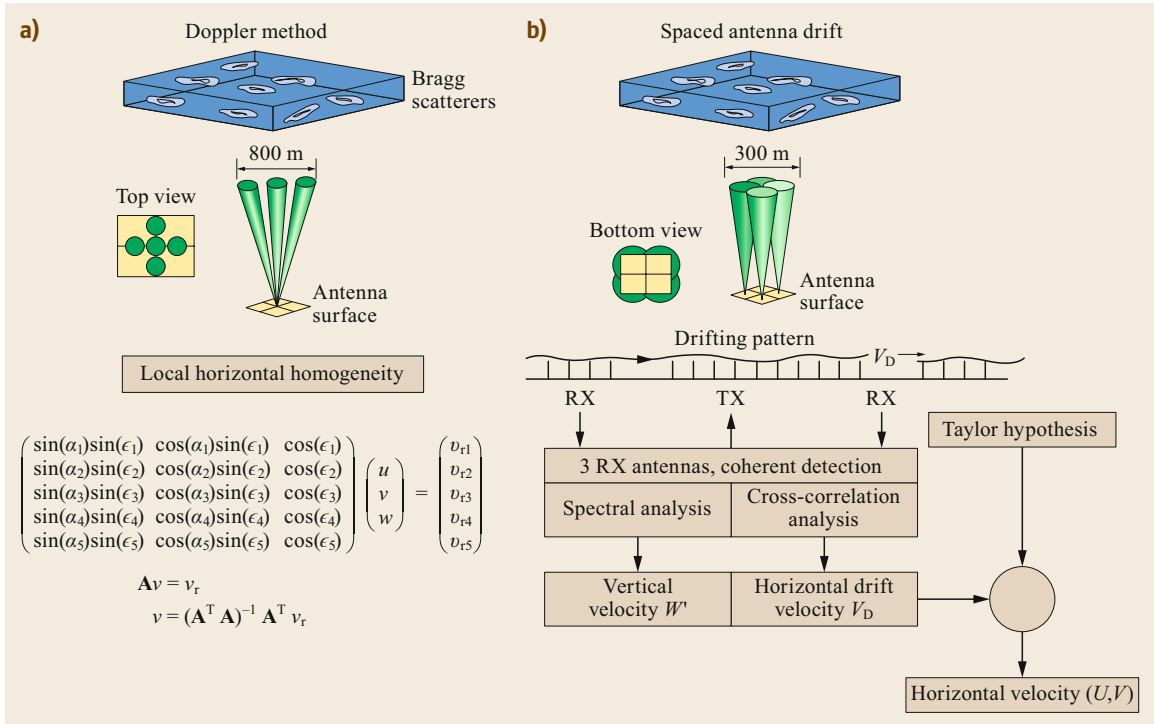

Fig. 31.6a,b Comparison of the Doppler (a) and spaced-antenna (b) RWP methods (after [31.118] reproduced with the permission of NCAR/EOL)

Fig. 31.7 Schematic representation of the SA method. The *three green squares* denote the spaced receiving antennas. Note that the diffraction pattern moves across the ground at a velocity of $2V$ due to the point source effect (after [31.119, 120])

Fig. 31.8 (a) Idealized auto- and cross-correlation functions. The time lag of the peak of the cross-correlation function (τ_{ij}) is used to determine the apparent velocity. (b) A correlation ellipsoid surface indicating surfaces of constant correlation in the temporal and spatial domains. A surface of 0.5 is typically considered, meaning that the time lags τ for the auto- and cross-correlation functions to fall to 0.5 are determined then mapped onto the ellipsoid. The vertical axes intersect at τ_{fad} (often called the fading time). The ellipsoid can then be parameterized geometrically, and the tilt—which is directly related to the wind velocity—can be determined

mate of the true motion of the atmosphere. In addition, if the backscatter is anisotropic due to waves or rolls, the direction of the apparent velocity can be similarly biased.

Many points in both the time and spatial domains would need to be sampled with a suitably large number of receivers to precisely characterize these distortions. While SA profilers typically do collect many samples in the time domain, most radars can only deploy a small number of receivers (a minimum of three are required), so the spatial variability of the scattering is not well characterized. Several approaches can be used to parameterize the distortions and estimate a corrected wind; the most commonly used method is known as *full correlation analysis* (FCA) [31.124].

FCA was developed by *Briggs* [31.124, 125] among others. The basic assumption of FCA and other correlation techniques is made that to first order, the variability in the time domain has a similar functional form to the variability in the spatial domain. For example, some correlation techniques make the assumption that the temporal variability can be described as Gaussian, and thus the spatial variability is also Gaussian. In FCA [31.124], the actual function is not important, but it must take the same form in the spatial and temporal domains. An ellipsoidal surface of constant correlation is considered in the spatial and temporal correlation space (Fig. 31.8). This surface can be parameterized by examining key points for the auto- and cross-correlation functions. The ellipsoid can be considered an average

representation of the backscatter in the spatial and time domains. Further details of this method are beyond the scope of this review, but essentially the tilt of the ellipsoid is related to a corrected velocity that is referred to in FCA as the *true velocity* [31.7, 124].

Other correlation techniques take different approaches, such as considering the intersection point of the auto- and cross-correlation functions (assuming Gaussian behavior) or the slopes of the cross-correlation functions. Error analyses of various correlation techniques have been performed by *Doviak et al.* [31.126], who found that FCA compared well with other techniques in this respect.

Fig. 31.9 Schematic showing the sampling performed for $N = 4$ (after [31.112] © Authors Creative Commons Attribution 3.0 License)

Interferometric techniques represent another approach to SA wind analysis. Consider Fig. 31.9 and the case in which all four samples are within a broad transmit pulse and the broad sampling volumes of multiple receivers. The backscattered signals from each of the four samples would have differing Doppler shifts. In addition, the backscatter would differ in phase at each receiver due to differences in the angle of arrival from that sample. SA interferometry techniques utilize the variation in the Doppler shift with respect to the angle of arrival to derive the estimated wind velocity. Typically, the cross-spectrum of signals received

at pairs of adjacently spaced receivers is analyzed. The phase of the cross-spectrum contains the angle of arrival information and, in the ideal case, varies uniformly across the spectrum. It was shown in [31.127] that interferometric techniques are equivalent to correlation techniques, as might be expected from the Fourier transform relationship between spectra and correlation functions, and that the wind velocity derived using interferometry is equivalent to the apparent velocity from correlation techniques. This led to the development of an analysis that allowed the wind velocity to be corrected in a similar manner to FCA.

31.4 Systems

RWPs come in many shapes and sizes. However, operationally relevant radars employ either the Doppler or the spaced-antenna method, so our discussion will be limited to these configurations. There are specialized research systems with additional sampling capabilities, such as those that use two [31.128] or multiple carrier frequencies to facilitate frequency-domain interferometry (FDI) or range imaging (RIM) [31.129–131], or those that employ a bistatic combination of a single transmit antenna and a multitude of receiving antennas to perform digital beamforming [31.132, 133]. The vast majority of RWPs are land-based, but there have been interesting technical developments relating to moving platforms such as ships, where the motion of the platform is compensated for during real-time operation [31.134].

31.4.1 Spectrum Allocation

A radar wind profiler can only be operated within a legal frequency allocation. Such allocations are defined

in resolutions COM5-5 and footnotes S5.162A and S.5.291A of the World Radiocommunication Conference 1997 (WRC-97). These documents assign RWP frequency allocations for the 50, 400, and 1000 MHz bands for each ITU region. A notable exception is the national allocation at 205 MHz for India [31.135, 136]. However, the radio spectrum is a precious resource, and the competition for frequencies continues to grow tremendously [31.137]. For this reason, all RWP spectrum allocations are constantly under pressure from other potential users of the respective bands. The importance of being able to utilize parts of the RF spectrum has been outlined in a number of official documents by the WMO and other international organizations [31.138, 139]. It is likely that this *spectrum congestion problem* will lead to changes in frequency management in the future [31.140]. Even today, it is already necessary to share profiler frequency bands with other services. One particular advantage of RWP is the near-vertical direction of the profiler beams, which helps to protect against horizontally propagating waves. Another is the relative flexibility in the selection of the operating frequency, as the clear-air scattering mechanism works across a broader range of wavelengths. This is in contrast to the rather strict constraints typical for passive remote-sensing instruments.

Nevertheless, the high sensitivity of RWPs makes them vulnerable to any sufficiently strong external radio-frequency interference that is in-band. RWP signal processing and quality control procedures must account for RFI to eliminate the spurious data which may otherwise occur in such cases.

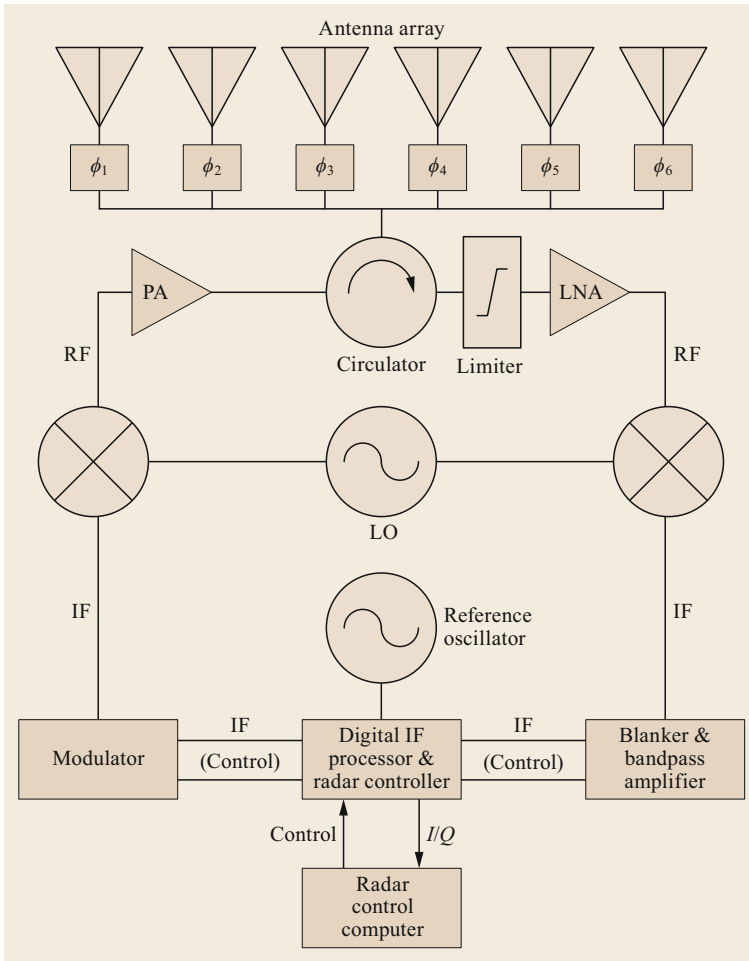

Fig. 31.11 Simplified block diagram of a single-signal radar wind profiler

31.4.2 Doppler Systems

The following discussion of the main RWP hardware components will be restricted to single-signal systems. Clearly, we can only describe the basic functionality here due to the great variety of possible hardware solutions for specific systems. More details about the general hardware aspects of radar can be found in [31.141–144].

A block diagram of the general architecture is given in Fig. 31.11. The central unit is the radar controller, which uses a highly stable oscillator as the single reference for all signals. This controller generates all of the timing and control signals needed to operate the radar, such as the transmit time, receiver blanking, A/D conversion (ADC) sample timing, and antenna control. It also generates the local oscillator (LO) signal and the transmit waveform, usually at an intermediate frequency (IF) that makes it easy to perform digital-to-analog conversion. The envelope of the transmit signal is often

shaped to minimize the occupied bandwidth of the transmitted wave group. Many radars are also capable of pulse compression; binary phase modulation using complementary codes is frequently used [31.145–149].

An additional modulator module is used to gate and amplify the pulse envelope before it is upconverted by mixing with the LO to give the transmitted radio frequency. The mixer is a three-port device with a non-linear component that ideally produces the sum and difference frequencies of two input signals at the output port [31.144]. The resulting low-level RF signal is passed to a linear power amplifier, which is generally a solid-state device nowadays. Finally, the transmit signal is delivered to the antenna and converted into an electromagnetic wave that is radiated into free space.

The antenna is typically designed as a phased array [31.81], although some simpler systems do use reflector antennas at shorter wavelengths [31.150]. The performance of the RWP is essentially determined by the antenna radiation pattern, which describes the an-

Fig. 31.12a,b Single coaxial-collinear antenna element with an ideal current amplitude distribution (a), and an array of such antenna elements (b). The planar CoCo array generates a linear polarized electromagnetic wave, with the electric and magnetic field vectors oscillating in the so-called E-plane and H-plane, respectively. The antenna beam can be steered in the H-plane by controlling the phasing of the CoCo lines

Fig. 31.13 Normalized radiation pattern $P(\theta, \phi)/P_{\max}$ of a coaxial-collinear phased array antenna in [dB]

gular dependence of the radiated energy as a function of the spherical antenna coordinates θ and ϕ (in contrast to an isotropic antenna). A simple and proven RWP antenna based on a planar array of coaxial-collinear antenna elements is shown in Fig. 31.12. The beam can be steered in the H-plane by imposing a linear phase progression between the CoCo rows. Figure 31.13 shows the ideal radiation pattern for this array, as calculated using the method described in [31.151]. The transmit energy is typically concentrated in a narrow angular region called the radar beam. The key performance parameters are the beam width and the gain of the antenna.

Due to the finite extent of the antenna array, the beam can not be made infinitely narrow. A phase-shifting unit generates the individual element phasing required to steer the beam in several directions. However, the electromagnetic wave is also radiated in direc-

tions other than that of the boresight through so-called sidelobes, which can be minimized but not eliminated completely. The sidelobes are influenced by the spatial distribution of the electric field across the antenna aperture, which can be tailored to some extent (this is known as tapering). The sidelobes are actually stronger and less regular in reality due to unavoidable (stochastic) differences in excitation between array elements resulting from hardware imperfections [31.81].

As the same antenna is used for signal reception, a duplexer is needed to protect the sensitive receiver electronics from the strong transmit signal. This typically incorporates a ferrite circulator and receiver-protecting limiters to achieve the isolation required to avoid transmitter leakage into the highly sensitive receiver. The scattered wave intensity has a rather large dynamic range of more than 100 dB, including signals that are well below -150 dBm (10^{-18} W) at the low end (close to the sensitivity limit of the radar receiver) as well as some types of clutter that induce receiver saturation. The receiver itself is of the classical superheterodyne type [31.152]. A broadband, high-gain, low-noise amplifier (LNA) is necessary to raise the signal level of the weak atmospheric return for further processing. For small input signals, LNA performance is fundamentally limited by microphysical processes, whereas the effects of nonlinearities need to be minimized for very strong signals. After frequency downconversion to the IF, a blanker and bandpass amplifier are used to provide additional protection against leakage during transmission and for signal amplification and filtering during the receive phase. In modern systems, the received signal is digitized at the IF by so-called digital IF receivers, which have largely replaced the analog quadrature detectors at baseband that were previously used. The IF signal undergoes A/D conversion and digital demodu-

Fig. 31.14 The NCAR Modular Profiler is an example of a spaced antenna radar. This 449 MHz radar uses a number of hexagonal antennas—three are employed in the boundary-layer configuration shown, but the system can also be deployed in a seven-panel configuration for higher altitude measurements. All of the antenna panels are used for transmission and each panel has its own receiver system

31.4.3 Spaced-Antenna Systems

The basic architecture of a SA radar is similar to that of a DBS radar except that there are at least three receiver channels that typically share a single transmitter system. SA radars do not tend to include a steering mechanism but they do have the additional complexity associated with the inclusion of multiple receiver channels. Figure 31.14 shows an example of a SA radar, the NCAR Modular Wind Profiler [31.153, 154]. The three hexagonal antennas are driven together for transmission, but the antennas have individual receivers and data channels. One unique feature of the Modular Profiler is its scalability—additional antennas can be added to increase the aperture of the antenna and thus its sensitivity.

lation. To maximize the per-pulse signal-to-noise ratio (SNR) and thus optimize signal detection, the bandwidth of the digital FIR bandpass filter is matched to the width of the transmitted pulse [31.87]. Further processing steps are performed in the radar processor.

SA profilers are capable of very rapid wind measurements, and Fig. 31.15 provides an illustration of this capability. A highly convective storm observed by the NCAR Modular Wind Profiler during the PECAN (Plains Elevated Convection at Night) field campaign [31.155] is shown. A very strong updraft (the red region) is apparent in the upper panel. At the same time, in the lower panel, strong circulating wind gusts with timescales of just a minute or two can be seen. The ability to record such brief wind gusts while simultane-

Fig. 31.15a,b Example demonstrating the rapid wind measurement capability of SA radars. The NCAR Modular Wind Profiler recorded the passage of a storm over a site in Kansas for the PECAN field campaign: **(a)** vertical velocity, with red areas indicating updrafts, green areas representing downdrafts, and blue areas corresponding to precipitation; **(b)** simultaneous one-minute wind measurements

Table 31.3 Comparison of the Doppler and spaced-antenna methods

	Advantages	Disadvantages
Doppler	Sensitivity across a wide range of scattering conditions, including weak SNR Single-channel transmit and receive system	Statistical homogeneity required over the area spanned by the beams Phase switches or steerable antenna can have undetected failures
SA	Higher time resolution due to less stringent homogeneity constraints No antenna steering required	Requires a higher SNR than DBS Three or more receiver chains required

ously measuring vertical velocities enabled the radar to capture the rapidly evolving dynamics of the storm.

One disadvantage of a SA radar is its need for increased transmit power to achieve the same altitude coverage as a DBS radar of the same size. The receiving antenna is divided among at least three receiver channels. In addition, the information content in the backscattered signals used by a DBS radar is in the first moment of the data, and can still be extracted at SNR levels of around -12 dB or even lower. For a SA radar, the information used to derive winds is present in higher-order moments, requiring SNR levels that are around $6-10$ dB more than those needed by a DBS radar [31.122].

SA radars are not as common as DBS radars, but there are some notable SA radars in operation. The Australian Bureau of Meteorology operates a network of ten SA boundary-layer radars scattered around Australia [31.28, 29]. These radars are also unusual boundary-layer radars in that they operate in the 50 MHz band rather than the more commonly used 1 GHz band. Another notable SA-capable radar is the

MU (Middle and Upper Atmosphere) Radar operated by Kyoto University in Japan [31.156]. This highly capable MST radar can operate in SA or DBS mode, leading to interesting comparison studies of the two techniques. In general, the results obtained using the MU Radar indicate that the two techniques produce comparable results [31.157].

31.4.4 Comparison of the Methods

From a user perspective, the most important consideration when selecting a particular RWP instrument is obviously the operating frequency, as it strongly influences the measurement range. However, the available operating frequencies are of course constrained by a number of practical factors, such as frequency allocation options, resources available for installation and long-term support, and (last but not least) the availability of real estate. When choosing the technique (either DBS or SA), it is important to consider the intended use of the radar system. Table 31.3 summarizes the advantages and disadvantages of both methods.

31.5 Specifications

The achievable altitude coverage and the accuracy of the wind data are key when selecting a RWP. It is important to appreciate that these performance parameters depend not only on the radar instrument and its properties but also on the state of the atmosphere itself. A theoretical appraisal is therefore difficult but nevertheless useful to understand the essential factors, at least in a qualitative way.

31.5.1 Measurement Range

The achievable measurement range or altitude coverage is determined by the lowest backscattered wave intensity that can be correctly analyzed by the radar. That is, the signal-to-noise ratio (SNR) must be above a certain level. The SNR depends on a number of factors that are present in the so-called radar equation. The general

form of this equation is [31.66]

$$P(\mathbf{r}_0) = \int_V I(\mathbf{r}_0, \mathbf{r}) \eta(\mathbf{r}) d^3\mathbf{r}, \quad (31.39)$$

where η denotes the volume reflectivity and

$$I(\mathbf{r}_0, \mathbf{r}) = \frac{P_t g^2 \lambda^2 f^4 (\Theta - \Theta_0, \Phi - \Phi_0)}{(4\pi)^3 l^2(\mathbf{r}) r^4} |W_s(\mathbf{r}_0, \mathbf{r})|^2 \quad (31.40)$$

is the radar instrument weighting function, which essentially depends on the antenna radiation pattern described by f , and the range weighting function W , and is furthermore scaled by the transmit power as well as by all gains and losses of the radar. I is essentially an integral kernel and (31.39) can be regarded as an inverse

Table 31.4 Simplified classification of RWPs based on typical parameters

	Stratospheric	Tropospheric	Lower tropospheric	Boundary layer
Frequency (MHz)	50	400–500	400–500	1000
Height range (km)	2–20	0.5–16	0.3–10	0.2–3
Vertical resolution (m)	150–500	150–500	150–300	50–300
Antenna size (m ²)	100 × 100	15 × 15	6 × 6	3 × 3
Peak transmit power (kW)	100–1000	10–20	1–5	1

problem, with all of the associated challenges. The advantage of active remote sensing is the ability to tailor this kernel function within the relevant technical limits.

The instrument function describes the capabilities of the radar; its main parameters are:

- The transmit power
- The antenna directivity and gain
- The receiver efficiency, including losses in the antenna feed
- The pulse width (expressed through the range weighting function)
- The distance from the radar to the sampled volume.

The first three items are determined by the technical design of the radar and are therefore subject to the principal physical limits that affect the components. The pulse width used has direct consequences for the altitude coverage. Since the pulse width also determines the range resolution, there is a direct tradeoff between range resolution and range coverage. For this reason, many RWPs are operated in two modes: a low mode that uses a short pulse to achieve the best possible vertical resolution at the expense of vertical range, and a high mode that employs a longer pulse to maximize height coverage at the expense of resolution. The choice of mode is dictated by the intended use of the measurements.

The other important factor is the state of the atmosphere, as expressed by the volume reflectivity η . For RWPs, both the clear-air scattering caused by inhomogeneities in the refractive index at a scale of half the radar wavelength (the Bragg scale, $\lambda/2$) and the scattering induced by hydrometeors must be considered.

If the Bragg scale lies within the inertial subrange of fully developed turbulence (i.e., $l_0 \leq \lambda/2 \leq L_0$, where l_0 denotes the inner scale and L_0 the outer scale of the turbulence), the volume reflectivity of clear air η_{ca} can be related to the refractive index structure parameter by the Ottersten equation (31.21). For scales smaller than l_0 , the viscous dissipation of kinetic energy dominates and the turbulence spectrum is extremely small or zero [31.73]. This is crucial to understanding why the height coverage of a RWP decreases towards smaller wavelengths.

When hydrometeors are present in the radar resolution volume, it is safe for the RWP to assume that the particles are much smaller than the radar wavelength. If the particles are also randomly distributed in the radar resolution volume, the volume reflectivity for incoherent particle or Rayleigh scattering is

$$\eta_p = \int \sigma_\lambda(D)N(D)dD = \pi^5 |K|^2 \lambda^{-4} Z, \quad (31.41)$$

where $\sigma_\lambda(D)$ is the backscattering cross-section of particles of diameter D at wavelength λ , $N(D)$ is the particle size distribution, Z is the radar reflectivity factor, and $|K|^2$ describes the refractive index of the particle [31.66].

It is customary to restrict the discussion of RWP altitude coverage to the case of clear-air scattering [31.158, 159], which means that the vertical and temporal statistics of C_n^2 must be taken into account [31.17, 160, 161]. For a boundary-layer RWP, it is also important to consider Rayleigh scattering effects, which can drastically improve the maximum attainable height of useful radar returns.

Given the large number of factors that affect RWP performance, it is useful to group these radars into four main categories, as shown in Table 31.4.

There are, however, notable exceptions to these classes, such as the 55 MHz boundary-layer wind profilers in the Australian Wind Profiler network [31.28].

31.5.2 Accuracy

Estimating the accuracy of the meteorological parameters determined by RWP is a difficult task due to the large number of factors that influence the measurement process. For a monostatic pulsed RWP, the accuracy of the final wind data depends on:

1. The accuracies of the position and shape of the measurement volume determined by the radar hardware (antenna radiation pattern and range weighting function defined by the envelope of the transmit pulse and the receiver filter properties).
2. The correct identification of the scattering process that generates the receiver voltage signal, as this ensures that the motion of the air (i.e., the wind) is

Fig. 31.16 Long-term intercomparison of wind speed measurements obtained from a 482 MHz RWP and a collocated radiosonde

indeed inferred from an atmospheric echo, and any clutter or RFI signal component is sufficiently suppressed.

3. The accuracies of the estimates for the Doppler shift (the first moment of the Doppler spectrum).
4. The validity of the assumptions implicitly used in the wind retrieval algorithm, such as horizontal homogeneity and stationarity.

A problem with any of these factors will propagate and increase the uncertainty in the wind vector. It is possible to verify the accuracies of items (1) and (3) with well-defined test measurements using calibrated RF instruments. Indeed, such tests should be performed as part of regular maintenance activities to verify the correct operation of the radar hardware and possibly also some low-level signal processing algorithms. Item (2) needs to be addressed with proven, validated, and robust signal processing algorithms, assuming their correct implementation in software. The last item (4) is dependent on the (unknown) state of the atmosphere, which needs to be assessed by appropriate consistency checks in the wind retrieval algorithm.

A large number of publications have discussed the accuracy and precision of RWP data based on compar-

isons with independent wind measurements from meteorological towers, tethered balloon sounding systems, radiosondes, aircraft measurements, and Doppler lidars [31.18, 45, 111, 114, 122, 162–164]. Furthermore, numerical weather prediction assimilation systems are increasingly being used to estimate the quality of RWP data [31.106]. The latter method is especially important for operational quality monitoring.

A statistical intercomparison of more than 10 000 vertical profiles of the horizontal wind obtained with a 482 MHz RWP and a collocated radiosonde at Lindenberg during 2010–2018 is shown in Fig. 31.16. The absolute wind speed difference bias was found to be less than 0.2 m s^{-1} up to a height of about 10 km (the wind speeds obtained from the profiler were slightly smaller than the wind speeds provided by the sonde). For the tropopause region, the values increased but were generally less than 0.8 m s^{-1} . The RMSE was smaller than 1.3 m s^{-1} up to a height of 10 km, but above that the values steadily increased to almost 3 m s^{-1} in the tropopause region. The bias in direction was smaller than 1° for the full depth of the troposphere and peaked at about 5° near the tropopause. These values are comparable to or even better than the results of an intercomparison of data obtained in 1997 [31.165].

31.6 Quality Control

For early RWPs, quality control for clear-air radar measurements involved a subjective edit of the data performed by experts who were familiar with the instrument. While this could indeed identify and partially remedy many of the deficiencies of those early systems, it was usually limited to special research applications. Even today, this technique may be included in the training of new radar operators. However, this methodology is clearly impossible to apply to operational radars, so fully automated algorithms that remove clutter or RFI effects from the data and identify unreliable wind retrievals have been developed. It is interesting to note that these algorithms were first developed for the final wind data, before increasing computational power allowed spectral or even I/Q data to be processed in real time.

31.6.1 Signal Processing: Clutter and RFI Filtering

Ignoring the clutter term leads to errors during parameter estimation, the severity of which varies with the type, strength, and duration of the clutter. This became obvious soon after the installation of the NOAA-WPDN [31.24, 59], and the need for improved signal processing methods was quickly recognized, so work began to develop new algorithms. These algorithms fall into two main groups:

- Those that improve the estimation of Doppler moments [31.102, 166, 167]
- Those that improve the estimation of Doppler spectra [31.85, 93, 168].

However, not all of these algorithms have achieved widespread acceptance. Some overly complex moment estimation algorithms remain experimental, as they were found to be error-prone due to the excessive use of weakly justified a-priori assumptions, like constraint for the vertical continuity of the estimated Doppler values, especially under conditions of low SNR.

31.6.2 Consistency Checks

Quality control postprocessing was initially developed as a way to address issues that quickly became apparent with the very first operational RWP [31.23, 24]. Today, the importance of these postprocessing methods is greatly diminished due to significant improvements in signal processing methods that have resolved most of the practically relevant issues. However, a notable exception is the test for the homogeneity of the wind field during the retrieval process.

31.6.3 Numerical Weather Prediction: O-B Statistics and the FSOI

An important practical way of a statistical quality control for RWP data is provided by numerical weather prediction (NWP). During the assimilation step, it is useful to compare the measurements with the background of the model, which is a short-term forecast from a previous analysis. While the difference between the measurements and the background is also affected by model issues, these so-called observation minus background (O-B) statistics offer a convenient way to identify problems with the observing system [31.169]. An example is shown in Fig. 31.17.

Yet another interesting way to gauge the the data quality is through forecast sensitivity methods in variational or ensemble-based assimilation systems [31.170–172]. This approach is even more indirect than O-B statistics, but it has the advantage of being estimated at the end of the weather prediction process. The forecast sensitivity to observations index (FSOI) measures the relative contribution of the observation to the reduction in the forecast error. This parameter actually depends on many factors, not just the quality of the measurement; however, when the results from different observation systems of the same type are compared, this parameter can be used together with all the other quality control measures to assess the usefulness of a particular RWP system in a holistic way.

Fig. 31.17 O-B statistics from the UK Met Office for the Lindenberg 482 MHz RWP (© Crown copyright Met Office)

31.7 Maintenance

RWPs are complex technical instruments, and regular maintenance of all subsystems is needed to guarantee a high level of data quality. While the systems are typically specified to operate for 10–20 years without requiring major technical upgrades, the mean time between failures (MTBF) is less than this for various system components. It is therefore necessary for the user to develop, implement, and document policy and procedures for routine maintenance, both preventive and corrective. Competent staff are of the utmost

importance if all maintenance requirements and responsibilities are to be met.

Regular preventive maintenance of all essential system components is typically specified by the manufacturer of the radar system as well as by the vendors of the specific subsystems. This includes hardware, software, telecommunications, and ancillary systems such as the air conditioning or uninterruptible power supply. The typical interval between regular on-site preventive inspections is a year, but this depends on factors

such as the age of the instrument and the environmental conditions. Preventive maintenance is especially important for components that can degrade or even partially fail without obvious consequences for the data quality. Such incidents often remain undetected by quality monitoring systems. A prominent candidate for such a degradation is a phased array antenna: as it is an outdoor element, the antenna is exposed to humidity, precipitation, and radiation, and needs to withstand temperature changes of at least 50 K over the course of the year. On the other hand, the failure of a single antenna in a phased array is extremely difficult to detect in the final meteorological data. Although the overall array performance degrades, such subtle changes in performance characteristics typically remain hidden

31.8 Applications

RWPs are mainly used to measure the local vertical profile of the horizontal wind vector (Fig. 31.18), although there is a great deal of other information about the state of the atmosphere bound up in RWP data too. Wind profiling can be done as part of a local atmospheric analysis [31.173], to monitor the vertical wind shear at airports [31.174, 175], to facilitate the launch of space vehicles [31.176], to assess local air quality [31.177], to continuously monitor the dispersion conditions near potential sources of hazardous substances such as nuclear power plants [31.178], or even for hydrological purposes (e.g., the atmospheric river observatories [31.179] on the west coast of the USA).

However, most of the RWPs used in operational meteorology perform continuous monitoring of the vertical profile of the horizontal wind, which is used to initialize numerical weather prediction models [31.27, 180–183]. The particular advantage of these systems is their ability to provide data at a high temporal resolution under almost all weather conditions around the clock.

Beyond this standard application, special measurements can be performed for a wide variety of other purposes ranging from basic meteorological research to ornithology. There are a huge number of scientific questions that RWPs can help to answer, especially when the information they provide aside from the Doppler shift—such as the echo power or spectral width—is utilized. Examples include research into mesoscale upper-air wind structures [31.184], turbulence research [31.185],

behind the high variability of atmospheric scattering processes.

Remote monitoring and diagnostic systems can significantly increase the effectiveness of inspection and supervision activities, and can trigger on-site corrective maintenance. This monitoring should include technical parameters of the radar and its subsystems, ideally supported by built-in test equipment as well as the radar data at various stages of the processing. The ability of qualified staff to perform at least some diagnostic tasks remotely can significantly increase the efficiency of on-site visits, thereby helping to achieve greater overall system uptime and operational quality.

A comprehensive discussion of the various aspects of RWP maintenance can be found in [31.165].

estimating the boundary-layer depth [31.186, 187], investigating atmospheric waves [31.188], upper-air wind climatology [31.189], measuring the vertical wind component when investigating cloud dynamics [31.190], and quantitatively assessing bird migration for ornithological research [31.191, 192]. Many more examples can be found in topical reviews such as [31.193–195].

31.9 Future Developments

The longterm operational use of RWPs is demanding, but has been successfully demonstrated. However, it should be emphasized that this rather complex technology needs to be understood and managed correctly. In particular, users must have enough organizational and budgetary flexibility to ensure that the systems can be operated according to the state of the art. Unfortunately, there have been cases where a lack of commitment or even knowledge has led to embarrassing failures followed by disappointment. In hindsight, it is probably safe to say that most of these unsuccessful cases could have been avoided with greater consideration of the research-to-operations problem [31.196]. As stated in [31.197] the “transitions from development to implementation are frequently difficult, and, if done improperly, these transitions often result in ‘skeletons in Death Valley’.”

From a purely physical point of view, the future of RWPs is bright because there is no other remote-sensing method that can provide wind data for a significant vertical range regardless of the atmospheric conditions. Given the importance of the wind vector in meteorology, it is hard to imagine that radar wind profiling will become obsolete in the future.

However, as with every nontrivial problem, a few research questions remain also for RWP, some of which will be briefly touched upon below.

Although the theory of clear-air scattering is fairly well developed, it remains an area of active research [31.36, 40, 68]. This is not surprising, given

the involvement of the notoriously difficult turbulence problem. Discussions focus on issues such as the applicability of simplifying assumptions (e.g., the Fraunhofer versus the Fresnel approximation [31.69]) and the (vertical) velocity bias of RWPs [31.198]. It would also be desirable to extend the existing theory to include particle scattering effects.

Increasing interest in renewable energy has led to the rapid development of large wind turbines, which unfortunately produce peculiar clutter echoes with a rather complex time–frequency signal structure. These clutter echoes are received through the sidelobes of antennas, and the width of the spectrum is significantly increased by the rotation of the propeller blades. There is currently no standard signal processing algorithm that can suppress or filter out this type of clutter. However, new methods such as adaptive clutter suppression using array processing methods appear to be quite promising [31.199–201] and may have the potential to overcome these difficulties.

A prerequisite for the successful operation of a radar wind profiler is the existence of uncontaminated frequency bands, as the high sensitivity of RWPs make them vulnerable to any sufficiently strong external in-band radio-frequency interference. Frequency management therefore remains an important issue, as available regions of the frequency spectrum have become scarce. Effective protection of allocated frequency bands is needed to maintain the quality of radar wind profiler data.

31.10 Further Reading

RWPs are rather complex instruments, so an in-depth discussion of all technical and scientific aspects of RWPs is obviously beyond the scope of this handbook.

Even though the book *Radar Observations of Clear Air and Clouds* by Earl Gossard and Dick Strauch [31.31] was published more than 35 years ago, it still provides a fairly comprehensive yet concise overview of the science of clear-air radar observations. More detailed and interesting in terms of a historical perspective on MST radars are the contributions from Jürgen Röttger and Michael Larsen (*UHF/VHF radar techniques for atmospheric research and wind profiler applications*) [31.118] and Ken Gage (*Radar observations of the free atmosphere: Structure and dy-*

namics) [31.202] in the AMS monograph *Radar in Meteorology* edited by David Atlas and published in 1990.

As far as textbooks are concerned, *Doppler Radar and Weather Observations* by Dick Doviak and Dusan Zrnić [31.66] is considered a classic, although it is not easily accessible for the novice. The more recent book *Radar for Meteorological and Atmospheric Observations* by Sho Fukao and Kyosuke Hamazu [31.80] covers many important aspects of clear-air radars in considerable detail.

Finally, the monograph *Atmospheric Radars* by Wayne Hocking et al. [31.7], which focuses exclusively on MST radars, is an essential resource for researchers as well as practitioners.

Volker Lehmann

Meteorologisches Observatorium
Lindenberg
Deutscher Wetterdienst
Lindenberg, Germany
volker.lehmann@dwd.de

Volker Lehmann is head of the Remote Sensing Group of Lindenberg Observatory of the Deutscher Wetterdienst (DWD). He received a diploma degree in meteorology from Humboldt University of Berlin in 1990 and a PhD from Bayreuth University in 2010. His research focuses on the operational use of ground-based remote-sensing systems.

William Brown

Earth Observing Laboratory
National Center for Atmospheric Research
Boulder, USA
wbrown@ucar.edu

William Brown is a project scientist in the Earth Observing Laboratory at the National Center for Atmospheric Research in Boulder, CO, USA. He leads the Atmospheric Profiling Group, which deploys the Integrated Sounding System suites of profiling instruments such as wind profilers, lidars, soundings, and other instrumentation for the National Science Foundation. His research focuses on the development and applications of radar wind profilers.

Radar in the

32. Radar in the mm-Range

Gerhard Peters 

Part C | 32.1

Although the potential of mm-wave radar for cloud observation was demonstrated already in the 1950s, it took another 30 years before the technological development of microwave components and of digital signal processing allowed the realization of polarimetric Doppler radars, which became a crucial tool for cloud observations in various applications from climate modeling to weather services. This chapter provides an outline of cloud detection with radar, the historical development, contemporary cloud radar technology, and approaches for retrieving quantitative cloud parameters. The following refers to ground-based systems. The role of cloud radar in airborne applications and in upcoming space missions is addressed in Chap. 39 and Part D of this book.

Here, clouds are understood as areas with enhanced concentration of suspended particles causing reduced visibility. They play an important role in meteorology due to their impact on the radiation budget, the hydrological cycle, and atmospheric dynamics. While the composition of particles can be very different, we focus

here on the most prevalent, namely water in the liquid and solid phases. Clouds are complex objects that defy a stringent general definition. Nevertheless, depending on the scientific question, it is often possible to define sets of variables that are relevant for describing certain cloud properties and that are observable by cloud radar.

32.1 Measurement Principles and Parameters

Why are mm-waves favorable for cloud observations? Clouds are nearly invisible for weather radars in the centimetric or decimetric range due to the small size of cloud particles. Just increasing the radar sensitivity would not help, because other scattering mechanisms, such as ground clutter or clear-air scattering would obscure the weak cloud signal. Since the scattering cross section of particles, which are small compared to the wavelength λ , is proportional to λ^{-4} , the use of shorter

waves specifically increases the scattering cross section of small particles, while the above-mentioned obscuring effects tend to become weaker. The typical wavelength of cloud radars is one order of magnitude shorter compared with weather radars. This corresponds to 40 dB enhancement of the cloud particle scattering cross section. Even more intense scattering at cloud particles would occur in the optical range, but optical waves cannot penetrate clouds. Thus, the mm-range is a tradeoff

Table 32.1 Measured primary variables of a mm-wave cloud radar

Variable	Description	Unit	Symbol
Received power	Backscattered power collected by the radar receiving antenna	W	P_r
Doppler spectrum	Spectral backscattered power as function of frequency f	W s	$s(f)$
Line-of-sight or radial velocity	First moment of spectrum	m s^{-1}	v_r
Spectral width	Standard deviation of spectrum	m s^{-1}	σ_v
Skewness	Deviation from symmetry of spectrum	–	SK
Kurtosis	Tailedness of spectrum	–	KU
Linear depolarization ratio	Ratio between received power in the cross-polarized and copolarized receiving channel	–	LDR

Table 32.2 Selection of secondary variables

Variable	Description	Unit	Symbol
Volume reflectivity	Backscatter cross section per volume	m^{-1}	η
(Equivalent) reflectivity factor	In the case of small water droplets: 6-th moment of drop-size distribution	$\text{mm}^6 \text{m}^{-3}$	Z_e, Z
Attenuation	Dissipation of wave energy per unit path due to interaction with matter divided by the local energy flux	m^{-1}	κ, κ_{wc}
Path-integrated attenuation	Relative reduction of energy flux after passing an attenuating medium	–	PIA
Liquid water content	Mass of condensed water per volume	kg m^{-3}	LWC
Ice content	Mass of ice per volume	kg m^{-3}	IWC
Particle size	Diameter of an equivolumic sphere	m	D
Radial wind velocity	Projection of velocity on the radar beam of tracers carried with the wind	m s^{-1}	w
Terminal fall velocity	Fall velocity of particles, when equilibrium of gravity acceleration and drag has been reached	m s^{-1}	v_t
Cloud thickness	Distance between cloud base and top	m	
Target class	Qualitative description of the type of targets (e.g., cloud drops, rain drops, ice crystal type, type of agglomerate, insects, seeds, ash)		

between scattering strong enough to be detectable and weak enough to allow penetration of clouds. Thus, mm-wave radars allow the observation of the inner structure of clouds, including multiple cloud layers.

Primary measured variables of a cloud radar do not contain any assumptions on the wave propagation or the scattering process. They comprise the received scattered power, its frequency distribution (spectrum), and spectral parameters. In the case of a dual-polarization receiver, these variables can be measured in different polarization states. In the case of linear polarization, one plane coincides with the transmitter polarization (cochannel) and the other one is orthogonal to it (cross channel). Full polarimetric radars can measure these variables also as function of the transmitter polarization. All variables are measured as functions of range.

A not-exhaustive list of primary variables, measured by a mm-wave cloud radar, is shown in Table 32.1. The actual set of variables can be much more comprehensive and depends on the design and complexity of the radar.

Secondary variables represent physical cloud properties and are derived from the primary variables using the physical relations of wave propagation, scattering processes, and target properties. They comprise volume reflectivity, cloud extension, cloud particle characteri-

zation, including their phase, turbulence intensity, and cloud water content. A selection of secondary variables is shown in Table 32.2.

A basic secondary variable is the equivalent reflectivity factor Z_e . It is related to P_r by

$$Z_e = \frac{1}{C} \frac{P_r}{P_t} \text{PIA} \frac{\lambda^4}{\pi^5 |K_w|^2} r^2, \quad (32.1)$$

where C = radar calibration constant, P_t = transmitted power, PIA = path-integrated attenuation (two-way), $K_w = (n_w^2 - 1)/(n_w^2 + 2)$, n_w = complex refractive index of water, and r = range. The idea behind the introduction of Z_e is the comparability of radars with different wavelengths; Z_e is in the Rayleigh range (drop diameter D small compared to λ) and, in the case of liquid phase, a descriptor of the drop-size distribution $N(D)$, which does not depend on the wavelength

$$Z_e = Z \equiv \int_0^\infty N(D) D^6 dD \quad \text{for } D \ll \lambda. \quad (32.2)$$

The subscript of Z_e is a reminder that the Rayleigh approximation is not always valid in case of mm-waves.

Fig. 32.1 Range of reflectivity (Z_e in $\text{mm}^6 \text{m}^{-3}$) for precipitation and clouds versus condensed water content. *Red area*: precipitation (rain [32.1] and snow [32.2]); *blue area*: clouds (water cloud [32.3] and ice cloud [32.4])

The range of Z_e -values expected for precipitation (red) and clouds (blue) is shown in Fig. 32.1 as a function of the condensed water content, referred to as CWC. It may be liquid water LWC, ice water content IWC, or a mixture of both. The thin dashed lines indicate the functions for monodisperse liquid particle sizes with diameters from $1 \mu\text{m}$ to 10mm .

Although there is no sharp distinction between clouds and precipitation, there is a conventional threshold of particle size at $D_t = 0.2 \text{mm}$ (thick black dashed line in Fig. 32.1). The rationale for this choice is the transition between dominating particle growth processes at this size. Smaller cloud particles tend to grow primarily by condensation, while larger particles grow by capturing smaller (more slowly falling) particles. The fall velocity of droplets with $D = D_t$ is $\approx 0.75 \text{m s}^{-1}$.

The thick colored lines represent the mean empirical relations between Z and CWC:

- Rain: $Z_e = 11\,080\text{LWC}^{1.75}$ [32.1]
- Snow: $Z_e = 14\,027\text{ICW}^{2.57}$ [32.2]
- Water cloud: $Z_e = 0.068\text{LWC}^{1.9}$ [32.3]
- Ice cloud: $Z_e = 25.5\text{ICW}^{1.44}$ [32.4].

The slopes of the empirical functions are always steeper than for the monodisperse case. This reflects the fact that higher values of CWC are correlated with a shift of the particle-size distribution $N(D)$ towards larger diameters.

It is obvious – particularly for clouds – that CWC cannot be retrieved with reasonable accuracy from Z_e without further knowledge about the particle habits. In the cloud domain, CWC varies by up to two orders of magnitude, depending on the phase for a given value of Z_e . The liquid and solid phases may coexist in clouds with any partitioning. Moreover, clouds may contain precipitation. In that case, the reflectivity tends to be dominated by the larger precipitation particles, even if their contribution to CWC is small. The range of ambiguity can be narrowed by analysis of the Doppler spectra structure, by use of multiple frequencies, by polarimetric measurements, and by combination with other observation techniques, such as, for example, lidar or radiometry. These techniques will be outlined in Sect. 32.3. A more in-depth introduction to the use and potential of mm-wave radars for cloud research can be found in [32.5], and a general overview of remote-sensing technologies for cloud studies is given in [32.6].

32.2 History

The first systematic survey of the capability of radar for cloud observation was carried out by *Vernon G. Plank* and coworkers in 1951–1952 [32.7]. It was based on existing knowledge of cloud particle-size distributions [32.8–10] and on radar data, collected for a period of 3 years with a 12.5 mm radar operated by the US Air Force Cambridge Research Center in the Boston, Massachusetts, area. The data were supplemented by sky-camera pictures, human observations, and aircraft missions. A correlation between detectability and internationally defined cloud types was established. It was concluded that nonprecipitating water clouds have the lowest scattering cross sections, while the ice phase is more favorable to being detected by radar. The visual and radar observations of the cloud base were often found to disagree. This was attributed to drizzle falling through the cloud base and evaporating at some distance below the cloud. The detection threshold of that early radar was -22 dBZ at a 1 km range. The authors were aware that most nonprecipitating clouds could not be detected with this modest sensitivity (Fig. 32.1). Recording techniques were still in an embryonic stage. The time–height cross section of signal power was stored on paper tape in gray-scale values produced by a facsimile recorder. Records of quantitative signal power were made by a *pulse integrator*-hardware, which was applied to selected range gates. Digital signal acquisition techniques and spectral analysis of radar signal time series were still far off the

horizon. Nevertheless, the main findings of this study are still valid.

In view of the missing Doppler capabilities of radars, it was suggested in [32.11] to use relations between the (unobserved) spectral width of the radar signal and statistical properties of the observable signal power time series (referred to as *audio signal*). In [32.12, 13], the performance of dedicated hardware devices was analyzed to estimate the spectral width (R-meter) and the mean Doppler velocity (frequency tracker) of weather echoes. These early steps towards Doppler radar techniques were prone to large systematic errors, depending on the signal-to-noise ratio and on the spectral width of the signals [32.13]. The first radars with satisfying sensitivity for cloud observation with 8.5 mm wavelength (K-band) were operated by the US Air Force in the late 1960s and early 1970s [32.14]. Nevertheless, the gain of insight into cloud physics remained limited by these one-parameter observations. A K-band system with all contemporary features of a cloud radar, including pulse-pair and Fourier analysis, as well as the retrieval of polarimetric variables, was developed at the NOAA Wave Propagation Laboratory [32.15]. It stimulated the development of increasingly sophisticated cloud radars in the mm-range at various laboratories in the 1980s, mainly in the United States. The introduction of a 3.5 mm-wavelength (W-band) cloud radar in 1987 [32.16] opened the path towards multifrequency mm-wave cloud observations.

32.3 Theory

In the following sections, some secondary variables and the corresponding retrieval schemes are described. They are arranged in the order of increasing complexity, which approximately agrees with the historical development.

32.3.1 Reflectivity Factor

The received power is related to the volume reflectivity η by the radar equation according to

$$\eta = \frac{1}{C} \frac{P_r}{P_t} \text{PIA} r^2; \quad (32.3)$$

η is converted into the equivalent reflectivity factor Z_e by

$$Z_e = \frac{\lambda^4}{\pi^5 |K_w|^2} \eta. \quad (32.4)$$

The combination of and (32.3) and (32.4) yields (32.1); K_w is nearly constant and by convention is set equal to 0.93 in (32.4). For some applications (e.g., [32.4]), the reflectivity of ice clouds is converted in Z_i , which is obtained by using the complex refractive index of ice in (32.4). This leads to

$$Z_i \cong 5.28 Z_e. \quad (32.5)$$

The exact relation depends on frequency and temperature.

An example for a high reaching cloud is shown in Fig. 32.2. At 16:50 UTC precipitation reaches the ground, and the melting layer becomes visible at 3.5 km height (bright band). The dotted ground-based layer of weak reflectivity (-30 dBZ) reaching up to 2 km is caused by insects and organic debris, sometimes referred to as atmospheric plankton.

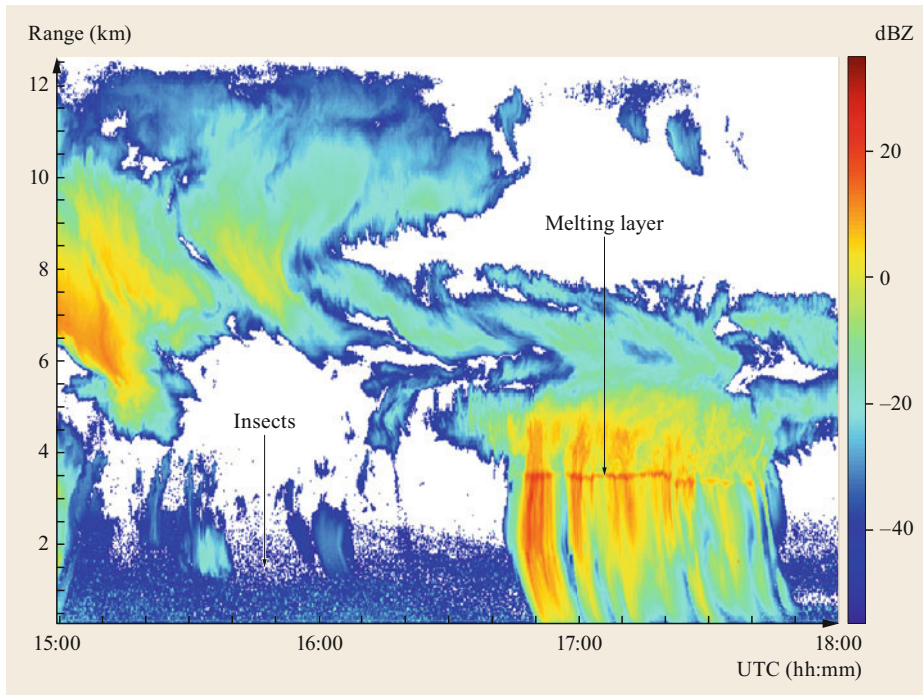

Fig. 32.2 Equivalent reflectivity factor from high reaching clouds (Date: 27.07.2006, 14:59–18:00)

32.3.2 Attenuation

Millimeter waves are attenuated in the atmosphere by gaseous absorption and by hydrometeors. Particularly, the attenuation by rain imposes a limitation to the range of mm-wave radars and prevents their use as universal weather radars. The local attenuation is defined as

$$\kappa(r) = \frac{1}{2} \left. \frac{\partial \text{PIA}(r')}{\partial r'} \right|_r. \quad (32.6)$$

At vertical incidence, attenuation is less important, because the range is anyway limited due to the depth of the troposphere, but nevertheless attenuation must be considered for all retrievals, which are based on calibrated values of radar reflectivity. Therefore, so-called window frequencies are preferred for cloud radars. They are between attenuation peaks at 23, 60, and 118 GHz, caused by molecular absorption of atmospheric water vapor and oxygen [32.17].

The attenuation κ_{CWC} by small particles increases monotonically with frequency and is a combined effect of scattering and absorption. In the case of water clouds, which are free of precipitation, absorption is the dominating contribution to attenuation. In the Rayleigh domain, it is linearly related to the liquid water content and can be described analytically (e.g., [32.18]) by

$$\kappa_{\text{LWC}} = \frac{82}{\lambda} \text{Im}(K_w) \text{ dB km}^{-1} \text{ kg}^{-1} \text{ m}^3, \quad (32.7)$$

κ_{LWC} can be calculated as a function of frequency and temperature by using, for example, the model in [32.19]. The attenuation is not only a disturbing mechanism, but it can also be exploited for estimating cloud-LWC. The strong attenuation of mm-waves allows its retrieval on reasonably short path lengths and at moderate values of LWC. An attractive feature of κ_{LWC} is its weak dependence on the drop-size distribution, which avoids uncertainties in retrieval schemes based on the reflectivity (Fig. 32.1). A further advantage of estimating attenuation is the independence of radar calibration, because only ratios of reflectivity are considered. While some drizzle is allowed for the application of (32.7) in clouds, it is not valid for rain, because the Rayleigh approximation is not applicable for larger rain drops in the mm-wave range. Nevertheless, relations between attenuation and rain rate, based on field data and on simulations, also show only weak dependence on the drop-size distribution at mm-wave frequencies [32.20]. Consequently, this property was exploited for estimating rain rates from attenuation retrievals of a vertically pointing K-band radar [32.21]. The application of the method is limited because it crucially depends on the homogeneous reflectivity on the attenuation path. This limitation can be overcome by using more than one radar frequency (Sect. 32.3.5). Typical values of attenuation by atmospheric gas molecules, liquid clouds, and rain for two frequencies are shown in Table 32.3.

Table 32.3 Attenuation for two frequencies (35 and 94 GHz) according to [32.22]

Parameter	Attenuation (dB km ⁻¹)	
	for 35 GHz	for 94 GHz
Atmospheric gas molecules		
Water vapor density = 2.5 × 10 ⁻⁴ kg m ⁻³	0.04	0.042
Water vapor density = 2.5 × 10 ⁻² kg m ⁻³	0.35	2.1
Liquid clouds		
LWC = 0.3 × 10 ⁻³ kg m ⁻³	0.3	1.47
LWC = 5 × 10 ⁻³ kg m ⁻³	0.96	24.5
Rain		
Rain rate = 0.3 mm h ⁻¹	0.06	0.35
Rain rate = 10 mm h ⁻¹	2	7

The absorption by ice particles is negligible. So – within some limits – the attenuation is a specific indicator of the liquid phase. The main effect of ice crystals on the propagation of mm-waves is scattering. If scattering becomes so strong that it contributes significantly to the total attenuation of the direct wave, attenuation-based retrieval methods may become impractical.

Multiple scattering can be an issue at W-band frequencies for airborne and space-borne applications in the case of strong precipitation, where the size of the radar footprint may become comparable with the free photon path length [32.23]. This introduces additional complication, because the basic radar equation is no longer applicable for converting received power versus time into reflectivity versus range.

32.3.3 Doppler

If the scattering targets move with respect to the radar, the frequency of the backscattered signal is shifted (nonrelativistic approximation) by

$$f_D = -2\frac{v}{\lambda}, \quad (32.8)$$

with v = the radial velocity component (positive away from the radar); f_D is derived from the phase shift $\Delta\phi$ between subsequent echoes separated by the pulse repetition time t_p according to

$$f_D = \frac{1}{2\pi} \frac{\Delta\phi}{t_p}. \quad (32.9)$$

Combining (32.8) and (32.9)

$$v = -\frac{\lambda}{4\pi} \frac{\Delta\phi}{t_p}. \quad (32.10)$$

Application of (32.10) requires that t_p be shorter than the coherence time τ of the scattered signal. For

ground-based radar, this condition is generally satisfied. (This is not the case for lidar wavelengths.) Then, the spectral resolution is ultimately limited by the analysis time T ($\delta f \propto 1/T$), and δf can be chosen small enough such that the observed spectral width σ is dominated by physical processes in the scattering volume. The most important contributions (inertial forces are neglected) to σ are

$$\sigma^2 = \frac{4}{\lambda^2} \sigma_t^2 + \frac{4}{\lambda^2} \sigma_p^2 + \frac{4}{\lambda^2} \sigma_m^2 + \frac{4}{\lambda^2} \sigma_s^2 + \sigma_d^2, \quad (32.11)$$

σ_t and σ_p are the spreads of turbulent velocity and of particle fall velocity distribution in the scattering volume; σ_m is the beamwidth broadening; $\sigma_m = u\sigma_\phi$ with u = transversal wind and σ_ϕ = beam-width; σ_s is caused by the horizontal and vertical shear of the radial wind component, and σ_d is the so-called dwell time broadening. In the case of a vertical beam $\sigma_d \propto u/(\sigma_\phi h)$, with h = height above the radar.

The motion of airborne particles is controlled by the drag of the ambient air and by gravitation. On a horizontal beam, the Doppler velocity is not affected by gravitation and indicates the horizontal wind component in the beam direction. At vertical incidence, the Doppler shift depicts the vertical motion of particles. The fall velocity – relative to ambient medium – represents an equilibrium between the drag and gravitational force, which is called terminal particle fall velocity v_p . For cloud drops ($D < 0.1$ mm) Stokes' law applies

$$v_p(D) = -\frac{1}{18} \frac{(\rho_w - \rho_a) D^2 g}{\mu}, \quad (32.12)$$

with ρ_w the density of water, ρ_a the density of air, μ the dynamic viscosity of air, and g gravity acceleration. For larger drops, the relation becomes more complicated; v_p of rain drops [32.24] has been determined in laboratory measurements as a function of the equivolumic diameter D at standard atmospheric surface conditions. The use of $v_p(D)$ for the retrieval of drop-size distributions from Doppler spectra was suggested in [32.25], and this concept was adopted in [32.26] to design a compact low-power rain radar at 24 GHz.

The observed vertical velocity v of particles is the sum of the vertical wind component v_t and v_p , $v = v_t + v_p$. For small and other slowly falling particles, v_t can be the dominating contribution to v . This is demonstrated in Fig. 32.3. for the same example as Fig. 32.2. Before the onset of precipitation and above the melting layer, the velocities (Fig. 32.3a) are close to zero with upward and downward excursions. We assume that these velocities are dominated by v_t , so that (a slightly biased) map of the turbulent vertical wind component is provided here. After onset of precipitation, the motion

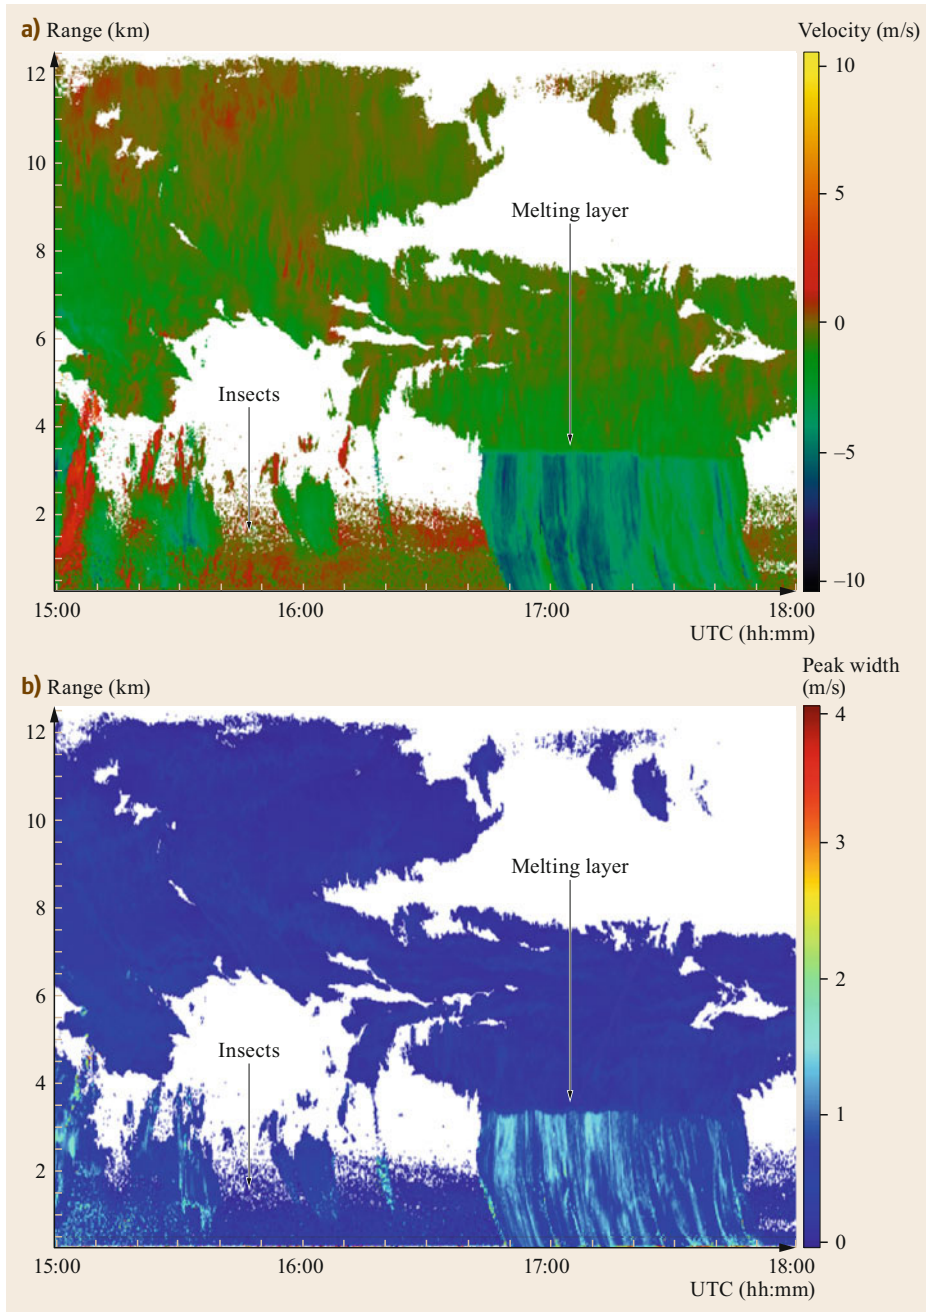

Fig. 32.3a,b The same example as in Fig. 32.2 but with (a) Doppler velocity and (b) spectral width (Date: 27.07.2006 14:59–18:00)

below the melting layer is consistently downward, with $|v|$ up to 6 m/s. Here, the fall velocity v_p is the dominating contribution to v . This interpretation is supported by the spectral width (in terms of velocity) shown in the Fig. 32.3b. We assume that σ is dominated by the first two terms of (32.11). The sudden increase from 0.1 to 1.5 m/s can be explained by the spread of fall velocity related to the rain drop-size distribution. The enhanced

values of σ in the left lower corner coincide with strong shear accompanying updrafts (Fig. 32.3a).

A scheme for deconvolution of Doppler spectra with respect to turbulence and particle-size distribution was described in [32.27] and demonstrated in [32.28] for K-band cloud radar data. It was applied in [32.29] to cirrus clouds and used for establishing a climatology of microphysical cirrus cloud properties [32.30]. These

schemes were based on pulse-pair analysis [32.31], which provides the first three moments of the Doppler spectrum. With the advent of affordable realtime spectrum analyzers, it was possible to observe more features of Doppler spectra. The multippeak structure occurring in mixed phase clouds and in drizzling clouds was exploited in [32.32] by using the slow-motion peak for estimating the vertical wind component and for retrieving v_t from $v_t = v - w$. Even overlapping cloud and drizzle spectra were separated in [32.33] by analyzing higher spectral moments in cloud regions, where drizzle is initially produced and does not yet dominate the reflectivity. Often, only the first two terms of (32.11) need to be retained. For these conditions, [32.34] proposed a scheme to separate σ_t and σ_p in (32.11) by independent estimation of turbulence via the time series of v . This way, σ_p may be retrievable in precipitating clouds to validate microphysical model parameterizations.

The potential of applying optimal estimation techniques to higher spectral moments for retrieving microphysical properties and turbulence parameters in ice clouds was demonstrated in [32.35]. The use of the structures of the Doppler spectra of rain echoes, which are caused by non-Rayleigh scattering, to separate v_t and w was suggested in [32.36]. The method works at W-band frequencies or higher, if sufficiently large rain drops exist.

A side-application of scanning mm-wave Doppler radars is the retrieval of wind profiles using Doppler beam-swinging methods, as was described in earlier chapters for other wavelengths. Albeit disturbing for the observation of clouds, particle targets in cloud-free regions are helpful tracers for this application.

32.3.4 Polarimetry

Polarization techniques as described in Chap. 30 are also used in mm-wave radars for target classification and quantitative estimation of cloud contents. A standard application is the distinction of biological targets (insects, seeds) from clouds using the linear depolarization ratio, referred to as LDR. The shape of biological targets tends to deviate from circular symmetry, and the particles are relatively large. Therefore, biological targets show much higher values of LDR than cloud particles do. This can be used for target separation, as is shown in Fig. 32.4. The time–height cross sections of the signal-to-noise ratio, referred to as SNR, and LDR were measured with a vertically pointing K-band radar (MIRA 36) at the German Meteorological Service in Lindenberg [32.37]. Figure 32.4a shows the SNR of the backscattered signal, which is dominated here by biological targets reaching up to 3 km AGL. This is suggested by LDR values of more than -10 dB, shown in

Fig. 32.4b. The black dotted lines indicate the cloud base detected by an optical ceilometer. After removing all pixels exceeding a certain threshold of LDR, in Fig. 32.4c only structures above the ceilometer-detected cloud base remain (with a few exceptions), which reveals the passage of thin boundary layer clouds.

The observation of other polarimetric parameters requires the transmission of two polarization states or at least hybrid mode operation [32.38] (this is explained in Chap. 30). They provide additional information about the microphysical habit, based on preferred particle orientations with respect to the radar pointing axis [32.39]. Deviations from uniform orientation distribution are typically related to gravitational forces and are, therefore, observable only on nonvertical beams.

32.3.5 Multifrequency

Under some conditions the combination of two or more radar frequencies can provide more information than the sum obtained by using the individual frequencies. While numerous studies consider the synergy of wavelengths ranging from meter to millimeter, we restrict the discussion to the combination of mm-waves.

In Fig. 32.5, the two-way path-integrated attenuation PIA for a 1 km range is shown as function of LWC for two window frequencies in the case of nonprecipitating water clouds (solid lines) based on (32.7) and for rain (dashed lines) based on empirical relations compiled in [32.40]. The rain rate corresponding to the liquid water content assuming exponential drop-size distributions according to [32.41] is indicated by the black dotted line.

LWC of stratocumulus clouds can be retrieved with reasonable accuracy according to [32.42] by combining vertically pointing radars at 35 and 94 GHz and evaluating the dual-wavelength ratio DWR_i (dB) $\equiv Z_{35,i}$ (dBZ) $- Z_{94,i}$ (dBZ) at two heights h_i ($i = 1, 2$) using the equation

$$LWC = \frac{1}{\kappa_{LWC94} - \kappa_{LWC35}} \times \left[\frac{DWR_2 - DWR_1 - \beta}{2(h_2 - h_1)} - \alpha_{94} + \alpha_{35} \right], \quad (32.13)$$

where

$$\beta = 10 \log_{10} \left[\frac{|K_{35}(T_2)|^2 |K_{94}(T_1)|^2}{|K_{35}(T_1)|^2 |K_{94}(T_2)|^2} \right] \quad (32.14)$$

is a small correction accounting for the temperature dependence of K , and α is the gaseous absorption. In

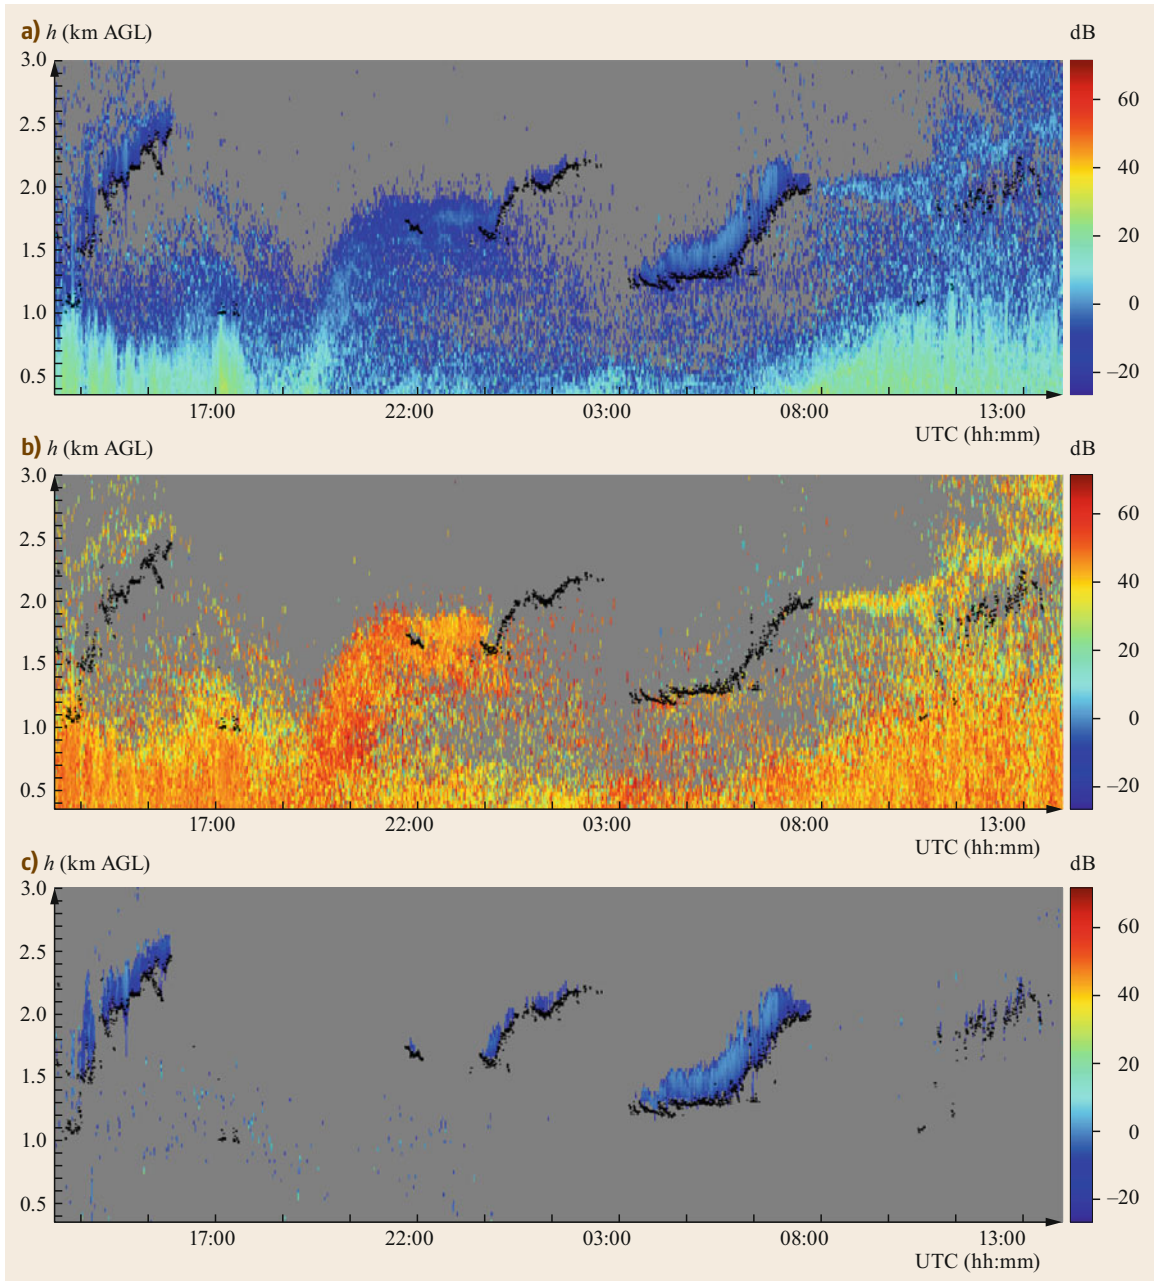

Fig. 32.4 (a) K-band echoes (SNR) from thin boundary layer clouds and from biological targets, (b) linear depolarization ratio, (c) all pixels removed where LDR exceeds a certain threshold (removal of biological targets). (a–c) Black dots indicate cloud base, detected by optical ceilometer (after [32.37])

Fig. 32.5, we recognize that significant differences of PIA exist between the two frequencies. It is also obvious that the result of (32.13) would be biased, if there were rain instead of cloud droplets between h_1 and h_2 . In rain clouds, rain and cloud drops coexist, and it depends on the partitioning whether the bias is acceptable.

The authors pointed out that some light drizzle is tolerable, even if it is the dominating backscatter source due to the D^6 proportionality.

An attractive feature of attenuation-based retrieval of LWC is its independence of the drop-size distribution for cloud droplets and only weak dependence in the

Fig. 32.5 Two-way path integrated attenuation PIA (for a 1 km range) and rain rate as function of liquid water content

case of rain. At higher rain rates, the attenuation is not only caused by absorption, but also scattering at larger particles extracts energy from the original wave.

If particle sizes are above the upper limit of the Rayleigh regime at least for the shorter wavelength, the ratio of the observed reflectivities at two frequencies allows inferences on the particle-size distribution (referred to as PSD). This was demonstrated in [32.43] for the crystal size of cirrus clouds observed with K- and W-bands. Snow PSDs and pertinent bulk parameters were estimated successfully in a similar approach in [32.44], combining reflectivities observed in Ka(35 GHz)- and Ku(13.6 GHz)-bands.

An extension of dual-frequency analysis to rain was demonstrated in [32.45]. The authors used the Mie oscillations of the scattering cross section at the W-band to separate the vertical wind from the (size-dependent) particle fall velocity, as proposed earlier in [32.46]. The novel element of this method [32.47] is the use of the Rayleigh part of the spectra (small particles) to estimate the differential attenuation and to use this information for correcting the reflectivity ratio in the non-Rayleigh part of the spectra. The result is a self-calibrated drop-size distribution including an estimate of vertical wind and turbulent broadening.

The potential benefit of a third radar frequency (combination of Ku-, Ka-, and W-bands) for separating snowflake classes, like aggregates and spheroidal particles, and for retrieving basic PSD parameters was discussed in [32.48]. Observational evidence for a direct

link of these model-based scattering regimes to bulk snowfall density, habit, and particle size was shown in [32.49, 50]. These studies suggest that traditional scattering calculations based on medium refractive index approximations are insufficient to explain the observed Z_e -variability in the triple frequency space. More advanced scattering schemes using discrete-dipole approximation seem to be significantly superior in linking the observed triple-frequency signatures with snowflake aggregation [32.51] and riming [32.52].

The upper three panels in Fig. 32.6 show simultaneous W-, Ka-, and X-band reflectivities measured during TRIPEX in the winter season of 2015, together with isolines of temperature (0 and -15°C). The corresponding differential reflectivities are shown in the lower two panels. In [32.53], methods how microphysical processes in the ice phase, such as, for example, aggregation and riming, can be deduced from such data are described.

32.3.6 Combination of Methods and Synergy with Other Remote-Sensing Techniques

While radar provides excellent spatial resolution, the quantitative relation between radar observables and physical variables of interest is often ambiguous. The characteristics of microwave radiometry are complementary to some extent. The spatial resolution is poor, but the retrieval of path-integrated values of physi-

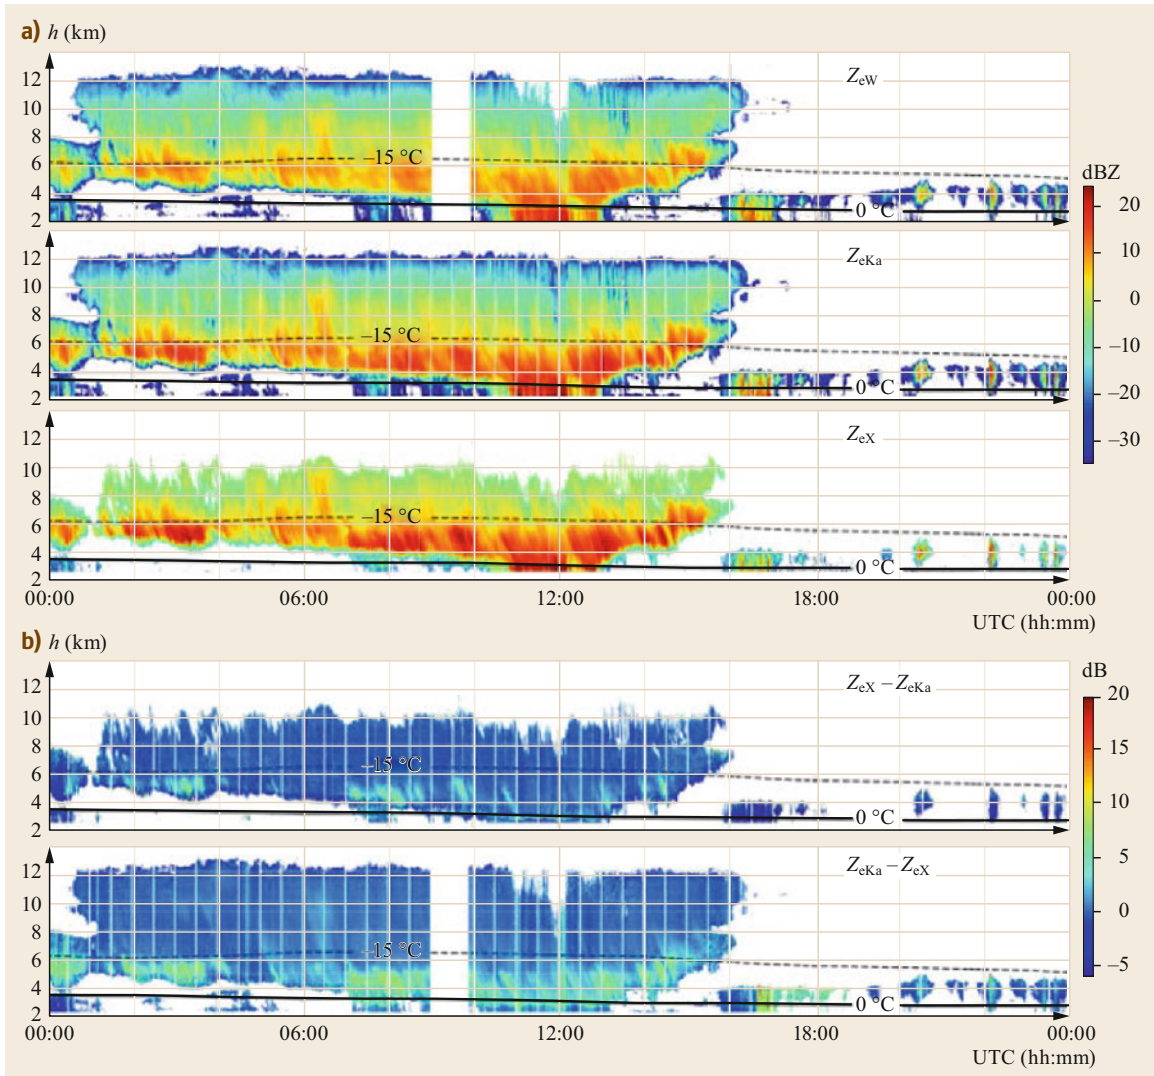

Fig. 32.6a,b Triple-frequency reflectivities measured on 20.11.2015 during TRIPEX (triple-frequency and polarimetric radar experiment). (a) Z_{eW} , Z_{eKa} , Z_X . cal variables, such as, for example, the liquid water path, are sometimes straightforward. Therefore, the combination of radiometers and mm-wave radar was suggested to describe the content distribution of water clouds [32.54, 55]. An optimal estimation framework that includes ceilometer cloud base information to retrieve physically consistent profiles of temperature, humidity, and cloud LWC was developed and demonstrated in [32.56]. The algorithms for operational cloud

characterization in the European CLOUDNET program using data from mm-radars in combination with microwave radiometers, lidars, and models are described in [32.57]. Continuing research aims at improving the quality and extending the range of retrieved variables within CLOUDNET, such as, for example, the quantitative separation of mixed-phase cloud contents using a suite of active and passive ground-based remote-sensing devices, including mm-wave radar [32.58].

32.4 Devices and Systems

The basic design of mm-wave cloud radars does not differ from that of weather radars. Most systems use pulsed transmitters, which can be divided into two classes. One uses magnetron transmitters, where the pulse-to-pulse coherence is achieved on the receiver side by storage of the phase of each transmitted signal [32.59]. The range resolution δr is related to the pulse width τ by $\delta r = c\tau/2$. The other class uses phase-stable continuous sources and switched transmit amplifiers with typically lower peak power than magnetrons. Here, the mean transmit power can be

increased by using longer transmit pulses, which are phase or frequency-coded, such that $\delta r \ll c\tau/2$ can be achieved [32.60]. The most efficient use of transmit power is made by continuous transmission. Here, the ranging is achieved by frequency modulation of the transmitted signal and frequency analysis of the heterodyne signal (FMCW radar (frequency-modulated continuous-wave radar)). Except for radars with very low transmit power, as used in [32.61], a separate antenna is needed for the receiver. A very sensitive FMCW W-band cloud radar is described in [32.62].

32.5 Specifications

In Table 32.4, specifications of some commercially available mm-wave radars are compared. Based on the radar equation for beam-filling water droplets in the Rayleigh range, the minimum detectable reflectivity was estimated. For all radars, the same range, resolution, averaging time, and losses in wave guides and T/R-switch were assumed. In addition to the Rayleigh dependence $\propto \lambda^4$, a factor $\lambda^{-0.5}$ was introduced, which describes the effects of wavelength-dependent coherence time on the SNR after some time of incoherent averaging. The most sensitive radar was used as a reference system for normalization of a *figure of merit*

(FOM), which is here defined as follows

$$\text{FOM} = 10 \log \left[\left(\frac{\lambda_0}{\lambda} \right)^{3.5} \frac{A_e \bar{P}_t}{A_{e0} \bar{P}_{t0}} \right] - \text{NF}, \quad (32.15)$$

with $A_e \equiv G\lambda^2/(4\pi)$ effective antenna area and \bar{P}_t mean transmit power and NF noise figure of the receiver. The index 0 indicates the reference system. Insertion losses in waveguides etc., are assumed identical in all systems.

The calculation is based on specifications as published in the documents [32.59, 62–64].

Table 32.4 Specifications of some commercial cloud radars (EIKA: Extended Interaction Klystron Amplifier; TWTA: Extended Interaction Klystron Amplifier)

Radar trade name	WACR	KAZR	MIRA36	RPG-FMCW-94	MRR
Manufacturer	ProSensing	ProSensing	Metek	RPG radiometer physics	Metek
Ranging method	Pulse compression	Pulse compression	Pulse	FMCW	FMCW
Mean transmitted power \bar{P}_t (W)	1.5	50	30	1.5	0.03
Frequency (GHz)	95	35	35	94	24
Transmitter type	EIKA	TWTA	Magnetron	Solid state	Solid state
Antenna type	Monostatic	Monostatic	Monostatic	Bistatic	Monostatic
Antenna gain G (dBi)	59.5	57.5	54.5	51.5	40.1
Effective antenna area A_e (m ²)	0.71	3.3	1.6	0.11	0.13
Noise figure NF (dB)	5.5	2.4	3	3	18
FOM (dB)	0	−2	−6	−16	−62

32.6 Quality Control

The quality of radar products can be deteriorated by various categories of influences. Generally, retrieval algorithms imply disregard or only first-order consideration of influencing physical variables (e.g., attenuation, target class, ground clutter). The management of such uncertainties should be an integral part of the retrieval algorithm, while the purpose of quality control is to monitor all relevant technical specifications of the radar system.

The most demanding is the validation of the absolute whole-system calibration S , which includes all system-related factors of the radar (32.1)

$$S = \frac{1}{C} \frac{P_r}{P_t} \quad (32.16)$$

Usually, cloud radars contain sensors, which monitor the transmit power, the impedance match of the antenna, and the transmit frequency and transmit pulse envelope. These and other housekeeping data should be stored in a log file. Often, the operation scheme of the radar includes a periodic recalibration mode, where the receiver gain and system noise figure are measured by switching the receiving channels to a calibrated noise source. These results can be compared with the noise level measured in clear air conditions to detect potential drifts of the noise source calibration. The stability of transmit power measurement is checked either by redundant sensors or by manual inspections. Verification of the antenna efficiency is the most difficult element of quality control. The degradation of sensitivity due to mechanical deformation increases with increasing antenna gain.

For scanning radars, antenna pattern measurements using a calibrated radio source or receiver yield SP_t or S/P_t . The sun can serve as a well-defined radio source. While the above-mentioned procedures provide only subgroups of factors constituting S , direct determination of S is possible by scanning an artificial, calibrated target. If the position of the target with respect to the radar is determined by an independent survey, also the ranging accuracy of the radar can be verified.

In some applications (e.g., multifrequency, polarization diversity, or radar network operation), a degree of agreement between participating systems is required, which is difficult to achieve by independent absolute calibration. Here, one may resort to a relative calibration, which is achieved by evaluating simultaneous measurements in common scattering volumes. In the case of multifrequency or polarization diversity, suitable meteorological conditions that allow a most accurate interpretation must be selected (e.g., negligible PIA, weak drizzle with spherical drops in the Rayleigh regime for all frequencies, exclusion of ice phase, absence of other contaminating targets, ...). For network homogenization, various methods are applied or under discussion from statistical evaluation over movable ground-based reference systems to comparisons with space-borne radars [32.65].

The general difficulty of absolute radar calibration calls for auxiliary observations. Constraints can be provided by radiometers via the path-integrated liquid water content (LWP) and/or by distrometers measuring the mass flux in the case of precipitation.

32.7 Maintenance

The antenna dish surface (or radome) must be kept clean. Wet leaves and, particularly, wet snow act as efficient absorbers compromising the radar calibration. Component lifetimes and maintenance schedules depend on the type of radar. If the radar uses vacuum

tubes (magnetron, traveling-wave tube, klystron, etc.), their lifetimes are to be specified by the manufacturer. If the transmit power is monitored, an alert should be issued, if some threshold – as specified by the manufacturer – is crossed. In the case of pressurized wave

Table 32.5 Maintenance schedule

Recommended interval	Transmitter type	
	Vacuum tube	Solid state
1 week	Check log file for drifts of transmit power and other tube related parameters and events	–
Depending on installation site and weather conditions:	Clean antenna dish	
1 month	Check log file for anomalies according to manufacturer's instructions Check air drying device	
2 years	Perform antenna calibration	

guides, the pump and air-drying device require regular inspection. Scanning radars require more maintenance than radars with fixed beam direction due to wear and tear of bearings and, possibly, of slip rings. Since the

technology and complexity of radar systems is very diverse, only a few general maintenance steps are listed in Table 32.5. A concrete maintenance schedule should be agreed upon with the manufacturer.

32.8 Application

At present, cloud radars are primarily used in various atmospheric research areas and in climatologic studies. Research areas include cloud physical processes such as particle growth, shape, interaction, phase, phase-mixture, phase transitions, habits, and the role of clouds in dynamics, cloud entrainment, and the cloud life cycle. Climatologic studies concern statistics of cloud coverage, including multilayer clouds, overlap factor, cloud height, cloud phase, and particle habit. Cloud radars are the backbone of several corresponding observation

networks. The Atmospheric Radiation Measurement (ARM) program, established in 1992 by the US Department of Energy, provides freely available cloud radar observations and various higher-level products for various sites and time periods. CloudNet [32.57] is another international long-term cloud observation program, which is going to become an EU research infrastructure. It aims to demonstrate the potential of operational cloud radar-based observation networks to improve the representation of clouds in weather prediction and climate models.

32.9 Future Developments

The potential benefit of combining cloud radars at different frequencies and with other sensing techniques has already been demonstrated in numerous studies. Some of them were mentioned above, but much more effort will be devoted to the exploration of synergistic effects with other sensing techniques. Cloud radar data are not yet used to support weather prediction. Although the benefit could be significant, the development of adequate tools in weather prediction models for ingesting cloud radar data is still a major task. The observation of fog develop-

ment – particularly in airport areas – may become a major practical and straightforward application. The ongoing progress of solid-state electronics will lead to cost reductions, increased sensitivity, and the availability of higher frequencies for cloud radars. The added value of using frequencies up to 300 GHz in atmospheric-window regions is discussed in [32.66]. First attempts of water vapor density retrieval in clouds by differential absorption using frequencies close to the water vapor absorption line at 182 GHz were published in [32.67].

32.10 Further Reading

A comprehensive review of the present state of the art of remote-sensing techniques, including mm-wave radar for clouds and precipitation, is given by:

GmbH
Elmshorn, Germany
peters@metek.de

Dr Gerhard Peters has been R&D consultant at METEK GmbH since his retirement from the University Hamburg in 2010. He received a PhD in Geophysics in 1978. He has developed ground-based remote-sensing methods for the atmosphere, participated in numerous field projects dealing with the arctic and maritime boundary layer, and contributed to VDI and ISO standards for measuring meteorological variables.

High Frequency Radar

33. High Frequency Radar

Jochen Horstmann , Anna Dzvонkovskaya 

High frequency (HF) radars operate at radio frequencies between 3 and 30 MHz, where electromagnetic waves have the ability to propagate along the ocean surface and therefore to obtain information beyond the horizon. All the information measured by a HF radar corresponds to physical parameters of the upper couple of meters of the ocean surface. Today, HF radar systems are typically used along the coast, as they offer the unique opportunity to monitor the coastal area within a distance of 40–200 km. A HF radar system transmits electromagnetic waves and measures the backscatter intensity and speed of ocean waves. This information is primarily used to estimate surface currents and ocean wave properties. However, in the last decade, HF radars have also been shown to be extremely useful for several other applications such as surface wind measurements and tsunami monitoring, as well as vessel traffic support.

With respect to the atmosphere, HF radars give a direct measure of the upper ocean response to lower marine atmospheric boundary layer forcing, and therefore the air–sea interaction. In this context, the main parameters retrieved from HF radar measurements are surface winds [33.1, 2], the sea state [33.3, 4], surface currents [33.5, 6], and tsunamis [33.7, 8]. Today, they

are utilized for the coastal monitoring of these parameters [33.9, 10], the short-term prediction of surface currents [33.11], search and rescue operations [33.12], and oil spill monitoring [33.13], as well as for the improvement and data assimilation of numerical circulation models [33.14, 15].

33.1 Measurement Principles and Parameters

HF radar systems utilize radio frequency transmission between 3 and 30 MHz, which correspond to electromagnetic wavelengths between 100 and 10 m. The electromagnetic waves are transmitted from an antenna, propagate as a ground wave along the electrically conductive ocean surface, and enable the measurement of radar backscatter beyond the line of sight. Therefore, these radars can measure the surface beyond the hori-

zon, which is why they are also named over-the-horizon radars. To first order, the transmitted radio waves are resonantly backscattered by ocean surface waves that are propagating along the radar look direction and have a wavelength equal to half the electromagnetic wavelength. These so-called Bragg waves lead to Doppler shifts, resulting in first-order and second-order peaks in the backscatter frequency spectrum. The measured

Table 33.1 Main parameters extracted from HF radar measurements

Parameter	Description	Unit	Symbol
Current speed	Current speed at the ocean surface	m s^{-1}	v
Current direction	Current direction at the ocean surface	$^{\circ}$	Φ_c
Wind speed	Wind speed at the ocean surface (similar to a 10 min mean wind speed at 10 m height)	m s^{-1}	u_{10}
Wind direction	Wind direction at the ocean surface (similar to a 10 min mean wind speed at 10 m height)	$^{\circ}$	Φ_w
Significant wave height	Mean wave height (trough to crest) of the highest third of the waves (defined as four times the standard deviation of the surface elevation)	m	H_S
Tsunami probability	Probability of a tsunami	%	

frequency spectrum is analyzed with respect to the location and shape of these peaks, allowing the retrieval of the parameters listed in Table 33.1.

Since a radar can measure the distance and angle to an ocean wave patch, it becomes possible to generate a map within the radar-covered range and azimuth (radar look directions) and obtain the frequency spectra at each grid point. The simplest way of measuring the range distance with a radar is to measure the time difference between the transmitted and received signals. To obtain high range resolution, a short pulse is needed, which in turn leads to a decrease in range. Therefore, the transmitted power has to be increased in order to get a sufficient signal-to-noise ratio, in particular at longer ranges. To overcome this drawback, HF radars transmit a linear chirped signal, where the frequency shift between the transmitted and received signals contains the distance information. With this chirped signal, also named frequency-modulated continuous wave (FMCW), the range resolution is related to the frequency bandwidth of the chirp and is independent of the transmitted power. Alternatively, the HF radar can be operated with a frequency-modulated interrupted continuous wave (FMICW). With the latter concept, the transmitter is switched off during the reception phase of the backscattered signal and operation is similar to that of a pulsed radar. If the transmit and receive anten-

nas are too close to each other, the transmitting antenna can saturate the receive antennas even before the signal reflected from the ocean arrives. Turning off the transmit antennas after one chirp, as in a pulsed radar, will prohibit this saturation and allow a smaller separation distance between the transmit and receive antennas. However, turning off the transmitter during the reception time also reduces the amount of transmitted energy and therefore the energy content of the received echo signals, which in turn reduces the maximum range distance of the radar. To get azimuthal coverage over the ocean surface, it is necessary to point the radar in different azimuth directions. Several systems for resolving the azimuth direction of the radar have been developed, which will be introduced in Sect. 33.4.

The measured frequency spectrum of the sea echoes at every range–azimuth grid point is subjected to a comprehensive spectral analysis to extract meteorological and oceanographic parameters. Today, HF radars are operationally utilized to measure ocean surface current fields [33.16, 17]. However, they have also been shown to be useful for measuring ocean wave parameters such as the wave spectrum [33.3] and the significant wave height [33.18] as well as surface winds [33.19]. Furthermore, they have been shown to be valuable for the detection of tsunami [33.20, 21] as well as for maritime surveillance [33.22, 23].

33.2 History

The era of HF radar for meteorological and oceanographic applications started in 1955 with *D.D. Crombie* [33.24], who observed Doppler shifts of the returned signal from the ocean surface with respect to that transmitted at HF frequency (3–30 MHz). The reproduction and analysis of the signal spectrum showed two narrow resonant peaks that corresponded to the ocean waves, had exactly half the radio wavelength, and moved along the radar look direction. A tentative explanation of these peaks included an assumption that the sea waves acted as a diffraction grating containing several wave crests. This occurrence was

later called resonant Bragg scattering, following the discovery of the scattering of x-rays in crystals by the English physicist *William Lawrence Bragg* (1890–1971) [33.25]. In 1966, Crombie's observations were analytically verified by examining the reflection of electromagnetic waves from a gently rippled ocean surface [33.26]. In 1972, *Donald E. Barrick* [33.27] derived a model for the first-order radar cross-section of the ocean surface that is consistent with *Crombie's* observations, and he presented the first surface current maps in 1977 [33.28]. In addition to surface currents, it was found that the HF radar backscatter can be used

to extract information on the wind [33.29] and sea state [33.30].

The first commercial HF radar was the Coastal Ocean Dynamics Applications Radar (CODAR) system introduced in 1977 at the National Oceanic and Atmospheric Administration (NOAA), USA [33.28]. This groundwave radar system was initially designed for the mapping of ocean surface current fields. The overall advantages and disadvantages of the system have been examined over the years, and many new ideas were

33.3 Theory

When the sea surface is illuminated by a HF radar, a portion of the incident energy is backscattered from the ocean surface waves that are propagating along the radar look direction. When the wavelength λ_{gr} of the ocean gravity wave is equivalent to half the transmitted electromagnetic wavelength λ_{el} , the so-called Bragg resonance phenomenon occurs [33.25] (echoes from successive crests of this oscillation are in phase). Ocean waves leading to Bragg resonant scattering are therefore called Bragg waves.

In deep water, the phase velocity of surface gravity waves is given by

$$C_p = \sqrt{\frac{g\lambda_{gr}}{2\pi}}, \quad (33.1)$$

where g is the acceleration due to gravity and λ_{gr} is the wavelength of the surface gravity wave.

The roughness of the ocean surface is a combination of waves of different wavelengths and directions. When the radar operates at different frequencies, the corresponding Bragg wavelength varies as well. Thus, if $\lambda_{gr} = \lambda_{el}/2$, a resonance Bragg frequency appears, which is defined as

$$f_{Bragg} = \pm \sqrt{\frac{g}{\pi\lambda_{el}}}, \quad (33.2)$$

where a positive Bragg frequency is associated with waves propagating radially towards the radar and a negative Bragg frequency is associated with waves propagating away from the radar.

Spectral analysis of the backscattered signal results in a Doppler frequency spectrum, as depicted in Fig. 33.1. In the Doppler frequency spectrum, the Bragg waves lead to Doppler shifts (33.2) that show up as two predominant peaks, the so-called first-order peaks. In the absence of currents, the frequency of the first-order

developed. These resulted in the development of the Ocean Surface Current Radar (OSCR) by Marconi in the United Kingdom [33.31], the SeaSonde by CODAR in the USA, and the Wellen Radar (WERA) by the University of Hamburg, Germany [33.6]. Developments independent of the first CODAR were made in Canada in 1991 (C-CORE (Centre for Cold Ocean Resources Engineering) Northern Radar), the UK in 1988 (University of Birmingham, PISCES), France in 1990 (University of Toulon), as well as in Australia and Japan.

peak has a Doppler shift caused by the phase velocity of Bragg waves (33.1) in the radial direction of the transmitting antenna (the radar look direction). In the presence of a surface current along the radar look direction, the first-order peaks are shifted with respect to the transmitting frequency. To determine the current velocity, it is necessary to find the central frequency of the two Bragg peaks. From the frequency shift, the radial current velocity can be calculated as

$$v_r = (f_o - f_{Bragg}) \frac{\lambda_{el}}{2}, \quad (33.3)$$

where f_o is the observed resonant frequency in the radar spectra.

The surface current estimated by HF radars has been suggested to include all or part of the wave-induced Stokes drift [33.32–35]; however, other researchers

Fig. 33.1 Normalized measured HF Doppler frequency spectrum for a selected range-azimuth cell. First-order peaks P_+ and P_- (red circles) and the second-order return (gray boxes) are indicated

have provided evidence against this assumption [33.36]. In any case, the magnitude of this component is typically smaller than the uncertainties in the HF-radar-retrieved surface currents [33.34, 37].

To obtain highly accurate radial velocities, a high-resolution frequency spectrum has to be measured by the HF radar. This is achieved by repeating the range measurements at a regular rate and performing a time-series analysis of each individual range measurement. The coherent integration time t provides a Doppler frequency resolution of $\Delta f_D = 1/t$, which consequently gives a velocity resolution of $\Delta v = \Delta f_D \lambda_{el}/2$. Due to its long integration time, an ocean radar is capable of measuring a radial velocity of a few centimeters per second.

As mentioned before, the positive first-order peak is associated with waves approaching the radar site, whereas the negative first-order peak is associated with waves receding from the radar site. The amplitudes of these peaks are directly related to the energy within the approaching and receding wave components. Under the assumption that the Bragg waves are locally wind driven and aligned with the wind, the relative ratio of the two first-order peaks contains information on the wind direction [33.37],

$$\frac{P_+}{P_-} = \tan^s \left(\frac{\beta}{2} \right), \quad (33.4)$$

where β is the angle between the wind direction and the receding Bragg waves and s is the spreading parameter (commonly, $s = 4$). Given the radar beam direction Φ , the wind at a selected grid point and the directional spreading pattern of the Bragg waves determine the strengths of the wave components receding from and approaching the radar site; hence, the wind direction Φ_w

is calculated via

$$\Phi_w = \Phi \pm \beta. \quad (33.5)$$

Several different models are available for extracting wind directions from HF radar backscatter. However, all of them require the power ratio of the two first-order peaks (33.4) combined with a directional distribution function for the Bragg waves. Although details of the various techniques differ, the principle is well established. However, most researchers simplify the calculation by setting the directional spreading parameter s to be a constant value.

Bragg scattering also leads to the second-order return in the radar frequency spectrum (Fig. 33.1). However, within these bands, the backscatter is from nonlinear ocean waves, which propagate at different speeds and hence result in different Doppler shifts. In addition, the second-order return contains backscatter from multiple surface scattering. Therefore, the second-order return is proportional to the wave-height nondirectional temporal spectrum [33.30]. A solution to this scattering problem has been given in the form of a two-dimensional nonlinear integral equation based on a perturbation expansion and the assumption that the sea surface is a perfect conductor [33.38, 39]. By inverting this integral equation, a two-dimensional wave height spectrum can be obtained from the HF-radar measurements [33.3, 40]. A further approach is based on an empirically obtained power law relating the wave height (e.g., as measured by a buoy) to the ratio of the power in the second-order return to that of the stronger first-order peak [33.41]. Other researchers have performed similar empirical approaches [33.4, 42] that, in general, relate the amplitude of the second-order return to wave buoy measurements.

33.4 Devices and Systems

The simplest antenna system is a phased array consisting of identical receiving elements spaced equal distances ($\leq \lambda_{el}/2$) along a line perpendicular to the center of the desired look directions [33.6]. The time delay between antennas on the receive array is used to sequentially point the radar in different directions. An alternative to the beamforming method is the so-called direction-finding technique [33.43]. It is based on comparing the relative amplitudes of the returned energy on the collocated antennas. When the beam pattern of each antenna is known, the direction of the received signal can be retrieved via the ratio of the antenna signal strengths. In contrast to the phased-array method,

where a sequential set of spectra are used to get information over the azimuth, a single combined spectrum is utilized in the direction-finding method.

Conventional beamforming is usually applied in HF radar systems where receive antennas are operated as uniform linear arrays of antenna elements, for example, WERA ocean radar systems [33.6]. After the received signal has undergone down conversion and fast Fourier transformation (FFT), the time delays between antenna elements are phase shifted. To maximize the output power from a certain direction Φ , the weighted signal at each array element is summed to steer a narrow beam in a desired direction, so that signals from partic-

Table 33.2 HF radar systems and the techniques utilized to obtain the range and azimuth of the sea echo

HF radar system	Range Radar waveform	Angle	
		Direction finding	Beamforming

WERA [33.6]	FMCW	+	+
LERA (least expensive radar)	FMCW	+	+

ular directions sum constructively while signals from other directions sum destructively. The weighted and summed signal $S(\Phi)$ for the azimuthal look direction Φ is given by

$$S(\Phi) = a(C)^H x, \\ a(\Phi) = \left[1 e^{-ik_{el}d \sin(\Phi)} \dots e^{-ik_{el}d(N-1) \sin(\Phi)} \right]^T, \quad (33.6)$$

where x is the fast-Fourier-transformed vector signal of the antenna elements, d is the spacing between antenna elements, and N is the total number of elements in the uniform linear array. The term H represents the conjugate transpose and $a(\Phi)$ is the steering vector with the beamformer weights equal to the inner product of the steering vector and the gain function of each antenna element. Sidelobes of the formed beam are generally reduced at the expense of beamwidth through the application of an amplitude taper over the elements, e.g., the Hamming window function.

Here, the classical spatial beamformed spectrum is obtained as

$$P(\Phi) = S(\Phi)S^H(\Phi), \quad (33.7)$$

and its local maxima yield the directions of incoming signals.

Direction-finding systems utilize a direction of arrival determination algorithm, e.g., Multiple Signal Classification (MUSIC) [33.44], which has been widely investigated in conjunction with antennas with a compact configuration (typically a single antenna) such as the Coastal Ocean Dynamics Applications Radar (CODAR) [33.43]. The CODAR system consists of two collocated cross-loop antennas and one monopole antenna. Antenna patterns of each element are utilized that can distinguish the directions of the incoming signals. The MUSIC algorithm determines the signal space (assuming the number of signal arrival directions is M) by diagonalizing the covariance matrix formed by the measured signals at each antenna. Projecting all the bearings associated with a particular range cell onto the

signal space allows the most likely bearing of the signal to be determined. In practice, an estimate of the covariance matrix of measurements is obtained and split into the signal and noise eigenvectors U_s and U_n , respectively. The orthogonal projector onto the noise subspace defines the MUSIC *spatial spectrum* as

$$P(\Phi) = \frac{a^H(\Phi)a(\Phi)}{a^H(\Phi)U_n U_n^H a(\Phi)}. \quad (33.8)$$

The main disadvantage of MUSIC is that it requires the number of signal components M to be known in advance, so the original method cannot be used in more general cases. The number of source components M is estimated from the statistical properties of the autocorrelation matrix under the assumption that coexistent sources are not correlated. For HF-radar surface sensing, the number of signal components for current estimation is usually assumed to be less than three, which means that the number of Doppler spectra to be averaged must be at least three.

The major HF radar developments that are being utilized in oceanography today are listed in Table 33.2, together with operational concepts—the waveform utilized to obtain a large range with high resolution and the techniques applied to obtain the azimuth direction of the sea echo return.

Phased-array and direction-finding systems differ significantly in antenna design and setup. Figure 33.2 shows a typical setup of a phased-array system on the island of Wangerooge in the North Sea off the German coast, which consists of a transmit (Tx) and a receive (Rx) antenna array. Each individual antenna is a pole with a height that typically varies from 1 to 3 m depending on the manufacturer and the transmission frequency utilized. The Tx array consists of 4 antennas, which are set up in a rectangle ($0.45\lambda_{el} \times 0.15\lambda_{el}$) with a distance of at least 100 m to the Rx array. The Rx array extends over a distance of $0.45\lambda_{el}(n-1)$, where n is the number of antennas. Distances below $0.5\lambda_{el}$ are preferably used to reduce the effect of side lobes. Typical Rx setups include between 8 and 16 antennas; increasing the number of

Fig. 33.2a–c Typical setup of a phased-array system (a). The photos show a phased-array setup of a WERA system on the island of Wangerooge in the North Sea off the German coast: (b) receive array (Rx) and (c) transmitter antenna array (Tx)

Fig. 33.3 Antenna beam patterns for a 12-element phased array with 0.45λ spacing (blue line) and a crossed-loop antenna (\sin^2 and \cos^2 function, red line)

antennas leads to higher azimuthal resolution. A phased-array antenna array consisting of 12 antenna elements spaced $0.45\lambda_{el}$ apart forms a beam width of 9° (at 3 db), while the beam pattern of a crossed-dipole antenna has a beam width of 66° (at 3 db), as shown in Fig. 33.3.

Figure 33.4 depicts the setup of a direction-finding system that consists of one Tx antenna (or two for larger ranges). The antenna length is between 8 and 15 m (de-

pending on the radar frequency) and one Rx antenna system typically separated by 80 m. The receive antenna system consists of one dome loopstick antenna unit and a vertical element with a total height of approximately 7 m. Some systems operating at shorter wavelengths (above 24 MHz) use a single-pole antenna system that combines the Tx and Rx antennas. The older direction-finding systems operate with four antennas set up in a rectangle, similar to the Tx of a phased-array system. The photo in Fig. 33.4b shows the main antenna of a SeaSonde system operating at 4.5 MHz, which is part of the Basque Operational Oceanography System (EUSKOOS) HF-Radar system at Cape Matxitxako (northern coast of Spain), operated by Basque Meteorological Agency (EUSKALMET).

A phased-array system requires a significant property for installation. However, since each backscattered power spectrum is from a single range–azimuth cell (the range and azimuth resolutions are determined by radar parameters), it is a straightforward measurement. Direction-finding systems require only a very small property, but the use of direction-finding methods can lead to limitations; for instance, if two different surface current patterns are located within one range cell and their components in the direction to the radar hap-

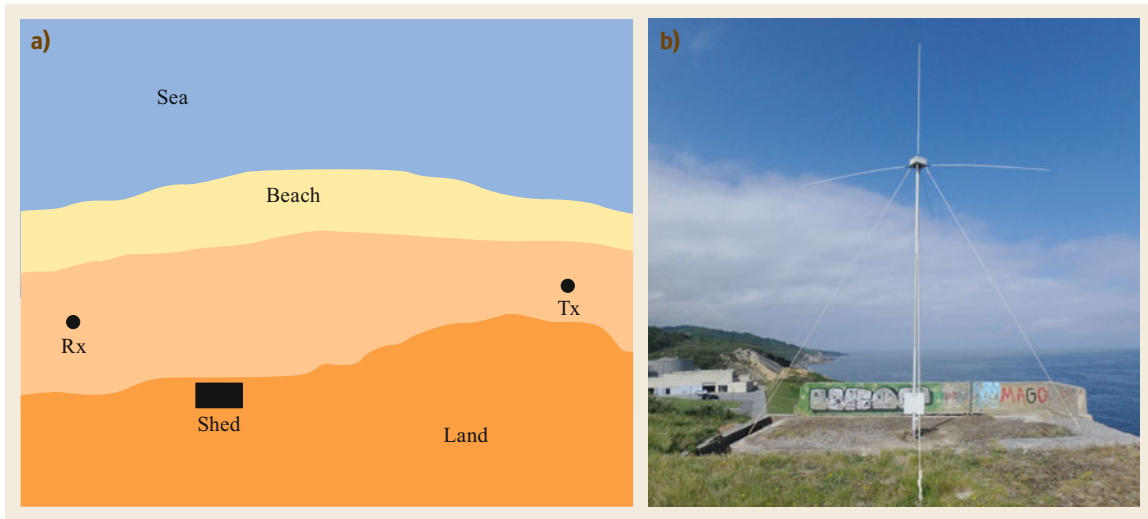

Fig. 33.4 (a) A typical setup of a direction-finding HF radar system. (b) This photo shows a direction-finding system from SeaSonde installed at Cape Matxitxako (northern coast of Spain). pen to be equal. The spectra for compact systems are from separate range cells but contain information from all directions simultaneously. Current measurements are resolved using direction-finding techniques, and better directional accuracy can be achieved. However, longer integration times (about an hour) are usually required to gather current data covering the whole area of interest using such methods. This can become a problem in rapidly varying marine environments. Furthermore, at higher radio frequencies and higher wave heights, the resonant peaks used for both current and wind measurements are less easily separated from the second-order return of the spectra, which yields the sea state information. This is likely to be a more serious problem with a direction-finding system, but it can be solved by operating the radar at lower frequencies. For more details on the pro and cons of the different systems, refer to [33.49].

HF radars can measure surface winds, waves, and currents spatially and temporally, while most other in-

struments can only obtain point measurements, albeit typically with higher accuracy. With respect to surface winds, only satellite-borne scatterometers [33.50], synthetic aperture radars [33.51], and platform-based marine radars [33.52] enable the measurement of two-dimensional surface wind fields. All other instruments typically measure a profile or at a single point over time. With respect to waves, there are a few systems that allow the two-dimensional wave field information to be measured. Those systems are either based on radars [33.53] or light detection and ranging (lidar) technology [33.54]. The main application of HF radar is the measurement of two-dimensional surface current fields over time. So far, only systems with significantly smaller spatial coverage, such as marine radars [33.55] or a video-based system [33.56], have given results of similar quality. However, a lot of effort goes into the development of satellite-based radar systems for obtaining surface currents [33.57].

33.5 Specifications

The working range of a HF radar depends on the attenuation of the electromagnetic wave between the transmitter and surface scatter elements and on the noise, such as that due to the atmosphere or radio interference. The operating range of groundwave-based HF radar systems is strongly dependent on the transmitted frequency and the conductivity (salinity) of the seawater.

High salinity results in high conductivity and therefore optimum range performance, while strong attenuation limits the use of HF radars for remote sensing, particularly in freshwater lakes and over ice-covered areas. In Fig. 33.5, the working ranges for a beamforming system with respect to surface current retrieval are shown as functions of the radar frequency and the water salin-

Fig. 33.5 Dependence of the maximum working range for surface current measurements by a typical beamforming system on the radar frequency and water salinity. The ranges for a direction-finding system are approximately 75% of those for a beamforming system if both systems utilize the same transmission frequency and sampling time. Data are valid for a phased-array-type WERA

Table 33.3 Typical specifications for a phased-array HF radar system operating at 16 and 24/26 MHz

Operating frequency (MHz)	16	24/26
Working ranges (km) using beamforming for:		
– Currents	80	50
– Wind direction	55	35
– Wave height	35	20
– Wave spectrum	25	15
Typical range (km) resolution	1.5	1.0
Azimuthal accuracy (°) using beamforming:		
– 4 antennas	±5	±5
– 8 antennas	±2	±2
– 16 antennas	±1	±1
Temporal resolution (min) for:		
– Currents	5–10	5–10
– Wind	5–10	5–10
– Waves	20	20

ity. The ranges for wind retrieval are between 25–100% of those ranges, depending on the local wind direction with respect to the radar look direction. The range for wave measurements is approximately 50% of that shown in Fig. 33.5. The working ranges for direction-

finding systems with the same operating frequency are approximately 75% of those of beamforming systems. Typical specifications for beamforming HF radar systems are listed in Table 33.3.

The availability of different types of HF radar systems allows the marine science and engineering community to select the system that best covers their needs with respect to the characteristics of the area, the parameters to be measured, and the required performance. Direction-finding systems require a significantly smaller antenna footprint and offer, due to their full azimuthal coverage, the option of chaining stations to achieve continuous coverage along a coastline. However, these benefits come at the cost of a reduced operating range as well as coarser azimuthal and temporal resolution [33.49].

Furthermore, direction-finding systems are more sensitive to atmospheric noise, necessitating longer time integration (≈ 90 min) to achieve a similar working range to phased-array systems. In addition, the direction-finding algorithm has a coarser azimuth resolution (18°). However, the main disadvantage of direction-finding systems relates to the extraction of sea state information, as first-order peaks associated with other directions mask the second-order return in certain directions. Another disadvantage arises from the assumption that different radial velocities come from different directions (with respect to the radar), which is invalid in the case of a current field that varies strongly at subradar resolution. Phased-array HF radars have a lower-noise antenna system that, for the same operating range, offers a higher temporal resolution (≈ 5 – 10 min) and, in the case of an 16-element receive array, has a higher azimuthal resolution ($\pm 4^\circ$ for a 16-element array).

The accuracies of the parameters retrieved with HF radar, e.g., wind, waves, and currents, are strongly dependent on the environmental conditions, on the HF radar frequency utilized, as well as on the setup system. Typical accuracies of beamforming systems are listed in Table 33.4. For details on the performance of an individual radar system at a specified operating frequency, please refer to the manufacturer’s specifications and scientific literature.

Table 33.4 Typical accuracies of HF radar systems operating at 16 and 24/26 MHz

Operating frequency (MHz)	16	24/26
Radial surface current speed ($m\ s^{-1}$)	0.04	0.03
Wind direction (°)	10–40 (depends on wind speed)	10–40 (depends on wind speed)
Wave height (%)	< 10	< 10
Mean wave direction (°)	< 5	< 5
Mean wave period (s)	±1.1	< ±0.6
Directional wave spectra (Hz)	0.01	0.01
Limits for wave height measurements (m)	0.3–7	0.25–4

33.6 Quality Control

The use of HF radar systems for monitoring ocean surface current fields is now widely accepted; however, quality assessment and control is an area of ongoing research. With respect to the proper technical operation of the system, many internal checks have been designed and implemented by manufacturers to make sure that the measurements are performed by a fully functioning system. However, there are several other sources that can lead to uncertainties in the retrieved parameters. From a technical point of view, these can be simplifications and errors within the analysis, such as a wrong determination of the first-order peaks or the utilization of an incorrect antenna pattern. However, they are most commonly due to noise in the spectral radar data, which can be induced by radio frequency interferences, ship echoes, ionospheric clutter, or other environmental noise induced by power lines or electromagnetic activity. Further sources of error are variations in the current speed or direction within the spatial resolution of the radar as well as variations during the integration time of the measurement. In particular, these

have to be taken into consideration in coastal areas with strongly changing bathymetry or strong tidal currents. One method of identifying such errors is to measure the width of the first-order peak, which will be wider for measurements affected by these variations than for those not affected by such variations [33.58]. Other approaches observe the likelihood of a measurement to be correct with respect to its location (in space and time) as well as with its direct neighborhood (meaning consistency with respect to space and time). Furthermore, there are methods that take into account measurements obtained over a certain amount of time and flag outliers accordingly [33.58]. Over the years, a great number of validation studies have been carried out to estimate the error in HF-radar-retrieved surface currents, and those studies have come up with errors of between 0.08 and 0.15 m s^{-1} [33.17, 59]. This huge span of error estimates is due to differences in radar setups, in particular with respect to frequency, resolution, and location, as well as due to differences in the accuracies of the systems utilized for comparison.

33.7 Maintenance

With respect to maintenance, HF radar systems are fairly easy to deal with. Nevertheless, it is useful to check the status of the system on a daily basis to identify any system components that are failing or degrading, in particular the outdoor components (antenna arrays). In general, HF radar sites operate in a fully automated manner. The systems perform daily self-checks and send reports to the operator (assuming remote access is available). In addition, many of the other units integrated on-site, such as air conditioning, the uninterruptible power supply (UPS), and the backup system, should be checked remotely on a daily basis. Besides the on-site checks, the creation and archiving of files containing results and—if applicable—the functionality of the web server should be investigated daily.

However, these daily checks should not replace on-site inspections and maintenance, which should be performed at least every 3 months. In the case of severe weather events such as strong storms, thunderstorms, or flooding, an immediate on-site visit is highly recommended. Typical on-site maintenance consists of

careful inspection of the antennas with respect to their condition, alignment, mounting, and guying, as well as to check that they are properly connected. The latter includes checking the cables and, in particular, the connection points. If any antenna or cable needs to be repaired or replaced, a new calibration of the antenna array may be required. It is also very helpful to monitor the levels and phase values of all antennas (especially for a phased-array setup), as any changes in these parameters give an indication of problems with the installation, such as bad connectivity of the antenna or broken radials or antennas. Furthermore, in the enclosure (typically a container), the functionality of the air conditioning should be checked, as should the electronics for corrosion, the UPS for battery status and functionality, and the backup systems and their hard drives. However, every individual HF radar system and site has its own characteristics, so each will require an adjusted maintenance plan. Typically, a quarter-yearly check of a 16 antenna phased-array system requires half a day of work, which includes some smaller repairs and adjustments.

33.8 Applications

As mentioned above, HF radars are well suited to monitoring the coastal zone within a range of 40–300 km, depending on their operating frequency. In the following, some examples of the application of HF radars to measuring surface winds, waves, and currents in the coastal zone are given.

33.8.1 Surface Wind Measurements

Although the main application of HF radar is the mapping of surface currents, the ability to map the wind direction at scales of one to several kilometers and over many hundreds [33.1, 2] to millions of square kilometers in the case of skywave HF radars [33.19, 60] offers huge potential. Maps of HF-radar-retrieved wind directions have shown variations in wind direction over horizontal scales of just a few kilometers. This enables the investigation of wind stress divergences and curl, as well as their impacts on coastal mixing and circulation, over time and space at scales on the order of a couple of minutes and kilometers [33.1]. Furthermore, HF-radar-retrieved maps of wind direction can be utilized to detect frontal boundaries (sudden changes in direction) and small-scale storms (e.g., waterspouts, thunderstorms) [33.61]. A typical map of HF-radar-retrieved wind directions is shown in Fig. 33.6. In this case, the wind directions result from simultaneous measurements by the phased-array radar systems located

on Wangerooge (12.1 MHz) and at Büsum (10.8 MHz), both of which are part of the German HF radar network for monitoring the German Bight located in the southern North Sea [33.62]. Note that only wind direction measurements are presented here; however, HF radars have also been shown to resolve information on the wind speed [33.2, 63, 64]. However, there are limitations on the minimum and maximum measured wind speeds and there are large errors in the retrieved wind speeds.

In contrast to ground wave radars, the capabilities of skywave HF radars have been demonstrated through their application to the monitoring of tropical cyclones [33.19, 60]. Two US Air Force over-the-horizon radar systems operating at 15.8 MHz were utilized to monitor large areas of the North Atlantic and northeastern Pacific Ocean. The systems were huge in size; their antenna arrays occupied a few kilometers of coastline. However, their ability to monitor a large portion of the ocean surface was demonstrated by tracking the wind directions of Hurricane Claudette in September 1991 and Hurricane Andrew in August 1992 at a distance of 2400 km [33.60]. Similar observations of Hurricane Hortense were made in September 1996 by a pair of relocatable over-the-horizon radar systems operating at 14.7 and 18.5 MHz. Simultaneous coverage of the area by both radars led to an unambiguous surface wind direction field and a surface current field with a spatial resolution of 15 km over a large portion of the

storm [33.19]. These measurements can help to improve the forecasting of tropical cyclones as well as our understanding of their intensities and propagation directions.

33.8.2 Waves

As mentioned above, the second-order return contains information on the sea state and can be utilized to retrieve sea state information such as the significant wave height, mean wave direction, and other spectral information. Therefore, two main approaches are followed: a theoretical approach that obtains the wave directional spectrum through the inversion of an equation describing the sea surface scattering [33.3] and empirical approaches [33.4, 42]. Nevertheless, as both

methods are based on information within the second-order return, which has a lower signal-to-noise ratio than the first-order peak, the range covered by the resulting wave fields is less than that covered by the corresponding current fields (Table 33.3). A typical HF-radar-retrieved wave field is depicted in Fig. 33.7. This shows the significant wave heights in the German Bight on January 17, 2019 at 13:19 UTC, as retrieved by the beamforming HF radar located on the island of Sylt, which was operating at a frequency of 10.8 MHz.

33.8.3 Surface Currents

Today, most installed HF radars are used for monitoring coastal ocean surface currents. A large number of

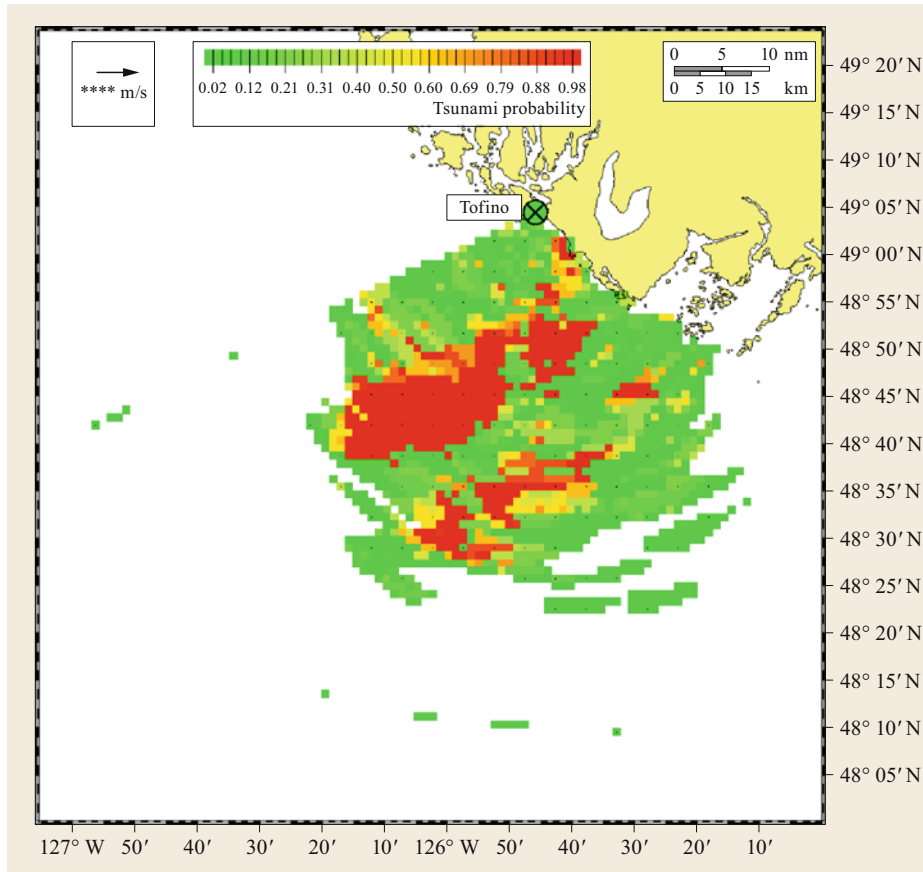

Fig. 33.9 Tsunami probability map of the west coast of Vancouver Island, Canada from October 14, 2016, at 06:12 UTC. The results were obtained by a phased-array system located at Tofino, Canada. (© Helzel Messtechnik GmbH 2015)

HF radars are being operated around the world, and most of the networks from Europe, North America, and Australia provide near real-time ocean surface current fields and make them available via the World Wide Web [33.10].

Figure 33.8 shows an example of a current field from the German Bight acquired on November 5, 2010 at 07:00 UTC. The current map was retrieved utilizing all radial currents from the three radar sites of the German HF radar network. The network resolves surface currents every 20 min. These currents are made available within 30 min of acquisition and are assimilated into a numerical simulation model [33.58] to improve the surface current forecast. Today, HF-radar-retrieved current fields are used in various applications such as search and rescue [33.12], oil spill monitoring [33.13], assimilation into numerical circulation models [33.14, 15], and marine traffic information [33.65].

One specific application of HF-radar-retrieved currents is the real-time detection and monitoring of tsunami [33.21]. In order to identify tsunami-like waves, the HF-radar-retrieved current fields are filtered. In general, the tsunami-induced velocity features

are extracted from the surface current fields measured by the HF radar by removing background current velocities, e.g., tidal currents. In contrast to direction-finding systems, phased-array systems require significantly shorter integration times to obtain an accurate surface current velocity that can be utilized to generate tsunami probability maps [33.21]. Figure 33.9 shows a tsunami probability map off the coast of Vancouver Island (Canada) during a tsunami event on October 14, 2016 at 06:12 UTC [33.66]. On that occasion, Vancouver Island was hit by a so-called meteotsunami, which is typically generated by a rapid change in barometric pressure that leads to the displacement of the water body. Meteotsunamis are restricted to local effects because they lack the energy available to significant seismic tsunamis. Although meteotsunamis are not as catastrophic as seismically induced events, they can become hazardous when amplified by resonance [33.67]. Several HF radar observations of tsunami have shown that phased-array radar technology is highly applicable for the monitoring of seismic and nonseismic tsunami, regardless of the generating mechanism, i.e., an underwater earthquake, a submarine landslide, or me-

teological conditions. Therefore, HF-radar-retrieved tsunami probability maps that become available sec-

onds after the acquisition provide valuable information for decision makers with respect to tsunami warnings.

33.9 Future Developments

From a technical point of view, a lot of effort is going into the development of active antennas (in particular for beamforming systems) as well as new antenna array concepts such as multiple-input multiple-output (MIMO) radar waveform designs [33.68]. Today, HF-radar current retrieval is well accepted, and such systems are being used on an operational basis along various coasts around the globe. Most HF radar networks are also made available to the public via the World Wide Web and gathered on platforms such as the EMODnet portal of the European Global Ocean Observing System (EuroGOOS).

Most developments in parameter retrieval are focused on improving sea state parameters such as the wave directional spectrum [33.3] or on improvements in tsunami detection [33.21] and ship detection [33.23] aimed at producing operational applications. Also, with regards to wind field retrieval, HF radar systems are not yet well suited for operational use. However, in particular with respect to wind field retrieval, satellite-borne scatterometers offer reliable wind fields with global coverage, which have been available on an operational basis for the last two decades from the European Organization for the Exploitation of Meteorological Satellites (Eumetsat).

33.10 Further Reading

A special issue on high frequency radars for coastal oceanography was published in *Oceanography* **10**(2), (1997). This can be accessed via the World Wide

Web at <http://tos.org/oceanography/issue/volume-10-issue-02>. Accessed 11 July 2021.

Jochen Horstmann

Ocean Surface Dynamics
Helmholtz-Zentrum hereon
Geesthacht, Germany
jochen.horstmann@hereon.de

Jochen Horstmann is a Department Head at the Institute of Coastal Ocean Dynamics of the Helmholtz-Zentrum hereon, Germany. Since 2007, he is also Adjunct Professor at the Rosenstiel School of Marine and Atmospheric Science, University of Miami. He has extensive experience in developing applications for radar- and video-based sensors, with a particular focus on ocean surface and subsurface processes, and has published more than 80 scientific papers in international peer-reviewed journals.

Anna Dzvonkovskaya

Helzel Messtechnik GmbH
Kaltenkirchen, Germany
dzvonkovskaya@gmail.com

Dr. Anna Dzvonkovskaya was an algorithm developer at Helzel Messtechnik GmbH, Germany (left in 2019). Her research interests include radar-based remote sensing of the marine environment and tsunami detection, signal processing algorithms, data fusion, and statistical analysis. An IEEE Senior Member and recipient of the Young Engineer Award at the international conference RADAR 2009 (Surveillance for a Safer World), she has authored more than 40 publications in highly rated journals and conference proceedings.

Scintillometers

34. Scintillometers

Frank Beyrich, Oscar K. Hartogensis , Henk A.R. de Bruin, Helen C. Ward 

Scintillometers consist of a transmitter–receiver pair for electromagnetic radiation separated from each other by a distance of 10^2 – 10^4 m. As the emitted radiation travels through the atmosphere, it is scattered by turbulent eddies of different density. At the receiver, the resulting high-frequency intensity fluctuations of the electromagnetic signal (*scintillations*) are recorded, from which the turbulent sensible and latent heat fluxes can be derived. Further, the wind component perpendicular to the path (crosswind) and, for a specific system configuration, the turbulent momentum flux can be determined from the correlation of the fluctuation time series between two parallel beams. The signal at the receiver represents an integrated effect of the conditions along the path; scintillometers, therefore, provide area-averaged values of fluxes and crosswind. This is of special relevance for applications like the validation of flux data from numerical weather prediction and climate models or from satellite retrievals, or for the estimation of regional-scale evaporation rates in agricultural management and hydrology. After a brief introduction to the theoretical background, the commercially available scintillometer types are characterized, and the conditions of their use are discussed.

Electromagnetic radiation propagating through the atmosphere experiences scattering by air parcels of different refractive index (i.e., density) which irregularly move in the atmosphere due to turbulence. This leads

to high-frequency intensity fluctuations of the electromagnetic signal detected at any point, so-called scintillations. Astronomers notice these scintillations as a blurring of star images and were among the first to study

them in order to avoid or correct their influence on astronomical observations. Scintillations may also be seen by the human eye as the apparent distortion of the back-

ground over strongly heated surfaces or the twinkling of stars at night. Meteorologists use these scintillations to derive turbulent fluxes of heat and momentum.

34.1 Measurement Principles and Parameters

Scintillometer measurements are based on the line-of-sight propagation of electromagnetic waves through the turbulent atmosphere. A scintillometer consists of a transmitter and a receiver unit, separated from each other over a (basically horizontal) distance of 10^2 – 10^4 m. The transmitter emits electromagnetic radiation of constant intensity at a given wavelength (λ), but turbulent density fluctuations of the air prevent straight propagation and cause a distortion of the wave fronts. These density fluctuations are essentially due to temperature and humidity fluctuations. At the receiver side, the cumulative effect of wave propagation disturbances along the path results in intensity fluctuations of the electromagnetic signal, which are mathematically expressed as variances (σ_λ). These variances can be related to the refractive index structure parameter, C_{nm} , of air; C_{nm} can be written in terms of the structure parameters of temperature and humidity, C_{TT} , C_{qq} , and C_{Tq} (Sect. 34.3.1), where the relative contribution of temperature and humidity fluctuations to the refractive index depends on the wavelength of the electromagnetic radiation. While temperature fluctuations dominate in the visible and near-infrared spectral range (wavelengths typically between 400 nm and 4 μ m), humidity fluctuations become relevant for millimeter waves (wavelength 1–20 mm). This has implications for the choice of a certain scintillometer setup, depend-

ing on the fluxes to be derived (Table 34.1). Using Monin–Obukhov similarity theory (MOST, Chap. 1), the turbulent surface fluxes of heat (Q_H) and moisture (Q_E) can be derived from the structure parameters. Further, analysis of the correlation of the received signal between two parallel beams allows for the determination of the wind component perpendicular to the path (crosswind). Finally, if the sensor geometry and system specifications of the two-beam scintillometer are sensitive to turbulent eddies close to the inner scale length of turbulence (Sect. 34.3.2), the turbulent kinetic energy dissipation rate and therefrom the turbulent momentum flux can be derived. An overview of the atmospheric variables determined from scintillometer measurements is given in Table 34.1. The different scintillometer types are characterized in Sect. 34.4.

As an example of the data processing chain, the steps to derive the turbulent fluxes of sensible and latent heat from the measurements with a combined optical-microwave scintillometer system are illustrated in Fig. 34.1.

As the signal at the receiver represents an integrated effect of the conditions along the path, scintillometers provide area-averaged information about the fluxes upstream of the path. This is of special relevance for applications like the validation of fluxes representing a grid cell in a numerical weather prediction (NWP) or climate

Table 34.1 Atmospheric variables derived from scintillometer measurements

Scintillometer type	Measured variable	Derived atmospheric variable	Symbol and unit
Single-beam optical scintillometer	Variance of electromagnetic signal intensity	Structure parameter of temperature Sensible heat flux density ^a	C_{TT} in $K^2 m^{-2/3}$ Q_H in $W m^{-2}$
Combined optical-microwave scintillometer	Variances and covariance of optical/microwave signal intensities	Structure parameters of temperature and humidity Sensible and latent heat flux densities ^a	C_{TT} in $K^2 m^{-2/3}$ C_{qq} in $kg^2 m^{-6} m^{-2/3}$ C_{Tq} in $K kg m^{-3} m^{-2/3}$ Q_H in $W m^{-2}$ Q_E in $W m^{-2}$
Dual-beam optical scintillometer	Variances and covariance of electromagnetic signal intensities of the two beams	Structure parameter of temperature Dissipation rate of turbulent kinetic energy ^b Sensible heat flux density ^a Crosswind perpendicular to path Momentum flux ^b (friction velocity)	C_{TT} in $K^2 m^{-2/3}$ ϵ in $m^2 s^{-3}$ Q_H in $W m^{-2}$ u_{cross} in $m s^{-1}$ τ in $kg m^{-1} s^{-2}$ (u_* in $m s^{-1}$)

^a Information on momentum flux must be available (Sect. 34.3.6)

^b Possible with optical small-aperture laser scintillometers (*inner-scale scintillometers*), for which the beam distance is of the order of the inner scale length of turbulence (a few mm, Sects. 34.3.2 and 34.4.1)

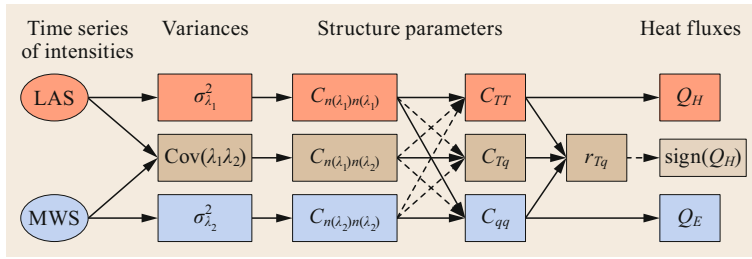

Fig. 34.1 Schematic representation of the data processing for a combined optical-microwave scintillometer (OMS) consisting of an optical large-aperture scintillometer (LAS, operated with an optical wavelength λ_1) and a microwave scintillometer (MWS, operated with a millimeter wavelength λ_2)

model, or a pixel of a satellite picture. Moreover, scintillometers allow for the estimation of regional-scale evaporation rates in agricultural management and hydrology. For these applications, scintillometers are an

easy-to-employ and low-maintenance alternative to networks of eddy-covariance flux stations (Chap. 55) or to airborne flux measurements using aircraft, helicopters, or unmanned aerial systems (Chaps. 47 and 48).

34.2 History

Scintillometry is a relatively young discipline in atmospheric science and measurement technology. First systematic studies of scintillations were performed in the middle of the twentieth century by astronomers, and by engineers and scientists dealing with communication systems (on both ground-based and satellite platforms) and for military purposes (related to the development of laser defense systems). After the theoretical description of wave propagation in a turbulent fluid and a theory to describe surface layer turbulence based on scaling arguments had been worked out in the 1950s and 1960s by *Monin*, *Obukhov*, and *Tatarski* [34.1–3], it was recognized that parameters characterizing atmospheric turbulent flows, notably, the dissipation rate of turbulent kinetic energy (ε) and the structure parameter of the refractive index (C_m) can be obtained from scintillation measurements wherefrom the vertical surface fluxes of momentum, sensible and latent heat can be derived. First prototype research scintillometer systems were built and tested in the 1970s and 1980s in the United States by *Wang*, *Hill*, *Ochs*, and *Frehlich* (e.g., [34.4–11]). These systems were employed to further develop and verify the theoretical concepts and to demonstrate possible applications. However, most of these basic studies found little attention in the meteorological community. In the 1980s *Kohsiek* brought the design idea of a large-aperture scintillometer (LAS) to Europe. Subsequently, he built a first prototype at the Royal Netherlands Meteorological Institute (KNMI) and participated in the EFEDA field campaign in Spain in 1991 [34.12] to determine the sensible heat flux of a sparse vineyard, a strongly heterogeneous surface at meter scale [34.13]. The scintillometer fluxes were shown to compare very well with independent eddy-covariance measurements. This success initiated

a very intense and fruitful period of scintillometer development and applications at the Meteorology and Air Quality Department at Wageningen University and Research (WURMAQ), The Netherlands, driven and guided by *de Bruin* [34.14] and continued by a number of PhD students and scientists [34.15–20]. In the second half of the 1990s, the WURMAQ group built a series of optical LAS, which were operated in several locations all over the world (e.g., in The Netherlands, Germany, Greece, Mexico, Brazil, Marocco, Ghana, South Africa, Indonesia, China, and New Zealand), where the potential of the method and the robustness of the instruments were demonstrated under different climate and surface conditions and for a wide range of applications in meteorology, ecology, hydrology, and agriculture [34.21–28]. A WURMAQ scintillometer setup in Lindenberg for the LITFASS project in 1998 [34.29–31] has been in almost continuous operation by the German Meteorological Service (Deutscher Wetterdienst, DWD) for about 20 years. In parallel, the WURMAQ group made important theoretical contributions to qualify the scintillometry method and to define algorithms for data analysis and quality assurance/quality control. This contributed significantly to the design and realization of the commercial scintillometers presently available from Kipp & Zonen and the Radiometer Physics Group (Sect. 34.4).

Independently of the work in the US and the Netherlands, a double-beam laser scintillometer (DBLS) was designed and tested in Germany in 1990 by *Thiermann* [34.32–34]. A modified version of this instrument was the first scintillometer introduced commercially to the market by Scintec AG, Germany, in 1991 for measurements in the surface layer and over distances of 50–250 m (Sect. 34.4.1). About 10 years later, Scintec

AG developed a multiple-LED LAS, which they called boundary-layer scintillometer (BLS) directing towards its application at larger spatial scales (Sect. 34.4.2).

Already in the early 1980s, *Kohsiek* and *Herben* [34.35] had shown that evaporation can be estimated from a combination of an optical LAS and a microwave scintillometer (MWS). Several prototypes of MWS were later built at Eindhoven University in The Netherlands [34.15, 25], at Rutherford Appleton Laboratory in the UK [34.36–38], and at the University of Bern, Switzerland [34.39]. Due to the more complex (and expensive) microwave technology it took

until 2014 before the first MWS became commercially available on the market (manufactured by Radiometer Physics GmbH, Meckenheim, Germany; Sect. 34.4.3).

Important contributions to the improvement of commercial scintillometer systems and their data processing software resulted from a number of instrument intercomparison experiments performed in New Mexico, USA, Chilbolton, UK, and Lindenberg, Germany [34.40–44].

Although this is still not a standard measurement technique, scintillometers are currently in wide use for a variety of applications (Sect. 34.8).

34.3 Theory

Scintillometry relies on the theory of electromagnetic wave propagation in the turbulent atmosphere, relating the measured intensity fluctuations of an electromagnetic signal to the characteristics of atmospheric turbulence, quantified by the structure parameters of refractive index, temperature, and humidity. Monin–Obukhov similarity theory (MOST) is then used to derive the surface fluxes of momentum, sensible and latent heat from these structure parameters. This implies a series of assumptions, such as weak scattering of the emitted light beam, sensitivity to frequencies in the inertial subrange of turbulence, homogeneous and locally isotropic turbulence, homogeneous surface and stationary atmospheric conditions (see the discussion in the following subsections). The principle of scintillometry is illustrated in Fig. 34.2.

Electromagnetic radiation of wavelength λ is emitted at the transmitter with constant strength and propagates over a distance X towards the receiver where the time series of its intensity (i.e., the intensity fluctuations) is recorded with a sampling frequency of

10^3 – 10^4 Hz. Along the propagation path, turbulent eddies of different size and thermodynamic characteristics cause scattering of the electromagnetic signal, which is, therefore, highly variable in time. Figure 34.2 also shows a number of length scales that are important in connection with the analysis and interpretation of scintillometer measurements. These are:

- The length of the scintillometer path (X)
- The (effective) height of the path above ground (z , see Sect. 34.3.7)
- The outer and inner scale lengths of turbulence (L_0 and l_0 , respectively, where L_0 marks the transition between the production and inertial ranges of the turbulence spectrum that usually scales with z , and l_0 marks the transition between the inertial and dissipation ranges of the turbulence spectrum, it typically amounts to a few mm; Sect. 34.3.2).
- The aperture of the transmitter and receiver units (in principle, they might be different, but for most systems $D(\text{transmitter}) = D(\text{receiver})$).

Fig. 34.2 Schematic representation of the scintillometer principle (after [34.16] modified)

Table 34.2 Exemplary values of the A_T and A_q coefficients in the optical and microwave ranges for typical atmospheric conditions according to [34.45]

Scalar y (unit)	Mean (y)	Fluctuation y'	Relative fluctuation y'/y	Optical range ($\lambda = 880 \text{ nm}$)		Microwave range ($\lambda = 3.4 \text{ mm}$)	
				A_y	$A_y y'/y$	A_y	$A_y y'/y$
T (K)	288	1	3×10^{-3}	-2.70×10^{-4}	-9×10^{-7}	-4.13×10^{-4}	-1.4×10^{-6}
q (kg kg^{-1})	10^{-2}	10^{-4}	10^{-2}	-6.85×10^{-7}	-6.9×10^{-9}	7.14×10^{-5}	7.1×10^{-7}
p (Pa)	10^5	10^{-1}	10^{-6}	2.70×10^{-4}	2.7×10^{-10}	3.40×10^{-4}	3.4×10^{-10}

Another important length scale is the Fresnel length $F = (\lambda X)^{1/2}$. F is the maximum diameter of the first Fresnel zone, an ellipsoid with the transmitter and receiver units at its focal points. Most of the scintillation signal originates from inside this region. Therefore, an undisturbed signal can only be recorded if the first Fresnel zone is free of obstacles.

It is the maximum of either F or D that determines the size of those eddies that contribute most to the measured intensity fluctuations. If $D < F$, the light source can be considered as a point source, and F defines the relevant eddy size. These systems are called small-aperture scintillometers. For $D > F$, the dominant eddies are of the dimension of the instrument aperture; the system is called a large-aperture scintillometer (LAS).

34.3.1 The Refractive Index of Air and the Structure Parameters for Refractive Index, Temperature, and Humidity

Scintillations detected by the receiver of a scintillometer are caused by fluctuations of the refractive index of air (n), which is generally a function of air pressure (p), air temperature (T), and water vapor content (q). Here, specific humidity is used to express the water vapor content of air, as q is a conservative variable invariant to changes of height and air temperature. The refractive index n at a given point and time can be expressed as $n = \bar{n} + n'$, where \bar{n} represents an ensemble mean value and n' the deviation of the actual value from the mean. For an individual eddy, n' is given by

$$\begin{aligned} n' &= \frac{\partial n}{\partial T} T' + \frac{\partial n}{\partial q} q' + \frac{\partial n}{\partial p} p' \\ &= A_T \frac{T'}{\bar{T}} + A_q \frac{q'}{\bar{q}} + A_p \frac{p'}{\bar{p}}, \end{aligned} \quad (34.1)$$

where A_T , A_q and A_p are functions of pressure, temperature, and humidity, and can generally be expressed as $A_y = \bar{y}(\partial n / \partial y)$ with $y = (p, T, q)$. In addition, they depend on the wavelength λ of the electromagnetic

radiation. Details on the determination of these coefficients are discussed, e.g., in [34.45, 46]. Typical values are given in Table 34.2.

It becomes obvious from the values given in Table 34.2 that the contribution of temperature fluctuations to the refractive index fluctuations dominates by two orders of magnitude for near-infrared radiation, while temperature and humidity fluctuations are similarly important for microwave radiation. The contribution of pressure fluctuations can generally be neglected. As a consequence, an optical scintillometer system alone may be used to derive the sensible heat flux, while a microwave scintillometer and an optical scintillometer operated simultaneously are needed to determine the latent heat flux (evaporation) from scintillation measurements. In many applications, just an optical scintillometer is operated to derive an area-representative value of the sensible heat flux from scintillation measurements while the latent heat flux is determined as a residual of the energy budget equation or with the Bowen ratio method using measurements or reasonable estimates of net radiation and soil heat flux (and the gradients of temperature and humidity for the latter method). Note that the latter data are usually of a very different spatial representativeness, adding additional uncertainties to the derived latent heat flux.

A key atmospheric variable considered in scintillometry is the refractive index structure parameter, C_{nn} . For homogeneous and isotropic turbulence, it is given by (e.g., [34.48])

$$C_{nn} = \overline{[n(x, t) - n(x + \Delta x, t)]^2} \Delta x^{-2/3}. \quad (34.2)$$

This definition indicates that the mean difference of the instantaneous values of n at position $x + \Delta x$ from a reference value at position x only depends on the distance Δx , which must be within the inertial subrange of the turbulence spectrum. This definition of a turbulent structure parameter can be formulated in the same way for any atmospheric variable, including T and q . With (34.1), the refractive index structure parameter can be expressed as a combination of the structure parameters for temperature, C_{TT} , humidity, C_{qq} , and

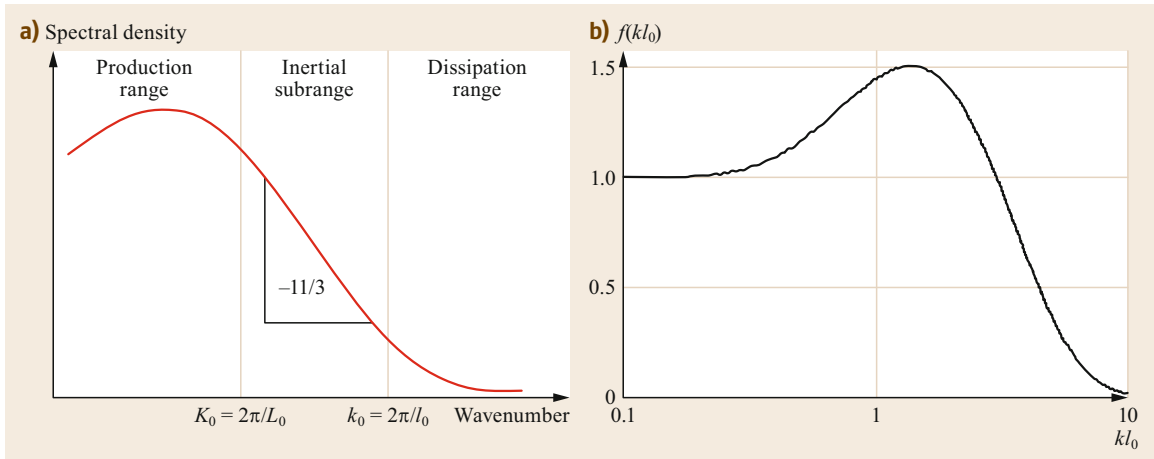

Fig. 34.3 (a) Schematic representation of the power spectrum of turbulence (courtesy of Radiometer Physics GmbH) and (b) the correction function $f(kl_0)$ for the power spectrum of turbulence for wavelengths around l_0 according to the model proposed (after [34.47])

of the temperature-humidity cross-structure parameter, C_{Tq} , [34.49]

$$C_{nn} = \frac{A_T^2}{\bar{T}^2} C_{TT} + 2 \frac{A_T A_q}{\bar{T} \bar{q}} C_{Tq} + \frac{A_q^2}{\bar{q}^2} C_{qq}; \quad (34.3)$$

C_{Tq} is related to the correlation between temperature and humidity fluctuations (e.g., [34.46])

$$r_{Tq} = \frac{C_{Tq}}{\sqrt{C_{TT} C_{qq}}}. \quad (34.4)$$

As discussed above, the first term on the right-hand side of (34.3) is dominant for visible and near-infrared wavelengths, such that C_{TT} can be directly related to C_{nn} with a correction factor accounting for the humidity effects via the Bowen ratio, Bo [34.46, 50]

$$C_{TT} = \frac{\bar{T}^2}{A_T^2} C_{nn} \left[1 + \frac{0.03}{\text{Bo}} \right]^{-2}. \quad (34.5)$$

The correction factor exceeds 10% for Bowen ratio values $\text{Bo} < 0.3$. Equation (34.5) is an approximation to the exact solution (presented in [34.46]) resulting in increasing errors for Q_H with decreasing absolute Bo values for $|\text{Bo}| < 1$. This, however, corresponds to situations where Q_H is small compared to Q_E , such that the absolute errors in Q_H and the impact on the total energy budget are reasonably small.

In order to derive both the sensible and latent heat fluxes from the simultaneous operation of a LAS and an MWS, r_{Tq} has to be either determined directly from correlating the fluctuation measurements at the two wavelengths (the so-called *bichromatic* method, [34.39])

or prescribed by a reasonable value [34.51]. Typical values are $r_{Tq} = 0.8$ for unstable conditions and $r_{Tq} = -0.5$ for stable conditions (see [34.52] for a summary).

34.3.2 Turbulence Spectrum

A schematic illustration of the power spectrum of turbulence is given in Fig. 34.3. The spectrum can be subdivided into three typical regions (Chap. 1):

- The production range where turbulent energy is generated by buoyancy and shear.
- The inertial subrange over which the energy is transferred from larger to smaller eddies.
- The dissipation range where turbulent energy is dissipated into heat.

Kolmogorov [34.53] provided a model for the three-dimensional refractive index spectrum for homogeneous and isotropic turbulence in the inertial subrange, $\phi_{nn}(k)$, as a function of the turbulent wavenumber, k ,

$$\phi_{nn}(k) = 0.033 C_{nn} k^{-11/3}. \quad (34.6)$$

In the inertial subrange, the intensity of turbulence decreases with $k^{-11/3}$. Close to L_0 or close to l_0 , outer and inner scale effects have to be considered, and the spectral shape deviates from the inertial subrange behavior. When operating a scintillometer, certain requirements regarding l_0 and L_0 must be matched. In any case, D and F should both be much smaller than L_0 . Except for inner-scale scintillometers, it is required that D or F is much larger than l_0 . Both conditions are usually fulfilled for optical LAS and MWS systems (although

for large values of l_0 , around 15 mm, $D \approx 10l_0$ holds for some LAS systems which makes a correction necessary, this correction amounts to about 10% for C_{mn} , see [34.17]).

For the spectral range around l_0 , which is of relevance for the operation of Scintec's dual-beam laser scintillometers (Sect. 34.6), Hill [34.47] has proposed a model to parameterize the deviations from the inertial subrange behavior (Fig. 34.3b). It describes a small increase in spectral energy (often referred to as the *Hill bump*) at the transition from the inertial subrange to the dissipation range, followed by a rapid decrease (with a slope exceeding the $k^{-11/3}$ behavior in the inertial subrange) towards very small values. Different analytical approximations to this model have been described in the literature [34.11, 17, 54].

34.3.3 Scintillometry Equations

Refractive index inhomogeneities along the propagation path cause a signal of electromagnetic radiation to exhibit both amplitude and phase fluctuations; in scintillometry it is the amplitude fluctuations that are analyzed. Amplitude fluctuations in the weak-scattering turbulence regime follow a log-normal distribution. However, what is usually recorded is not the amplitude but the intensity, I , of the electromagnetic signal (or a voltage that is proportional to the intensity). The conversion from intensity fluctuations to amplitude fluctuations assuming a log-normal distribution is given by

$$\sigma_{\ln(A)}^2 = \frac{1}{4} \ln \left(\frac{\sigma_I^2}{\bar{I}^2} + 1 \right). \quad (34.7)$$

The fundamental scintillometer equation is given by the solution of the wave propagation equation in a turbulent medium [34.3] using Rytov's perturbation method. For spherical waves propagating from a point source to a point detector through a statistically homogenous and locally isotropic turbulence field it was presented by [34.55]

$$\sigma_{\ln(A)}^2 = 4\pi^2 k_\lambda^2 \int_0^X \int_0^\infty k \phi_{mn} \sin^2 \left(\frac{k^2 x(X-x)}{2k_\lambda X} \right) dk dx, \quad (34.8)$$

where k_λ is the wavenumber of the electromagnetic radiation ($k_\lambda = 2\pi/\lambda$), and x is the distance along the path between transmitter and receiver (0– X).

This equation relates the variance of the log-amplitude fluctuations, $\sigma_{\ln(A)}^2$, to the three-dimensional spectrum of turbulence, ϕ_{mn} . The other parameters in (34.8) are determined by the measurement setup (λ, X).

With (34.6) for ϕ_{mn} , and (34.7) to convert from signal intensities to amplitudes, integration of (34.8) provides the relation between the refractive index structure parameter and the variance of the logarithmic signal intensities measured by a scintillometer.

Additional terms in the fundamental equation (34.8) have to be considered in order to account for aperture averaging at the transmitter and the receiver (in the case of the LAS), for inner and outer scale contributions (if applicable, depending on the system characteristics), as well as for saturation effects, and to describe the covariances between two scintillometer beams (for the dual-beam laser scintillometer and for the optical-microwave scintillometer). For a LAS and for an MWS, the following relations result [34.4]

$$C_{mn}(\text{LAS}) = 4.48 \sigma_{\ln(A)}^2 D^{7/3} X^{-3}, \quad (34.9a)$$

$$C_{mn}(\text{MWS}) = 8.06 \sigma_{\ln(A)}^2 k^{-7/6} X^{-11/6}. \quad (34.9b)$$

The integral over x in (34.8) represents the path-weighting function; it shows to what extent fluctuations at the relative position x/X along the path contribute to the measured scintillation signal. Path-weighting functions for a typical configuration of an optical LAS combined with an MWS are presented in Fig. 34.4.

Figure 34.4 illustrates that the path-weighting functions for a symmetric scintillometer setup are symmetric and have a clear peak in the middle of the path. They decrease towards the edges of the path, indicating that fluctuations close to the transmitter/receiver do not contribute significantly to the measured signal. This implies that flow distortion effects by the mount-

Fig. 34.4 Normalized path-weighting function W , vs. normalized path position x/X , for a combined LAS/MWS system with symmetric setup. Here, OMS means optical-microwave scintillometer (Sect. 34.4) and stands for the crosscorrelated signal between the LAS and the MWS systems (courtesy of Radiometer Physics GmbH)

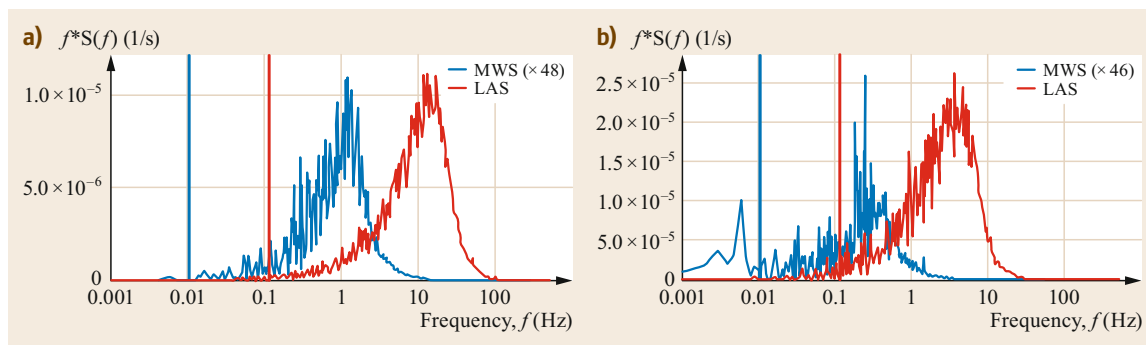

Fig. 34.5a,b Scintillation spectra from simultaneous LAS and MWS measurements with a Wageningen University and Research LAS (WURLAS) and an RPG-MWSC-160 (for the instruments, Sect. 34.4) measured at Lindenberg and visualized with the MWSC.exe software (Radiometer Physics GmbH) for realtime system watch. (a) 26.09.2018 00:00–00:17 UTC (moderate crosswind), (b) 30.09.2018, 00:00–00:17 UTC (low crosswind) – the vertical red and blue solid lines mark the cut-off frequencies of the high-pass filters

ing structures of the scintillometer units are not an issue for scintillometer measurements. This can be an advantage when selecting the positions where to install the scintillometer units, since it allows installation on, e.g., church towers or the roofs of buildings. The peak in the center of the path is broader for the MWS, while the curve for the optical LAS exhibits a sharp drop already at $x \approx X/2 \pm X/6$. This different behavior has to be kept in mind for the interpretation of combined optical-microwave scintillometer measurements over a heterogeneous land surface.

34.3.4 Saturation and Absorption

The proportionality between the measured scintillometer signal intensity fluctuations and the refractive index structure parameter as described by (34.9) is based on the theory of weak scattering, assuming that each wavefront of the electromagnetic signal coming from the transmitter is distorted only once before reaching the receiver. A criterion for the weak-scattering regime is given by the relation $\sigma_A^2 < 0.3$ [34.56]. Beyond this limit, when turbulence becomes stronger, the signal variance gets saturated and no longer increases with C_{nn} . In a transition region between both regimes, saturation effects cause deviations from the linear proportionality given by (34.9), but there is still an increase of the signal variance with C_{nn} , and models have been proposed to correct for these deviations from the single-scattering theory (e.g., [34.56–58]). The saturation issue is particularly relevant for the LAS. In practice, the effects of saturation can be reduced by increasing the LAS aperture, i.e., employing an extra large-aperture scintillometer (XLAS) instead of a LAS (Sect. 34.4), by reducing the scintillometer path length and/or by increasing the path height.

Scintillometers often operate at wavelengths where electromagnetic radiation is absorbed by water vapor or aerosols. Absorption fluctuations, however, typically occur at lower frequencies than the scintillations. In practice, they are often removed through a suitable high-pass filtering of the received signal. However, the position of the scintillation-caused spectral peak in the frequency domain is different for optical waves and microwaves (Fig. 34.5). Moreover, it depends on the crosswind (a property that allows to derive the crosswind speed from scintillation spectra, see Sect. 34.3.7), for low crosswind speeds, the spectrum is shifted towards lower frequencies. It is, thus, strongly recommended to allow for a variable high-pass-filter cutoff frequency when analyzing scintillometer data. If fixed filters are applied, different values should be allowed for the raw signal from an optical LAS and from an MWS. For the examples presented in Fig. 34.5, the LAS filter applied to the MWS signal would cut a significant part of the spectrum. In practice, the scintillation signal is often bandpass filtered in order to additionally remove unwanted electronic noise in the high-frequency range. Further unwanted contributions to the scintillation spectrum may result from vibrations of the mounting platforms; these are difficult to filter because their appearance may vary with wind speed, wind direction, or human activities around the site (traffic, building activities, tower maintenance, etc.). It should be noted that any filter has to be applied to the raw signal time series before calculating the variances.

Water droplets or dust may lead to additional extinction, in particular for visible and near-infrared radiation, such that only a weak or no detectable signal reaches the receiver. As a rule of thumb one may assume that optical scintillometers can only be operated if the visibility surpasses X , the scintillometer path length (Sect. 34.6).

34.3.5 The Derivation of Heat Fluxes Based on Similarity Theory

Monin–Obukhov similarity theory (MOST) is used to derive the surface fluxes of sensible heat, latent heat, and momentum from the structure parameters and from the eddy dissipation rate derived from the scintillation measurements. MOST represents a framework to parameterize the vertical profiles of atmospheric variables (temperature, humidity, and wind speed, but also variances and structure parameters) using a limited number of scaling parameters and a set of universal functions (Chap. 1). It has been developed to describe the structure of the atmospheric surface layer over a homogeneous surface under stationary atmospheric conditions. These assumptions should be kept in mind when defining a scintillometer setup and when interpreting the results of the measurements. In practice, MOST is often routinely applied to nonideal surfaces and under nonideal conditions. The surface layer is generally assumed to roughly cover the lowest 10% of the atmospheric boundary layer (ABL); hence, under daytime convective conditions scintillometer measurements with typical path heights < 50 m can be assumed to represent surface-layer turbulence. For stable conditions, this assumption may be violated, particularly in situations with weak winds and strong near-surface inversions. However, heat fluxes are usually small under these conditions, and even large relative errors often cause only rather small absolute errors. Quasi stationarity can usually be assumed over reasonably short averaging intervals, and it is a clear advantage of scintillometer measurements (when compared to, e.g., eddy-covariance measurements; Chap. 55) that statistically stable results can be obtained for averaging intervals down to a few minutes (1–10). The homogeneity assumption is usually fulfilled for a typical scintillometer setup at field scale. For a LAS setup at several decameters above ground (intended to provide regional-scale fluxes), it may be assumed that the path height is above the blending height where the varying signatures of small surface patches are blended by turbulent mixing.

MOST relates the nondimensional temperature and humidity structure parameter profiles to the surface fluxes via [34.48]

$$\frac{C_{TT}(z-d)^{2/3}}{\bar{T}_*^2} = f_{TT} \left(\frac{z-d}{L} \right), \quad (34.10a)$$

$$\frac{C_{qq}(z-d)^{2/3}}{\bar{q}_*^2} = f_{qq} \left(\frac{z-d}{L} \right), \quad (34.10b)$$

where T_* and q_* are the turbulent temperature and humidity scales (Chap. 1) defined through

$$T_* = -\frac{Q_H}{\rho c_p u_*}, \quad (34.11a)$$

$$q_* = -\frac{(1-\bar{q})Q_E}{\rho L_V u_*}, \quad (34.11b)$$

and f_{TT} and f_{qq} are universal functions of the height, reduced by the displacement height d , and nondimensionalized by L , the Obukhov length, which is given by

$$L = -\frac{\rho c_p u_*^3}{\frac{g}{T} \kappa Q_H}. \quad (34.12)$$

Here, κ is the von-Kármán constant, for which a value of $\kappa = 0.4$ is commonly accepted.

Most of the universal functions f_{TT} and f_{qq} proposed in the literature are of the general form

$$f_{XX} = a \left[1 - b_1 \left(\frac{z-d}{L} \right) + b_2 \left(\frac{z-d}{L} \right)^{c_1} \right]^{c_2} \quad (34.13)$$

The coefficients a , b_1 , b_2 , c_1 , and c_2 were determined by various authors based on data from field experiments; for an overview, see [34.59, 60]. Both the coefficients and the functional form differ for stable and unstable conditions. Some of the most common sets of coefficients that have been used to derive the sensible heat flux from scintillometer data are given in Table 34.3.

Depending on the choice of the similarity functions and their coefficients, the fluxes derived may differ substantially (Fig. 34.6). It has been demonstrated that the values of a and b_1 in the most common function used for unstable conditions (with b_2 not determined, $c_2 = -2/3$) depend on the observation height, on the stability range covered by the data, and on the regression approach used to fit the data [34.67].

The coefficients for the universal functions should, therefore, be carefully selected based on either recommended mean values [34.60] or on values that were determined for surface and climate conditions comparable to the actual application. In any case, a methodical uncertainty of the derived fluxes of about 10–20% must be assumed based on the uncertainty of the similarity coefficients. In practice, the same coefficients are often used for the universal functions f_{TT} and f_{qq} . This implies that temperature and humidity behave similarly and are perfectly correlated ($r_{Tq} = 1$) in the surface layer, which is, again, a simplifying assumption. There are a very few studies available only that have experimentally determined the coefficients for the humidity function f_{qq} [34.60, 64].

Table 34.3 Commonly used values for the coefficients in the universal functions for C_{TT} (see (34.13)), empty cells indicate that the model fitted by the authors to their data did not consider this specific coefficient/term

Fig. 34.6 Sensitivity of the derived sensible heat flux, Q_H , to the similarity coefficients in (34.13) for unstable stratification used by different authors (Table 34.3; the calculations were done assuming $z = 43$ m, and $u_* = 0.2$ m s⁻¹)

For the calculation of the sensible and latent heat fluxes via MOST based on (34.10)–(34.12), friction velocity is additionally needed in order to determine L , θ_* , and q_* . Methods to derive u_* are discussed in Sect. 34.3.6.

In the special case of free convection (weak wind conditions, unstable stratification above the surface layer), friction velocity no longer plays a role as a scaling velocity, and the similarity relationship between Q_H and C_{TT} is given through (e.g., [34.2, 48])

$$\frac{Q_H}{\rho c_p} = c C_{TT}^{3/4} \left(\frac{\bar{T}}{\kappa g} \right)^{-1/2} (z - d). \tag{34.14}$$

This equation allows for a direct estimation of the surface sensible heat flux from C_{TT} without the need for additional data on wind speed or friction velocity. The constant c depends on the choice of the similarity

constants for unstable stratification ((34.12) and Table 34.3), it is related to a and b_1 through

$$c = \frac{(b_1)^{1/2}}{a^{3/4}}$$

for the most common similarity model with no b_2 term and $c_2 = -2/3$.

34.3.6 Determination of Friction Velocity Using Similarity Theory

The dual-beam laser scintillometer (Sect. 34.4) is sensitive to eddy sizes close to the inner length scale of turbulence, l_0 ; it operates with two parallel laser beams a few millimeters apart from each other. For this specific setup, a scintillometer equation analogue to (34.8) can be formulated for the covariance between the signal amplitudes of the two beams. It can be shown that the correlation coefficient, r , calculated from this covariance and from the amplitude variances of the two beams becomes a function of l_0 only such that l_0 can be directly determined from r . The inner scale length is related to the dissipation rate of turbulent kinetic, ε , energy via

$$\varepsilon = \nu^3 \left(\frac{7.4}{l_0} \right)^4, \tag{34.15}$$

where ν is the kinematic viscosity of air, which depends on temperature, humidity, and pressure. MOST relationships can be formulated to link ε to the surface flux of momentum (represented by the friction velocity, u_*) using universal functions f_ε , which, again, have the general form given in (34.13)

$$\frac{\varepsilon \kappa (z - d)}{u_*^3} = f_\varepsilon \left(\frac{z - d}{L} \right). \tag{34.16}$$

For the calculation of the sensible and latent heat fluxes via MOST from the measurements with a single-beam and/or large-aperture scintillometer (Eqs. (34.10)–(34.12)), friction velocity is normally derived from independent representative wind measurements. Based on MOST, horizontal wind speed, V , and friction velocity are related through

$$u_* = \frac{\kappa V}{\ln\left(\frac{z-d}{z_0}\right) - \psi_M\left(\frac{z-d}{L}\right) + \psi_M\left(\frac{z_0}{L}\right)}, \quad (34.17)$$

where z_0 is the roughness length, and ψ_M is the integral of the universal function f_M , which, again, is given by a functional relationship of the type described by (34.13) with different forms for stable and unstable stratification, respectively (Chap. 1). The equation system defined by (34.10)–(34.12) has to be solved iteratively.

34.3.7 The Effective Path Height

The derivation of surface fluxes from scintillometer measurements using similarity theory as described in the previous sections always involves the height z as a key variable. Determination of the representative scintillometer path height above the surface is, therefore, an important issue. For a short path (magnitude 10^2 m) at low heights over a basically flat and homogeneous surface, the mean geometric height of the transmitter and receiver units, possibly reduced by the displacement height d (which can be roughly estimated as $2/3$ of the vegetation height), usually provides a reasonable value. For longer paths (10^3 – 10^4 m, the typical path length of LAS and MWS systems), over heterogeneous or very rough surfaces (e.g., cities) and over orographically structured terrain (e.g., across valleys with the transmitter and receiver units installed on the valley slopes or ridges), an effective path height has to be determined from a convolution of the variable geometric height above ground with the scintillometer path-weighting function [34.68]. In the case of strong surface or oro-

graphic variability perpendicular to the path, the height above ground should not be determined just from below the path but for the footprint area upstream of the path [34.24]. For a combined optical-microwave system, the different path-weighting functions of the two scintillometers have to be taken into account [34.69]. The estimation of representative values for displacement height and roughness length is important (since uncertainties in d and z_0 may cause appreciable uncertainties in the fluxes) but challenging in particular above strongly structured surfaces (e.g., heterogeneous forest or urban areas).

34.3.8 The Determination of Crosswind

In addition to the turbulent fluxes of heat and momentum, scintillometers also allow for the determination of the so-called crosswind, i.e., the component of the horizontal wind vector perpendicular to the scintillometer path. Basically, two types of method are available for this application [34.70–73]. The first type (e.g., [34.73]) is based on scintillation measurements with two parallel beams. Assuming Taylor's frozen turbulence hypothesis to be fulfilled, the turbulent eddy field does not change while being transported through the two scintillometer beams. The fluctuation time series recorded for the two beams should, therefore, show the same signatures, but with a time shift that depends on the mean wind perpendicular to the path. This crosswind can, thus, be derived from the time lag of maximum correlation between the two signals. This method is implemented with Scintec's dual-beam instruments (Sect. 34.4). The second type of method can be applied to single-beam large-aperture scintillometers [34.72]. It makes use of the fact that the position on the frequency axis of a characteristic inflection point in the scintillation spectrum depends on the crosswind speed. This approach cannot determine the sign (direction) of the crosswind and has so far not been implemented in the software of any of the commercially available scintillometer systems.

34.4 Devices and Systems

The scintillometer types in use mainly differ with respect to the wavelength of the radiation emitted, the beam configuration, and the geometrical dimensions of the transmitters and receivers. These instrument characteristics also determine the setup of a system (e.g., path length, path height). Scintillometers operating at wavelengths $\lambda \approx 400$ nm– 4 μ m are called optical scintillometers; systems using a wavelength

$\lambda \approx 1$ – 10 mm are called microwave (or millimeter-wave or radiowave) scintillometers (MWS). Most scintillometers emit one beam of electromagnetic radiation. The optical systems manufactured by Scintec AG (Sects. 34.4.1 and 34.4.2) use two parallel beams (dual-beam system or dual-disk system). This allows for an estimation of the crosswind (Sect. 34.3.8) and—for the laser scintillometers (Sect. 34.4.1)—the friction

Fig. 34.7 (a) The SLS20/SLS40-A and (b) SLS40/SLS40-A units by Scintec AG (courtesy of Scintec AG; the right background photo was kindly provided by C. Jarman – South Africa)

velocity (Sect. 34.3.6) from analyzing the correlation between the two scintillation signals that are distinguished at the receiver side by a different polarization of the two beams. The following sections give a brief description of the scintillometer types widely applied and/or commercially available.

34.4.1 Optical Small-Aperture Scintillometers

The German manufacturer Scintec AG introduced to the market a series of optical dual-beam, small-aperture laser scintillometers (DBLS), called surface-layer scintillometers (SLS). Their basic application is the determination of the turbulent fluxes of sensible heat and momentum at field scale. They are generally operated within the atmospheric surface layer. A crosswind option is available. Scintec's SLS systems operate with visible laser light at 670 nm wavelength (red light); the laser is categorized as class 2M (IIIa).

There are four system versions available, the SLS20 and SLS40, and an A type of both systems (Fig. 34.7). The SLS20 is the basic version, the SLS40 has implemented special features to correct for possible vibrations of the mounting platforms (e.g., towers), while the A-version of both types offers automatic beam steering, a feature especially suited for operation on soft ground.

A careful calibration of the transmitter and receiver beam separations (which is offered by the manufacturer) is highly recommended, since specifically the calculated momentum flux is rather sensitive with respect to small deviations from preset standard values [34.43].

Special features implemented with the system hardware and software include:

- Window heating to prevent dew and ice deposition
- Radiation modulation for background elimination and interference filter for use in direct sun light
- Background noise and crosstalk measurement and correction options
- Amplitude and statistics tests on the mean and scintillation signals resulting in an internal data quality assessment
- Realtime data monitoring, including raw data and fluxes, and special display for alignment purposes
- Viewing and postprocessing options for previously recorded data.

Auxiliary pressure and temperature sensors can be directly connected to the system data acquisition unit to provide the meteorological input parameters necessary for the flux calculations and stability estimation.

34.4.2 Optical Large-Aperture Scintillometers

A series of research LAS was built by the Meteorology and Air Quality Department at Wageningen University and Research (WURMAQ) at the end of the 1990s. These instruments use a wavelength of 940 nm. The signal is emitted from an LED placed in the focal point of a concave mirror with a diameter of 15 cm. At the receiver side the same type of mirror is used to focus the scintillation signal on a photodiode (Fig. 34.8).

Fig. 34.8 The WURMAQ LAS transmitter mounted at the Falkenberg tower of DWD

In 2001, Kipp & Zonen adopted elements of the WURMAQ scintillometer design with its LAS MkI instrument, in which the signal is created by one single LED, and a Fresnel lens is used both at the transmitter and receiver sides to form the beam and to focus the received signal on a photodiode. This instrument was redesigned in 2012, resulting in the LAS MkII (a change of the infrared LED emitter and detector to improve range and performance, the addition of an infrared (IR) bandpass filter with a center wavelength at 850 nm to improve the signal-to-noise ratio, a larger detector area for easier instrument setup and alignment in the field, a change of the housing and internal optical mounting to allow outdoor alignment by hand and easy focusing of the LED and detector at the factory, replacement of the analogue electronics with internal

digital processing). The LAS MkII (Fig. 34.9) can be easily installed and configured using its built-in display and keypad without the need for any extra equipment. The receiver has a built-in data logger and digital outputs for direct PC connection. Realtime measurements are shown on the display. The C_{nm} data and demodulated signal are also available as an analogue output to be recorded using virtually any type of data acquisition system. The internal clock is automatically synchronized with a global positioning system (GPS) antenna. All systems are tested outdoors for 2 weeks and compared against reference instruments before being shipped to customers to ensure consistency and high data quality.

The EVATION[®] software included with the LAS MkII scintillometer is a fully featured configuration, monitoring and data processing program. The scintillometer can be controlled using EVATION[®] and it offers many data processing options and real time data display. The processing parameters are customizable for more advanced or application-specific processing options. Data files can be read to process data from LAS MkII analogue or serial outputs recorded on virtually any type of external data logger. The standard operating range of the LAS is 0.25–4.5 km, but this can be reduced to 0.1–1 km using the included reduction aperture set.

In 2018, a new version of the extra-large aperture scintillometer (XLAS) MkII was released with all the benefits of LAS MkII but extending the range to 12 km (Fig. 34.9). An additional design feature is the lightweight carbon fiber housing, which provides increased stiffness and reduced thermal expansion of the enclosure to maintain optical alignment.

Fig. 34.9a,b The receiver units of the LAS MkII (a) and XLAS MkII systems (b) by Kipp & Zonen (courtesy of Kipp & Zonen B.V.)

Special features of the system include:

- Low maintenance and low power consumption
- Integrated data logger with analogue and digital outputs
- Stand-alone operation or direct PC connection
- Modulated IR beam and narrowband filter to avoid interference from surrounding light sources and sunlight
- Internal configuration option for high and low-pass filters
- Optional meteorological sensor (wind speed, air temperature and pressure sensors) plugs directly in the sensor port.

The system is also available as a LAS MkII ET (Evapo-Transpiration) system, which comes complete with scintillometer, meteorological sensors, and data acquisition capability.

Scintec AG offers three types of LAS, which are called boundary-layer scintillometers (BLS, to be distinguished from their surface-layer scintillometers, SLS): the BLS450, the BLS900, and the BLS2000. The transmitter signal originates from a large number of LEDs (444, 888, and 1756, respectively; these numbers also determine the system names) arranged on one (BLS450) or two disk(s) (BLS900, BLS2000 – Fig. 34.10), the transmitter divergence is 16° , resulting in a quite large illuminated area with increasing path length. This reduces the sensitivity to misalignment or instability of the mounting structures. At the receiver side, a glass (BLS450

Fig. 34.10 The BLS-900 transmitter and receiver units (courtesy of Scintec AG; background photo kindly provided by C. Jarman – South Africa)

and BLS900) or Fresnel lens (BLS2000) acts to focus the signals on two photodiodes. The BLS450 and the BLS900 are classified as LAS systems; the BLS2000 is an extra-large aperture scintillometer (XLAS). An aperture-reduction is available for operation of the BLS over paths shorter than the specified lower limit (500 m and 1 km, respectively – Table 34.6). The dual disk transmitter of the BLS900 and BLS2000 emits two parallel beams allowing both the determination and correction of possible contributions from absorption fluctuations to the scintillation signal and the determination of the cross-wind perpendicular to the path.

Special features implemented with the system hardware and software include:

- A selectable transmitter pulse repetition rate (which is of relevance in particular if available transmitter power is limited for operation with batteries or solar panels).
- A series of 18 red-light LEDs in each transmitter LED row to indicate the transmitter status.
- Radiation modulation for background elimination and interference filter for use in direct sunlight.
- Optical alignment aid for the receiver using two detectors.
- Automatic corrections for saturation, absorption fluctuations, and outer scale effects.
- Error identification based on the received signal characteristics.
- Comprehensive realtime data monitoring, including raw data and fluxes, and special display for alignment purposes.
- Viewing and postprocessing options for previously recorded data files.

Auxiliary pressure, temperature, and wind sensors can be directly connected to the system data acquisition unit to provide the meteorological input parameters necessary for the flux calculations.

34.4.3 Microwave Scintillometers

Several noncommercial microwave scintillometers have been built over the last three decades; they have mainly been used within research projects. An overview on these systems is given in Table 34.4.

Due to the large wavelength (when compared to optical scintillometers), all microwave scintillometers are so-called small-aperture systems for which the diameter of the first Fresnel zone determines the size of the eddies that contribute to the scintillation signal detected at the receiver.

In 2014, the commercial microwave scintillometer MWSC-160 was introduced to the market by Radiome-

Table 34.4 Research type microwave scintillometers used over the last 30 years

ter Physics GmbH (RPG). The system combines the experience from previous design versions with the theoretical expertise from WURMAQ and the experience in microwave technology available at RPG. It can be combined with each of the commercially available optical LASs and even with the noncommercial WURMAQ LAS to form an optical-microwave scintillometer system (OMS) suitable for estimating both the sensible and latent heat fluxes (Fig. 34.11). A standard WXT-5xx (Vaisala Oy) weather station can be directly connected to the system data acquisition unit to provide the meteorological input parameters necessary for the flux calculations. It also gives a rain flag to remove data during precipitation when the assumptions of scintillometer theory are violated.

Special features implemented in the system software include:

- Comprehensive realtime data monitoring, including raw data, spectra, derived fluxes, and system internal (housekeeping) data.
- Corrections for saturation and absorption fluctuations.
- User-selectable configuration of high-path filters; A_T and A_q coefficients (34.1), similarity function coefficients (34.13)
- Internal calculation of the effective path height based on prescribed topography along the path and on the mounting heights of the transmitter/receiver units.
- Viewing and postprocessing options for previously recorded data files.

34.4.4 Summary of Assumptions, Advantages and Disadvantages of Scintillometers

Table 34.5 gives a brief overview of the basic assumptions behind scintillometry methods and applications and of the advantages and disadvantages of scintillometers to derive the turbulent fluxes of sensible heat, latent heat, and momentum.

Table 34.5 Assumptions, advantages and disadvantages of scintillometry

<p>Assumptions and limitations</p> <ul style="list-style-type: none"> • Weak scattering ($\sigma_A^2 < 0.3$, otherwise saturation may occur) • Log-normal frequency distribution of instantaneous measured signal intensities • Relevant eddy size within the inertial subrange of turbulence, for $(D, F) \approx l_0$ a model parameterization for the turbulence spectrum of refractive index must be applied • Prescribed values for r_{Tq} to determine C_{TT} and C_{qq} from C_{mm} (except for the bichromatic method) • Parameterization of the humidity contribution to C_{mm} for a stand-alone optical scintillometer with increasing uncertainty for $Bo < 0.3$ • Effective path height above the blending height (above heterogeneous surfaces) • Applicability of Monin–Obukhov similarity theory (horizontal homogeneity, stationarity) 	
<p>Advantages</p> <ul style="list-style-type: none"> • Provides line-/area-averaged flux values at scales of 10^2–10^4 m resulting in an improved spatial representativeness, especially over heterogeneous surfaces • No absolute calibration of signal strength required because relative intensity fluctuations are evaluated • Statistically stable results even for short averaging times (since the size of sampled eddies is more than three magnitudes smaller than the path length and the wind fetch, i.e., the product of effective crosswind speed and averaging time) allowing to study fast processes • Low maintenance requirements • No flow distortion (since the path weighting function goes to zero at the transmitter and receiver positions) • Operation at (very) low heights possible (for the DBLS: $F \ll z$ is fulfilled for $z > 0.1$ m, for a LAS $D \ll z$ is fulfilled for $z > 1.5$ m) 	<p>Disadvantages</p> <ul style="list-style-type: none"> • Need for additional temperature and pressure data for the flux calculations (default values may be used but increase uncertainty) • Need for additional wind data (except for the DBLS) and estimates of d and z_0 for the flux calculations, derived fluxes linearly depend on uncertainties in d and z_0 • Need for additional measurements/assumptions to distinguish between stable/unstable stratification • Large relative uncertainty due to pronounced minima of C_{mm} at near-neutral stratification (but low fluxes under these conditions) • Water vapor absorption at optical and mm wavelengths (absorption fluctuations can be removed by spectral separation and filtering or by the dual-beam technique) • Reduced signal strength (and data availability) in case of precipitation, haze/fog and strong turbidity because of heavy smoke or dust due to particle/droplet extinction of radiation • Uncertainty of the derived fluxes due to different MOST stability functions and coefficient values available

Part C | 34.5

34.5 Specifications

Table 34.6 gives an overview of the basic system specifications, the typical setup conditions, and the basic output variables of the scintillometer systems commercially available at present.

Most commercial scintillometers are specified for environmental conditions between -20 and $+40$ °C for temperature and between 0 and 100% for relative humidity.

Table 34.6 Basic specifications of scintillometer systems commercially available in 2018

34.6 Quality Control

Scintillometers measure intensity fluctuations of electromagnetic radiation around a mean value, hence no (absolute) calibration is needed against any standard or reference instrument (except of the internal analogue system electronics, in the case of the WURMAQ design, but this is probably a historical aspect). Geometrical dimensions (e.g., aperture size of a LAS/XLAS, transmitter and receiver beam separations of Scintec's dual-beam surface-layer scintillometer) have to be accurately prescribed, and instrument-specific values should be used instead of default values [34.43].

When interpreting the derived fluxes, the assumptions behind the method should always be kept in mind (Sect. 34.4.4). Commercial scintillometer systems have often implemented certain corrections in their software (e.g., for saturation, absorption, inner/outer scale effects), as well as some quality tests (e.g., mean signal strength, statistical distribution of the fluctuations). Correction factors and quality flags given in the output files should always be considered during data interpretation. Figure 34.12 illustrates the frequency distribution of correction factors applied to two types of BLS systems. The correction for high-pass filter effects is almost negligible except under low crosswind conditions. The corrections for inner scale effects and saturation are less relevant for the BLS2000 because of the larger aperture diameter when compared with the BLS900. However, the different corrections may partly compensate for each other such that the total effect (Fig. 34.12b) is smaller than $\pm 10\%$ in more than 2/3 of the cases. When using the bichromatic method to derive the sensible and latent heat fluxes from a combined optical-microwave scintil-

lometer, the r_{Tq} values determined from the correlation between the two signals should always be critically examined for unphysical values ($|r_{Tq}| > 1$); in the case of $|r_{Tq}| < 0.3$, the fluxes should be interpreted with caution, since low values of the correlation indicate a violation of the assumptions behind MOST.

The definition of structure parameters (34.2) is based on the absolute differences of atmospheric variables at positions x and $x + \Delta x$ without taking into account the sign of the differences. Therefore, scintillation measurements alone generally do not allow for a determination of the sign of the heat fluxes. Since different MOST functions have to be applied to derive the surface fluxes under stable and unstable conditions, the software of commercial systems often provides calculated fluxes for both stability regimes in the output data files. Alternatively, ad-hoc assumptions might be implemented, such as a prescribed change of the heat flux sign in relation to sunrise and sunset. If fluxes for both stable and unstable conditions are reported, the decision as to their choice has to be made by the user. Gradient measurements of mean temperature and humidity in the vicinity of the scintillometer path may support this decision. Moreover, with a clear diurnal cycle of ABL development, in particular C_{TT} exhibits pronounced minima in the case of (near-)neutral stratification indicating the change from stable to unstable conditions and vice versa (Fig. 34.13). The occurrence of these minima can be taken as an indicator for the change of flux signs directly from the scintillometer measurements. An assessment of various methods to determine the stability transition can be found in [34.76].

Fig. 34.12a,b Frequency distribution of correction factors to the measured signal intensity variances for BLS900/BLS2000 measurements: (a) Single corrections and (b) total correction. Measurements were performed in 2011 (BLS900), 2014/2015, and 2018 (BLS2000) over a distance of 4.8 km at Lindenberg Meteorological Observatory, Richard-Aßmann-Observatory, Germany

Fig. 34.13 Diurnal cycle of the temperature structure parameter C_{TT} , global radiation Q_g , sensible heat flux Q_H , and the temperature difference ΔT near ground ($T_{2m}-T_{0.5m}$) on 26.08.2016 at Falkenberg (Germany) under clear-sky conditions. Pronounced minima in C_{TT} occur when the gradients and fluxes change sign in the morning/evening (note that global radiation is multiplied by a factor of 0.2 and the temperature difference by a factor of 100, respectively, for scaling purposes)

Part C | 34.6

As with all measurement techniques, it is recommended to check the derived meteorological variables for plausibility. This should include a consistency check between the flux sign and the sign of the gradients of temperature and humidity below the path (if these gradients are not used earlier to decide on the flux sign). Note also that for operation heights of several decameters AGL of LAS, MWS, and OMS systems, MOST links the surface fluxes to elevated measurements of the structure parameters, which only holds if the gradients do not change sign between the surface and the scintillometer path height; this makes scintillometer fluxes uncertain during morning and evening transition in the near-surface layer. In addition, the sum of sensible and latent heat fluxes determined from LAS and MWS measurements should be critically compared versus measurements (or estimates) of net radiation and soil heat flux not to exceed the energy available for turbulent exchange processes over longer time periods.

A summary of the different steps of quality control recommended for scintillometer measurements is given in Table 34.7.

Based on the performance of these tests, the availability of good-quality derived flux values can be expected for about 60–90% of the operation time, which is comparable to the eddy-covariance method (Fig. 34.14).

Results of scintillometer intercomparison experiments have been reported, e.g., in [34.40–44]. These studies reveal that the instrumental differences result in a flux uncertainty of typically 3–10%. A larger uncertainty may be due to methodical issues, i.e., the application/realization of certain corrections within the system software, the difficulty in determining representative values of roughness length and displacement height, and the choice of the similarity coefficients; these aspects may lead to flux uncertainties of about 15–25%.

Table 34.7 Quality control criteria for scintillometer measurements

Category	Test
Mean and scintillation signal (tests are usually implemented in the system software provided by the manufacturer, but can be applied by the user if the scintillation raw data are recorded) Assumptions behind the methodology	<ul style="list-style-type: none"> • Mean signal intensity above a certain threshold minimum value • No singular spikes in the signal intensity time series • Statistical distribution of the scintillation signal close to log-normal • No pronounced/broad peaks in the spectra (due to vibrations or electronic noise) • No saturation ($\sigma_A^2 < 0.3$) • No precipitation • $Bo > 0.3$ (for LAS, to ensure applicability of (34.5)) • $0.3 < r_{Tq} \leq 1$ • Consistency of the gradients below the scintillometer path height
Resulting fluxes	<ul style="list-style-type: none"> • Flux sign in agreement with gradients or rule-of-thumb assumptions • Sum of the derived turbulent fluxes should not exceed available energy (i.e., the sum of net radiation and soil heat flux)

Fig. 34.14 Monthly mean values of data availability of heat and momentum fluxes from SLS-40 measurements at Falkenberg (Germany) (the NOK parameter indicates the percentage of sampling intervals with good statistics of the scintillation signal; a value of 70% has been found as a reasonable threshold for good quality fluxes – note the change in system software in July 2012)

34.7 Maintenance

Scintillometer systems are generally well-suited for unattended long-term operation and require only a minimum of maintenance efforts, basically a cleaning of the units depending on the environmental conditions.

A number of different aspects has to be taken into account in connection with the installation of a scintillometer system; these include scientific (path should be centered around the flux source area of interest and preferably oriented perpendicular to the prevailing mean wind direction), logistic (mounting structures, power supply, LAN availability, accessibility for maintenance, security), and methodical aspects (path height well above the roughness sublayer, path height in relation to path length to avoid frequent saturation, no obstacles within the first Fresnel zone, for optical systems: receiver should be positioned such that it does not receive direct sunlight). For the operation of microwave scintillometers, a frequency allocation permission has to be obtained from the responsible national agency. Care has to be taken during installation and set up with respect to mounting stability and optimum alignment. Path length, path height, and (in the case of a combined optical-microwave system) the relative distances of the transmitter and receiver units with respect to each other in both y and z -directions should be determined with an accuracy of 2% or better, since these geometric variables directly enter the internal calculations of the spectral filter and path-weighting functions. Bird protection measures of the scintillometer units and/or connected meteorological sensors might be required, depending on the site conditions.

The formation and accumulation of water droplets or ice crystals at the transmitter and receiver windows or antenna surfaces under humidity conditions close to saturation and during precipitation is normally prevented by transmitter/receiver heating. However, water or ice may temporarily accumulate on the surfaces if the wind acts on the windows during heavy precipitation or snow drift. Strong wind load on the transmitter and receiver units may cause some misalignment, and regular checks of the signal strength and of the optimum alignment are thus recommended; these should include checking the proper fixing of the positioning screws. Moderate to strong winds may also cause vibrations of the mounting structures, which might add additional variance to the measured scintillation spectra, although not all vibration frequencies are necessarily seen or are inside the relevant frequency range of the scintillation spectra (e.g., [34.77]). Single narrow peaks in the scintillation spectra might be removed in data processing by fitting a model spectrum to the measured one (e.g., [34.28]).

Regular system supervision should be performed according to the user's request for data availability and completeness to be able to rapidly react on a persisting drop or breakdown of the receiver signal that might occur as a result of an instrument fault, of mechanical (misalignment due to mechanical forces, e.g., strong wind), electrical (power failure, empty batteries, broken cables, overvoltage), or weather-related (e.g., snow/ice on the transmitter/receiver windows/antenna surfaces) events. Note that precipitation or fog generally reduce the re-

Fig. 34.15 Long-term behavior of monthly mean receiver signal intensity and its standard deviation for a WURMAQ LAS system operated at Lindenberg, Germany. A mean annual cycle and phases of gradual decrease can be clearly seen; in spring 2005, the transmitter light source was replaced, and in summer 2009, the transmitter power was increased

ceived signal (normally below an acceptance threshold, resulting in no output data) without the need for user-specific action. Supervision should include an inspection of error flags given in the data files or error messages contained in the system log files, and attention to the messages related to time synchronization.

It is recommended to check the status of the transmitter and receiver windows/surfaces, the transmitter output power (control LED status in case of the Scintec BLS disk systems), and the alignment of the transmitter and receiver units at monthly to yearly intervals. For the SLS instruments, a background/crosstalk measurement should be performed at the same time. The frequency of these checks (in particular of the (re)alignment) strongly depends on the mounting and surface conditions. For concrete roof or tower mountings, annual alignment control might be sufficient; with tripods on soft ground, monthly control might be necessary.

For long-term operation (several years to decades) the mean received signal intensity should be calculated

as a monthly block or moving average in order to detect a possible slow degradation of the transmitter source (Fig. 34.15). Initial reduction of the emitted radiation intensity can usually be compensated by an increase of transmitter power.

Note that a pronounced annual cycle in mean signal intensity – depending on the site conditions – can often be observed, which is related to the mean water vapor content in the atmospheric surface layer. Such seasonal variations are particularly pronounced for microwave scintillometers. For these systems, it might be recommended to change transmitter power regularly in spring and autumn to ensure optimum signal strength both in humid summer and in dry winter conditions. A summary of supervision and maintenance activities is given in Table 34.8. The frequency of the single measures strongly depends on the user's need and on the site conditions. The recommended regular control activities listed in the first row can be done remotely with no site access needed.

Table 34.8 Recommended supervision and maintenance activities for scintillometers

Frequency	Activity
Regularly (daily to weekly)	<ul style="list-style-type: none"> • Check for data availability and reasonable mean signal behavior • Check for system error messages and time synchronization
From time to time (monthly to seasonally)	<ul style="list-style-type: none"> • Check status of units/windows, cleaning if necessary • Check/optimize alignment (soft ground)
Occasionally (seasonally to annually)	<ul style="list-style-type: none"> • Check/optimize alignment (stable mounting) • Check/adjust transmitter power

34.8 Applications

Scintillometers have demonstrated their value for a great variety of applications for which area-averaged meteorological quantities over short averaging times are of special relevance. The following sections provide some examples without the claim of completeness.

34.8.1 Field-Scale Fluxes Using the Dual-Beam, Small-Aperture Scintillometer

The dual-beam, small-aperture scintillometer is typically operated at installation heights of 1–5 m AGL and over path lengths of 100–200 m. It thus allows for the determination of the turbulent fluxes of sensible heat and momentum at field scale; the latent heat flux can be estimated as the residuum of the energy budget equation or by using the Bowen ratio method (Chap. 58), if the scintillometer is supplemented by measurements of net radiation, soil heat flux, and the gradients of temperature and humidity. For the determination of sensible heat and momentum fluxes at field scale, scintillometers can be seen as an alternative to turbulence measurements using the eddy-covariance method (Chap. 55). Compared to the latter, scintillometry has several advantages:

- Due to the path averaging of the scintillation signal, the footprint area of a scintillometer-based flux is considerably larger than for a point measurement using a sonic anemometer-thermometer; resulting fluxes may thus be more representative, especially over locally heterogeneous surface patches.
- The light beam is influenced by thousands of eddies along the propagation path sampled at frequencies of 10^3 – 10^4 Hz, which results in statistically stable

results even for short averaging times, down to the order of a minute, while the eddy-covariance method always requires averaging times of 10–30 min to obtain reasonable spectral coverage. This is of special relevance in nonstationary conditions, e.g., with rapidly changing cloud cover (Fig. 34.16).

- The dominant eddy size seen by the laser scintillometer is ≈ 1 cm, which allows for very low measurement heights above ground (even < 1 m is possible over flat surfaces with no or short vegetation) and, thus, for flux measurements over small surface patches of a rather limited upstream extension, where the fetch requirements of the eddy-covariance method are often not met.

Numerous examples of laser-scintillometer-based fluxes can be found in the literature for various types of natural and managed surfaces, preferably over low vegetation and in different climate regions [34.34, 79–82]. A few studies also report on fluxes over urban surfaces [34.83, 84]. The path-averaging effect becomes of particular relevance over sparse vegetation, where a suitable averaging over patches with plants and patches of bare soil can be achieved. Comparisons of the scintillometer-based fluxes versus eddy-covariance data usually give comparable statistics to eddy-covariance intercomparison experiments, i.e., typical deviations around 10–15%.

A special application is the derivation of trace gas fluxes (water vapor, carbon dioxide) for short averaging times (1 min) over a homogenous agricultural surface using scintillometry in combination with the variances derived from the raw data of a fast-response infrared gas analyzer (Fig. 34.16) [34.78].

Fig. 34.16a,b Time series of net (global) radiation (grey lines) and of the fluxes of water vapor (a) and carbon dioxide (b) derived with 1 min resolution from a combination of scintillometer and infrared gas analyzer measurements. Data were collected at Merken (Germany) on 14.08.2008, r_0 and r_1 are the correlation coefficients between the time series of the radiation and the trace gas fluxes for a time delay of 0 and 1 min, respectively (after [34.78] with permission from Elsevier)

34.8.2 Meso- γ Scale Fluxes from LAS and OMS

LAS and OMS systems are typically operated over a path length of several kilometers, thus providing surface fluxes at regional scale; such fluxes are of special interest for a variety of applications, including:

- The development and validation of parameterizations in numerical weather prediction and climate models, the grid resolution of which matches well with the scintillometer path length (e.g., [34.29, 85])
- The validation of flux retrieval schemes from satellite data – again the pixel resolution is similar to the scintillometer path length (e.g., [34.22, 85, 86])
- The determination of evaporation at the scale of small catchments for hydrological applications (e.g., [34.76, 87, 88])
- The determination of evaporation over agricultural farmland in connection with irrigation management (e.g., [34.26, 27, 89])
- The determination of heat and water vapor transport over cities in connection with the management and development of urban structures (e.g., [34.37, 38, 90]).

With an OMS, both the sensible and latent heat fluxes can be determined directly from the scintillometer measurements. A single LAS only provides the sensible heat flux; evaporation is then usually determined as the residual of the energy budget, which additionally requires radiation measurements and a reasonable assumption for the soil heat flux representative for the LAS path.

Heat fluxes from LAS and OMS systems have been demonstrated to be reliable over various types of un-

derlying surface and in different climate regions of the world, including heterogeneous midlatitude farmland [34.24, 25, 31, 36, 74, 91], Mediterranean dry landscape and irrigated farmland [34.13, 21, 27], sparse steppe and desert vegetation [34.22, 92–94], wetlands and rice paddies [34.95], and over both midlatitude and tropical forests [34.28, 57]. A few experiments were realized over moderately complex terrain, along mountain slopes and across valleys [34.36, 68]. Over the last two decades LAS and OMS measurements were increasingly performed over cities [34.37, 38, 90, 96–99]. For these two types of surfaces, complex terrain and urban regions, special attention has to be paid to the determination of the effective path height taking into account the considerable variability across the footprint area and variations in the displacement and roughness heights as well as potential issues with MOST.

Considering heterogeneous land surfaces, scintillometry appears to be the only method suited for routine operational estimation of area-averaged surface fluxes. Alternative methods such as airborne flux measurements, the application of budget considerations to observed boundary layer evolution or the operation of eddy-covariance systems at all relevant surface types occurring in a certain region are either too expensive from the point of instrumentation and operation, not suited for continuous operation or limited to specific situations because of certain methodical assumptions. An assessment of scintillometer fluxes compared to aggregated surface layer measurements using more than ten eddy-covariance systems operated over different types of farmland and to airborne flux measurements within the LITFASS-2003 experiment [34.74, 91] demonstrated their reliability (Fig. 34.17). With the same data set, it could be shown that a better closure of the surface energy budget could be achieved

Fig. 34.17 Diurnal cycle of sensible heat fluxes over farmland and forest as determined from eddy-covariance measurements (lines, over farmland data from 11 eddy-covariance systems provided the *farmland mean*), LAS (triangles), and airborne measurements (circles) on 25.05.2003 over the LITFASS area (after [34.91])

when compared to eddy-covariance data [34.74], which is still an open issue in micrometeorological research (e.g., [34.100] and Chap. 55).

34.8.3 Crosswind Determination

Dual-beam scintillometry allows for the determination of the line-averaged crosswind component perpendicular to the path. This capability is of special interest for a number of applications including:

- The determination of bulk transport in regions with dominant wind directions, e.g., along valleys (e.g., [34.101, 102])
- The determination of the source strength of trace gases or aerosols at the borders of farms or waste disposal sites [34.18]

34.9 Future Developments

Very reliable and stable scintillometer systems – from a technical point of view – are nowadays commercially available for the different applications described above. Their operation and data analysis relies on a profound theoretical basis, and on often evaluated methods and algorithms. Scintillometers can be seen as advantageous over classical turbulence measurement techniques, e.g., eddy-covariance systems, for the determination of representative flux values above structured terrain, such as valleys, urban areas, and heterogeneous land surfaces. Despite this potential, scintillometers are still rarely employed beyond the research community. Further qualification of the data analysis and presentation software of commercial scintillometers for non-

Fig. 34.18 Monthly mean values of the 12 UTC sensible heat fluxes from LAS measurements and from the regional operational numerical weather prediction models at DWD

- The determination of the wind component perpendicular to the runway at airports [34.20, 103].

34.8.4 Applications in Geodesy and Astronomy

Refractive index fluctuations in the atmosphere deteriorate the straight propagation of any electromagnetic signal coming from a star to be detected by a telescope; they cause the typical shimmering of star light and, thus, represent an unwanted disturbance for astronomical measurements and observations. In order to quantify these disturbances, the refractive index structure parameter as a direct primary output of scintillometer measurements is of special interest in connection with astronomical measurements and in precision geodesy using optical methods [34.104].

science applications is considered necessary to result in a significantly broader use. This should include features such as the automatic and reliable distinction between stable and unstable stratification or the direct presentation of derived parameters, e.g., the daily evaporation sum for the scintillometer footprint area, together with some uncertainty and quality information.

Further perspectives are seen in the use of scintillometers for operational validation of turbulent flux parameterization schemes implemented in NWP and climate models (Fig. 34.18) and for an operational validation and coupling of models to derive the surface heat fluxes from satellite data. A continental-scale scintillometer network with instruments operated routinely over different surface types and in different climate regions could provide a reasonable number of reference points to operationally calibrate satellite-based flux estimation algorithms (as was already suggested in [34.105]).

It should also be mentioned that some theoretical ideas behind scintillometry still call for further refinement; this does concern, e.g., the possible effect of saturation on r_{Tq} , the uncertainty of the latent heat flux estimates from an MWS for $Bo \approx 2$ (when the contributions from C_{TT} , C_{qq} and C_{Tq} almost cancel out), the applicability of the footprint and blending height concepts (which have been developed for fluxes, see Chap. 1) to structure parameters, the determination of representative values of the roughness length and displacement height, the possible impact of temperature-humidity dissimilarity on the derived fluxes using the bichromatic method, the interpretation of scintillometer

data for intermittent turbulence, or the relation between area-averaged and local similarity functions and the applicability of surface-layer scaling to measurements at a few decameters above ground, particularly under stable conditions. Important results that may support the interpretation of scintillometer data can be obtained from large-eddy simulations [34.106, 107].

Concerning the methodology, a successful proof of the reliability of the path-averaged values of C_{TT} , C_{Tq} , and C_{qq} derived from scintillometer measurements is still missing. An experiment on this issue has been performed at Lindenberg, Germany, by flying with an un-

manned aerial vehicle along a 4.8 km LAS path [34.77], the authors were able to correctly reproduce the diurnal cycle qualitatively but they could not achieve quantitative agreement better than a factor of two in many situations [34.108].

Another interesting perspective, for which first research and demonstration results have already been presented, is the use of telecommunication links as scintillometers to monitor precipitation and evaporation (e.g., [34.109, 110]). Broad application of these methods is presently hampered by commercial and data security/privacy restrictions.
