Foreword

Obesity and diabetes mellitus are two interrelated, chronic, debilitating, incurable diseases that have increased in incidence worldwide. In the USA, over 60% of adult Americans are overweight or obese. Most countries around the world are also seeing dramatically increasing rates of obesity. Although not all people with type 2 diabetes are overweight or obese, the majority are. In addition, while most individuals who suffer from obesity are not diabetic, the incidence of T2DM increases as adiposity increases. So intertwined are these seemingly independent metabolic disorders that some refer to them together as "diabesity."

Despite spending billions of dollars on research and the development of a multitude of different treatments, we have failed to control either disease and find ourselves heading off the cliff. While there has been an explosion of new medications, surgical procedures, and the introduction of metabolic/bariatric devices, the incidence of both diseases continues to rise. It has been estimated that within a few short years, the cost to treat the various related medical conditions of these two diseases will be financially unsustainable for most countries.

To better manage this impending crisis, clinicians and researchers need to broaden our understanding of the pathophysiology of both diabetes and obesity. It is far too simplistic to blame patient behavior, societal pressures, or the environment for the epidemic. One must consider other possibilities as well. Recently, researchers have taken a closer look at potential causes or contributors such as bile salt composition, genomics, microbiomes, inflammation, and the deep brain. A better understanding of the pathophysiology is necessary to guide the development of more efficacious and cost-effective treatments. In addition, to be the most beneficial, the research findings need to be properly organized and be available worldwide.

This new book entitled, *Obesity and Diabetes*, edited by Joel Faintuch, MD, a surgeon and a highly regarded nutrition support specialist, and Salomao Faintuch, MD, a Harvard Director of Interventional Radiology, should accomplish these goals. The book is extremely thorough and very well organized. Its nine sections (blocks) cover a wide range of current and cutting-edge information from the epidemiology of diabetes and obesity to bariatric and metabolic surgery to treat both disorders. The blocks and chapters of the book are strategically organized. They begin with basic science and epidemiologic chapters and conclude with clinical treatments and

ongoing developments. As previously stated, we as a human race cannot continue as we have, partially understanding and inadequately managing obesity and diabetes mellitus. We cannot sustain the costs nor the effects on health and quality of life. *Obesity and Diabetes* may become a valuable tool for researchers and clinicians alike.

Harvard Medical School, Scott A. Shikora
Center for Metabolic and Bariatric Surgery,
Brigham and Women's Hospital, Boston, MA, USA

Preface

About 6 years ago, the first edition of this book was being organized. At that time, obesity and diabetes were already counted among the leading non-communicable diseases in the world; however, the global burden had not been elucidated yet. As underscored in the current Introduction chapter, the figures were soon unearthed: USD2 trillion for obesity in 2014 and USD1.3 trillion for diabetes (2015), summing up to USD3.3 trillion. Only major addictions fluctuate in the same range. If one adds up the values for smoking (USD2.1 trillion) and alcoholism (USD1.4 trillion), the total will reach USD3.5 trillion. However, one should consider that whereas alcoholism is a mounting concern, the smokers' curve is receding in many countries, and could turn flat in the coming decades. Metabolic diseases in turn, with obesity and diabetes spearheading the trend, continue to grow unabatedly, so that it is projected that half of the world will be overweight or obese by 2030.

No other disease group comes close. Does that mean that medical schools should sidestep gastroenterology, rheumatology, and gynecology, concentrating instead on obesity/diabetes, and prevention of substance abuse (interspersed with classes on emerging infectious epidemics)? The healthcare domain is not that much utilitarian. Results-based performance management is important; however, it does not supersede the requirements for a global technical and scientific professional background. Moreover, one is not allowed to forget the ethical commitment toward the patient as an integral human being, not as a collection of disease labels. All these factors notwithstanding, practically all specialties will be touched, if not overwhelmed by the new scenario. Orthopedists are already having difficulty to cope with knees and hips damaged by excessive body weight, whereas ophthalmologists, nephrologists, neurologists, and even pediatricians are facing a deluge of diabetics in their daily practice, to mention just a few examples.

The same is true for the allied healthcare professions. Becoming familiar with the intricacies of obesity and diabetes is a must for nurses, psychologists, dietitians, hospital social workers, and specialists in biomedical engineering, given the sheer numbers of this population. Of course, the commonalities as well as the diversities of the illnesses need to be understood, from the vantage point of new achievements in an array of fields, from drug therapy to bariatric and metabolic surgery, and from appetite control to artificial pancreas. Among the cutting-edge science highlights of this edition, omics biomarkers originated from genomic, metabolomic, and immunologic profiling are

dissected within the framework of diagnosis, disease monitoring, prognosis, and new therapeutic targets, in obesity and diabetes. Anti-obesity vaccines ? Outlandish and whimsical as they may sound, and past false starts notwithstanding, there are robust experimental investigation lines in this arena. Similarly microbiomic pathways and signatures are becoming indispensable in the assessment and follow-up of metabolic diseases and treatments. There is compelling evidence that part of the surgical response to bariatric and metabolic procedures is microbiome dependent, analogously to an array of other treatments and circumstances.

Both type 1 and 2 diabetes are benefitting from genetic sequencing and immune profiling, with results which can be harnessed for diagnostic and therapeutic purposes. Bariatric and endoscopic interventions are in rapid mutation, including robotic platforms and innovative approaches, as described by respected authorities. Cell therapy and nanoparticle carriers are put into context. Public health initiatives were not neglected either. From government-mandated taxes for unhealthy foods to scrutinized school canteen menus and the contrast between personalized dietetic counseling and general guidance for the population, including Internet-based initiatives, smartphones, and wearable devices, no stone was left unturned in the effort to bring the latest and most practical information.

Contents

Abstract

Obesity and diabetes are not just associated with heart attack, stroke, kidney failure, shortened life span, and sudden death. They represent the three trillion question of the twenty-first century. Indeed the combined world financial burden of obesity and diabetes already exceeds USD3 trillion, and could get 50% higher or more around 2030. No other disease category comes close. Healthcare budgets which are already strained could become overwhelmed worldwide. The purposes of this introduction and this book are not stern advices or scary threats. On the contrary, the aims are to present and discuss feasible, sensible, and up-to-date approaches for prevention, diagnosis, and handling of obesity and diabetes.

The Problem

Type 2 diabetes (T2D) is the major cause of blindness, kidney failure, heart attack, and stroke. Obesity is currently the number one predisposing factor to T2D and is independently associated with cardiovascular and kidney disease, thus closing the circle. However, that is not all. Both shorten the life span, predispose to sudden death (Chen et al. 2019; Aune et al. 2018), and their clinical trajectory is rarely free from the mentioned comorbidities, along with myriads of others (Bray et al. 2018; Aga et al. 2019). Diabetics can suffer from as much as 97.5% prevalence of multimorbidity (Aga et al. 2019). Among the obese the metabolically healthy individual, exempt from associated illnesses, is a recognized category, however many suspects this status to be intrinsically unstable and short lived, eventually migrating to multimorbidity as well (Bray et al. 2018).

The Solution

Weight loss ameliorates these diseases and most comorbidities in a dose-related manner—the more weight lost, the better the outcome (Bray et al. 2018). With a reductionist approach, one could affirm that this entire book is redundant and dispensable. Why worry about biomarkers, omics, and complex diagnostic and prognostic algorithms, if health can in many circumstances be restored just by shedding the unnecessary pounds of weight? Who should be interested in specialized and expensive teamwork, pharmacologic breakthroughs, or ingenious surgical and endoscopic interventions, if reconfiguring one's diet will suffice?

The fact is that both obesity and diabetes are "curable," or at least amenable to prolonged, drug-free remission. Intensive lifestyle interventions can do the trick, along with bariatric and metabolic surgery (Ang 2018; Hirukawa et al. 2018; Willmer and Salzmann-Erikson 2018; Chen et al. 2018). What are the odds? And what does prolonged remission really mean?

Pediatric and Adult Obesity

Children and adolescents are among the best candidates for obesity "cure." Exaggerated adiposity is an unfavorable omen concerning adult life, however the prognosis is not necessarily ominous. Spontaneous normalization of body weight is still a possibility at these age brackets, particularly if a durable passion for sports and active life arises. Of course, structured dietary and lifestyle changes would be ideal, and the family should be actively engaged, not leaving the responsibility on the immature shoulders of the youngster (Ferraro and Adamo 2015).

Stress- or lifestyle-induced, recent onset obesity in adults is also a comparatively fertile ground for successful interventions. As long as the precipitating factors can be neutralized, never-obese people who for a short while accumulated adipose tissue will rather easily revert to their previous, eutrophic condition. The expanded fat cell population will shrink, however, it is unlikely it will actually vanish. Adipocyte size, number, and metabolic status respond to lifestyle and pharmacologic interventions with tissue remodeling, sometimes quite remarkable, however the potential for weight regain survives. Consequently, lifelong surveillance and prevention measures will be advised (Moreira-Pais et al. 2020).

Obesity-Induced Prediabetes or Diabetes

There are reasons to believe that recent onset, obesity-related T2D in reasonably young people, much more than in the lean, the aged, and those with a diabetes history >5 years, is the most amenable to satisfactory remission, whether achieved by lifestyle (Ried-Larsen et al. 2019), drug (Hirukawa et al. 2018; Bohula et al. 2018) or surgical means (Hirukawa et al. 2018). Conversion of prediabetes to T2D is inhibited, new cases become more sparse, and even established disease can be fully compensated. How long will the honeymoon last?

The longest available follow-ups are after bariatric surgery. The Swedish Obesity Study, which tracks a large cohort of adults submitted to a variety of operative techniques, has documented 38.1% and 30.4% remission after 10 and 15 years of follow up respectively (Sjostrom et al. 2014). Definition of prolonged remission is at variance with the recommendations of the American Diabetes Association, namely glycated hemoglobin HbA1c $<$ 5.7% and fasting plasma glucose (FPG) $<$ 100 mg/dL) without drugs for at least 5 years (Buse et al. 2009). In the alluded to the protocol, the adopted criterion was more lax, namely FPG $<$ 110 mg/dL in the absence of antidiabetic treatment (Sjostrom et al. 2014). Discrepancies notwithstanding these results are respectable, not only because they robustly exceed those observed in the controls, but also because micro and macrovascular complications were similarly benefitted.

State of the Art

The massive research efforts directed at obesity and diabetes in recent decades, confirmed what many had long suspected, namely that these diseases, in keeping with other metabolic aberrations, are preventable and potentially reversible, at least within certain limits. The requirements are early detection, removal of known drivers, and notably the implementation of a healthy and supervised lifestyle, with emphasis on diet, weight control, elimination of addictions, regular exercise, and combat of sedentarism.

The Three (or Five) Trillion Dollar Question

For how long is that feasible with full compliance of the individuals, and how many would actually be touched by such policies? That is not the million-dollar question. It already involves over three trillion dollars, and in the coming decade could advance beyond five trillion, as outlined below. During the last century, and especially a couple of decades after World War II, humanity has unwillingly cradled an obesogenic and hedonic environment, which started in industrialized countries and is spreading to all latitudes. What could be more gratifying than palatable food and drink on demand, especially because it is available, affordable, breaks no laws, and is not followed by a terrible hangover on the next day? Of course, the bathroom scale will protest, larger clothes will eventually be purchased, and sooner or later an appointment at a primary care facility will have to be scheduled. However, who cares about the future?

Market Stratification

The global diabetes care drugs market reached USD69.7 billion in 2019 and is growing at a compound annual growth rate (CAGR) of 4.6% (www.mordorintelligence.com/industry-reports/diabetes-drugs-market). The blood glucose monitoring systems market is smaller (USD10.1 billion in 2018), however it is expanding more rapidly (CAGR of 6.7%), thus the forecast for 2026 is USD17.1 billion (www.fortunebusinessinsights.com/industry-reports/blood-glucose-monitoring-market-100648).

The obesity prescription market is currently tiny, with few and not exceptionally effective agents. Only in 2026 is it expected to cross the billion-dollar barrier (www.bloomberg.com/press-releases/2019-06-18/anti-obesity-prescription-drugs-market-to-cross-us-1-000-million-by-2026-says-tmr). In turn, the weight management market boasts a CAGR of 8.2% and will be worth a more hefty USD442 billion in 2026 (www.marketwatch.com/press-release/weight-management-market-2019-size-statistics-growth-revenue-analysis-trends-industry-forecast-report%2D%2D2025market-research-engine-2019-12-19).

Wearable medical devices, an important share of which is devoted to obesity, diabetes, and weight management, was worth USD9 billion in 2018 and is growing at the exponential CAGR rate of 39% (www.gminsights.com/industry-

analysis/wearable-medical-devices-market). In one considers other lifestyle products and services, along with more specialized treatments such as bariatric operations and devices, the total market cap for these metabolic derangements could advance substantially beyond half-trillion dollars until 2025/2026.

Calculations for the absolute global economic burden are more staggering. For diabetes, they are believed to increase from USD1.3 trillion in 2015, up to $2.5 trillion according to the past trends, by 2030. This translates as a share of global GDP from 1.8% in 2015 to a maximum of 2.2% (Bommer et al. 2018).

Obesity weighs more, in all senses. Its 2014 global economic impact was USD2.0 trillion or 2.8% of the global gross domestic product (GDP). One should not be surprised if's up to 50% more by 2030, given the current epidemiological trajectory. The only current combined burden of smoking (USD2.1 trillion) and alcohol addiction (1.4 trillion) is in the same range (Dobbs et al. 2014).

No other disease category comes close. The industry forecast for inflammatory bowel disease drugs is in the range of USD22 billion for 2026 (www.grandviewresearch.com/press-release/global-inflammatory-bowel-disease-ibd-treatment), hepatitis C treatment is estimated at USD11 billion (2025) (www.worldhepatitisalliance.org/news/sep-2015/cost-comprehensive-global-viral-hepatitis-prevention-and-treatment-effort-might-peak/), and the oncology drug market should not exceed a comparatively negligible USD176.5 million (2025) (www.alliedmarketresearch.com/oncology-cancer-drugs-market). Devices, palliative assistance, and ancillary care, along with indirect costs (absenteeism, premature death) could tip the scales a lot further, however still far away from the figures mentioned above.

Ongoing Initiatives

Of course academic and government healthcare planners and scientists are not staying idle. Major local or nationwide diabetes and obesity initiatives are going on in the USA, the UK, Australia, Canada, New Zealand, Austria, India, China, Israel, and United Arab Emirates, among others. From taxes and legislation inhibiting intake of risky foods and drinks, not overlooking planned cities and buildings that stimulate walking and stair climbing, to targeted anti-obesity and antidiabetic lifestyle and pharmacological interventions, policy makers have their hands full (Galaviz et al. 2018).

What are the prospects for a "magic pill" in the obesity and type 2 diabetes context? Even though the industry is putting out safer and more powerful drugs nearly every year, and invasive as well as intensive lifestyle interventions improve, prolonged remission is still not within the grasp of the masses, only of limited groups (Ang 2018; Hirukawa et al. 2018; Willmer and Salzmann-Erikson 2018; Chen et al. 2018; Ferraro and Adamo 2015). Incidentally, there is much hope also for candidates with type 1 diabetes, as stem cell therapy and immunotherapy are making large strides (https://labiotech.eu/features/immunotherapy-type-1-diabetes. Breakthrough type 1 diabetes).

Final Considerations

In the first chapter of The Descent of Man, and Selection in Relation to Sex, published in 1871, Charles Darwin argued that some anatomical structures were useless, and would eventually disappear. These included toes, wisdom teeth, paranasal sinuses, cervical ribs, and even body hair (Darwin 1981). He was not the only one to engage in phenotypic futures studies. In more recent century, specifically in 1993, Nebel and Wright predicted that man will eventually increase brain capacity, and undergo leg atrophy (Nebel and Wright 1993). Indeed the more gray and white matter, the better to deal with sophisticated computers and to analyze big datasets. On the other hand, who needs to carry around long and heavily muscled legs if elevators, escalators, cars, and other conveyances are ubiquitous?

Both prophecies failed to include obesity and diabetes. Men and women are becoming smarter, communicating instantly, and moving around at increasing speed, however they are paying dearly

in the form of metabolic illnesses. If one does not intend to pass on these scourges to the coming generations, one has to act here and now. This book represents an effort by highly regarded specialists and respected scholars from different continents, to present new ways and means not only to identify and manage obesity and diabetes, but also to prevent it before it moves out of control.

Nutrition Transition and Obesity Trends in Argentina Within the Latin American Context

2

Sonia Alejandra Pou, Natalia Tumas, and Laura Rosana Aballay

Contents

Abstract

The world population has undergone a rapid shift in dietary and physical activity patterns, from traditional diets to a dietary pattern characterized by highly processed foods and sugar-sweetened beverages, coupled with increasingly sedentary lifestyles. These shifts have been concomitant with demographic, macroeconomic, and technological changes, and closely related to the widespread obesity

epidemic. Barry Popkin (University of North Carolina at Chapel Hill, USA) has defined the entire process as Nutrition Transition and has written extensively about its stages, drivers, and consequences. Based on this literature and on our previous work, in this chapter we present the key elements of the nutrition transition process in developing countries, describing its distinctive features in the Latin America region, especially in Argentina. We also describe obesity trends in this context. Finally, we discuss public health interventions in the developing world, and future perspectives to deal with a still unresolved consequence of the nutrition transition, the obesity and noncommunicable diseases epidemic.

Obesity burden · Obesity epidemic · Obesity trends · Obesity public health · Highly processed foods · Nutrition transition

Understanding the Path to the Obesity Epidemic

The nutrition transition theory describes the process of shifts in the diet and in the physical activity patterns that result in changes in stature, body composition and body size of populations (Popkin 1994, 2004). Both quantitative and qualitative dimensions are involved in these changes (Popkin 2002a, 2009).

Several societies seem to converge on a shift away from traditional diets toward a more globalized pattern characterized by less legumes, vegetables, and fruits, and more animal-source foods, edible oils, and processed foods—high in refined carbohydrates, added sugars, and sweeteners (Popkin 2002a, 2015, 2017; United Nations System, Standing Committee on Nutrition 2010). Physical activity decreases rapidly, driven by more sedentary jobs and leisure activities, and the increasing use of vehicles (Popkin 2006, 2015). In regard to the nutritional status, a shift from increased prevalence of undernutrition toward a high prevalence of overweight and obesity is observed (Popkin 1994, 2004).

The Population Context

Two historic processes affect and are affected by nutritional transition: the demographic transition and the epidemiologic transition (Popkin 2002a). The demographic transition is defined as the shift from a population pattern of high fertility and high mortality, to another of low fertility and low mortality, with the consequent life expectancy increase (Notestein 1945). Closely related to these demographic changes is the epidemiological transition, which refers to the evolution from a pattern of high prevalence of infectious diseases, to predominance of noncommunicable diseases (NCDs) (Omran 1971).

These transitions have some elements in common: they describe the changes observed in the demographic, health and diet dynamics of the populations (mainly in developed countries) through a succession of stages; they share common pathways; they consider that the stages (with more or less delay) will occur in all regions worldwide; and they were designed with the purpose of making forecasts and planning new socioeconomic, food, and health policies (Popkin et al. 2012; Nicolau-Nos and Pujol-Andreu 2011). The interplay among these epidemiologic, demographic, and social changes is such, that it determines the nature and pace of nutritional shifts (Popkin 2001).

Five broad nutrition patterns were proposed by the lead author of this theory, Barry Popkin (Popkin 1993, 2002a), to describe the nutrition transition. Although the patterns were outlined as historical stages, they are not restricted to the periods in which they first arose. In point of fact, some nutrition transition patterns coexist at the same time, with spatial and socioeconomic variations. We summarize these broad nutrition transition patterns in Table 2.1.

The shifts involved in these patterns occur in different regions at different rates; however, there is a consensus regarding that the most rapid

Table 2.1 Summary of the nutrition transition patterns according to the dimensions involved

Nutrition transition pattern	Diet	Physical activity	Nutritional status	Other features
Collecting food	Varied diet, high in carbohydrates and fiber, and low in saturated fat	High level of physical activity	Robust, lean, low malnutrition prevalence	Typical of hunter–gatherer
Famine	Less varied diet, cereals predominant. Periods of food scarcity	Little modification in physical activity levels	Nutritional deficiencies, stature reduction	Agriculture, livestock farming Deepening of social stratification
Receding famine	Less starchy staples and more fruit, vegetables and animal protein intake. Lower variety of diet and famines	Physical activity levels started to decrease	Several nutritional deficiencies disappear, stature grows	Crop rotation, fertilizer use, industrial revolution. Women join the labor force
Nutrition-related noncommunicable diseases	Higher in fat (specially saturated), cholesterol, refined carbohydrates and processed foods. Lower in fiber and polyunsaturated fatty acids	Increasing sedentary jobs and lifestyles	Obesity prevalence increases, many disabling conditions	Technology revolution. Characteristics of high-income societies and increasing low-income societies
Behavioral change	More carbohydrates, fruits and vegetables; less fat and processed food	High leisure exercises, sedentary jobs	Lower body-fat and obesity; better bone health	Service sector mechanization. Changes aimed to increase the disability-free life expectancy

Data from Popkin (1993), (2001) (2002a), and (2004)

change is observed in developing countries (Popkin 2009; Hawkes et al. 2017). Specifically, the shifts in diet and physical activity patterns seem to be particularly accelerated in the low- and middle-income countries (LMICs) (Popkin et al. 2012; Popkin 2002b).

It is worth mentioning that Popkin has written extensively about the influence of changes in the food system and macroeconomic factors, that underlie many of these worldwide dietary shifts (Popkin 2009, 2017; Popkin et al. 2012), remarking that the major influence on the obesity epidemic must be viewed as environmental rather than personal or genetic (Popkin 2001). In line with this assumption, other authors state that along with income, relative food prices and preferences are a major determinant of dietary patterns (Finaret and Masters 2019), and therefore of the obesity outcome.

Worldwide Changes in Recent Decades

Four interrelated macroeconomic and technological factors have been pointed out. A critical driver is the *technology* that affects economic and domestic works, the production and processing of foods, and the expansion of mass marketing, which leads to changes in dietary patterns and related health conditions. Additionally, transportation facilities (e.g., trains) and leisure sedentary-promoting devices (e.g., television, mobile phones, and computers) had a central impact on the reduction of physical activity levels (Popkin 2006, 2015).

Another widely studied driver is *urbanization*. This demographic process is associated with a greater variety and availability of food, more marketing activities on foods, higher food processing, and increased intake of food away from home (Since jobs are more frequently incompatible with home food preparation). The urbanization process has experienced an enormous acceleration, and nowadays approximately 55% of the world's population is urban (United Nations 2017). The Latin American and Caribbean region are the most urbanized in the world (about 80% rate), and in Argentina, around 91% of the population live in urban areas (Pou et al. 2017).

More robust per capita *income* and *expansion of global trade* are great drivers of the nutrition transition process. While income has increased worldwide, the prices of many foods have diminished, thus leading to lower proportions of income allocated to food. Besides, income increase allows acquiring labor-saving devices and others that foster a sedentary lifestyle (Popkin 2015). The opening of global trade in goods and services provides more opportunities to access modern media, food retail, food services, and technologies that reduce physical activity (Popkin 2006, 2015). A recent analysis about trade openness and the obesity epidemic that included 175 countries during the 1975–2016 period, concluded that trade openness was positively associated with country obesity prevalence, and its influence concentrated among developing nations (An et al. 2019).

Despite the general tendencies, wide inequalities remain in many LMIC countries, where undernutrition (underweight, stunting, micronutrient deficiencies) persists and coexists with increased prevalence of overweight, obesity, and associated NCDs (United Nations System, Standing Committee on Nutrition 2010; Popkin et al. 2012; Ng et al. 2014). This is the so-called "double burden of malnutrition," which can be observed at the country, community, household, and even at the individual levels (United Nations System, Standing Committee on Nutrition 2010; Popkin et al. 2012). This complex nutritional and epidemiological scenario constitutes an enormous challenge for the public health of these countries, and particularly for the Latin American region, as described in detail below.

The Burden of Obesity Worldwide

Most of the world's population lives in countries where overweight and obesity kill more people than underweight, and it is estimated that at least 2.8 million people die each year as a consequence of overweight or obesity (World Health Organization 2017, 2018a), even though these nutritional conditions are preventable.

In the Americas, in 2016 the prevalence of overweight and obesity in adults was 66.2% and 59.3% in men and women, respectively. Among the countries with the highest prevalence are the USA (68%), Mexico (65%), Canada, and Bahamas (64%) (Organización Panamericana de la Salud 2019). In Latin America and the Caribbean, it has been noted that 7.5% of children under 5 years of age live with overweight, whereas worldwide prevalence is 5.9% (FAO, OPS, WFP, UNICEF 2019).

Obesity is not only a disease, but also a metabolic risk factor associated with other NCDs such as cardiovascular problems, diabetes, and cancer (Finucane et al. 2011; Ford et al. 2017), which are the main causes of death and disability worldwide. The World Health Organization (WHO) reported that 71% of the global disease burden is due to NCDs and that these diseases disproportionately affect people in LMICs (World Health Organization 2018b). In Argentina, NCDs were responsible for the largest proportion of deaths in 2016 (almost 80% of total mortality) (World Health Organization 2018c). Based on the last National Survey of Risk Factors, it was estimated that 61.6% of the adult population living in urban areas of Argentina in 2018 have overweight and among them, 25.4% present obesity. This level of prevalence is similar to developed countries and represents a growth of almost double in 13 years (from an obesity prevalence of 14.6% in 2005) (Ministerio de Salud y Desarrollo Social de la Nación 2019).

According to the World School Health Survey (Ministerio de Salud y Desarrollo Social de la Nación 2018), the prevalence of overweight and obesity in students aged between 13 and 17 in Argentina was 30.3% and 7.4%, respectively, with higher values in men than in women. Excess weight in the specific group of adolescents (aged 13–15 years old) has increased progressively throughout the three editions of the World School Health Survey; the overweight prevalence increased from 24.5% (2007) to 28.6% (2012) and 33.1% (2018) and the percentage of students with obesity was about 4.4% in 2007, with values to 5.9% and 7.8% in 2012 and 2018, respectively

(Ministerio de Salud y Desarrollo Social de la Nación 2018).

General Dietary Patterns

The dietary pattern descriptions are based on extensive research carried out in higher-income countries, while the scientific evidence is comparatively scarce in LMICs. Yet Popkin (2015) sheds light on this matter and points out that, nowadays, there is sufficient data available about LMICs to document this generalized dietary trend in all urban areas and, increasingly, in rural ones: (1) a huge increase in the consumption of vegetable oils and the practice of frying food, instead of using traditional healthier cooking methods; (2) very high levels of sugar-sweetened beverages and fruit juice intakes; (3) increased consumption of animal-source foods; (4) a diet shift toward the intake of highly processed food products and a reduction of legumes, fruits, and vegetables; (5) away-from-home meals, frequent snacking and a rise in eating frequency (Popkin 2009, 2011, 2015).

Findings in Latin America

Although these trends are widespread even in Latin American countries, there is much heterogeneity between and within countries (by age, gender, and sociodemographic conditions) (Popkin 2002a; Kovalskys et al. 2019). A multicenter cross-sectional study assessing food consumption in adults (15–65 years old) in an urban sample from 8 Latin American countries (Argentina, Brazil, Chile, Colombia, Costa Rica, Ecuador, Peru, and Venezuela), called ELANS (Latin American Study of Nutrition and Health) (Kovalskys et al. 2019), indicates in general, deficiencies for nutrient-dense food groups; healthy food tends to be more consumed by high socioeconomic persons and older people; vegetables and red meat remain the two most consumed food groups in the region, although their amounts are below and over recommendations, respectively, in most of the countries (Kovalskys et al. 2019).

Focus on Argentina

According to the ELANS (Kovalskys et al. 2019), Argentina was the leading consumer of sugar-sweetened beverages (mean of 1245 g/day) and red meat (prevalence of consumption of 82.3%, average consumption of 129.7 g/day), during 2014–2015. Particularly in Argentina and Chile, processed meat consumption was more common among low socioeconomic groups. Inversely, Argentina is among the countries with less legumes consumption in the region. Regarding fruits and vegetables mean intakes were markedly below current recommendations (at least five servings/day), as in all the countries of the region. This is consistent with the results of the last National Surveys of Risk Factors that reported a mean intake of only two servings/day of these vegetable -source foods in the Argentinian adult population in 2018 (Ministerio de Salud y Desarrollo Social de la Nación 2019). Nevertheless, both fruits and vegetables were consumed in greater amounts among the low socioeconomic groups in most of the Latin American countries, including Argentina (Kovalskys et al. 2019).

In the 1996–2013 National Survey of Household Expenditure (Zapata et al. 2016; Zapata and Rovirosa 2016), the traditional diet of the Argentinian people in the past (mainly unprocessed or minimally processed foods) is now moving to a diet rich in processed foods. Similar to the ELANS results, but from a dynamic perspective, the authors highlight the higher and increased apparent consumption of sugar-sweetened soft drinks or juices and processed meats (This consumption has doubled and tripled, respectively, in the last 20 years). Moreover, total fruit consumption decreased by 41% in the study period. Yet when income increases, consumption and fruit diversity improve as well. The consumption of ready-to-eat foods also grows as household income becomes more elevated (Zapata et al. 2016; Zapata and Rovirosa 2016).

Highly Processed Foods

Processed food products have been defined as "substances extracted and refined from unprocessed or minimally processed foods that are 'ready-to-eat' or 'ready-to-heat,' made from industrially prepared ingredients and additives, usually highly palatable and intensively marketed, and often high in free sugars, trans-fats and low in micronutrients" (Sievert et al. 2019). Although the health costs or benefits of food processing are still discussed, a report of the Pan American Health Organization on this matter discourages their consumption; it also indicates that sales of ultra-processed food products (also called highly processed food products) are associated with weight gain and obesity in Latin America (PAHO-OMS 2015). It was estimated that the volume sales of ultra-processed drinks per capita is about 184.5 kg/capita/year in Argentina, which ranks among the highest values, along with the USA (238.8 kg/capita/year) and Mexico (188.5 kg/capita/year) (Vandevijvere et al. 2019).

Regarding food selection among Argentinian adolescents, a tendency to low consumption of fruits and vegetables was observed from the World School Health Survey 2018 (Ministerio de Salud y Desarrollo Social de la Nación 2018). Only 21% and 10.5% of them consumed fruits and vegetables, respectively, two or more times per day. A public health issue that needs to be considered is that approximately 10% of those adolescents currently eat fast food 3 or more days a week away from home, around 50% more than in 2012 when only 6.8% of the total of number of participants aged between 13–15 years old adopted this dietary practice. Moreover, a third of the adolescents declared a consumption of sugar-sweetened drinks of 1 or more times a day.

Physical Activity Patterns

A sedentary lifestyle or low level of physical activity is an indicator of low energy expenditure and constitutes one of the main modifiable risk factors of most NCDs (World Health Organization 2018b). Some researchers argue that physical inactivity or sedentary lifestyle is the fourth-ranking risk factor for global mortality (6% of deaths recorded worldwide) (Guthold et al. 2018).

The results of the National Surveys of Risk Factors show that people from this country have a low level of physical activity, increasing its prevalence from 54.7% in 2013 to 65% in 2018 (Ministerio de Salud y Desarrollo Social de la Nación 2019).

The World School Health Survey confirmed that only 16.5% of students aged between 13 and 17 were physically active in 2018, and 55.3% of them spent at least 3 h a day sitting, outside school hours. This is a clear indicator of sedentary behavior in this population. Meanwhile, the percentages of physical inactivity among young people remain high, mainly among women (Ministerio de Salud y Desarrollo Social de la Nación 2018).

Disease Burden

Latin America, along with the Middle East and North Africa, is one of the low- and middle-income regions with the highest burden of obesity (Popkin and Reardon 2018). Changes in diet and activity patterns lead to the emergence of chronic disease problems and increased disability (Popkin and Gordon-Larsen 2004; Popkin et al. 1996). In Latin America (Popkin 2002a), many countries entered into the so-called nutrition related-NCDs stage far earlier than others. Haiti and some Central American subpopulations, in 2002 were still in the receding famine stage. In contrast, Mexico experienced an accelerated transition in the 1990s (Popkin 2002a). While obesity prevalence continued to increase among all socioeconomic groups, the highest burden was among disadvantaged women (Pérez-Ferrer et al. 2018).

Argentina, an upper-middle income country, with a current total population that exceeds 40 million people (40,117,096, census 2010) is ranked as the fifth most populous country in this region. The nutrition transition process presents geographical differences within this country. In

Table 2.2 Summary of the nutrition transition profiles in Argentina (2005–2013) according to the dimensions involved

Nutrition transition profiles	Nutritional features	Sociodemographic characteristics	Provinces in cluster	Related patterns of nutrition transition theory
Socionutritional lag	High prevalence of stunting in children; low prevalence of childhood obesity	High proportion of poverty households and population without health insurance; low proportion of population with higher education; relatively high infant mortality rates.	Misiones, Corrientes, Tucumán, Santiago del Estero, Jujuy, Formosa, Río Negro, San Juan, Chaco, Salta	Receding famine
Double burden of malnutrition	High prevalence of childhood and adult obesity; intermediate prevalence of stunting in children	High proportion of urban households	Catamarca, La Rioja, Santa Fe, Buenos Aires, Neuquén, Chubut, Santa Cruz, Tierra del Fuego	Moving from "receding famine" to "degenerative diseases" stage
Incipient socionutritional improvement	Low prevalence of stunting in children and adult obesity	Low proportion of poverty households	Córdoba, San Luis, Mendoza, La Pampa, Autonomous City of Buenos Aires, Entre Ríos	Behavioral change

Data from Tumas et al. (2019)

our recent work (Tumas et al. 2019), we identified three profiles, which were named "socionutritional lag" (characterized by undernutrition and socioeconomically disadvantaged conditions), "double burden of malnutrition" (undernutrition by stunting and overweight in highly urbanized scenarios), and "Incipient socionutritional improvement" (low prevalence of malnutrition and more favorable poverty indicator values). These profiles allowed us to differentiate the Argentinian provinces into three groups according to the nutritional status and sociodemographic characteristics of their populations. The key issues in each of the profiles identified are summarized in Table 2.2.

As discussed by Tumas et al. (2019), the "socionutritional lag" profile is closely related to the so-called "receding famine" pattern proposed in the NT theory, given that child undernutrition problems are distinctive characteristics in both scenarios. The "double burden of malnutrition," in turn, could reflect a transitional situation of these populations between the "receding famine" and the "degenerative diseases" stage stated by Popkin, which is also a distinctive characteristic of many developing regions. On the other hand, the "incipient socionutritional improvement" profile could be linked to the last stage of the nutrition transition, the "behavioral change" pattern, because the low prevalence of malnutrition (both under- and over-nutrition), together with favorable socioeconomic conditions were the most dominant features. Interestingly, this was the only profile that showed no associations with the obesity burden in Argentina.

These results highlight the important role of sociodemographic factors such as urbanization and poverty levels in shaping nutrition transition profiles in Argentina (Tumas et al. 2019). Previous studies focused on the link between specific dietary patterns and obesity or NCDs in urban populations of Argentina already found an association between unhealthy dietary patterns with obesity (Pou et al. 2016), as well as with several diet-related cancers (Niclis et al. 2015; Pou et al. 2012, 2014a, b; Tumas et al. 2014).

Public Health Interventions and Future Perspectives

In response to the growing burden of NCDs, the global community has worked through the World Health Organization and the United Nations,

aiming to reduce premature mortality from NCDs by 25% until 2025 (World Health Organization 2018b). However, the results of the global consensus and derived interventions have not been successful.

As Popkin anticipated, achieving the pattern of behavioral change (Popkin 2009), seems to be quite difficult in the current scenario of the Latin American region.

The accelerated speed at which nutritional and epidemiological changes occur in developing countries often exceeds the national capacity of these countries to address the rapid increase of NCDs and to engender a healthy transition (Popkin 2002b; *Lancet* 2017). In addition, the rapidly increasing burden of overweight and obesity coupled with increased waist circumferences and major diet shifts, adversely affect the burden of diabetes and other metabolic disorders (Popkin 2015), which are capital public health problems in the developing world.

In LMICs, it is also noticeable that the double burden of malnutrition underlies a context of food insecurity coupled with energy imbalance (Popkin 2002b); this may reflect persistent social inequalities in health distribution that should be addressed.

Childhood Undernutrition and Adult Obesity

Current hypotheses of the developmental origins of adult disease merit special attention in these regions, where obesogenic environments are expanding while undernutrition persists (Popkin et al. 2012; Wells et al. 2020). According to Wells et al. (2020), early undernutrition in life (during fetal and infant development) followed by later energy imbalance, impose a high metabolic load on a depleted capacity for homeostasis; this may exacerbate the health costs of adult obesity especially among individuals who have previously suffered from undernutrition. Public health policy interventions and programs should simultaneously address malnutrition caused by energy imbalance linked to nutritional deficiencies (i.e., stunting, anemia, and other nutritional deficiencies), along with an excess of body weight (i.e., overweight or obesity). These need to focus on the early stages of life and to adopt a life-course perspective.

Tirado et al. (2016) found that all 18 countries Latin American countries under study had relevant policies to address malnutrition, especially undernutrition, and micronutrient deficiencies, but only some of them had policies to address overweight and obesity (Tirado et al. 2016). Especially in LMICs, it has been highlighted the central role of breastfeeding (Wells et al. 2020). This practice, economically affordable for the population living in poverty, increases the chances of achieving a healthy weight and growth during early childhood.

Ongoing initiatives include taxation of sugar-sweetened beverages, marketing control especially concerning child-oriented, front-of-package labeling profiles with a positive or negative logo, and special regulations related to schools and/or other public facilities (Popkin 2017). Tirado et al. (2016) report that regulatory frameworks to address overweight and obesity have been introduced. However, the authors highlight the scarcity of data on the allocation of human and financial resources to promote balanced nutrition (a crucial element in terms of the efficacy of public policies), and that most of the countries studied had food-based dietary guidelines, but lacked the legislation to increase access to healthy food and/or address the obesogenic environment (Tirado et al. 2016).

We want to emphasize the relevance of timely feedbacks on current policies. Besides, we highlight the need to improve systems and instruments for data collection on nutrition and diet in developing countries, especially from Latin America. In this regard, Walls et al. (2018) reported that the standardized instruments commonly used to assess diets in LMICs are not appropriate for measuring, for example, the consumption of ultra-processed foods (2018). In accordance with Popkin, we believe that in order to tackle obesity and NCDs epidemics, we must focus our major efforts on finding "environmental solutions" (Popkin 1998). Individual-level interventions conceived from a biomedical approach, are too

simplistic for addressing these complex and multifactorial diseases. An intersectoral approach is essential for the definition and implementation of public policies; this means involve multiple actors, including in the first place the food and beverage industries as well as government officials.

Abstract

Diabetes imposes a huge financial burden on affected individuals, their families, society, and country. Undesirable changes in lifestyle coupled with inadequate health care systems are some of the major drivers of diabetes burden in sub-Saharan Africa (SSA), where there will be the greatest increase of diabetes in the world of 143%, within the next 25 years. Only 5.5% of the GDP in SSA was spent on health in 2016 compared to the global estimate of 10%. Although SSA has witnessed a recent increase in diabetes incidence, the current diabetes-related expenditure of US$9.5 billion represents only 1% of the overall global expenditure on this disease. These include the direct costs associated with medical care, and the indirect costs resulting from cessation or reduced productivity because of disease-related disability/premature mortality. Indirect cost per patient with diabetes in SSA is higher than direct expenditures, contributing over 60% of the total cost.

Diabetes burden · Diabetes cost · Indirect cost · Direct cost · Sub Saharan Africa

Introduction

Nearly 80% of noncommunicable disease (NCDs) related deaths including diabetes, occur in low- and middle- income countries, which constitute the majority of countries in sub-Saharan Africa (SSA) (WHO 2019a). Available estimates show that 7.1% of adults living in Africa or 33 million people suffer from diabetes, although in 2019 the International Diabetes Federation estimated that diabetes affected over 19 million people in the region, while an additional 45 million adults had impaired glucose tolerance (IGT) (IDF Diabetes Federation 2019a). Nigeria is among the top ten countries in the world with the highest number of people with IGT (8.2 million people). If current trends persist, both the number of people with type 2 diabetes (T2D) and IGT in SSA will increase by 143% by 2045; the highest global predicted increase. However, the true number could be much higher, given that as many as two thirds of those with the disease remain undiagnosed (IDF Diabetes Federation 2019a).

This rising burden of diabetes in SSA has been triggered by increasing obesity and changing lifestyles in both rural and urban communities (Mbanya et al. 2014). As in other parts of the world, more than 90% of patients have type 2 diabetes with diagnosis often made late in the course of disease progression, or at the time of complications. Also, approximately 10,300 children and adolescents are diagnosed each year with type 1 diabetes (T1D) which carries a high mortality rate (IDF Diabetes Federation 2019a).

Social and Financial Burden

Delayed diagnosis and poor metabolic control contribute to the high morbidity and premature

mortality in the region (Dalal et al. 2011). The mortality rate is increasing and occurring at younger ages in SSA compared with the other regions; three of four deaths due to diabetes occur in the active age group less than 60 years old (IDF Diabetes Federation 2019a; Miranda et al. 2019). Total disability adjusted life-years (DALYs) due to diabetes increased by 126.4% between 1990 and 2017, and the Lancet Diabetes and Endocrinology Commission estimated that in 2015, the overall cost of diabetes in sub-Saharan Africa was US$19.45 billion, or 1.2% of cumulative gross domestic product (GDP) (Gouda et al. 2019; Atun et al. 2017).

Despite progress in health coverage, access to medications especially insulin and quality healthcare facilities remain a challenge, with wide disparities between African countries (Mutyambizi et al. 2018). Poor access to insulin is the major cause of mortality in children with T1D (Atun and Gale 2015; Choukem et al. 2019). This has a huge financial implication for the economy of households and the already overburdened healthcare systems.

Few African countries have a national diabetes plan and there is a lack of access to full coverage for essential health services (IDF Diabetes Federation 2019a). Due to the lack of primary data and the high proportion of undiagnosed diabetes to estimate the real-world cost of diabetes in the SSA, public health interventions have relied on results from modeling methods (Afroz et al. 2018). Africa's health service delivery capacity has improved, yet this is still insufficient to meet current and future needs of the care of diabetes (WHO 2019b).

Challenges to Diabetes Management in Africa

These challenges are of two magnitudes: the increase in diabetes growth and those related to the implementation of effective diabetes care in Africa (Fig. 3.1).

Epidemiological transitions:

In the 1980s, diabetes was still uncommon in Africa, but today it has exploded in many communities. This trend in T2D has been strongly linked to obesity, suboptimal diet, and physical inactivity, resulting from the rapid epidemiologic shifts involving urbanization and changing lifestyles in both the rural and urban communities of SSA (Mbanya et al. 2014). The age-standardized diabetes prevalence increased in parallel with body mass index from 3.4 to 8.5% in men, and 4.1 to 8.9% in women between 1980 and 2014 (NCD Risk Factor Collaboration (NCD-RisC)—Africa Working Group 2017). Global rise in BMI is usually linked to the increase in BMI in rural communities, except in SSA where BMI rose faster among urban women, and at a similar rate among urban and rural men (NCD Risk Factor Collaboration (NCD-RisC) 2019). The expansion of supermarkets with access to highly processed food and sweetened beverages as well as reduced physical activity could be driving the rural-urban differences (Pastakia et al. 2017; Assah et al. 2011).

Access to Health Care

Many African countries are not prepared to effectively manage diabetes and they provide only suboptimal care to patients. Early identification, management, and control are important determinants for the reduction of diabetes complications, thus leading to a substantial reduction of the economic burden (Atun and Gale 2015; Kapwata and Manda 2018).

Timely diagnosis and prevention rely mostly on the availability of health care practitioners, regular screening, and management of comorbidities (Pastakia et al. 2017). The proximity of healthcare facilities has been strongly linked to increasing utilization of these services in developing countries, especially in rural communities (Feikin et al. 2009). Financial

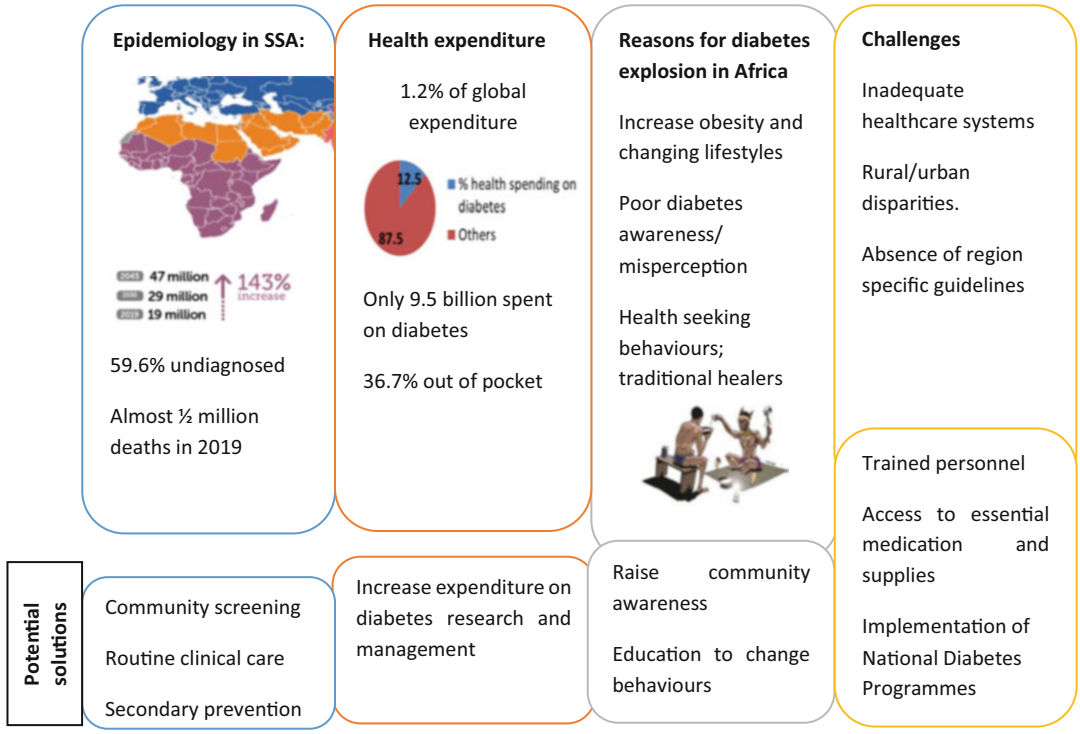

Fig. 3.1 Socioeconomic burden of diabetes and healthcare challenges in Africa (IDF Diabetes Federation 2019a; Choukem et al. 2019)

availability and accessibility of health services, transportation facilities, and cost, as well as the receptiveness of the healthcare professionals to the cultural and social norms of the community are equally relevant (Huerta Munoz and Källestål 2012). Poor access to insulin is the leading cause of mortality in patients with T1D (Gale 2006). Among the 400 million people globally who do not have access to basic healthcare services, the majority live in SSA (Sanogo et al. 2019).

Knowledge, Beliefs, and Health Seeking Behaviors in Africa

Obesity which is a major risk factor for T2D is still perceived by some people as a sign of wealth and good living, while physical activity like regularly walking is a sign of poverty. Although most patients recognize that health care facilities are the ideal places to turn to, it is not unusual for patients to seek solely or as complementary care, the traditional healers (Choukem et al. 2019). Diverse knowledge, beliefs, and perceptions in addition to finances are key factors that influence a patient's decision to seek medical advice during an illness. Moreover, misconceptions associated with hospital facilities contribute to increasing the total cost associated with diabetes, as some patients tend to be managed at home or seek traditional healers, thereby presenting to health facilities mostly at the time of complications (Choukem et al. 2019).

Lack of Political Will

There is still a lack of appropriate action taken by key decision leaders in SSA, in order to halt the progression of diabetes (Atun and Gale 2015). The misconception that diabetes is a disease of the rich and the elderly, hampers commitments to

mobilize adequate resources for the management of diabetes and its complications. In fact, less than 30% of African countries have operational integrated policies for diabetes care (Kengne et al. 2013).

Under-Allocation of Resources

Inadequate financing of NCDs like diabetes constitutes a major barrier to the early diagnosis and management of diabetes complications (Atun and Gale 2015). Although infections, maternal and perinatal mortality continue to threaten African healthcare systems, the idea that infectious diseases should be controlled before tackling NCDs is mostly misleading. According to WHO estimates in 2015 infectious diseases, maternal, perinatal, and nutritional conditions accounted for 59.1% of all age total DALYs, while NCDs were responsible for 30.7% (WHO 2019a). In addition, NCDs are responsible for up to 37% of total loss of productivity in SSA, compared to only 27% for infectious diseases (WHO 2019b).

Complications and Mortality Attributable to Diabetes

Noncommunicable diseases like diabetes and cardiovascular account for 41 million deaths each year; the leading cause of mortality globally. Over 85% of these deaths occur in low- and middle-income countries (WHO 2019a), and the acute and chronic complications associated with the disease make it very costly to manage (Kengne et al. 2013). Diabetes is a major cause of non-traumatic lower limb amputation, blindness, kidney failure, heart attacks, and stroke (IDF Diabetes Federation 2019a).

Prevalence and Incidence of Diabetes Complications

Chronic complications of diabetes may be present at the time of diagnosis especially in patients with T2D, but can also appear soon after the diagnosis in patients with T1D (IDF Diabetes Federation 2019a). In early 2000, macrovascular complications of diabetes were considered rare in Africa, with coronary heart disease affecting 5–8% of type 2 diabetic patients (Mbanya and Sobngwi 2003). However, there is increasing evidence suggesting an increase in the burden of cardiovascular disease in SSA (Kengne et al. 2013), as a result of poor glycemic control in addition to other cardiovascular risk factors such as high blood pressure and dyslipidemia (Kengne et al. 2005).

Five percent of patients with diabetes have cerebrovascular accidents at diagnosis, and up to 9.5% and 25% of patients with type 1 and 2 diabetes respectively also have retinopathy at diagnosis. Depending on the glycemic control and duration of diabetes the prevalence of diabetic retinopathy varies between 13 and 55 %, with severe retinopathy representing 15% of all cases (Mbanya and Sobngwi 2003; Kengne et al. 2005). Eight to 49% of patients with diabetes exhibit nephropathy and neuropathy is present in 11–66% depending on the diagnostic method used (Dalal et al. 2011). Long-standing complications in patients with T1D do not differ greatly from those with T2D (Motala et al. 2001).

Lower extremity amputation varies from 1.5 to 7% (Mbanya and Sobngwi 2003). Diabetes complications in Africa are increasing as the prevalence and incidence of diabetes continue to rise. In Ghana, the incidence of diabetes-related lower limb amputations increased from 0.6 per 1000 follow up years in 2010 to 10.9 in 2015 (Sarfo-Kantanka et al. 2019). This is in contrast to industrialized countries where the complication rates are reducing (IDF Diabetes Federation 2019a). The coexistence of multiple chronic complications of diabetes is common, like in Nigeria where 51.7% of patients with diabetes and renal complications also had the peripheral vascular disease (Agaba 2004). Interactions between peripheral damaged organs and infection occur in up to 53% of patients with diabetes (Dalal et al. 2011). Heavy investment in the health care system like dialysis units and coronary care units are necessary to take care of these diabetes-related complications.

Disability and Mortality

In 2017, NCDs accounted for 80% of disabilities globally with diabetes being the fourth leading cause (Mbanya et al. 2014). The age-standardized DALY rates for diabetes are higher amongst men than women (Gouda et al. 2019). Disability and the premature mortality caused by diabetes occur at a younger age in SSA compared to other regions. Globally in 2019, diabetes was responsible for 366,200 deaths with 3 of 4 deaths occurring before 60 years whereas, in 2009, diabetes-related mortality was highest in the age group of 30–39 years (IDF Diabetes Federation 2019a, b). High blood pressure which is common in blacks, was found to be about twice more common in people with diabetes compared to age-matched controls, while dyslipidemia ranged from 16 to 89% and overweight 50–83%. Cardiovascular complications are amongst the leading cause of mortality from chronic complications in patients with T2D (Kengne et al. 2005).

Although there is poor documentation on the causes of deaths in Africa, available estimates suggest that diabetes-related mortality ranges between 8 and 41% of all-cause mortality, and this is primarily due to acute complications and infections (Peer et al. 2014). In Cameroon, acute complications were the leading cause of mortality (22.2%) followed by cardiovascular complications (16.7%) and nephropathy (14.8%) (Foryoung et al. 2018). The life expectancy in children with T1D could be as low as 1% in Africa (Beran and Yudkin 2006). In South Africa, the predominant cause of mortality in patients with T1D is nephropathy, accounting for over 40% of all deaths (Gill et al. 2005). Table 3.1 shows the number of deaths in adults aged 20–79 years for some SSA countries.

Economic Burden of Diabetes Mellitus

Three alternative approaches exist to estimate the economic burden of public health problems like diabetes including the willingness to pay approach, the macroeconomic/production function approach, and the cost of illness approach (COI). The last one is the most commonly employed and takes into account the direct cost, indirect cost, and intangible cost (Fig. 3.2).

Costs Attributable to Diabetes Mellitus in Africa

Since 2001, there has been a steady rise in the gross domestic product (GDP) of many sub-Saharan African countries, reaching its peak in 2014. In 2016, the mean GDP per capita spent by SSA countries was equivalent to US$1511.3 with a wide range from US$282.1 in Burundi to US$15,077.8 in Seychelles (The World Bank 2019). Overall, less than 5.6% of the GDP was spent on healthcare in the low- and middle-income countries of SSA. The World Health Organization (WHO) estimates that up to 11 million Africans fall into poverty each year, due to high out of pocket payments for healthcare (WHO 2019b). Few studies have quantified the economic burden of diabetes at the regional level. A major difficulty in collating data for the cost of illness studies is that authors report on only one type of cost; mostly the direct cost (Afroz et al. 2018). In South Africa, where the diabetes age-adjusted prevalence is 12.7%, mean diabetes-related expenditure was US$1245.0 per patient (Table 3.1), while in Benin, the age-adjusted diabetes prevalence was 1% and mean expenditure was US$163.8 pp.

Diabetes costs have increased from 1.4 billion in 2010 to 9.5 billion in 2019. This is due to both an increase in the prevalence of diabetes by 57%, and an increase in the cost of persons living with diabetes from US$222.6 to US$509 (IDF Diabetes Federation 2019a, b). According to current reports, the cost of care for people with diabetes in Africa accounts for 12.5% of healthcare expenses, with the highest percentage in South Africa (23.0%) (IDF Diabetes Federation 2019a).

Purchasing Power Parity Calculations

Nineteen million adults with diabetes recorded in Africa in 2019 resulted in a total economic cost of US$9.5 billion. Using the 2005 purchasing power parity (PPP), Kirigia and colleagues estimated the cost of diabetes per patient at Int$3633, giving a total burden of Int$25.51 billion, with indirect cost contributing 68% of it (Kirigia et al. 2009). Consistent with this, other reviews have reported the indirect costs of diabetes per patient to be higher than the direct costs (Mutyambizi et al. 2018). Nevertheless, Bommer and colleagues found a lower contribution of indirect cost (44.4%) (Bommer et al. 2017).

Cost of medication and hospitalization are the major causes of direct expenses (Afroz et al. 2018). A review reported the cost of medication to contribute as high as 50% of the total cost (Mutyambizi et al. 2018).

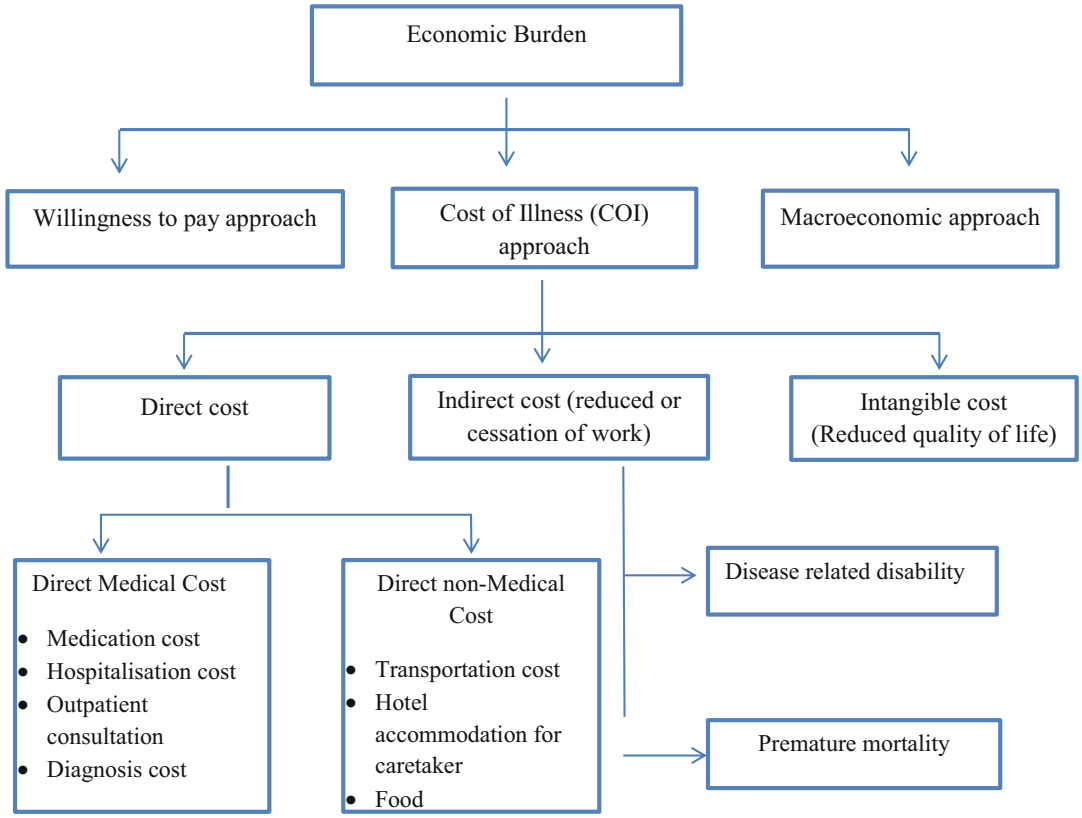

Fig. 3.2 Measurements approaches to the economic burden of diabetes (Adapted from Kirigia et al. (2009))

Direct Cost

The direct cost of a disease refers to resources used for the treatment of the disease regardless of whether they are born by patients themselves, by private or public payers, or by the government (IDF Diabetes Federation 2019a). This is usually divided into the direct medical cost which are expenses, borne as a result of direct medical treatment like medications, outpatient visits, laboratory tests, and hospitalizations. The second is the direct nonmedical cost which are expenses incurred as a result of transportation, food, lodgment. In COI studies, cost of medications, diagnostic cost, cost of the consultation, and inpatient cost is the most commonly reported (Mutyambizi et al. 2018).

Profile of African Countries

The direct cost of diabetes differs greatly between African countries with reported costs estimated from Int$3.5 billion to Int$4.5 billion and over US$10.8 billion per annum (Mutyambizi et al. 2018; Bommer et al. 2017) (Table 3.2). There are inconsistent findings of the major contributors, with some reviews reporting the cost of hospitalization as predominant, and other medication costs (Mutyambizi et al. 2018; Afroz et al. 2018). For outpatients in Nigeria, the cost of medication varied between Int$420.63 to Int $1025.00 per patient per annum for type 1 and 2 diabetes respectively, thus contributing as high as 90% of all treatment cost. For hospitalized patients, the cost of medication ranged from Int

Table 3.2 Summary of studies on diabetes costs from Africa (adapted from Mapa et al. (2019))

Year of costing	Setting/Reference	Perspectives	Type of diabetes	Direct cost (US$)	Indirect costs (US$)	Total cost (US $)
2019	Africa (IDF Diabetes Federation 2019a)	Societal	1 and 2			9.5 billion

1995	Sudan (Elrayah et al. 2005)	Patients	1	283[b]		

Abbreviation: *pp* per person
Unless otherwise stated, costs are annual cost in US$
Common perspectives used in COI studies are the patient perspective, the employer perspective (loss of productivity), health system perspective, government perspective and societal perspective
Int$: International dollar (local cost converted to the purchasing power of one US$)
[a]Annual cost of minimum care diabetes supplies
[b]Median cost

$553 to 1438 per admission in Nigeria and Int$80 to 461 in South Africa. In Cameroon, the cost of medication was estimated at I$3.9 per patient per month (Mutyambizi et al. 2018). The greatest expense incurred for diabetes medications comes from insulin. Indeed, the annual treatment for diabetes with insulin is US$104.4 compared to US$26.9 with metformin (Atun et al. 2017).

Several factors are associated with the direct cost of diabetes include socioeconomic factors like age, level of education and income class, factors related to diabetes like duration of diabetes, number of complications, mode of treatment, hospitalizations, and surgery (Afroz et al. 2018). As shown in Table 3.2, the cost of T1D is consistently higher than for type 2 diabetes across the studies.

Indirect Cost

The indirect cost is the opportunity cost resulting from reduced or loss of productivity at work by patients and their accompanying persons, because of the disease-related disability or premature mortality (Afroz et al. 2018). This includes the productive time lost for medical reasons like traveling for medical consultations and waiting to be admitted, hospital admissions for complications, absence from work for disease-related disability, and years of work lost due to premature deaths. Depending on the approach used to calculate the indirect cost of diabetes, the economic burden might be overstated. Some methods estimate the indirect cost for the unemployed while others use a more conservative approach like the friction-cost approach (Van den Hout 2010).

The COI study in 2015 used four sources of indirect costs: labor-force drop out; mortality; absenteeism; and presenteeism (Bommer et al. 2017). Globally, the first two contribute 48.5% and 45.5% respectively of indirect cost, however, this is different in LMICs where mortality dominates, contributing 63.6% of the indirect cost in middle-income countries and 90.6% in low-income countries. As shown in Table 3.2, the annual indirect cost of diabetes per patient was estimated at US$762.20 in Mali, for an annual total cost per patient of US$365.48, while in Morocco, the indirect cost per patient per month was US$1113 (Bermudez-Tamayo et al. 2017; Boutayeb et al. 2013). Because most studies report only on the direct cost, there is a dearth of information on the indirect cost of diabetes in Africa. Nonetheless, its contribution to total cost could contribute to over 60% of the total cost (Kirigia et al. 2009; Mapa-Tassou et al. 2019).

Intangible Cost

Intangible cost relates to the reduced quality of life as a result of the physical, psychological, and social handicap of disease. The quality of life can be severely affected by chronic diseases and examples include pain, worry, anxiety, loss of independence, and lack of participation in social events (Afroz et al. 2018).

Intangible costs are the most difficult to assess given that they are related to emotions. Because the quality of life is difficult to express in terms of money, many studies do not report on the intangible cost. Intangible cost of diabetes may range between US$30.8 per month if the patient had no complications, to US$143.9 if four or more complications were present. If patients had blood glucose levels within targets, the intangible cost was estimated at 10.3 per month, compared to US$41.1, if poorly controlled, with an annual estimate of US$496.7 (Afroz et al. 2018).

Cost of Diabetes Complications

The major contributor to direct costs for diabetes-related complications is hospitalization, and for indirect cost are absenteeism, disability, and premature mortality. There is a linear relationship between expenditures and the number of complications present. According to the International Diabetes Federation estimates, the treatment of diabetes-related complications accounts for over 50% of the direct cost attributable to diabetes, and this expenditure is highest in the

60–70 years age group (IDF Diabetes Federation 2019a).

Nephropathy, diabetic foot, and stroke are the complications associated with the highest expenses in Africa (Mutyambizi et al. 2018). Patients with diabetes are likely to spend up to four times more if they have diabetes-related complications compared to those with no complication, and this varies greatly by countries. In Mali, up to Int$1346.5 per patient was spent on nephropathy while only Int$33.03 was spent in Guinea. For acute complications like diabetic ketoacidosis, the cost of management differs in those with and without chronic complications. In Guinea, the cost of treatment for diabetic ketoacidosis ranged from Int$22.1 to Int$39.2, and in Burkina Faso from Int$628.27 to Int $1085.4 (Mutyambizi et al. 2018).

Mean annual health expenditures for people with four or more complications are expected to be about 20 times more than in people without complications (IDF Diabetes Federation 2019a). Consistent with this, the presence of one or more complications increased the cost ratio by 1.1 for retinopathy and up to 4.3 for an infected diabetes foot in another study. This is because, in Africa, foot complications in patients with diabetes often progress to infection or gangrene, resulting in longer hospitalizations and higher mortality rates (Mutyambizi et al. 2018).

Comparative Health Care Expenditures in Africa

In 2016, 5.5% of the GDP in Africa was spent on health against 10% at the global level, with SSA having the highest out of pocket expenses (36.7%) (WHO 2019b; The World Bank 2019). In SSA, the GDP percent spent on health is not related to the national expenditure. For example, Sierra Leone with GDP per capita of US$501.4 spent 16.53% of its budget on healthcare, while others like Equatorial Guinea and Nigeria having a GDP of US$9738.4 and 1968.6 spent only 3.38% and 3.35% respectively. Similarly, out of pocket expenses on health care were highest in Equatorial Guinee and Nigeria (72.83% and 75.21% respectively) (WHO 2019c).

Globally, at least US$760 billion is expected to be spent on diabetes annually, and it could reach US$845 billion by 2045 (IDF Diabetes Federation 2019a). The expenditure per person in high-income countries (US$5339) was over 30-folds and almost sevenfold higher than in low- and middle-income countries respectively in 2019. Reduced or missed production opportunities due to diabetes contribute an additional 35% to the annual global health expenditures. Overall, direct expenses on diabetes have increased by 4.5% over the last 2 years, and it is predicted to increase by 11.2% over the next 25 years (IDF Diabetes Federation 2019a). It is possible that the real estimates are more important as actual projections are conservative, and based on the assumption that diabetes prevalence and expenditures are not changing. One can find substantially higher estimates for the global economic burden of diabetes at US$1.31 trillion, equivalent to 1.8% of the world GDP, with indirect cost contributing 34.7% of the overall burden in a COI study of 2015 (Bommer et al. 2017).

In 2015, North America had the highest economic burden at US$499.40 billion (2.6% of its total GDP), while Africa had the lowest diabetes-related expenditure; US$9.45 billion (1.2% of its total GDP). The contribution of the indirect cost was more important in high-income countries compared to LMICs (40.0% versus 33.5%) (Bommer et al. 2017). While the cost of medication is the major contributor to direct cost in Africa, there are conflicting reports between the cost medication or cost of hospitalization at the global level (Ng et al. 2014). Indirect cost contributed as high as 44.6% in SSA and 57.4% in South Asia as opposed to only 21.9% in Latin America and the Caribbean, although there is a report of a higher contribution of the indirect cost of 68% to the total cost in SSA (Bommer et al. 2017). (Kirigia et al. 2009).

The lowest annual expenditure per person spent in SSA was in the Central African Republic, with similar estimates in Bangladesh (US$64), and Nepal (US$80). Overall, slightly higher expenditure was spent in 2019 in women than

men across all the regions (US$382.6 billion versus US$377.6 billion) and this difference is predicted to be maintained over the years (IDF Diabetes Federation 2019a).

Perspectives

Countries with the lowest GDP have the highest burden of NCDs in terms of DALYs, therefore if nothing is done, the rapid increase in diabetes will badly affect the African region. The potential strategies to address the economic burden of diabetes are listed below.

National Diabetes Programs (NDPs)

Early management and lifestyle changes can delay or prevent T2D in 80% of individuals (IDF Diabetes Federation 2019a). Therefore, the development and implementation of diabetes programs may reduce the incidence of diabetes and mortality. Unfortunately, less than one-third of SSA countries have a national diabetes plan (IDF Diabetes Federation 2019a). Important areas for the focus of NDPs are conducting community cost-effective interventions, aiming at raising awareness on diabetes and its risk factors, increasing physical activity, losing weight, eating healthily, along with routine screening and clinical care, and access to essential medication and supplies.

Sustainable Development Goals

The third UN summit in New York in September 2018 recognized the challenges posed by diabetes and other NCDs on the socioeconomic development. To achieve the 2030 targets related to sustainable development goal 3, especially item 3.4 which aims at reducing premature mortality from NCDs by at least 33%, there is a need for governments, leaders, and stakeholders in SSA to urgently react to the threat imposed by diabetes and other NCDs. SSA healthcare systems continue to prioritize infectious diseases and currently, less than 30% of ministries in SSA have integrated policies for the management of diabetes and other NCDs (Kengne et al. 2013). Given that over 70% of deaths globally are due to NCDs, there is value in investing in strengthening the health care system and undertake more translational research to reduce the burden of diabetes (WHO 2019a). Furthermore, because diabetes mortality is highest in low-income countries, prioritization of the limited resources using cost-effective strategies, like the WHO Best Buys interventions (e.g., taxation on alcohol and tobacco products) to change behaviors may improve health outcomes (Atun et al. 2017; Kengne et al. 2013).

Universal Health Coverage (UHC)

Most countries in SSA do not have a national health care insurance coverage, and therefore out of pocket payment of care limits access for individuals with low income. Such an objective could be achieved by ensuring an equitable tax payment system, and compulsory health insurance (Sanogo et al. 2019).

Abstract

The scientific community is leading efforts to find efficient therapies for obesity and diabetes, which led to the rediscovery in 2009 of the presence of functional brown adipose tissue (BAT) depots in adult humans. In this chapter, we describe the main characteristics of this tissue and the image techniques available for its detection. In addition, we discuss the secretory capacity of BAT that is responsible for crosstalk with other organs and confers a regulatory role in several processes beyond the canonical generation of heat. Finally, we explain the mechanisms through which obesity and diabetes interrupt the physiological role and development of BAT and we summarize the latest results of the studies that use BAT transplant as a new therapy in the treatment of metabolic diseases.

Abbreviations

Ad-MSCs	Adipose tissue derived-mesenchymal stem cells
ARC	Arcuate nucleus
BAT	Brown adipose tissue
BMP	Bone morphogenetic protein
BOLD	Blood-oxygen-level-dependent
^{14}C-FBnTP	^{14}C-fluorobenzyl triphenyl phosphonium
CGRP	Calcitonin gene-related peptide
^{11}C-MBR	(S,S)-O-methyreboxetine
CNS	Central nervous system
^{11}C-PBR28	Peripheral benzodiazepine receptor tracker
CT	Computational tomography
CXCL14	Chemokine (C-X-C motif) ligand 14
12, 13-diHOME	12, 13-dyhidroxy-9Z-octadecenoic acid
DIO	Diet-induced obesity
DMH	Dorsomedial hypothalamic nucleus
ECM	Extracellular matrix
eWAT	Epididymal white adipose tissue
FA	Fatty acids
FGF21	Fibroblast growth factor 21
^{18}F-FDG	^{18}F-fluorodeoxyglucose
^{18}F-THA	^{14}(R,S)-fluoro-6-thiaheptadecanoic acid
GDF15	Growth differentiation factor-15
HFD	High-fat diet
IL-6	Interleukin-6
iPSCs	Induced pluripotent stem cells
IRT	Infrared thermography
LepRB	Leptin receptor
MnPO	Median preoptic subnucleus
MR	Magnetic resonance
MSCs	Mesenchymal stem cells
NE	Norepinephrine
NGF	Nerve growth factor
NIRTRS	Near-infrared time-resolved spectroscopy
NOD	Non-obese diabetic
NRG4	Neuregulin 4
NTS	Nucleus of solitary track
PET	Positron emission tomography
POMC	Precursor proopiomelanocortin
PRV	Pseudorabies virus
scWAT	Subcutaneous white adipose tissue
SNS	Sympathetic nervous system
SUV	Standardized uptake value
TH	Tyrosine hydroxylase
TNFα	Tumor necrosis factor α
UCP1	Uncoupling protein 1
VEGF-α	Vascular endothelial growth factor-α
WAT	White adipose tissue

Adipose Tissue Classification: Types, Location, and Function

Traditionally, adipose tissue has been classified by its energy profile. According to this classification, white adipose tissue (WAT) is composed of adipocytes that are mainly comprised of a single, large lipid droplet that constrains the nuclei against the plasma membrane. This tissue mainly acts as an energy store, although it also has a secretory role, exerting autocrine, paracrine, and endocrine functions. In humans, there are major depots in subcutaneous (abdominal, gluteofemoral) and visceral regions (omental, mesenteric, mediastinal, and epicardial) while inclusions of minor depots can be observed in organs such as the liver, muscle, or kidneys.

Brown adipose tissue (BAT) has a completely distinct developmental origin as it comes from $Pax7^{+}/Myf5^{+}$ stem cells (in contrast to WAT that comes from stem cells that do not express either of these progenitors). The whole tissue is densely vascularized and innervated, but its main feature is the presence of multilocular adipocytes that contain small lipid droplets and have an elevated mitochondrial content, which is responsible for its thermogenic function. This is due to the characteristic presence of uncoupling protein 1 (UCP1). UCP1 is a channel located in the inner mitochondrial membrane that returns protons pumped by the electron transport chain from the intermembrane space to the mitochondrial matrix, avoiding their use by ATP synthase, so the released energy is dissipated as heat. In humans, it was thought that the presence of this tissue was mainly restricted to interscapular and perirenal regions in babies and infants, that require this thermogenic function to maintain body temperature until they acquire the shivering reflex. However, in 2009, five independent researchers rediscovered the presence of BAT in cervical, supraclavicular, para-vertebral, suprarenal, and periaortic regions in adults and, more importantly, determined that this tissue can still be activated. This discovery rapidly boosted interest in BAT as a potential therapeutic tool against metabolic diseases (Cypess et al. 2009; Zingaretti et al. 2009; van Marken Lichtenbelt et al. 2009; Virtanen et al. 2009; Saito et al. 2009) (Fig. 4.1).

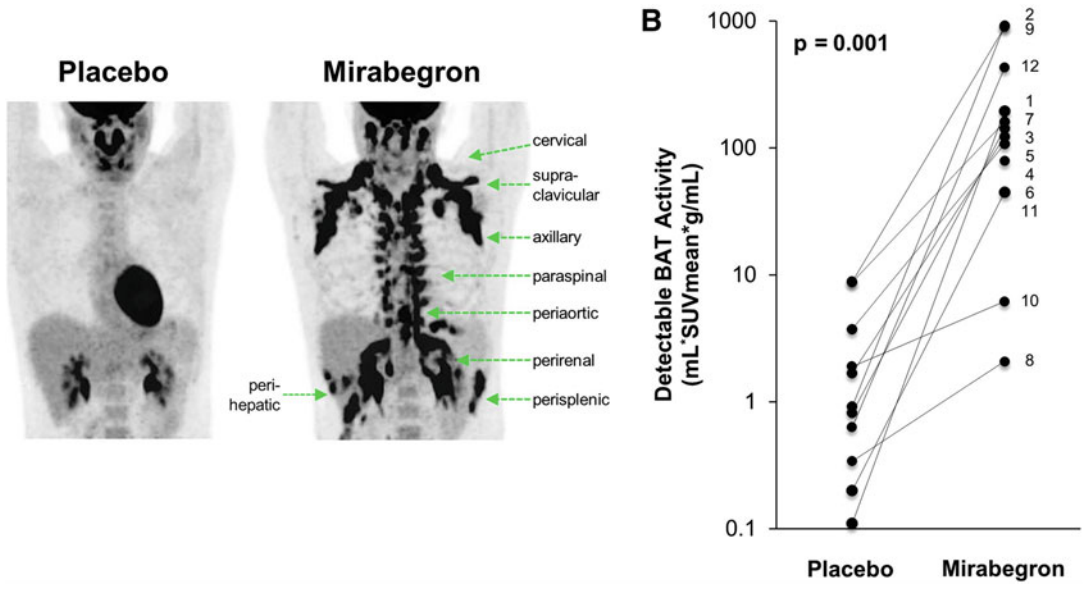

Fig. 4.1 Brown adipose tissue detection and activation by ^{18}F-FDG uptake. (**a**) PET images of a 21-year-old man who was given a placebo (left) or 200 mg of the β3-AR agonist mirabegron (right). Twelve male subjects were given a placebo or 200 mg mirabegron. (**b**) BAT metabolic activity as reflected by ^{18}F-FDG uptake. Reproduced with permission from Cypess et al. (2015)

Finally, it is known that under certain conditions, such as cold or a high-fat diet (HFD), in some WAT depots a population of UCP1 positive adipocytes can emerge, although they come from a Pax7$^-$/Myf5$^-$ origin. These adipocytes are called brite (brown-in-white) or beige, but also "inducible" since they are responsible for adaptative thermogenesis or "browning." As an example of this adaptation capacity, if BAT is removed from mice, there is a significant "browning" process triggered in WAT as a compensatory mechanism (Piao et al. 2018).

Clinical Measurement of Brown Adipose Tissue

There are currently 91 clinical trials registered in the USA that target BAT in obesity, diabetes, or cardiovascular disease. In this context, it is essential to have imaging-based tools that unequivocally identify the presence and effect of regulators on BAT activity in humans. Below, the most commonly used techniques will be described, together with some promising new approaches. We recommend as additional reading the reviews by Sampath et al. (2016) and Ong et al. (2018).

Positron Emission Tomography (PET) Imaging

^{18}F-fluorodeoxyglucose PET (^{18}F-FDG PET) has been used in oncology to detect tumors, since FDG is internalized by glucose receptors and trapped intracellularly by the action of hexokinase in areas with an elevated consumption of glucose. On several occasions, the signal was detected in areas other than tumors. The combination of this result with morphological information obtained from computational tomography (CT) scans, allowed the co-localization of FDG-positive areas with a high-lipid density. In 2009, the set of independent research that triggered BAT rediscovery used ^{18}F-FDG PET/CT to track BAT mass and activity in humans (Cypess et al. 2009; van Marken Lichtenbelt et al. 2009; Virtanen et al. 2009; Saito et al. 2009). As this technique relies on glucose uptake by active tissue, non-stimulated adult humans can sometimes be wrongly categorized as BAT-negative because of a lack of signal in the PET, when they would be better classified as BAT-inactive. In fact, cold exposure or drug-driven activation in these patients usually leads to an increase in the standardized uptake value (SUV) (Garcia et al. 2006).

Although ^{18}F-FDG PET/CT is probably the most common technique used for BAT visualization, there are several limitations to this approach. First, it requires the use of ionizing radiation and trained personal. Second, the technical protocols to measure BAT activation also differ (from temperature-controlled rooms or cooling vests to adrenergic stimulation by drugs), which leads to wide dispersion of observed effects. In this context, a panel of experts established the BARCIST recommendations to enhance comparability across experiments (Chen et al. 2016). The technique is based on glucose uptake, which is not even the preferential energy substrate in BAT and can be modified by disease (obesity, diabetes), drugs (β-blockers, anxiolytics), outer temperature or individual factors such as age, gender, or ethnicity (Soderlund et al. 2007; Pfannenberg et al. 2010; Pace et al. 2011; Rakheja et al. 2011).

Consequently, the use of other molecular trackers has been proposed, although most of them rely on BAT activity. For instance, (^{14}C)-FBnTP (^{14}C-F-fluorobenzyl triphenyl phosphonium) is used as a tracker of membrane potential, which decreases after BAT activation (Madar et al. 2011). ^{11}C-MRB (^{11}C-(S,S)-O-methylreboxetine) (Hwang et al. 2015) and ^{18}F-THA (14 (R,S)-^{18}fluoro-6-thiaheptadecanoic acid) (Ouellet et al. 2012) are used as trackers of fatty acid uptake and oxidation, and ^{15}O-O_2 detects increased mitochondrial oxygen consumption after BAT activation (Mueez et al. 2016). More recently, ^{11}C-PBR28 (^{11}C-peripheral benzodiazepine receptor tracker, an outer membrane protein in the mitochondria) has shown promising results, detecting BAT mass independently of its activation degree (Ran et al. 2018).

Magnetic Resonance (MR)

MR is a noninvasive technique based on the use of magnetic fields and electromagnetic radiation to detect mainly the hydrogen, carbon, or xenon nucleus. In the presence of a magnetic field, protons will align with it in two differential spin states: a stable, low-energy spin and a high-energy spin. With the application of electromagnetic radiation, low-energy nuclei suffer a transition to high-energy protons, absorbing a discrete amount of energy called precession frequency, that can be detected. This value differs in aqueous or lipid environments, allowing the detection of fat depots. The application of this technique to BAT detection has been brilliantly reviewed by Karampinos et al. (2019).

Due to the lack of ionizing radiation, this technique can be safely used in infants or to establish protocols using repeated measurements, such as pre- and post-intervention studies or time-course analysis. This methodology can structurally identify BAT and even distinguish it from WAT (Hamilton et al. 2011), although MR fat fraction measurements have certain limitations as the spatial resolution is restricted to 1 mm^3. For instance, it may not be possible to resolve differences between intracellular water and non-lipid structures, such as vessels or connective tissue. In addition, it is not possible to differentiate white, brown, and beige adipocytes when they coexist in the same depot, as occurs in obese patients or in the supraclavicular regions. Nevertheless, modifications in the protocol have been published that solve this issue, based on the smaller size of BAT lipid droplets (Branca and Warren 2011).

In addition, MR technology can be adapted to determine BAT activity. Water-fat composition studies can be used to determine intracellular lipid extinction, used as a fuel to generate heat during cold-induced BAT activation. The increase in blood flow can be tracked using a technique known as the blood-oxygen-level-dependent (BOLD) effect, that relies on the differential paramagnetic properties of oxyhemoglobin and deoxyhemoglobin (Iris Chen et al. 2013). Other emerging but still experimental approaches involve hyperpolarized MR imaging, using the lipophilic accumulation of ^{129}Xe to measure BAT perfusion or the breakdown of hyperpolarized ^{13}C-pyruvate into bicarbonate and lactate (Branca et al. 2014).

Preclinical Imaging Techniques (Thermometry, Ultrasound, and Near-Infrared Spectroscopy)

The increase in skin temperature associated with the thermogenic activity of the BAT can be directly measured using infrared thermography (IRT). This approach is widely used in animal models in preclinical studies. In the last decade, the technique has also been applied in humans due to its simplicity, reduced cost, and safety, which allows repetitive measurements and use in sensitive populations. In humans, IRT is used to detect changes in skin temperature, although it is limited to the supraclavicular region, where BAT is more superficial. Several authors have demonstrated that cold-induced activation of BAT determined by ^{18}F-FDG PET/CT correlates with an increase in skin temperature detected by IRT (Law et al. 2018).

However, this approach has several limitations. First, it is a method based on tissue activation, which implies that inactive BAT will not be detected unless there is a change in temperature generation. Second, it currently lacks a standardized protocol in terms of patient preparation (acclimatization, cold intensity, and duration) or data analysis (image acquisition and analysis of the region of interest). Finally, but crucially, the determination of supraclavicular BAT-generated temperature can be highly limited by (i) the shielding effect of the surrounding tissues and (ii) the contribution to skin temperature of increased blood flow after BAT activation. For instance, the thickness of the subcutaneous adipose tissue in obese patients hampers the diffusion of the temperature toward the skin, misleading the signal acquisition. To our knowledge, only two reports have evaluated BAT activation using this approach in obese patients, and both of them explicitly acknowledge the

limitations of the protocol (El Hadi et al. 2016; Hartwig et al. 2017).

Ultrasonography

Ultrasounds are based on identifying increased blood flow in activated BAT by detecting microbubbles injected into patients. This technique has obtained promising results in mice, in which norepinephrine activated BAT was detected and estimated BAT mass was obtained, that correlates with the observed results after necropsy. However, its application in humans is currently limited to a small pilot project in 13 lean patients, in whom ultrasound-detected BAT mass activation was similar to that detected by ^{18}F-FDG PET/CT (Flynn et al. 2015).

Near-Infrared Spectroscopy (NIRTRS)

NIRTRS is based on the relative transparency of tissues to near-infrared wavelengths, and the differential absorption of hemoglobin and myoglobin in relation to oxygenation state. The technique can be used to detect hemoglobin oxygenation in the microvasculature, which is inversely related to oxidative activation of BAT. However, while the first studies in humans reported comparable results in the detection of supraclavicular BAT to the gold standard ^{18}F-FDG PET/CT (Nirengi et al. 2015), later reports noted that this technique is apparently unable to detect changes after BAT activation (Hartwig et al. 2017; Acosta et al. 2019), which would potentially limit the use of this simple, noninvasive method.

Secretory Activity of Brown Adipose Tissue

The secretory profile of WAT in lean, obese, and diabetic individuals has been thoroughly studied in the past two decades (Lee et al. 2019). However, a focus on the BAT secretome has been more recent. Due to the distinct roles of both adipose depots in energy metabolism, it is not likely that the type, amount, roles in signaling pathways and targets of the molecules secreted by BAT are similar (Villarroya et al. 2019a).

Brown Adipokines or "Batokines"

The term "batokines" (BAT-secreted mediators or brown adipokines) refers to the proteins, peptides, metabolites, regulatory factors, or miRNAs released by brown fat tissue, including BAT-resident cells other than brown adipocytes such as immune cells, preadipocytes, neurons, etc. They can be classified according to their chemical nature, their role in the regulation of the thermogenic process (Villarroya et al. 2017a, b, 2019a), or their mechanism of action in cellular communication (autocrine, paracrine, or endocrine) (Villarroya et al. 2017b). Table 4.1 summarizes the BAT-secreted signaling molecules that have been identified in basal conditions.

Using a proteomics approach, two recent studies (Ali Khan et al. 2018; Villarroya et al. 2019b) reported a set of proteins secreted after cAMP and noradrenaline stimulation of brown adipose murine cells. The studies show 60% coincidence, but interestingly both identified extracellular matrix (ECM) components (distinct types of collagens) or regulators (matricellular proteins: non-structural proteins in the ECM with a regulatory role) as members of the secretome of thermogenically activated brown adipocytes. This highlights the importance of BAT remodeling when the tissue has to be expanded in response to thermogenic activation (Villarroya et al. 2019a). In humans, a pilot study using comparative proteomics between white and brown adipocytes identified 101 proteins that are exclusively secreted by the BAT (Deshmukh et al. 2019).

Batokines and Transplantation

A direct way to identify the endocrine secretion of batokines is through BAT transplantation studies. For example, BAT transplantation in animal models of type I diabetes (Gunawardana and Piston 2012, 2015) has been shown to improve glycemia. In type II diabetes (high-fat diet-induced and ob./ob mice), BAT transplantation increased energy expenditure and improved glucose tolerance (Stanford et al. 2013; Liu et al. 2013, 2015; Zhu et al. 2014). BAT

Table 4.1 Secreted molecules by BAT after cold/adrenergic activation with recognized function

Gene	Protein	Function
Adipoq	Adiponectin	Thermogenesis inactivation.
Angptl8	Angiopoietin-like protein-8	Thermogenesis inactivation.
Agt	Angiotensinogen	Enhances BAT differentiation.
Bmp8b	Bone morphogenetic protein-8b	Enhances BAT differentiation. Increases sympathetic tone in BAT.
Cxcl14	C-X-C motif chemokine 14	Thermogenesis activation by M2 macrophage recruitment.
Edn-1	Endothelin-1	Thermogenesis inactivation.
Fgf2	Fibroblast growth factor-2	Enhances BAT differentiation.
Fgf21	Fibroblast growth factor-21	Thermogenesis activation.
Fst	Follistatin	Thermogenesis activation.
Gdf15	Growth and differentiation factor-15	Acts in immune cells to reduce inflammation.
Igf1	Insulin-like growth factor-1	Glucose homeostasis. BAT differentiation.
Il6	Interleukin-6	Glucose homeostasis. Regulation of Inflammation.
Ptgds	Lipocalin prostaglandin D synthase	BAT activation and WAT browning. Control of substrate choice in BAT (glucose vs lipids)
Lr11	Low-density Lipoprotein receptor relative, soluble form	Thermogenesis activation
Metrnl	Meteorin-like	Thermogenesis activation through immune cells-mediated catecholamine release
Mstn	Myostatin/growth and differentiation factor-8	Thermogenesis inactivation
Ngf	Nerve growth factor	Enhances BAT activity by increasing innervation
Nrg4	Neuregulin-4	Hepatic lipogenesis, fuel oxidation. Promotes BAT activation by increasing angiogenesis.
Pm20d1	Peptidase M20 domain-containing protein 1	Thermogenesis activation UCP1-independent.
S100b	S100-B protein	Enhances BAT activity by increasing innervation.
Slit2	C-terminal fragment of SLIT2 protein	Thermogenesis activation.
Vegfa	Vascular endothelial growth factor A	Enhances BAT activity by increasing vascularization.
Non-peptidic		
	Adenosine	Thermogenesis activation.
	(9Z)-12,13-Dihydroxy-9-octadecenoic acid (12,13-diHOME)	Promotes fatty acid uptake by BAT.
	Endocannabinoids	Thermogenesis inactivation.
	Hydrogen peroxide (H2O2)	vasodilation and second messenger in BAT differentiation.
	miR-99b	Inhibits hepatic FGF21 expression.
	Nitric oxide	Vasodilation in BAT and activation of thermogenesis.
	Prostaglandins	BAT activation and WAT browning. Control of substrate choice in BAT (glucose vs lipids)
	Triiodothyronine	Thermogenesis activation

transplantation can increase sympathetic tone and affect the endogenous BAT, WAT, heart, and muscle of recipient mice (Zhu et al. 2014). These effects cannot be exclusively explained by an increase in thermogenesis, so the consensus conclusion is that the BAT secretome should account for the observed phenotypical improvements.

Brown Adipose Tissue Signaling to Other Tissues

There is still little evidence about the role of the BAT endocrine secretome and its effects on target organs (Fig. 4.2). Here we highlight some of the more recent and relevant findings.

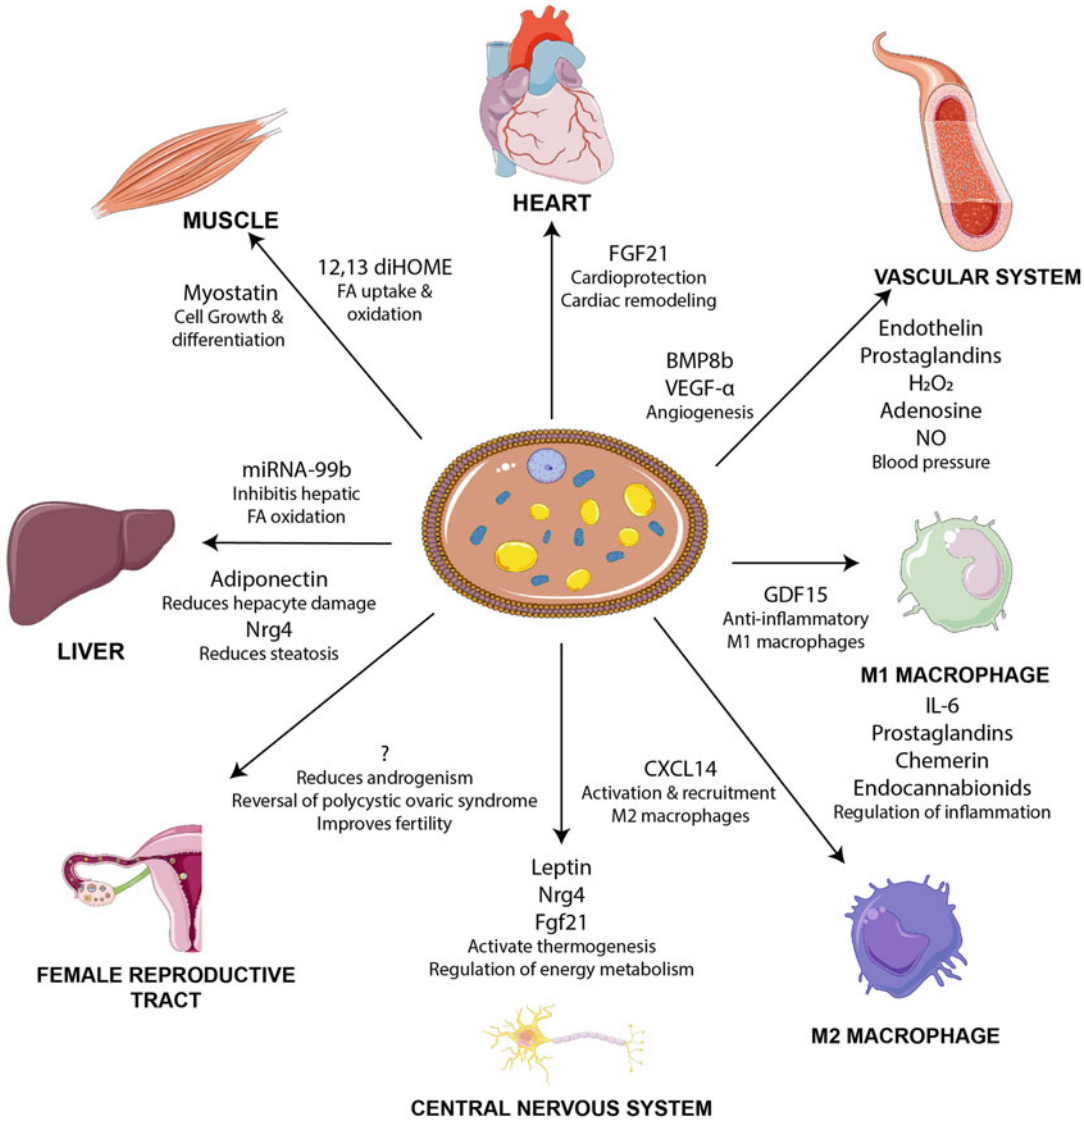

Fig. 4.2 Brown adipose tissue crosstalk. The activation of BAT stimulates the secretion of signaling molecules that target different organs, exerting regulatory roles in fatty acid oxidation and glucose uptake by the muscle, cardioprotective effects in the heart, regulation of blood pressure and arterial stiffness in blood vessels, the promotion of an anti-inflammatory phenotype in immune cells, regulation of lipid metabolism in the liver, regulation of ovulation and participation in the regulatory mechanism of the metabolism by the central nervous system

Muscle Physical exercise is a common non-pharmacological approach to treat metabolic diseases. Besides enhancement of muscular function per se, the study of bidirectional communication between muscle and BAT is beginning to reveal new agents that regulate the beneficial effects of exercise. For instance, exercise increases WAT browning through the secretion of myokines (Boström et al. 2012), and mildly increases BAT thermogenic activity in a lactate-driven mechanism (De Matteis et al. 2013). In the other direction, BAT seems to modify skeletal muscle function through the secretion of myostatin, which inhibits skeletal muscle cell growth and differentiation. Under thermoneutral temperature, BAT inactivation led to increased

myostatin secretion, reducing the exercise capacity of skeletal muscle. However, BAT activation lowered myostatin levels and favored exercise performance (Kong et al. 2018). BAT also participates in fatty acid uptake and oxidation by muscle, through the secretion of 12,13-dihydroxy-9Z-octadecenoic acid (12,13-diHOME) after exercise (Stanford et al. 2018).

Cardiovascular System Under thermogenic activation, BAT strongly releases fibroblast growth factor 21 (FGF21) (Hondares et al. 2011). Tissues and organs such as WAT, brain, pancreas, and heart are known to be sensitive to FGF21 action. In the heart, FGF21 seems to have a strong cardioprotective effect (Planavila et al. 2013) by attenuating hypertensive cardiac remodeling (Thoonen et al. 2015; Ruan et al. 2018).

There is also increasing evidence of the role of BAT signaling to blood vessels. For instance, bone marrow protein 8 b (BMP8b, one of the most abundantly expressed genes after BAT activation) and vascular endothelial growth factor (VEGF-α) promote angiogenesis, which is required to increase vascular density and thermogenesis in the BAT (Bagchi et al. 2013; Pellegrinelli et al. 2018). In addition, BAT removal in lean mice caused aortic stiffness, which suggests a key contribution to vascular remodeling (Grunewald et al. 2018).

Finally, several proteins and non-proteins secreted by BAT play a key role in maintaining blood pressure both by causing contraction (endothelin, some prostaglandins) and/or relaxation (adenosine, H_2O_2, nitric oxide). Although this indicates that BAT is an important regulator of vascular function, more research is required to understand its specific contribution.

Immune Cells Polarization of the infiltrated immune cells within BAT or beige adipocytes conditions the thermogenic programming of the tissue (Villarroya et al. 2018a, b). While the recruitment of M2-alternative activated macrophages promotes BAT function, M1-pro-inflammatory macrophages are negatively associated with the thermogenic activity (Villarroya et al. 2019a).

In normal circumstances, stimulated brown adipocytes can decrease the inflammatory response in macrophages in a paracrine fashion (Dowal et al. 2017). The release of chemokine (C-X-C motiv) ligand 14 (CXCL14) batokine leads to the alternative activation and recruitment of M2-macrophages in response to noradrenergic stimulation (Cereijo et al. 2018), while growth and differentiation factor-15 (GDF15) exerts anti-inflammatory effects on M1-macrophages (Verdeguer et al. 2015; Campderrós et al. 2019).

One of the most studied cytokines, interleukin-6 (IL-6) plays a dual pro-inflammatory and anti-inflammatory role. In BAT, it is secreted in response to cold and noradrenergic stimulation and it has been reported as crucial to maintain the thermogenic response. As an example, BAT transplantation from IL-6 KO mice loses the capability of promoting a healthy metabolic response in HFD-fed mice (Stanford et al. 2013).

Other factors secreted by BAT exhibit pro- and anti-inflammatory functions, such as endocannabinoids, chemerin, or prostaglandins, whose endocrine role and implication in BAT crosstalk to other tissues is yet to be defined.

Liver Considering that BAT activation relies mainly on glucose and fatty acid flux rather than on intracellular stored fuels, it seems reasonable that there is crosstalk between both organs, as the liver is the key regulatory organ in glucose and lipid homeostasis. FGF21 has been identified as a key molecule in this communication. In normal conditions, most circulating FGF21 is synthesized in the liver, where it participates in fatty acid oxidation and insulin sensitivity (Markan et al. 2014). To maximize fuel efflux for thermogenic activity under adrenergic or cold stimulation, BAT responds in a dual mode. First, it induces the expression of miR-99b, which, along with other miRNAs, is packed in exosomes and travels to the liver, where it inhibits FGF21 expression (Thomou et al. 2017) to minimize fuel consumption by the liver.

The second effect is the induction of BAT FGF21 expression, which will act in an autocrine fashion enhancing triglyceride-rich lipoprotein uptake and oxidation (Hondares et al. 2011; Schlein et al. 2016).

Another batokine, neuregulin 4 (Nrg4) reduces steatosis by controlling *de novo* lipogenesis in the liver. It may be a useful strategy to treat non-alcoholic fatty liver disease, as Nrg4 levels are downregulated in obesity (Wang et al. 2014). In a similar manner, adiponectin secreted by the BAT may reduce hepatocyte damage and death in alcohol-induced steatosis (Shen et al. 2019).

Female Reproductive Tract In ovariectomized mice, the development of obesity appears to be partially mediated by loss of BAT activity (Bartness and Wade 1984; Pedersen et al. 2001), probably related to the estrogen receptor present in BAT (Wade and Gray 1978). Women with polycystic ovary syndrome report lower BAT activity (Flávia et al. 2019), whereas transplantation of BAT in rats reversed polycystic ovaries and hyperandrogenism, and reduced infertility by reversing anovulation (Yuan et al. 2016). Whether this improvement is related to the thermogenic activity or the secretory role of BAT is still to be determined.

Brain Some of the autocrine/paracrine factors released by BAT act in the brain to activate neural circuits that innervate adipose tissues and cooperatively regulate lipid metabolism and energy homeostasis. One of these well-defined adipose-derived secretory factors is leptin. The expression of this gene is similar in WAT and BAT in lean mice, but WAT expresses significantly greater levels than BAT in obese mice. Leptin acts through leptin receptor (LepRb) to enhance the excitability of neurons of different parts of the brain including the arcuate nucleus (ARC), dorsomedial hypothalamic nucleus (DMH), median preoptic subnucleus (MnPO) and the nucleus of the solitary tract (NTS), implicated in the regulation of BAT (Zhang et al. 2011).

The ARC nucleus in the hypothalamus is in contact with the blood-brain barrier and is considered one of the gates for the brain to sense circulating factors. Leptin action in ARC increased thermogenesis in BAT by activating the efferent sympathetic nervous system (SNS) (Rahmouni and Morgan 2007; Harlan et al. 2011), through the induction of anorexigenic neuropeptide precursor proopiomelanocortin (POMC) expression and increasing the release of POMC products in second-order neurons (Yasuda et al. 2004; Dodd et al. 2015).

Another population of ARC neurons, the GABAergic RIP-Cre (Cre-mediated expression of rat insulin II promoter) are also activated by leptin and are involved in the neural circuits that activate BAT thermogenesis (Kong et al. 2012). Mice fed with a high-fat diet had impaired BAT sympathetic neuronal activation in response to systemic leptin, but the leptin intraparenchymal injection in diet-induced obese (DIO) mice increased BAT temperature (Enriori et al. 2011). Other batokines such as FGF21 (Mutsnaini et al. 2019) and Ngr4 (Rosell et al. 2014) interact with neural circuits to modulate BAT activity and cooperatively regulate whole-body energy metabolism.

Systemic Influences Other hormonal and nutritional signals and stimuli (temperature, immunologic responses, stress, and hypoxia) may have neurochemical influences on the central nervous system (CNS) networks that govern BAT sympathetic nerve activity. They may drive sympathetic BAT activation or inhibition and control BAT thermogenesis and energy expenditure, and contribute to whole-body energy homeostasis (see reviews by Morrison et al. 2014; Contreras et al. 2017).

Neuroendocrine Regulation of Brown Adipose Tissue

The central nervous system (CNS) integrates a wide array of environmental stimuli: diet, fasting, exercise, temperature, and behavioral states, sending outward neural signals via the autonomic nervous system that directly contact multiple

tissues to control metabolism and energy balance. Crosstalk between adipose tissues (BAT and different WATs) and CNS has emerged as an important issue for maintaining energy balance and promoting survival in response to metabolic challenges such as obesity. Therefore, intense research is focused on understanding the bidirectional communication between fad pads and brain. This encompasses endocrine signals from adipose tissues to CNS and neural signals through efferent sympathetic nerves and afferent sensory nerves and provides a framework for understanding overall BAT thermogenesis by the CNS (recently reviewed in François et al. 2018; Blaszkiewicz et al. 2019; Zhu et al. 2019).

Sympathetic BAT Innervation

The sympathetic innervation of BAT was described nearly a century ago. The physiological effect of sympathetic stimulation of neurons that innervate BAT is increased thermogenesis. The secretion of norepinephrine at the terminal nerves that surround adipocytes activates β3-adrenergic receptor and the signaling pathways that promote lipolysis, fatty acid (FA) oxidation, UCP1 protein expression and heat dissipation of the energy of FA (Cannon and Nedergaard 2004; Contreras et al. 2017). Several technologies have been used to demonstrate sympathetic innervation of BAT. Bartness and colleagues have provided important histological and functional evidence of brain sympathetic neuronal connectivity with adipose tissues by using pseudorabies virus (PRV), a retrograde trans-synaptic neuronal tracer that only traces sympathetic neurons that are synaptically connected.

They showed the hierarchical neuronal pathways defining pre- and postganglionic sympathetic innervation of BAT (Bamshad et al. 1999; Song et al. 2008) in Siberian hamsters and rats, and the description of a higher order of neurons located in different parts of the brain such as the hypothalamus and raphe pallidus (Bamshad et al. 1999; Oldfield et al. 2002; Cano et al. 2003). In addition, immunohistochemical labeling with tyrosine hydroxylase (TH), a specific marker for sympathetic nerve fibers involved in the biosynthesis of norepinephrine, have shown dense innervation of BAT (Giordano et al. 1996; Murano et al. 2009). Under cold exposure, it has been shown that TH increases at BAT parenchymal nerve fibers with a concomitant increase of UCP1 expression, which indicates enhanced sympathetic and thermogenic activity (Brito et al. 2008; Murano et al. 2009).

Experimental Denervation

Other techniques such as surgical or chemical denervation of BAT decreased UCP1 expression and highlighted the functional relevance of BAT innervation in regulating thermogenesis, energy expenditure, body mass, and browning (Dulloo and Miller 1984; Klingenspor et al. 1994; Nguyen et al. 2017). In addition, BAT sympathetic denervation can activate the sympathetic activity of other adipose tissues. For example, it can promote browning in inguinal WAT and suggests tissue crosstalk with the brain to modulate energy balance (Nguyen et al. 2017). Diet can modulate the sympathetic activity of BAT. Acute HFD treatments increase the norepinephrine (NE) turnover in BAT but this decreases after long treatments with HFD (Levin et al. 1983). More recently, it has been shown that diet-induced obesity increases UCP1 protein in mice and rats (Fromme and Klingenspor 2011; Alcalá et al. 2017) and BAT temperature after 20 weeks of diet (Enriori et al. 2011), which suggests that sympathetic activity in BAT increases to promote energy expenditure in conditions of excess calories.

Sensory Innervation of BAT

The first studies that suggest the presence of sensory neurons in BAT were performed by immunohistochemical detection of sensory nerve associated markers, such as calcitonin gene-related peptide (CGRP) and substance P (Giordano et al. 1996). More recent studies with anterograde transneuronal tracer have confirmed the presence of sensory nerve projections from BAT to dorsal root ganglia, which propagate their

signal to the CNS (Bartness et al. 2010; Ryu et al. 2015). In addition, it has been demonstrated that there is considerable crosstalk between adipose tissues and the CNS. BAT and WAT can share some sympathetic outflows from the CNS, and sensory information circuits of BAT and sympathetic circuits of WAT and vice versa have important overlaps in the CNS (Nguyen et al. 2017; Ryu et al. 2017).

In addition, it has been shown that sensory information about activated lipolysis in WAT can influence the efferent CNS circuits to BAT, by activating thermogenesis in this tissue (Garretson et al. 2016). All these data suggest a feedback mechanism that sensory information from each adipose tissue is communicated to the brain by an afferent pathway, which integrates the signal and regulates the efferent sympathetic outputs to each specific adipose tissue. Nevertheless, the nature of the signals that activate sensory neurons in different adipose tissues is unknown. Only a few brown adipokines (nerve growth factor [NGF], NRG4) have been identified as an outgrowth of promoters of sympathetic neurites (Néchad et al. 1994; Murano et al. 2009).

Adipose Tissue Dysfunction in Obesity and Diabetes

Since the mid-1990s, WAT has been seen not just as a storage depot, but also as an active, secretory tissue that establishes crosstalk with other organs. Dysregulation in this communication is a typical feature in obesity and diabetes and is partly responsible for adverse metabolic outcomes in organs such as muscle, liver, and blood vessels.

Sick Fat

WAT malfunction in obesity is characterized by the following anatomical and functional processes:

- Structural changes in the size (hypertrophy) and number (hyperplasia) of adipocytes and stiffness of the extracellular matrix
- Infiltration of immune cells, together with increased inflammatory secretion
- Oxidative and endoplasmic reticulum stress
- Defective lipolysis and increased energy metabolism
- Insulin resistance
- Mitochondrial dysfunction

These processes are not isolated events, but they are interconnected. For instance, oxidative stress increases endoplasmic reticulum stress, promotes inflammation, and participates in insulin resistance.

The WAT Expandability Hypothesis

The WAT expandability hypothesis tries to establish a time-course description of the events that begin with the increased demand for triglyceride storage (Tan and Vidal-Puig 2008). This hypothesis claims that there is an individual limit for fat accumulation within WAT. As long as this limit is not exceeded, the expansion of WAT will be healthy, which explains the presence of approximately 20% of morbidly obese patients who do not exhibit the expected comorbidities (dyslipidemia, type 2 diabetes or hypertension).

However, if the limit is surpassed, fat accumulation begins in ectopic tissues, leading for example to fatty liver or cirrhosis or loss of insulin sensitivity in the muscle. In this unhealthy expansion model, the extracellular matrix is remodeled and becomes fibrotic, impeding the hypertrophy of adipocytes, which get isolated from oxygen and food supply from blood vessels. As a response, the recruitment of immune cells begins through adipokine secretion, with a triple mission: (i) to attract blood monocytes to the tissue, which will become pro-inflammatory macrophages to phagocyte the apoptotic adipocytes; (ii) to generate new blood vessels to maximize oxygen and food supply to the hypertrophic adipocytes, whose size can become bigger than the oxygen diffusion limit (~100 μm) and (iii) to reduce insulin sensitivity, in order to limit the accumulation of triglycerides mediated by the insulin lipogenic effect. However, when obesity

becomes chronic, these changes in the biology of the adipocyte are not self-controlled, and the secretory profile of WAT negatively affects other tissues (Sun et al. 2011).

Brown Adipose Tissue in Obesity and Diabetes

In spite of the technical problems when it comes to measuring BAT amount and activity with current imaging methods, particularly in obese or type 2 diabetic patients, it is well-established that both the basal activity and its response to stimuli (cold, adrenergic agonists) is considerably diminished in these patients (Cypess et al. 2009; Eriksson et al. 2019).

BAT Dysfunction During Obesity

Recent studies in animal models have demonstrated that BAT from obese individuals undergoes similar pathological processes during obesity development, such as changes in the extracellular matrix, infiltration of immune cells and pro-inflammatory secretion, oxidative stress and changes in energy metabolism. Nonetheless, in comparison to WAT, the appearance of these processes is delayed since WAT preferentially uptakes the circulating fat (McGregor et al. 2013; Alcalá et al. 2017). However, once fat begins to accumulate within the brown adipocyte, a clear change in the phenotype is observed (commonly known as "whitening"). The change is characterized by an increase in the size of the multilocular lipid droplets, which gives the adipocyte a "white" appearance that is translated into a loss of thermogenic potential.

Reduced adrenergic stimulation, the role of adipokines/batokines, oxidative and endoplasmic reticulum stress, and some miRNAs are potentially responsible for the obesity-related decrease in BAT mass (Alcalá et al. 2019). Infiltration of activated M1 macrophages and pro-inflammatory cytokines promote a decline in UCP1 expression, which alters thermogenic activity (Sakamoto et al. 2016; Villarroya et al. 2018a). Oxidative stress is also responsible for BAT activity decline (Cui et al. 2019) (Fig. 4.3).

Therapeutic Perspectives for Brown and White Adipose Tissue Manipulation

As one of the regulators of body temperature, BAT controls triglyceride levels and uses glucose and lipids to fuel thermogenesis to produce heat. Therefore, the process of thermogenesis is associated with several metabolic pathways such as mitochondrial respiration, lipolysis, lipogenesis, or FA uptake, transport, storage, and oxidation (Calderon-Dominguez et al. 2016). In experimental animals, activated BAT is the major plasma lipid-clearing organ and has the highest FA oxidation rate (Doh et al. 2005; Bartelt et al. 2011).

The fact that aging, obesity, and diabetes have been associated with a decrease in the presence and activity of BAT in humans has highlighted BAT as a potential therapeutic target for metabolic diseases (Hany et al. 2002; Nedergaard et al. 2007; Cypess et al. 2009; Zingaretti et al. 2009; van Marken Lichtenbelt et al. 2009; Virtanen et al. 2009; Saito et al. 2009). These studies indicated that, in addition to its role in cold-induced thermogenesis, BAT also plays a key role in diet-induced thermogenesis. Efforts to enhance either the activity or the mass of thermogenic adipocytes include the increase in brown adipocyte differentiation or *de novo* brown adipogenesis, the transdifferentiation of white into beige and thermogenic adipocytes, boosting BAT activity, and the transplantation of thermogenic adipocytes.

Chemical Activation of BAT

In addition to natural activators of thermogenesis such as cold or exercise, several other activators have been described, such as bone morphogenetic protein 7 (BMP7) (Tseng et al. 2008; Boon et al. 2013) and BMP8b (Whittle et al. 2012), irisin (Boström et al. 2012), natriuretic peptides (Bordicchia et al. 2012), norepinephrine (Villarroya and Vidal-Puig 2013), meteorin-like (Rao et al. 2014), bile acids (Watanabe et al. 2006), adenosine (Gnad et al. 2014), FGF21

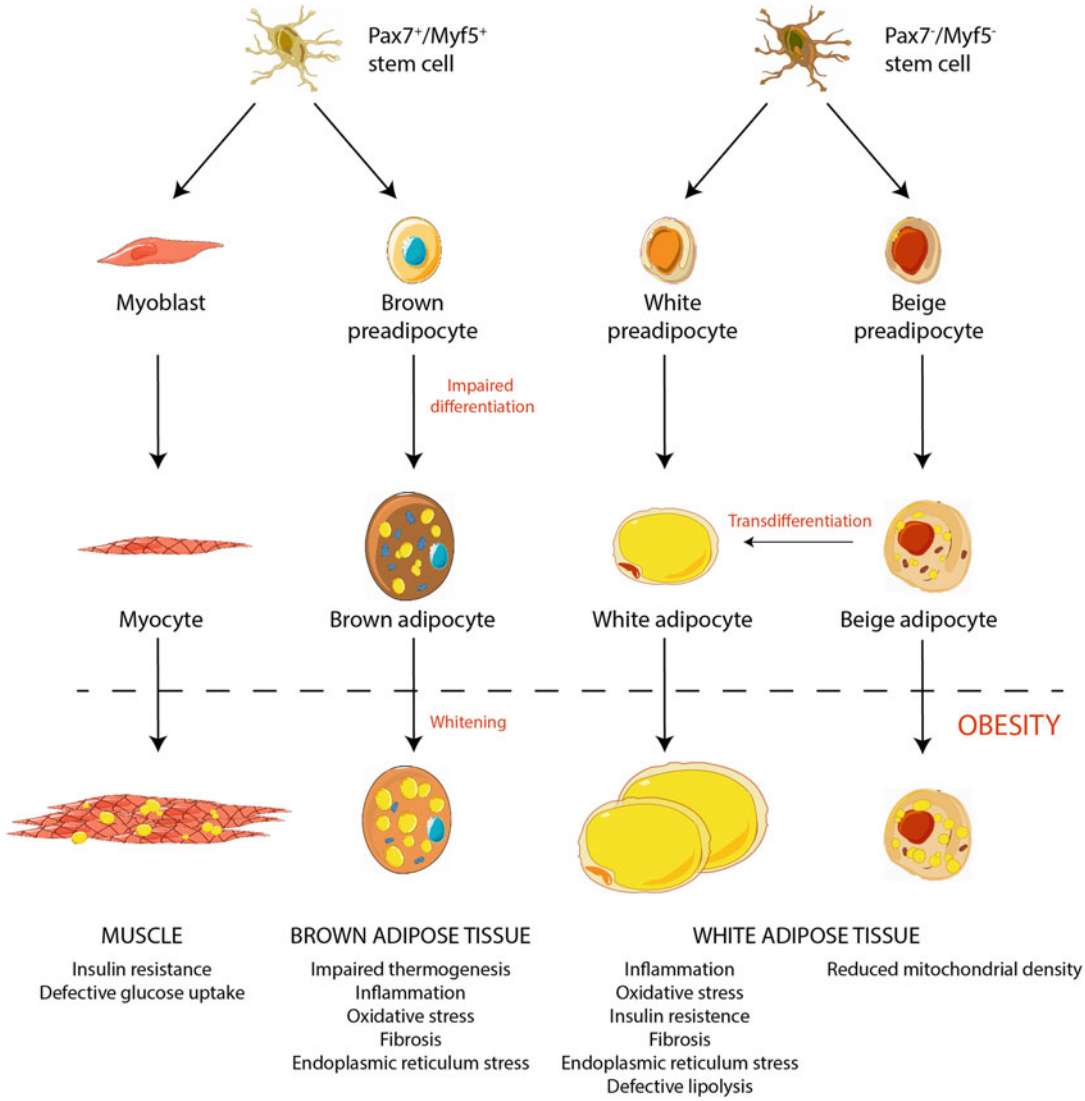

Fig. 4.3 Effects of obesity and diabetes in the development and function of adipose tissue. The pathological mechanisms that characterize obesity and diabetes can disturb the differentiation of brown adipocytes from precursor cells. They can also interfere in transdifferentiation processes, initially by promoting browning of white adipocytes to overcome the excess of nutrients and finally shifting the phenotype of brown adipocytes toward a white adipocyte (whitening). The thermogenic activation of BAT is also interrupted

(Hondares et al. 2010), or the β3-adrenergic receptor agonist mirabegron (Cypess et al. 2015). These factors have been shown to boost the browning of adipose tissue, *i.e.*, increased expression and activity of UCP1 within WAT, and have been extensively reviewed (Bonet et al. 2013; Wu et al. 2013; Calderon-Dominguez et al. 2016).

Bat Transplantation

The potential benefits of transplanting functional BAT are currently under study in animal models (Soler-Vázquez et al. 2018; White et al. 2019). In the case of adipocyte implantation, adipocytes could be obtained from mesenchymal stem cells (MSCs). MSC sources include embryonic stem

cells, and stem cells isolated from bone marrow, umbilical cord, peripheral blood, adipose tissue, bone marrow, cartilage, tendon, muscle, and dental pulp. Adipose tissue derived-MSCs (Ad-MSCs) are currently predominant in the study of metabolic diseases since a large number of MSCs can be isolated, and because they have a higher capacity to differentiate into mature adipocytes (Rashnonejad et al. 2018). Lee *et al*. injected human MSC-derived brown adipocytes intraperitoneally into obese mice for 10 weeks (Lee et al. 2017). This treatment successfully decreased bodyweight, triglyceride and cholesterol levels, hepatic steatosis, glucose intolerance, and inflammation.

Silva et al. found a reduction in body weight and glucose levels in non-obese diabetic (NOD) mice fed an HFD, that had been transplanted with differentiated Ad-MSCs isolated from human mediastinal brown fat depots (Silva et al. 2014). Improvements in glucose and lipid homeostasis have also been described in obese and diabetic mice subcutaneously transplanted with brown adipocytes, generated by cellular reprogramming procedures using induced pluripotent stem cells (iPSC) or from mouse embryonic fibroblasts (Kishida et al. 2015). Another example of the successful effects of adipocyte implantation on metabolic phenotype is an elegant study by Min et al. (2016). Beige adipocytes were derived from human capillary network progenitors and activated *in vitro* with adrenergic stimuli. The subcutaneous implantation of these thermogenic adipocytes into NOD mice treated with HFD led to an improvement in systemic glucose tolerance.

Direct BAT Grafting

Several studies have performed direct BAT transplantation in mouse models of diabetes and/or obesity (Gunawardana and Piston 2012, 2015; Stanford et al. 2013, 2015; Liu et al. 2013, 2015; Zhu et al. 2014). Regardless of the BAT donor (embryonic or adult), the location of the transplantation (subcutaneous or the visceral cavity), or the type of transplanted fat (exercise-induced beige fat or BAT), these studies showed a reduction in glucose and insulin levels, adiposity, inflammation, hepatic steatosis and an increase in oxygen consumption. Finally, BAT transplantation has shown metabolic improvements in other derangements such as Parkinson's disease (Wu et al. 2017), cardiovascular disease (Thoonen et al. 2015), polycystic ovary syndrome (Yuan et al. 2016) and atherosclerosis (Kikai et al. 2017).

Promises and Pitfalls of Human BAT Transplantation

First, in humans, there might be differences in the MSCs source, isolation method, duration, and capacity for differentiation to mature adipocytes, and the obtained outcomes. Second, due to its body distribution, adipose tissue in humans might be less accessible than in rodents. Ad-MSCs can be isolated from WAT during elective surgical interventions such as liposuction. Third, the beneficial effects of BAT transplantation might include several mechanisms, such as the endocrine release of batokines that should be further investigated. Fourth, most of the transplantation experiments have been performed with mice housed under thermal stress (22 °C), in order to activate BAT. Cannon and colleagues correctly claim that if animal experiments are to be translated into humans, mice should be housed at thermoneutrality (30 °C for mice; 22 °C for humans) since humans usually live at thermoneutrality throughout the year (Fischer et al. 2019).

As thermogenesis is tightly adjusted to ambient temperature, it is not known whether BAT thermogenesis might reach a threshold. Thus, the effectiveness might be questionable if the individual is at thermoneutrality. Finally, BAT activation could be associated with excessive body temperature, or perhaps enhanced food intake as a compensatory effect to normalize energy balance. Clinical administration of the BAT-stimulating β3-adrenergic receptor agonist Mirabegron to young lean males was associated with increased glucose uptake into BAT, elevated resting metabolic rate, and tachycardia (Cypess

et al. 2015), even though the protocol is criticized because the dosage was atypically high. Thus, the search for potential therapies that aim to increase BAT mass or activity at thermoneutrality to fight against obesity and its associated metabolic diseases should continue.

Abstract

It has become increasingly evident that the diversity of adipose tissue types may play distinct and potentially important roles in human physiology. White adipose tissue (WAT), the primary energy storage tissue, is important in homeostasis but when found in excess can predispose individuals to severe insulin resistance and diabetes. Human life is compatible with WAT composing between 4 and 60% of total body mass, pointing to its incredible adaptability. In contrast, brown adipose tissue (BAT), typically thought to occur only in hibernating animals and babies, is becoming recognized for its role in human energy expenditure, hormone production, immune regulation, among others. BAT usually comprises around 0–2% of total body mass; however, recent scientific advances in noninvasive imaging and molecular biology have allowed to explore unknown functions of this dynamic tissue. We discuss here the anatomy and physiology of WAT and BAT in the lean and obese human, and potential mechanisms regarding the interplay within obesity and Type 2 diabetes. Later, we review the current methodology for measuring and detecting WAT and BAT, how to experimentally modulate BAT activity, as well as future investigations to yield greater insight into BAT's functional role in human health.

Distribution and Functions of Human Adipose Tissue

It is estimated that in 2025, global obesity rates will reach 18% in men and 21% in women (NCD Risk Factor Collaboration 2016), with diabetes prevalence reaching nearly 400 million people globally (Nathan 2015). Obesity, defined clinically by a body mass index (BMI) of greater than 30 kg/m^2, is accompanied by an excess of white adipose tissue (WAT). Obesity is the result of long-term energy intake exceeding energy expenditure, being one of the main comorbidities Type 2 Diabetes (T2D). A diagnosis of T2D is most often made with a glycosylated hemoglobin (HbA1C) of $\geq$6.5% or a fasting plasma glucose of $\geq$126 mg/dl (Association, A. D. 2 2019). T2D is more likely to be obesity-related and can progress to loss of pancreatic beta-cell insulin secretion, often in the background of insulin resistance. Because the risk for T2D is increased substantially by obesity, the mechanisms that we will discuss throughout the chapter will pertain to both obesity and T2D, unless stated otherwise.

White Adipose Tissue

Humans have several types of adipose tissue, although the most studied are white adipose tissue (WAT) and brown adipose tissue (BAT). WAT is normally distributed subcutaneously and in the visceral compartments, the latter known as visceral adipose tissue (VAT). The amount of WAT in humans varies a lot between individuals, with minimal levels sustainable with life around 2% of body mass for men and 6% of body mass for

women, and maximal levels reaching over 60% of body mass. In simple terms, the higher the BMI, the higher the WAT accumulation in both compartments. Subcutaneous WAT is found in all areas beneath the skin surface but has a propensity to be stored in central, or proximal, locations. The distribution of subcutaneous WAT differs between men, who typically have an "android" distribution and women, with a "gynoid" distribution (Min and Min 2015).

VAT is also found in central locations, however within the abdominal cavity, surrounding vital organs. VAT contributes a much smaller percentage to total body fat (~5% in men and ~3% in women) (Sasai et al. 2015), yet the accumulation of VAT confers greater risk for T2D and cardiovascular disease than subcutaneous WAT. This phenomenon partly explains the occasional metabolically unhealthy, normal weight phenotype, where individuals that do not have BMIs classified as obese suffer from metabolic syndrome comparable to individuals with much higher body mass. Some data show that physical exercise can selectively reduce VAT, even in the absence of significant weight loss.

As WAT is a tissue for energy storage, it is evolutionarily designed with the ability to expand to a great extent, so that high energy density lipids can be available even in times of food shortage. In the modern era with food shortage being less of a concern, this expansion has occurred without periods of energy deficit. Though WAT exists in excess in patients with obesity, WAT in itself is not causative of insulin resistance (the inability for insulin to perform its usual functions). Lessons from patients with lipodystrophy demonstrate this fact, as they have nearly nonexistent WAT, but often develop severe T2D. The contributions of excess adiposity to diabetes may be a result of adipose-derived cytokines (adipokines) or accumulation of ectopic lipids in skeletal muscle and the liver that disrupt insulin signaling. Much has been learned since the discovery of WAT as an endocrine organ (the discovery of leptin, as an adipokine) (Zhang et al. 1994), yet there is still much to be investigated.

Brown Adipose Tissue

The main function of BAT is to generate heat (thermogenesis), principally through dissipation of the proton gradient in the inner mitochondrial membrane by way of uncoupling protein 1 (UCP1) (Cannon and Nedergaard 2004). Thus, as fuel sources including glucose and fatty acids are utilized by the brown adipocyte, rather than the generation of adenosine triphosphate (ATP), heat is released, resulting in energy-depleting thermogenesis. BAT is extremely important in maintaining euthermia in the hibernating animal during prolonged periods of fasting in cold temperatures.

Though the depots of human BAT were extensively defined nearly 50 years ago by autopsy (Heaton 1972), advances in noninvasive imaging have brought a resurgence in the interest in BAT. Classically thought only to exist in the interscapular adipose tissue region of human newborns, ^{18}F-Fluorodeoxyglucose (^{18}F-FDG) positron emission tomography (PET) combined with X-ray computed tomography (CT) studies have shown that active BAT exists in a large portion of the adult population, and can be reliably activated by cold (Cypess et al. 2009; van Marken Lichtenbelt et al. 2009) and by other means. Indeed, over 450 publications on PubMed have studied adult BAT in humans since just 2008. BAT's functions include substrate metabolism, immune system modulation, endocrine functions, and others. To begin a thorough understanding of BAT function in adults, we have characterized the depots of adult men and women with and without obesity (Leitner et al. 2017; Martinez-Tellez et al. 2019a).

Anatomical Sites

Generally, BAT lines visceral locations surrounding major vasculature in the abdomen, neck, and axilla, vital organs including the kidneys and adrenal glands, and alongside the sympathetic trunk. The highest proportion of BAT exists in the supraclavicular region, making

it the most commonly studied BAT depot across various studies, followed by the paraspinal, cervical, abdominal (mostly retroperitoneal), axillary, and mediastinal (Leitner et al. 2017). Previous evidence showed that newborns have huge amounts of subcutaneous BAT in the dorsocervical area, as adequate skeletal muscle has not yet been developed for shivering or activity thermogenesis. It has been thought that this subcutaneous BAT disappeared when the newborn grew older; however, recent evidence suggests that it could be still present in young healthy adults, mostly in women (Martinez-Tellez et al. 2019a; Kim et al. 2019). The discovery of this new depot will boost research.

Beige Adipose Tissue

Beige and/or brite adipose tissue has been discovered as an inducible form of brown adipose tissue, with morphological features between those of white adipocytes and brown adipocytes, however physiological functions (thermogenesis) of BAT (Wu et al. 2012; Jespersen et al. 2013) remain under intense investigation. In humans, very few studies have been able to characterize anatomical differences throughout the human body, with both functional and biochemical confirmation (Cypess et al. 2013). We have also shown that depots outside of these listed likely have very little capacity for browning or the conversion of white to brown adipocytes; however, depots currently harnessing metabolically active adipocytes comprise up to 5% of total body fat, thus making BAT an organ of appreciable size in adult humans.

Though anatomical characterization has come to higher resolution in recent years, it is unclear whether or not there are differential functions harbored by white adipocytes or brown adipocytes that exist in different regions. As most functions seem to operate at an organism-wide level, impactful studies can still be conducted without this knowledge. Yet, as noninvasive imaging and other biochemical techniques become more advanced, perhaps soon we will be able to create a functional atlas of human WAT and BAT. It is interesting that most anatomy textbooks do not have a chapter that maps adipose tissue. Maybe that points to our need to better understand adipocytes in all forms (Zwick et al. 2018).

White Adipose Tissue and Insulin Resistance

WAT can account for as little as 4% of total body mass in patients with congenital generalized lipodystrophy (Lima et al. 2016), a disease characterized by the absence of WAT, and as much as nearly 60% of body mass in patients with morbid obesity (Shah and Braverman 2012). Adipose tissue expansion by hypertrophy (increase in adipocyte size) or hyperplasia (increase in adipocyte number) is frequently followed by unfavorable metabolic consequences, such as insulin resistance and inflammation, and as such, WAT plays a major role in the development of insulin resistance.

Insulin, a major anabolic hormone, mediates an integrated metabolic response in the presence of nutrients, and insulin signaling is highly active in the adipocytes of lean and obese humans. Most importantly, insulin's role in the white adipocyte is to suppress lipolysis and stimulate glucose uptake. In the lean individual, these functions are tightly regulated to ensure no excessive freeing of fatty acids and the disposal of glucose. However, leading up to the development of and in the setting of T2D, insulin resistance ensues, manifesting as both blunted insulin signaling in adipocytes, and reduced insulin receptor content (Petersen and Shulman 2018). Functionally, insulin's main roles in the adipocyte, to stimulate glucose uptake and to suppress lipolysis are less effective. The effects of insulin resistance lead to an excess of plasma insulin, non-esterified fatty acids, and glucose levels, and implicates WAT as a major player in the pathogenesis of insulin resistance.

Interestingly, WAT plays a small role in whole-body glucose disposal (less than 5%), however has a significant impact on the development of insulin resistance. Several mechanisms

have been proposed for WAT's role in the pathogenesis of T2D, despite a seemingly minor participation in glucose disposal. Most convincingly, WAT dysfunction includes altered crosstalk with skeletal muscle and liver at maintaining energetic homeostasis and chronic low-grade inflammation.

Glucose Homeostasis Crosstalk

There is substantial coordination between the skeletal muscle, liver, and WAT to maintain normoglycemia in the fed and the fasted states. As humans transition to the fasted state (hours after the previous feeding), leptin and the hypothalamic–pituitary–adrenal (HPA) axis become activated to regulate WAT lipolysis, in order to free fatty acids to the plasma and to the liver for gluconeogenesis (Perry et al. 2018). This integrated response causes a whole-body shift from carbohydrate to fat oxidation. Studies have shown that this coordinated response may be altered in obese men, suggesting that nonesterified fatty acids are not released as readily, resulting in a net storage of fat. In addition, insulin's roles in suppressing WAT lipolysis and endogenous glucose production (from the liver) become less effective, which has been suggested as a link between WAT inflammation and the development of hyperglycemia (Roden and Shulman 2019).

Inflammatory Adiposopathy

Inflammation in WAT has been characterized by inadequate tissue vascularization, fibrosis, and hypoxia, which develop in the setting of increased WAT mass and cell size. Thus, obesity and the accompanying excess of WAT has been characterized as a state of chronic low-grade inflammation, with possible impaired immune function and activation of stress pathways. Much research has been dedicated to elucidate the mechanisms of WAT inflammation, including upregulation of the inflammatory cytokines tumor necrosis factor (TNF alpha), interleukin (IL)-1B, and IL-6 within adipose depots. Evidence for treatability of obesity-induced inflammation came from a clinical trial in obese humans, where Amlexanox, an anti-inflammatory drug typically used in the treatment of asthma, improved glycemic control in a subset of obese, T2D (Oral et al. 2017). Clearly, excess WAT and obesity are accompanied by multiple mechanisms that factor into the development of insulin resistance and diabetes, yet it is important to mention that obesity is not required for the development of these conditions.

Ectopic Fat Depots

WAT is not the only player in the development of T2D. Patients with lipodystrophy lacking adipocytes, and thus all adipose-derived hormones including leptin, often become hyperphagic due to the absence of leptin's hunger-suppressing effect. With the incapacity to store excess food intake in adipocytes, ectopic lipids are stored in skeletal muscle and the liver, sometimes to extreme extents. In the setting of massively increased ectopic lipid storage, patients without treatment often develop severe insulin resistance and poorly controlled diabetes, which highlights the role of ectopic lipids rather than excess WAT in the causal pathway of insulin resistance (Grundy 2015). It is possible that this same mechanism could underlie non-lipodystrophic patients who develop T2D, with contributions from genetics, epigenetics, and other factors.

Brown Adipose Tissue and Insulin Resistance

Preclinical models have suggested that BAT is a great tool to combat adiposity and T2D. Some of these studies have demonstrated that the transplantation of interscapular BAT from lean to obese mice, induced a significant weight loss and improved levels of HbA1C, alleviating insulin resistance. This is the main reason why this tissue has aroused a great interest in human physiology. Although human clinical studies have developed interventions, based on cold exposure, to activate and recruit the amount of BAT in obese and T2D individuals, they have failed to

replicate the positive effects of preclinical models (Jensen 2015). The main reason could be that human BAT can represent as little as 1% of total body mass, whereas in preclinical models BAT reaches up to 30–40% of the total body mass.

Moreover, it is important to note that BAT consumes glucose and fatty acids, and brown adipocytes have glucose transporter 1 (GLUT1, non-insulin-dependent) and 4 (GLUT4, insulin-dependent). The most used technique to quantify BAT in humans is ^{18}F-FDG-PET/CT scan, which is based on a glucose tracer. This technique is also used to quantify BAT in T2D. As one can imagine, in the scenario of insulin resistance this technique is far less accurate for the quantification of such tissue, which hampers understanding of the role of BAT in insulin resistance in humans.

Activation of Human Brown Adipose Tissue

The interest in BAT lies in its previously mentioned ability to uncouple ATP production from the electron transport chain, providing a means to "waste" energy in the form of heat. Studies that have attempted to examine the maximal energy expending capacity for BAT have been difficult to perform in humans, but have ranged from 5 to 730 kcal/day at maximal activation (Ruiz et al. 2018; Marlatt et al. 2018). These measures range from clinically meaningless, to having a measurable effect on reducing weight.

Because BAT is inactive in thermoneutral resting conditions, maximal thermogenesis must be measured in the active state. Researchers have attempted many approaches to BAT activation, including cold exposure, exercise, and dietary/pharmacological modulation (Ruiz et al. 2018) (see Fig. 5.1). Most often, cold exposure is used to study active BAT. This is a reasonable method to use, as it highlights BAT's most obvious role in nature: non-shivering thermogenesis to defend against the cold. Cold is sensed by free nerve endings in the skin, and the hypothalamus begins a coordinated whole-body response to defend core body temperature: intense vasoconstriction occurs at the distal extremities to shunt warm blood to vital organs, contributing to a slowed heart rate.

Even at temperatures too low to activate detectable shivering, metabolic rate increases (up to 17% above resting in lean men and 6% above resting in obese men) (Brychta et al. 2019). The blunted response in non-shivering thermogenesis in obese men is likely due to a thicker "shell," and perhaps greater insulation from cold exposure. This insulation requires less heat production in response to the same cold stimulus, as the heat is trapped in the core, and loss is prevented. If this is the sole mechanism for reduced BAT activity in obese men, it may be expected that pharmacological agents may yield more success for energy expenditure than what cold exposure can reveal.

Cold Exposure Techniques

Methods for studying cold-induced thermogenesis and BAT in humans include ambient cold air exposure, the wearing of liquid-perfused cooling suits, and placing the feet on ice blocks. It is uncertain whether all of these methods are comparable, yet studies suggest that the degree of BAT activation is likely reproducible when maintaining a standardized protocol (Fraum et al. 2019). All methodologies considered, BAT is quickly activated in response to cold exposure (Leitner et al. 2018), it can contribute to cold-induced energy expenditure in the absence of shivering, and BAT metabolizes a combination of both fatty acids and glucose when active.

In addition, cold-acclimation studies have demonstrated that BAT volume and metabolic activity can be increased over the course of a week in both lean and obese individuals (Lee et al. 2014; Hanssen et al. 2016). Detectable BAT is found in most obese patients, though consistently to a lesser extent than their lean counterparts. One of the only studies that has rigorously measured BAT in type 2 diabetic

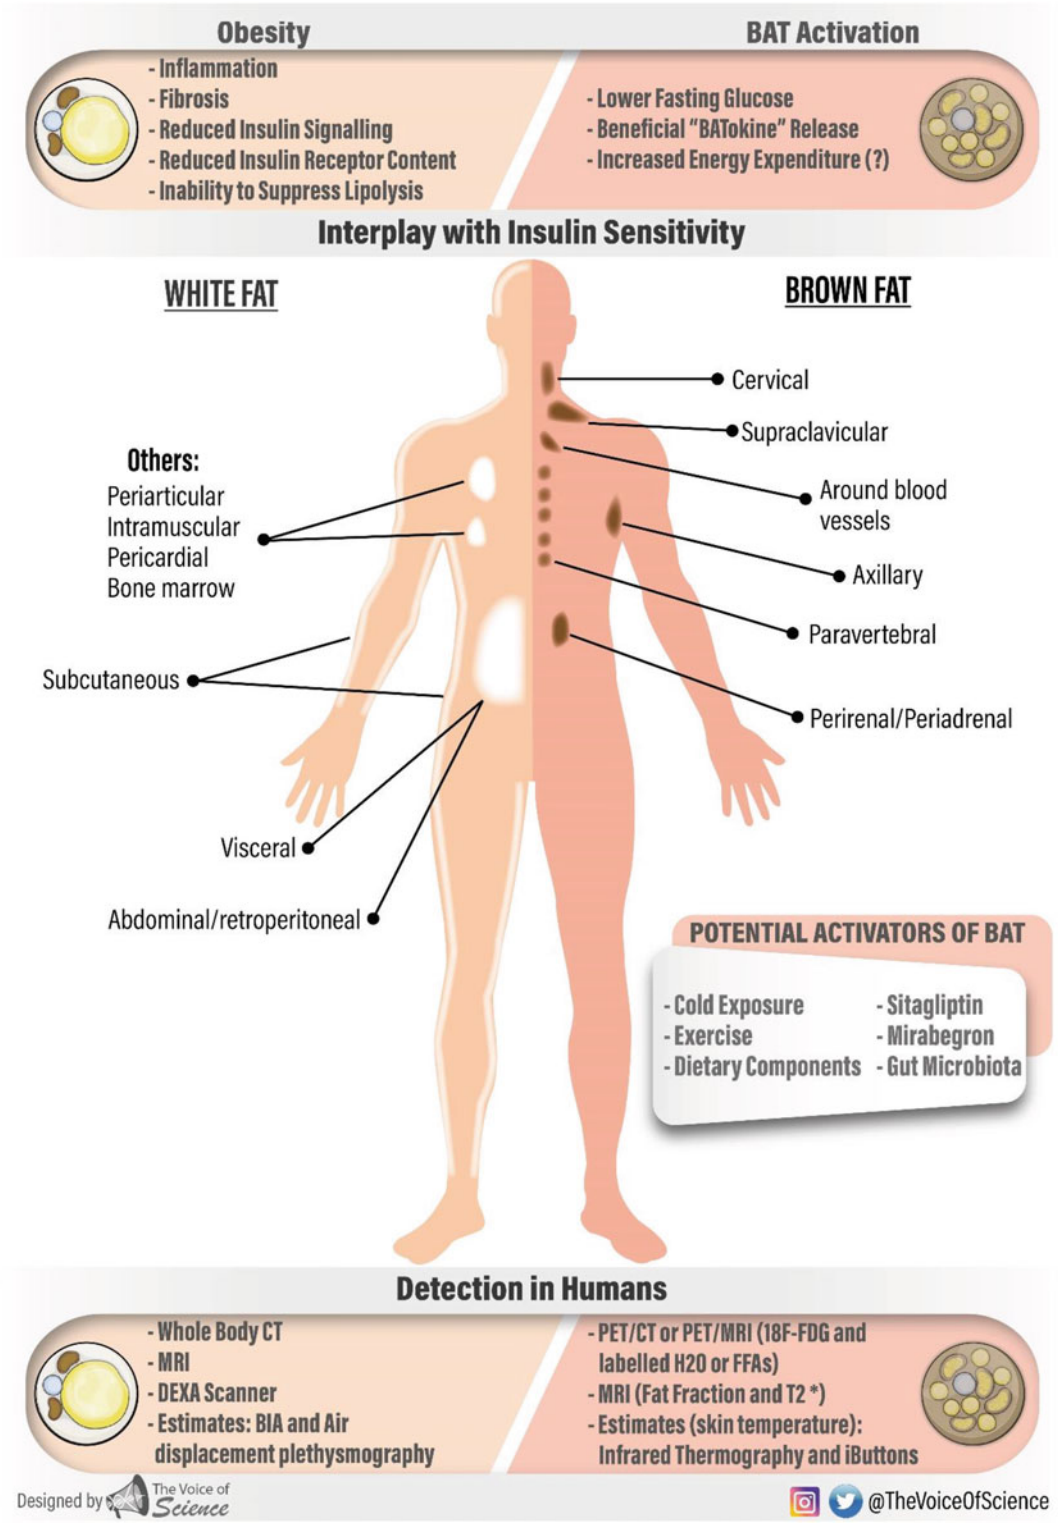

Fig. 5.1 This schematic figure summarizes the main issues discussed in the present chapter. *18F-FDG* 18F-fluorodeoxyglucose, *BAT* brown adipose tissue, *CT* computed tomography, *DEXA* Dual-energy X-ray

patients has shown that an improvement in insulin sensitivity following chronic cold exposure, can be mostly attributed to skeletal muscle adaptation rather than BAT glucose uptake (Hanssen et al. 2015), thus the utility of chronic BAT activation for energy expenditure must certainly be considered carefully. Importantly, nearly all studies that have examined subcutaneous WAT for features of BAT in response to chronic cold exposure, have yielded negative results.

Recently, a new study nicely shows that human BAT is rapidly activated upon cold exposure, achieving its maximum activity after 35 min of cold exposure (Oreskovich et al. 2019). This study was performed by a dynamic magnetic resonance imaging (MRI) scan. After 2 h of cold exposure, a warm-up phase during 30 min followed, and no replenishment of the lipid content of the BAT depots ensued. This study revealed that BAT is only active during the first part of the cooling protocols, questioning much evidence published so far. To date the most used cooling protocols to activate BAT applied a total duration of 2 h; therefore, they have quantified BAT when it was not truly activated.

Exercise Activation

Exercise is a non-pharmacological tool that induces a myriad of physiological adaptations, enhancing human cardiovascular health and insulin sensitivity in almost every single human being. Therefore, it is biologically plausible that exercise will affect BAT function, although it is unknown in which direction. Preclinical studies have suggested that exercise could increase BAT function and induce browning in almost all WAT depots (Stanford et al. 2015). However, it seems that most of these studies were not performed under strictly thermoneutral conditions, rendering it impossible to discriminate whether this browning effect is caused by the exercise, by the temperature, or by the combination of both stimuli (McKie et al. 2019).

Regarding humans, the evidence is even more contradictory. There are only a few cross-sectional studies that showed that trained-individuals had lower levels of BAT ^{18}F-FDG uptake in comparison to sedentary controls. Moreover, we recently demonstrated that objectively measured physical activity by accelerometers and cardiorespiratory fitness protocols, were not associated with BAT ^{18}F-FDG uptake (Acosta et al. 2019). Surprisingly, we observed that handgrip strength was positively and slightly related with BAT ^{18}F-FDG uptake, suggesting that maybe resistance training could have a different role in terms of BAT activation in comparison to endurance training. However, much more studies are needed (Martinez-Tellez et al. 2019b). Lastly, only a few studies performed exercise interventions including BAT ^{18}F-FDG uptake and browning markers in humans, and again the results are quite controversial.

Food Intake and Thermoregulation

Recently, we demonstrated that BAT activity is not related to energy intake assessed by an ad libitum meal and by 24-h dietary recalls (Sanchez-Delgado et al. 2020). Moreover, we did not detect the role of BAT in the regulation of appetite-related sensations either before or after the subjects ate. In a submitted study, we also observed that BAT activity was not related to the adherence to a Mediterranean diet, which is one of the healthiest diets. On the other hand, an independent study showed that the oxygen consumption of BAT depots increased after a single meal intake. It seems that BAT is not playing a role in appetite perception, energy, or nutrition intakes, although it could be playing a minimal role during meal intake.

Role of Brown Fat in Human Metabolism in Healthy, Obese, and Diabetic Individuals

One option to prevent and combat obesity and related comorbidities is to increase thermogenesis, which leads to increased energy expenditure. In mice, BAT is responsible for 20% (Blondin et al. 2017) of both resting metabolic rate and adaptive thermogenesis, i.e., cold-induced thermogenesis (CIT) and meal-induced thermogenesis (MIT) (Nathan 2015), and can account for up to 60% of total energy expenditure when fully stimulated. Human BAT becomes metabolically active upon cold exposure in most individuals. However, a recent study nicely demonstrated that the contribution to the increase observed in CIT is almost negligible (Din et al. 2016; Carpentier et al. 2018). The same research group, demonstrated that BAT was active after eating a carbohydrate-rich meal to a similar extent than during mild cold exposure, yet its contribution to the increase in MIT is quite low. These novel studies confirm that BAT is contributing to human thermogenesis, but in a lower proportion than was thought at the beginning. What is the main role of BAT in the human metabolism? After 10 years of thoughtful research in human trials and mice studies we still do not know, although several new roles have been attributed, such as a secretory organ orchestrating the shivering and non-shivering responses or immune system modulation, among others.

BAT Hormone-Like Secretions

Some specialists suggest that the role of BAT in the human metabolism is negligible because it represents only 1% of total body mass. On the other hand, humans have similarly small organs (i.e., thyroid, adrenal, pituitary) that have very important roles in metabolism, so it could be reasonably expected that BAT has unknown and relevant functions. BAT has the ability to secrete several hormones (batokines) that could coordinate/orchestrate the responses of other tissues to different stimuli. For instance, we know that when humans are exposed to cold there is an increase of the energy expenditure, which could be explained by the contribution of two thermogenic tissues (BAT and skeletal muscles) (Villarroya et al. 2017). One of the hypotheses that is open for discussion is that BAT could be releasing a set of batokines that could boost the involvement of skeletal muscle during cold exposure.

BAT has been proposed to interact with bone (via IGFBP2), WAT, brain, pancreas, heart (via FGF-21 or IL6), and liver (IGF1), and therefore, impact tissue plasticity and metabolism. A research group from Copenhagen performed the first human BAT secretome. In this particular study, they discovered that ependymin-related protein 1 (EPDR1) was a novel batokine important for brown fat commitment (Deshmukh et al. 2019). They suggest that this batokine could be involved in the regulation of human metabolism.

Correlations with Obesity and Diabetes

Originally, it has been thought that obesity is negatively related to the amount of BAT; however, we recently discovered that obesity was positively related to BAT volume in 150 young healthy adults. This controversial finding could be explained by several factors: (1) BAT normally is measured with a glucose analog. Since the individuals of our study were quite young (<25 years old), they might not have developed insulin resistance yet; (2) most studies that found a negative relation between the degree of obesity and BAT activity, were performed without cold stimulation; and (3) another possible explanation is that the prevalence of T2D or insulin resistance increases with age, and those studies that were showing the inverse relationship between the degree of obesity and BAT activity did not include age as a possible confounder.

In an alternative study, it was shown that BAT measured with glucose, in T2D patients, was diminished in comparison with a free fatty acid tracer, suggesting that BAT could be playing a role in obese and T2D individuals (Blondin et al.

2015). Moreover, there is a group of obese individuals characterized by a lower risk of obesity-related cardiometabolic complications, the so-called metabolically healthy obese (MHO) (Blüher 2010). MHO individuals have a normal metabolic profile, i.e., do not have dyslipidemia, hyperglycemia, hypertension, or T2D, whereas their counterparts that present any of these conditions are known as metabolically unhealthy obese (MUO).

In an unpublished study, we observed that MHO individuals had higher BAT activity, cold and meal-induced thermogenic responses in comparison to MUO individuals (Sánchez-Delgado 2018). We also observed that MHO perceived the temperature as colder than MUO controls (Martinez-Tellez 2018). Both groups were similar in body mass index, although they were different in terms of the amount of VAT.

Methods for Detecting Human Brown Adipose Tissue

The contribution of BAT to adult human energy expenditure, thermogenesis, and other systemic functions remains difficult to fully uncover. One major reason for this difficulty is the variety of methods used to examine BAT in vivo. In general, methods either employ a noninvasive imaging strategy or a measurement of another physiological parameter as a surrogate of BAT activity.

Monitoring of Skin Temperature

The impetus for using skin temperature as a measure of BAT activity derives from BAT's inherent function as a thermogenic organ, which, by definition generates heat to be dissipated from the body. This heat dissipation is thought to be captured at the surface of the skin, as a reflection of heat transfer from the deeper tissues to dilated blood vessels superficial to BAT. The inherent shortcoming of this technique is that skin vasculature is impacted by a number of other systemic factors, including catecholamines and nitric oxide among others, such that the blood flow beneath a skin surface measurement may be reflecting physiological process unrelated to underlying BAT activity.

A major benefit of using skin temperature is the ability to capture physiological shifts in long-term bouts, free-living conditions, and during multiple environmental settings (such as exercise, and entering cold or warm rooms). Skin temperature is commonly measured with either infrared thermography, where photos are taken of exposed skin, or with surface temperature probes like iButton chips (www.maximintegrated.com). As supraclavicular BAT is detected in the highest proportion of individuals, and because it is the depot least obstructed by other structures such as bone and muscle, infrared photos and surface probes often capture this location on subjects.

It is important to take into account that supraclavicular fossa is a complex anatomic region that is contiguous with the neck above and axilla below (Kellman et al. 1987). There are several structures in this region, such as the scalene and omohyoid muscles, subclavian vessels, and brachial plexus. Other contents of the supraclavicular fossa include small branches of the subclavian vessels, fat, lymph nodes, and the posterior lung apex. The benefits of supraclavicular skin temperature measurements are the ease of use, minimal discomfort to study participants, the ability to be employed in a variety of settings, and relatively low cost. However, observers still deal with the inability to rule out other physiological factors that influence skin blood flow and therefore temperature (Jimenez-Pavon et al. 2019; Martinez-Tellez et al. 2019c, d).

Radiolabeled Glucose Analog

The most commonly used technique for detecting BAT is ^{18}F-FDG PET/CT, which utilizes a radioactive glucose analog coupled with anatomic and radiodensity data from X-ray computed tomography. This technique has likely been studied most due to a number of factors including active BAT's avidity for glucose, the current availability in

many clinical settings because of its utility in cancer staging, and the largest breadth of preprocessing and image processing protocols associated with it. In general, subjects undergo a protocol in order to activate BAT (cold exposure, dietary or physical intervention, pharmacological intervention) and are then injected with the ^{18}F-FDG glucose analog tracer. The tracer accumulates in metabolically active tissue by entering the cell and becoming phosphorylated by hexokinase, then trapped as ^{18}F-FDG-6-phosphate.

The concentration of the trapped glucose analog can be quantified as a standardized uptake value (SUV) relative to the subject's body weight or lean mass and represents a reflection of tissue-specific glucose uptake. Static ^{18}F-FDG PET/CTs give no information regarding metabolic flux rates, nor the fate of glucose within the tissue (whether or not the tissue utilizes the glucose for glycolysis, oxidative phosphorylation, or anaplerosis), which constitute some of the method's largest limitations for studying in vivo physiology. Though ^{18}F-FDG still provides rich information about whole-body metabolic activity, it is important that a CT scan accompanies the PET scan.

The CT scan is necessary to determine the density and structure of the underlying tissue.

Attempts to classify metabolically active tissue (obtained from PET) as BAT requires that the CT detects this tissue within the range of densities known to be adipose tissue. On CT alone, brown and white adipose tissue have nearly indistinguishable densities, with BAT being slightly denser due to its higher vascularization, lower lipid content, and higher mitochondrial content. Thus, CT alone cannot reliably distinguish WAT from BAT. Similarly, metabolic activity from the PET scan cannot differentiate any tissue from another, as the only output is tracer accumulation. Only the combination of the density of adipose tissue (from CT) and the metabolic activity above a certain threshold (from PET) are able to quantify active BAT (Fig. 5.1).

Tracer and Imaging Alternatives

The goal of these alternatives, such as fatty acids, is to reduce radioactivity exposure to subjects (i.e., with MRI), or examine metabolic flux rates (i.e., with dynamic PET/CT imaging). Studies from animal models have suggested that the primary fuel for BAT thermogenesis is lipid, thus a glucose tracer misses much of the information. Tracers to measure fatty acid uptake (Blondin et al. 2017) have been used, and labeled water (Muzik et al. 2013) can also be considered to examine adipose tissue perfusion. MRI has been used both on its own or in combination with PET, in order to detect BAT. MRI can be used in many ways in order to examine features of living tissue, and most commonly fat fraction has been employed, in order to distinguish WAT from BAT. Limitations include the possible presence of beige adipose tissue, long scanning duration in which physiological changes in BAT activation may impact the fat fraction and very few validation studies to date (Rasmussen et al. 2013). Dynamic PET imaging holds promise but awaits further validation. In summary, all noninvasive imaging methods have positive and negative aspects, none of which outperforming all others in accuracy.

Immunohistochemical or Gene-Expression Confirmation

Ideally, evidence from all studies should be complemented with immunohistochemical evaluation of BAT, WAT, or beige adipose tissue markers from biopsy (Cypess et al. 2013). Due to the technical complexity and discomfort of obtaining adipose tissue biopsies from deep locations, these studies are quite limited. Additionally, not all studies that have performed adipose tissue biopsies in the abdomen have found expression of thermogenic genes or presence of browning in WAT, even after a cold exposure intervention, which is the best stimulus to activate BAT.

Future Investigations into Human Brown Adipose Tissue Physiology

Since 2009 researchers have been looking for alternative strategies to activate human BAT without exposing participants to cold, which is not very comfortable (Fig. 5.1).

Dietary Components

Capsinoids are substances naturally present in chili peppers and they are particularly abundant in *C.annuum L.* or "CH-19 Sweet" (non-pungent red pepper). Capsinoids include capsiate, dihydrocapsiate, and nordihydrocapsiate. Although capsinoids are structurally similar to capsaicin, they are 1000 times less pungent but are as potent as capsaicin in increasing thermogenesis. The thermogenic activation pathways of capsinoids include transient receptor potential cation channel (TRPV1), which have possible mechanisms of action on BAT.

Tea catechins are polyphenolic components present in green tea. The most abundant and bioactive component is epigallocatechin gallate. The thermogenic effect of tea catechins has repeatedly been shown in humans. The mechanisms of action are similar to capsinoids, via TRP channels. However, there is no solid evidence that capsinoids and tea catechins can activate and recruit BAT in humans. Therefore, studies are needed to elucidate the role of dietary components as possible BAT activators (Osuna-Prieto et al. 2019).

Pharmaceutical Compounds

Mirabegron, an antimuscarinic drug, is a β3-adrenergic receptor agonist normally used to treat overactive bladder in adults. Cypess et al. showed that the acute ingestion of 50 or 200 mg of mirabegron was able to increase the ^{18}F-FDG uptake by BAT in young healthy adults (Baskin et al. 2018). Chronic administration of mirabegron was also able to increase the levels of BAT ^{18}F-FDG uptake. In an alternative study, we have observed that a single dose of 200 mg of Mirabegron was not able to induce a decrease of the fat fraction of BAT measured by magnetic resonance imaging. Moreover, we observed that mirabegron did not have any effect of the lipidomic profile in humans. However, there is still a debate ongoing about whether mirabegron is directly activating human BAT. Recently, Blondin et al. demonstrated that human brown adipocytes lacked β3-receptors, suggesting that mirabegron has specificity for others β-receptors (Blondin et al. 2019).

The antidiabetic agent *Sitagliptin* is a dipeptidyl peptidase-4 (DPP-4) inhibitor, which increases the production of insulin and decreases the production of glucagon by the pancreas. Recently we aimed to study the long-term effect (12 weeks) of 100 mg/day of sitagliptin on the levels of BAT in overweight individuals. Although we observed that insulin resistance of the participants was attenuated, BAT ^{18}F-FDG uptake was not affected by sitagliptin (Nahon et al. 2018). Curiously, sitagliptin induced an increase in subcutaneous WAT in the abdomen, suggesting a possible increase in browning markers. We also demonstrated that sitagliptin induced upregulation of the mitochondrial gene *PGC1B* in skeletal muscle.

Gut Microbiota as a New Target to Combat T2D

Case–control studies have shown differences in gut microbiota composition, diversity and function between healthy people and obese individuals, and have suggested that modifying the gut microbiota composition of obese individuals toward a healthy phenotype might be a useful therapy to combat T2D. In that respect, Plovier et al. showed that fecal microbiota transplantation (FMT) from healthy donor mice to obese recipient mice reduces adiposity and energy intake, while improving lipoprotein metabolism and glucose tolerance (Plovier et al. 2017). The bacteria *Akkermansia muciniphila* appeared to be the cause of these beneficial effects, and it was successfully used and tested

in a human trial. They also showed that modifying the gut microbiota composition had a strong impact on the parameters of cardiometabolic health in humans.

Gut microbiota regularly produces short-chain fatty acids (SCFA) (e.g., butyrate or acetate), which can play an important role in the regulation of metabolic health, mitigating T2D. Butyrate also acts on the gut–brain neural circuit to improve energy metabolism, by activating brown adipose tissue (BAT) in APOE*3-Leiden. CETP male mice (Li et al. 2018). Further studies are needed to confirm this hypothesis in a human setting.

Future Perspectives

- BAT is present in obese and T2D individuals but its role is unknown.
- Cooling protocols for BAT activation may not be longer than 1 h based on the new evidence, which shows that BAT could be only activated during the first 35 min of cold exposure.
- BAT depots are not easily biopsied. However, several studies suggest that humans could have a subcutaneous BAT in the dorsocervical area, which is an accessible depot. The confirmation of this finding could mean a step forward in the field.
- Nuclear medicine techniques should be further developed in order to better quantify the thermogenic activity of BAT and WAT during dynamic processes. This new technique could be applied to cold exposure, but also to acute responses such as meal-intake, drugs, or even exercise interventions.
- Supraclavicular skin temperature should be interpreted as the result of several thermogenic tissues and blood vessels that are activated in response to the stimulus, not only BAT activation. The fact that supraclavicular skin temperature did not decrease after a cold exposure is disturbing, and further studies are needed that help to understand which are the main tissues that could be explaining this lack of a decrease.
- There is a lack of translational models' studies, promoting the transition of findings from preclinical to human studies.

Acknowledgments This chapter was made possible by support from the NIH Medical Scientist Training Program Training Grant T32GM007205 and a postdoctoral grant from the Fundación Alfonso Martin Escudero.

Abstract

microRNAs (miRNAs) have emerged as key regulators of metabolic processes, playing critical roles in maintaining energy balance and metabolic homeostasis. Dysregulation of miRNAs may contribute to metabolic abnormalities since they play pivotal roles in body fat accumulation, obesity, and obesity-related diseases by directly affecting the status and functions of adipose tissue, pancreas, liver, and muscle. The discovery of circulating miRNAs highlighted their potential as either endocrine signaling molecules or disease indicators. This chapter aims to provide recent findings concerning the contribution of miRNAs to obesity and obesity-related morbid conditions.

Keywords

Obesity, metabolic disease · Disease biomarkers · microRNA, miRNA

List of Abbreviations

ABCA1	ATP-binding cassette transporter 1
AGO	Argonaute
Apo	Apolipoprotein
BMI	Body mass index
BMPs	Bone morphogenetic proteins
C/EBPs	CCAAT/enhancer-binding proteins
c-miRNAs	Circulating miRNAs
Creb1	cAMP-Responsive element binding protein 1
ERK	Extracellular signal-regulated kinases
FABP4	Fatty acid-binding protein 4
FASN	Fatty acid synthase
FGF21	Fibroblast growth factor 21
Foxa2	Forkhead box protein A2
FOXO1	Forkhead box O1
HbA1c	Glycated hemoglobin A1c
HNF	Hepatocyte nuclear factor
HOMA-IR score	Homeostatic model assessment for insulin resistance
INSR	Insulin receptor
IRS-1	Insulin receptor substrate 1
LETFs	Liver-enriched transcription factors
LXRα	Liver X receptor α
miRNAs	microRNAs
ncRNAs	Small noncoding RNAs
N-CoR	Nuclear receptor corepressor
Ngn3	Neurogenin3
NGS	Next-generation sequencing
NOD	Nonobese diabetic mice
NPM-1	Nucleophosmin-1
Pdx1	Pancreatic and duodenal homeobox 1
PEPCK	Phosphoenolpyruvate carboxykinase
PI3K	Insulin/phosphoinositide-3 kinase
PPARγ	Proliferator-activated receptor-γ
RB	Retinoblastoma susceptibility protein
RISCs	RNA-induced silencing complexes

RNAseq	RNA sequencing
RXRα	Retinoid X receptor alpha
SFA	Saturated fatty acids
SHIP1	SH2 (Src homology 2)-containing inositol phosphatase-1
SIRT1	Sirtuin 1
SMRT	Silencing mediator for retinoid and thyroid hormone receptors
SREBP1	Sterol regulatory element-binding protein
T2D	Type-2 diabetes
TGF-β	Transforming growth factor beta

Obesity: The Worldwide Epidemic

Up to four million deaths worldwide can be connected to overweight and obesity, and more than two-thirds of these deaths are due to cardiovascular diseases (Hurt et al. 2010; Branca et al. 2007; D'Adamo and Caprio 2011; Ahima and Lazar 2013; Bluher 2013). The obesity epidemic and the resulting consequences threaten both developed and developing countries, although a plateau in prevalence rates has been reported for childhood obesity in several Western countries (WHO Library Cataloguing 2016). Besides the secular changes in energy intake and expenditure invoked as the underlying cause, a number of loci on the human genome have been consistently associated with obesity (Berndt et al. 2013; Kunej et al. 2013; Loos and Yeo 2014; Fall and Ingelsson 2014). Currently, it is well accepted that "common" obesity is the result of a mixed effect of environmental risk factors and multiple gene variants, additively conferring a degree of susceptibility (polygenic obesity) (Stranger et al. 2011). Actually, the individual susceptibility to weight gain may vary significantly due to the interaction between genetic background, lifestyle, and environmental factors.

Most of the genes associated with obesity predisposition are also correlated with food intake and energy balance control (O'Rahilly and Farooqi 2008; Rankinen and Bouchard 2006; Locke et al. 2015). Nowadays, despite extensive study of obesity genetics, most of the genetic variability in BMI remains unexplained and the effect of a single candidate gene is quite limited.

White Adipose Tissue: An Overview

White adipose tissue is the main tissue for energy storage in humans. Besides the storage function, this tissue is metabolically active by releasing hundreds of different factors, including hormones as leptin and adiponectin, growth factors such as IGF-1 and PDGF, and cytokines such as IL-6, IL-8 or TNF-α acting as inflammatory mediators (Booth et al. 2016), possibly involved in the regulation of appetite and insulin sensitivity. Growing evidence supports the notion that chronic low-grade inflammation is a basic feature of obesity that contributes to insulin resistance in target organs, including adipose tissue, liver, muscle, and the vascular system (Jung and Choi 2014).

Nutrient excess, particularly fats and carbohydrates may concurrently trigger inflammatory responses, which further interfere with metabolic function, stress, and inflammation. Therefore, the nutrition-immunity theory suggests that obesity induced by overnutrition triggers low-level inflammatory processes into adipose tissue (Wellen and Hotamisligil 2005; Kammoun et al. 2014). This state is related to the large macrophage recruitment and enhanced immune cell proliferation/activation/infiltration associated with adipocyte hypertrophy and impaired adipogenesis (Kraakman et al. 2014). The latter process is closely controlled by a combination of regulatory signals including extracellular circulating hormones, endocellular transcription factors, and post-transcriptional modulators of gene expression (Arner and Kulyte 2015; Kim et al. 2014; Li et al. 2015; Rottiers and Naar 2012; Xie et al. 2009; Tang and Lane 2012).

Adipose Tissue Proliferation

Adipogenesis is a process in which fibroblast-like pre-adipocytes are differentiated into mature

adipocytes, a complex cascade that embraces cell commitment, clonal expansion, and terminal differentiation (Ali et al. 2013). More in-depth, the differentiation from pre-adipocytes to mature adipocytes is a step coordinated by several transcription factors such as the peroxisome proliferator-activated receptor-γ (PPARγ) and CCAAT/enhancer-binding proteins (C/EBPs), which direct the regulation of gene expression required for adipocyte phenotypes. C/EBPβ and C/EBPδ are induced by adipogenic stimuli and are the main adipogenesis regulators. C/EBPβ and C/EBPδ targets are the promoters of genes encoding essential adipogenic factors such as C/EBPα and PPARγ, as well as the sterol regulatory element-binding protein (SREBP1), the primary lipogenic gene regulator. The C/EBPα intronless gene encodes a leucine zipper transcription factor, that can bind as a homodimer to specific promoters and enhancers, or it can form heterodimers with the related C/EBPβ and C/EBPγ. As an example, C/EBPα binds to the promoter and modifies the leptin gene expression, providing a key role in body weight homeostasis.

C/EBPα is sufficient to cause differentiation of pre-adipocytes into mature adipocytes (Linhart et al. 2001). Peculiarly, PPARγ directly triggers endogenous C/EBPα transcription. Besides, through a virtuous circle, C/EBPα activates the PPARγ gene, thus supporting adipogenesis (Tang and Lane 2012). PPARγ and C/EBPα concurrently support the expression of genes implicated in insulin sensitivity, lipogenesis and lipolysis, and finally in the terminal differentiation of mature adipocytes. The dynamic series of events regulating cell commitment and adipocyte differentiation also includes an anti-adipogenic signaling cascade mediated by Wnt, BMPs, TGF-β, and hedgehog (Moseti et al. 2016). As expected, an increase in adipocyte volume (hypertrophy) and number (hyperplasia) results in higher fat mass and energy storage levels in adipose tissue, likely contributing to an increased risk of obesity.

miRNAs: Small RNAs with a Big Role in Gene Regulation

At present, hundreds of post-translational modifications of core histones including acetylation, methylation, phosphorylation, and ubiquitylation have been discovered. A wide number of dynamic regulatory systems are responsible for histone modifications and chromatin remodeling mechanisms, contributing to a complex epigenetic regulation network of gene activity (Iacomino et al. 2001, 2006; Venkatesh and Workman 2015). Essentially, any step in the gene expression flow is wisely controlled, and the discovery of small noncoding RNAs (ncRNAs) has added new players to the broad range of existing mechanisms (Catalanotto et al. 2016).

Epigenetic Control Mechanisms

Epigenetics is usually defined as heritable modifications in a gene that occur in the DNA without sequence modification. This definition encloses the concept that epigenetics is a heritable trait (Ling and Ronn 2019). Nevertheless, the study of epigenetics contribution to obesity/altered metabolic conditions is still in early infancy.

Based on their working mechanism, synthesis, and structure ncRNAs are classified as small interfering RNAs, PIWI-interacting RNAs, endogenous small interfering RNAs, promoter-associated RNAs, small nucleolar RNAs, and microRNAs (miRNAs). In a few years, miRNA study has progressed from a single article reporting the discovery of a noncoding RNA in *C. elegans* (Lee et al. 1993), to thousands of publications describing their critical association to a variety of physiological processes and diseases (Rupaimoole and Slack 2017).

miRNAs in Multicellular Organisms

miRNAs are small ncRNAs with a length of 20–24 nucleotides involved in gene expression

regulation (Bartel 2009; Ghildiyal and Zamore 2009; Ha and Kim 2014). Today more than 2000 different miRNAs have been identified, showing them to be one of the most abundant classes of gene regulatory molecules in multicellular organisms, and their number is still increasing in the miRBase database (Kozomara and Griffiths-Jones 2014). Release 22 of the repository contains 38,589 entries representing hairpin precursor miRNAs, expressing 48,885 mature miRNA products, in 271 species. miRNAs are essential elements of the cellular epigenetic machinery and behave as specific gene silencers by base pairing to 3′ untranslated sequence of a target mRNA. However, they have also been evidenced to bind anyplace along the nucleotide sequence. miRNAs exert their actions by either inhibiting translation or by affecting mRNA stability and degradation (Ebert and Sharp 2012).

The bases in position 2–8 of a miRNA are essential for base-pairing with a target mRNA and are referred to as "seed sequence." New advances in a transcriptome-wide method of mapping miRNA binding sites revealed that a large proportion of miRNA–targets during in vivo interactions are mediated not only through the canonical "seed sites," but also via noncanonical seed-like motifs (Seok et al. 2016). miRNAs have been clustered into families built on seed region similarity, which is responsible for the ability to target common clusters of transcripts (Wang et al. 2016). Some miRNAs show a tissue-specific localization, but most miRNAs have a wide-ranging tissue distribution (Li et al. 2013).

Transcriptome Sculpting

Interestingly, a single miRNA can regulate at the same time large cohorts of transcripts, and a distinct mRNA usually includes multiple interaction sites for diverse miRNAs leading to intricate regulatory circuits (Ebert and Sharp 2012; Krek et al. 2005). A single miRNA usually has a weak modulatory effect on a distinct target, but often its action coordinately affects multiple transcripts in a signaling pathway, so exercising significant cumulative effects in complex regulatory networks. In this view, the metazoan miRNAs have been defined as the "sculptors" of the transcriptome (Bartel 2018).

Scientific literature supports the view that endogenous miRNAs influence the expression of up to 60% of mouse and human genes (Friedman et al. 2009; Lewis et al. 2005). Accordingly, miRNAs have been described to be involved in an extraordinarily large array of physiologic processes, both in health and in disease conditions (van Rooij 2011; Bartel 2004; Iacomino et al. 2020). While some miRNAs are expressed ubiquitously in the body, other miRNAs are specifically enriched in certain tissues. A compilation of knockout phenotypes showing crucial biological functions of miRNAs has been recently published (Bartel 2018). Finally, expanding evidence suggests that miRNAs dysregulation acts as an etiologic factor and/or indicator of numerous diseases including cancer (Mendell and Olson 2012; Paul et al. 2018; Bracken et al. 2016; Li et al. 2014; Pedroza-Torres et al. 2019).

miRNA Biogenesis and Action Mechanisms

In recent years, the miRNAs biogenesis has been comprehensively described (Fig. 6.1) (Finnegan and Pasquinelli 2013). miRNA coding genes are evolutionary conserved and are located in the introns or exons of protein-coding genes (about 40% of mammalian miRNAs are found within introns of protein-coding genes), as well as in intergenic regions (Kim et al. 2009a). In the cell nucleus, pri-miRNAs are transcribed using the genomic DNA as a template by RNA polymerase II together with the host gene (intragenic miRNAs), or independently of the host gene with the use of their promoter (intergenic miRNAs), as large primary transcripts long several hundred bases (Gulyaeva and Kushlinskiy 2016). miRNAs transcription, as well as for protein-coding genes, is regulated by transcription factors (Kim et al. 2009a).

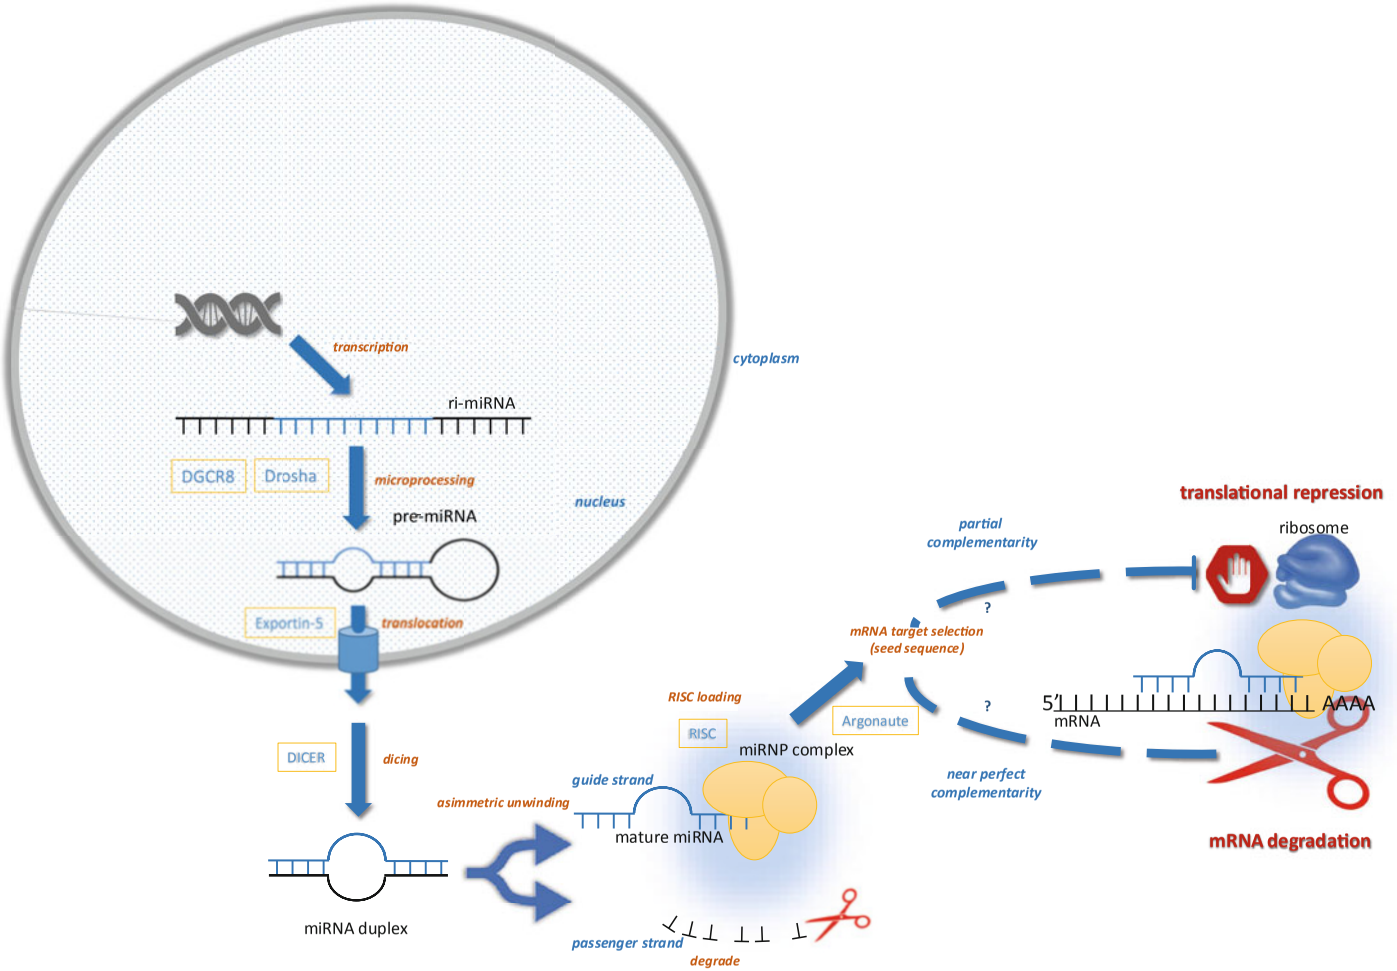

Fig. 6.1 Single miRNAs are transcribed from genomic DNA by RNA polymerase II (pri-miRNA). Drosha-DGCR8 processes the pri-miRNA to pre-miRNA. Exportin-5 moves the pre-miRNA to the cytoplasm where it is recognized and cleaved to create a miRNA duplex by the DICER complex. The duplex unwinds and the mature miRNA assembles into RISC. The miRNA guide strand base-pairs with target mRNA and determines gene silencing via mRNA cleavage or translation repression depending on the degree of homology between the miRNA "seed" to the 3′ UTR target sequence of the mRNA

miRNAs are often encoded by multiple loci, some of which are structured in co-transcribed clusters. The pri-miRNA exhibits an exclusive structure which is represented by a hairpin and three spiral turns, flanked by a single-stranded RNA. This arrangement can be recognized by an enzymatic complex containing the RNA-binding cofactor DiGeorge Syndrome Critical Region 8 (DGCR8, Pasha) and the RNase III Drosha (a double-strand endonuclease). The resulting processing produces a 60–70 nucleotide long precursor miRNA (pre-miRNA) that, interacting with Exportin-5 and Ran GTPase, is exported to the cytoplasm, where it is subsequently processed by the enzyme Dicer RNase III that cuts pre-miRNA into 19–24 nucleotide long mature miRNA duplex (Okada et al. 2009).

The duplex is then unwound and only one strand produces the mature sequence that is integrated into the RISCs' (RNA-induced silencing complexes) ribonuclear complexes containing the Argonaute (AGO) family proteins, that target mRNAs by complementary base pairing, resulting in a posttranscription gene silencing either by translation repression or degradation of the target transcript (Xiong et al. 2015). When the miRNA and the target mRNA are fully complementary Ago2 activity cuts the target RNA between nucleotides complementary to positions 10 and 11 of the guide strand (Pratt and MacRae 2009). Otherwise, as with almost all miRNA–target interactions, RISC promotes a cascade of inhibitory steps that lead the targets to canonical degradation pathways (Filipowicz et al. 2008).

For some exonic miRNAs, such as miR-22, miR-155, and miR-146a, both spliced and unspliced transcripts may act as primary miRNA transcripts. Since these are partly localized in the cytoplasm they are not completely accessible for handling. The integration of splicing and transport to the cytoplasm may denote an extra mechanism for the modulation and functioning of exonic miRNA (Pawlicki and Steitz 2008). Genetic and somatic mutations in miRNA motifs can disrupt the interactions between miRNAs and their targets. However, mutations can also make the miRNA able to interact with a set of new targets, rewiring the miRNA regulatory networks.

Detection of miRNAs

A variety of approaches have been developed to determine miRNAs in biological samples using different technologies including Next-Generation Sequencing (NGS), microarray, and reverse transcription-quantitative PCR (Mestdagh et al. 2014). Characterization of miRNAs is generally more difficult to perform compared to mRNA profiling, because techniques should be able to discriminate miRNAs that differ by as little as one nucleotide, also taking into account variations between mature miRNAs and their precursors. Likewise, the profiling of circulating miRNAs may be complex due to low concentration, undesirable inhibitors that may interfere with downstream quantification procedures (i.e., hemoglobin in blood-derived samples) and, eventually, cellular components which may lead to an additional bias. Consequently, the inconsistencies identified among different studies maybe at least partly explained by different extraction and detection procedures, experimental setup, and finally, data analysis, emphasizing the need for well-standardized procedures (El-Khoury et al. 2016).

miRNAs Target Prediction

Due to multiple target recognition, the identification of a miRNA interaction with a target mRNA remains a challenge (Riffo-Campos et al. 2016; Seitz 2017). This difficulty is usually circumvented through bioinformatics tools, aimed at a subsequent bench validation of predicted interactors. Computational methods identify miRNA targets, typically selecting binding sites that have been retained evolutionarily. A partial list of the in silico prediction tools for miRNA targets identification is reported in Table 6.1. Existing approaches, however, often uncover difficulties in achieving effective

Table 6.1 Relevant "web-based" tools for miRNAs analysis

Tool	URL	Description
Diana Tools	http://diana.imis.athena-innovation.gr/DianaTools/index	Databases and software for interpreting and archiving data in a systematic framework ranging from the analysis of expression regulation from deep sequencing data, the annotation of miRNA regulatory elements and targets to the interpretation of the role of ncRNAs in various diseases and pathways.
MirGeneDB	https://mirgenedb.org/	A catalog of miRNA genes that have been validated and annotated.
miRTar	http://mirtar.mbc.nctu.edu.tw/human/	A complete toolbox for identifying the biological function and regulatory relationships between a group of known or putative miRNA and their targets. It also provides an integrative pathway analysis.
miRandola	http://mirandola.iit.cnr.it/index.php	A comprehensive manually curated classification of different extracellular circulating noncoding RNA types.
miRanda	http://www.microrna.org/microrna/getGeneForm.do	A comprehensive resource of microRNA target predictions and expression profiles.
miRò2	http://microrna.osumc.edu/miro/	A computational knowledge base for the inference of miRNA associations.
miRSystem	http://mirsystem.cgm.ntu.edu.tw/	A database that integrates well-known miRNA target gene prediction programs: DIANA, miRanda, miRBridge, PicTar, PITA, rna22, and TargetScan.
HMDD	http://www.cuilab.cn/hmdd	A human miRNAs disease database which contains miRNA names, disease names, dysfunction evidences, and relative literature.
PROGmiR	http://xvm145.jefferson.edu/progmir/	A prognostic database for cancers based on their miRNA expression signature.
VIRmiRNA	http://crdd.osdd.net/servers/virmirna/	A viral RNA database including functional targets.
miRIAD	https://www.bioinfo.mochsl.org.br/miriad/	A web search tool designed to help users to access integrated information concerning intragenic miRNAs and their host genes.
Exocarta	http://www.exocarta.org/	ExoCarta, an exosome database, provides with the contents that were identified in exosomes in multiple organisms.
microPIR	http://www4a.biotec.or.th/micropir/	An integrated database of miRNA targets within human promoters.
miRNAtools3	http://mirnatools.eu/index.html	A catalog of utilities for miRNA analysis.
miRDeep	http://www.australianprostatecentre.org/research/software/mirdeep-star	An integrated standalone application useful for the prediction of miRNAs from small RNAseq data.
Ingenuity® Pathway	https://www.qiagenbioinformatics.com/products/ingenuity-pathway-analysis/	An integrated web server for identifying miRNA–target interactions. Commercial software.
miR2GO	http://compbio.uthsc.edu/miR2GO/home.php	Comparative functional analysis for microRNAs.
miRTargetLink Human	https://ccb-web.cs.uni-saarland.de/mirtargetlink/	Detailed information on human microRNA–mRNA interactions in the form of interactive interaction networks.
mirDIP	http://ophid.utoronto.ca/mirDIP/searchSummary.jsp	Find miRNAs that target a gene, or genes targeted by a miRNA, in Homo sapiens.
miRmine	http://guanlab.ccmb.med.umich.edu/mirmine/index.html	Human miRNA expression database.
miTALOS2	http://mips.helmholtz-muenchen.de/mitalos/#/search	Localize miRNA targets within cell signaling pathways.

Table 6.1 (continued)

Tool	URL	Description
miRGator	mirgator.kobic.re.kr/	miRNA portal encompassing miRNA diversity, expression profiles, target relationships, and various supporting tools.
miRDB	http://mirdb.org/miRDB/	An online database for miRNA target prediction and functional annotations.
PITA	https://genie.weizmann.ac.il/pubs/mir07/mir07_prediction.html	PITA test the UTR for potential miRNA targets.
TargetScan	http://www.targetscan.org/vert_71/	Predicts biological targets of miRNAs by searching for the presence seed region of each miRNA.
PhenomiR	http://mips.helmholtz-muenchen.de/phenomir/	Provides information about differentially regulated miRNA expression in diseases and several biological processes.
GeneTrail2	https://genetrail2.bioinf.uni-sb.de/start.html	Statistical analysis of molecular signatures. Enrichment analysis based on miRNA categories like miRDB or miRTarBase, or map miRNAs to gene targets.

performance given the high false-positive and false-negative rates of discovery (Liu et al. 2014).

miRNA in Obesity and Obesity-Associated Comorbidities

miRNAs are useful tools in clinical applications (Keller and Meese 2016), with the majority of reports focusing on "circulating" miRNAs as cancer theranostic biomarkers (Pratt and MacRae 2009; Filipowicz et al. 2008; Pawlicki and Steitz 2008; Mestdagh et al. 2014; El-Khoury et al. 2016; Riffo-Campos et al. 2016; Seitz 2017; Liu et al. 2014; Keller and Meese 2016; Calin and Croce 2006; Matsuzaki and Ochiya 2017; Torres et al. 2020). Yet, recent studies have demonstrated that changes in miRNA profiles of various tissues (e.g., pancreas, adipose tissue, and liver) are also related to obesity (Fig. 6.2) (Kunej et al. 2013) and several metabolic diseases (Jiang et al. 2009; Dumortier et al. 2013).

miRNAs are affected by nutrition and lifestyle factors (Slattery et al. 2017), and many microRNA families have been associated with dietetic interventions (Palmer et al. 2014). Lastly, dietary miRNAs have been supposed to survive gastrointestinal digestion (Liang et al. 2014). However, the role and ability of food-related miRNAs to interfere with cross-species mRNA remains puzzling (Pastrello et al. 2016).

Role of miRNAs in Adipose Tissue

The first evidence of a role for miRNAs in fat cells originated from a study of miR-14 function in Drosophila, negatively affecting the fat metabolism by targeting p38 and MAPK (Xu et al. 2003). Then, a wide-ranging spectrum of miRNAs activities in regulating glucose and lipid metabolism was recognized, by mediating adipocyte differentiation, regulating cell mass and insulin-signaling pathways in physiological and pathological conditions in humans (Arner and Kulyte 2015; Hartig et al. 2015).

There are many elements involved in regulating the multiple steps of adipogenesis and emerging evidence support miRNAs' contribution to adipose tissue development and pathophysiology (Yi et al. 2020). Nowadays, adequate information regarding miRNAs acting mechanisms remains still limited (Zhang et al. 2013a). As a working example, it has been shown that the miRNAs reported in Fig. 6.3a interfere with adipocytes differentiation, while others promote adipogenesis (Fig. 6.3, panel b) (Price and Fernandez-Hernando 2016).

Adipogenesis Pathways

miR-130 and miR-143 are the best studied of adipogenesis-related miRNAs. miR-143 and miR-145 are frequently analysed together because they are closely located and can be co-transcribed. miR-143 was recognized as a positive human adipocyte differentiation regulator acting through ERK5 signaling. Expression of miR-143 and miR-145 is also increased in the liver of a mouse model of obesity; miR-143 overexpression adversely affects insulin-stimulated AKT activation and homeostasis of glucose. Besides, mice missing the miR-143–145 cluster do not develop insulin resistance associated with obesity (Jordan et al. 2011).

Another remarkable example is represented by miR-27a and miR-130a, overexpression of which suppresses adipocyte differentiation through PPARγ downregulation (Qin et al. 2010; Lee et al. 2011). Lower levels of miR-130a and -130b have been documented in abdominal subcutaneous adipose tissue of obese women (Ortega et al. 2013). Furthermore, circulating miR-130b is higher in obese children (Prats-Puig et al. 2013). A study from Wang et al. documented miR-130b as a potential biomarker for overweight, hypertriacylglycerolemia, and metabolic syndrome, suggesting a mechanism connecting obesity and obesity-related metabolic diseases, through a circulating miRNAs crosstalk between adipose and muscle tissues (Wang et al. 2013a).

The authors also established that the addition of TGF-β to mature adipocytes (3T3-L1) significantly increased the level of miR-130b in the culture medium and slightly decreased intracellular level, confirming that this miRNA is released from adipocytes during adipogenesis. Other miRNAs affect lineage determination. As an example, miR-124 has a pro-adipogenic effect by targeting Dlx5, a pro-osteogenic transcription factor that governs cell fate in human bone marrow-derived mesenchymal stem cells (Qadir et al. 2013). The best-characterized polycistronic miRNA cluster is miR-17-92 (encoding for miR-17, miR-18a, miR-19a, miR-20a, miR-19b-1, and miR-92a), essential for many developmental and pathogenic processes (Concepcion et al. 2012). This cluster is overexpressed in the clonal expansion of adipocytes and acts by directly targeting the RB family Rb2/p130 so controlling the cell checkpoint mediated by RB-E2F. In the same path, miR-363 inhibits the differentiation of adipocytes by targeting E2F and simultaneously reducing C/EBPα and PPARγ (Chen et al. 2014).

Let-7 miRNA and Diabetes Prevention

Let-7 was the first identified human miRNA. It belongs to a well-conserved family of 11 members connected with numerous critical cell functions such as apoptosis, proliferation, and cell cycle checkpoints. Members of this miRNA family directly regulate oncogenes such as RAS and HMGA2 and play a key role in developmental processes and pathogenesis of metabolic diseases, being important regulators of glucose metabolism and peripheral insulin resistance by addressing IGF1R, insulin receptor (INSR), and insulin receptor substrate-2. Also, let-7 negatively controls adipogenesis by modulating the expression of the high mobility group AT-hook2.

Let-7 is upregulated in the model of 3T3-L1 adipogenesis. The ectopic introduction of let-7 in 3T3-L1 and 3T3-F442A reduced the cell clonal expansion as well as the terminal differentiation (Sun et al. 2009). This miRNA serves as an anti-adipogenic factor regulating the transition from clonal expansion to terminal differentiation. Moreover, let-7 is directly involved in the metabolism of glucose and insulin resistance by acting on the insulin/IGF-1R pathway (Zhu et al. 2011). Knockout mice with reduced expression of let-7 do not develop insulin resistance despite a diet-induced obesity, supporting the potential of let-7 in developing new therapeutic strategies for diabetes (Frost and Olson 2011).

Other Tissue-Specific miRNAs and Metabolic Diseases

miR-375 has been reported to promote adipocyte differentiation through its ability to concurrently induce *C/EBPα*, *PPARγ2*, the adipocyte fatty

acid-binding protein (*aP2*), and, ultimately, to promote triglycerides accumulation. Conversely, miR-375 suppresses phosphorylation of ERK1/2 (Ling et al. 2011).

Many papers reported the central role of miR-206 in the growth and development of the skeletal muscle by promoting myogenic differentiation. Besides, it has been correlated to several diseases, including heart failure, chronic obstructive pulmonary disease, Alzheimer's disease, and some cancers (Novak et al. 2014). Interestingly, miR-206 is downregulated in most of these conditions, suggesting a role of this miRNA as a "disease-avoiding" molecule (Novak et al. 2014). This miRNA is highly expressed in brown adipocytes but missing in white adipocytes (Walden et al. 2009). miR-206 suppresses the liver X receptor α (*LXRα*), a key target of PPAR, thus inhibiting lipogenesis and modulating lipid metabolism (Zhong et al. 2013).

miR-26b inhibits human preadipocytes differentiation (Nishimura et al. 2008; Song et al. 2014), while knockdown of miR-26b improves adipocyte differentiation with an establishment of adipocyte-specific transcripts and lipid droplets.

Recent findings indicate that miR-146b is markedly expressed during adipogenesis (Ahn et al. 2013). Sirtuin 1 (SIRT1) is negatively regulated by miR-146b. SIRT1 controls gene activity by deacetylating various transcription factors, including forkhead box O1 (FOXO1). Forkhead box O transcription factor family converts the multiplicity of extracellular stimuli, including growth factors, nutrients, and oxidative stress, into different biological responses through modulation of specific genes. SIRT1, by interacting with PPARγ co-repressors N-CoR and SMRT, inhibits PPARγ and precludes adipogenesis (SIRT1 level is reduced during adipogenesis). Accordingly, overexpression of miR-146b induces differentiation of 3T3-L1 cells, while inhibition of miR-146b reduces adipocyte differentiation (Jing et al. 2007).

The highly conserved miR-8/miR-200 family consists of a single ortholog (miR-8) in *Drosophila melanogaster*, and of five members (miR-200a, miR-200b, miR-200c, miR-141, and miR-429) in vertebrates (Trumbach and Prakash 2015). miR-8/miR-200 have been reported as repressors of the evolutionarily conserved Wnt/Wingless pathway in Drosophila eye and in mouse mesenchymal stem cells, controlling the eye size and the differentiation of the mesenchymal stem cells into adipocytes, correspondingly (Kennell et al. 2008). Drosophila miR-8 and human miR-200 family also prevent the expression of an inhibitor of the insulin/phosphoinositide-3 kinase (PI3K) signaling in adipose and liver cells, thus affecting cell growth and proliferation (Hyun et al. 2009). Overexpression of members of this miRNA family increases the level of the fatty acid-binding protein 4 (FABP4), promotes lipid accumulation and, finally, induces adipogenesis.

In 3T3-L1 cells, the expression of miR-210 increases significantly during adipogenesis (Liang et al. 2013). Transfection of miR-210 miRNA mimics into cells resulted in the expression of adipogenic markers through activation of the PI3K/Akt pathway by addressing SHIP1, a negative regulator of the pathway, and in the terminal differentiation. Moreover, ectopic inhibition of the endogenous miR-210 during adipogenesis halts adipocyte differentiation (Liang et al. 2013). Similarly, miR-21 significantly promotes 3T3-L1 adipocyte differentiation, increasing adiponectin expression, and decreasing AP-1 protein level. Also, miR-21 may enhance differentiation of human adipose-derived stem cells by directly inhibiting TGF-β receptor 2 expression (Kim et al. 2009b).

Adipose Tissue Cross Talk and miRNAs

Recently, Thomou et al. identified new potential implications of adipose tissue in the mechanism of the cell crosstalk (Thomou et al. 2017). Mice with an adipose-tissue-specific knockout of Dicer miRNA-processing enzyme, as well as humans with lipodystrophy, show a significant decrease in circulating miRNA levels. White and brown adipose tissue transplantation can restore levels of many circulating miRNAs, an event associated with increased glucose tolerance and decreased hepatic fibroblast growth factor 21 (FGF21)

mRNA and circulating FGF21. This factor plays a major role in stimulating the oxidation of fatty acids in the liver and the absorption of glucose in adipocytes. Interestingly, FGF21 levels are significantly increased in patients with T2D, nonalcoholic fatty liver disease, and are correlated with BMI, so indicating obesity as a possible FGF21-resistant condition (Thomou et al. 2017).

Intercellular Message Signaling

Li et al. found that adipose tissue-secreted extracellular vesicles (containing miRNAs) deliver intercellular signaling. miR-221-3p mediates a mechanism by which perivascular adipose tissue triggers early-stage vascular remodeling in the context of obesity-associated inflammation (Li et al. 2019).

Role of miRNAs in the Pancreas

A decrease in β-cell function/mass has been linked to falling levels of insulin in T2D (Butler and Dhawan 2015). Dedifferentiation and cell identity processes of β-cells can likewise contribute to the decline in insulin production. The first indication of the relevance of miRNAs in hormone secretion came from a cloning approach of small RNAs from the β cell-derived cell line MIN6 (Poy et al. 2004). It has been recognized that miR-124a2 and miR-375 are involved in regulating the differentiation and establishment of pancreatic islets (Kaviani et al. 2016; Sebastiani et al. 2017), and high levels of miR-7 and miRNA-375 are expressed during pancreatic development. A panel of 40 miRNAs primarily expressed in islets has been identified, comparing islet-cell miRNAs profile with those of other human tissues (van de Bunt et al. 2013).

miR-375 is the most abundant miRNA in pancreatic islets and its presence is mandatory for normal tissue differentiation. The wide expression of miR-375 is observed during the development of pancreatic islet cells, while β-cell activity is connected to its reduction (Wei et al. 2013). During pancreas development, miR-375 targets various genes associated with cell growth (Joglekar et al. 2009) in addition to many transcription factors such as PDX1, HNF6, and INSM1, which are involved in the functioning of islets (Avnit-Sagi et al. 2009). Notably, the transcription factor neurogenin3 (Ngn3), which had a prominent role in the development of pancreatic islet (Gu et al. 2002) also interferes with miR-375 expression. miR-15a, miR-15b, miR-16, and miRNA-195 likewise target Ngn3. Of note, miR-375 has been reported to be involved in modulating insulin secretion in stimulated cell line MIN6 (Poy et al. 2004), whereas other miRNAs (let-7, miR-103, and -107) have an impact on rodent insulin sensitivity.

miR-375 decreases glucose-stimulated insulin secretion by downregulating mRNA of myotrophin (involved in insulin-granules cell membrane fusion) and thus inhibits exocytosis. miR-375 simultaneously affects insulin expression by targeting the phosphoinositide-dependent kinase-1 in INS1-E cells (El Ouaamari et al. 2008). Besides, Sedgeman et al. found that pancreatic beta-cells export miR-375-3p to HDL, and that this process is inversely related to insulin secretion (Sedgeman et al. 2019).

Additional miRNAs expressed in pancreatic islets, such as let-7 and miR-143, are connected to glucose homeostasis by targeting key components of the insulin signaling pathway (Zhu et al. 2011). There is evidence for miR-7 involvement in pancreas development (Kredo-Russo et al. 2012), and high levels of miR-7 are detectable in the pancreas both in the developing and adult phases. Overexpression of miR-7 in pancreatic progenitors has been shown to impair the differentiation of α- and β-cells and is connected with the repression of Pax6. On the contrary, knockdown of miR-7 during early embryonic life determines a downregulation of insulin production, a reduction in the number of β-cells, and the post-natal onset of glucose intolerance. Additionally, the in vitro inhibition of miR-7 promotes β-cell death in explanted pancreatic buds. In brief, dysregulation of the miR-7 signaling network in response to metabolic stress or cellular insults contributes to the loss of β-cell

identity and T2D progress (Martinez-Sanchez et al. 2016).

Other miRNAs, such as miR-34a and miR-146a, are overexpressed in the pancreas only during the differentiation processes, and partially contribute to cytokine-mediated adjacent cell dysfunction in nonobese diabetic (NOD) mice, during the first stage of type 1 diabetes (Dumortier et al. 2013).

Additional Pancreatic Activities of miRNAs

miR-96 and miR-124a control the expression of proteins involved in insulin exocytosis and affect β-cell secretion (Lovis et al. 2008). miR-124a is upregulated during the late pancreas development. This miRNA targets the cAMP-responsive element-binding protein 1 (Creb1) and the forkhead box protein A2 (Foxa2) mRNAs. The last transcriptional factor modulates the expression of the insulin gene in multiple pathways responsible for the secretion of this hormone, primarily through the regulation of pancreatic and duodenal homeobox 1 (Pdx1) which is critical for glucose balance and pancreas development and, together with Ngn3, is indispensable for β-cell differentiation. Furthermore, miR124a promotes SNAP25, Rab3A, and synapsin-1A levels and decreases those of Rab27A and Noc2, key components involved in the exocytotic release of insulin granules (Lovis et al. 2008).

Noteworthy, Islet-specific miRNAs remain of singular interest for identifying islet stress or damage. It has been shown that during prediabetes, islets undergo stress and release miRNAs with consistent miRNA signatures specific to different stages (Vasu et al. 2019).

Role of miRNAs in the Muscle

Striated muscle tissue is the largest consumer of glucose in the human body since skeletal muscle makes up to 40% of the total body mass, contributing to nearly 75% of insulin-mediated glucose adsorption. Regular physical activity and fitness lead to successful improvements in health status partly due to positive effects on insulin resistance and T2D.

Several miRNAs, known as myomiR family, display enriched expression in the skeletal muscle and operate as modulators of skeletal and cardiac myogenesis, proliferation, metabolism, exercise as well as hypertrophy. MyomiRs include miR-1, miR-133a, miR-133b, miR-206, miR-208a, miR-208b, miR-486, miR-499 and are under the transcriptional control of myogenic regulatory factors (McCarthy 2011).

miR-206 is expressed primarily in the skeletal muscle, while miR-208a is cardio-specific; however, most of these miRNAs are co-expressed in the cardiac and skeletal muscles (Kirby and McCarthy 2013). MyomiRs directly target pathways that control skeletal muscle homeostasis. Their deregulation occurs in several muscular disorders and wasting, but is also as biomarker of muscle status, regeneration, and therapy effect (Polakovicova et al. 2016).

Reduced expression of miR-133 was established in cardiac hypertrophy models of mouse and human models (Feng et al. 2010). Acute exercise leads to an increase in the levels of miR-1, miR-133a, and miR-206 (Gomes et al. 2014), relevant miRNAs that potentially contribute to cell-to-cell communication.

Insulin Resistance

miR-29a induces insulin resistance by addressing PPARδ in skeletal muscle cells in rodents. The overexpression of miR-29a inhibits PPARδ finally affecting the expression of its PGC-1α coactivator. PPARδ/PGC-1α-dependent signaling results in a reduction in glucose transporter levels 4, the main transporter of glucose in the skeletal muscle, along with a reduction in insulin-dependent glucose intake and adenosine triphosphate (ATP) levels (Zhou et al. 2016). Analogously, miR-29a levels are noticeably elevated in diabetic mice (db/db) liver. Overexpression of this miRNA leads to an attenuation of insulin action on phosphoenolpyruvate carboxykinase (PEPCK) expression in the liver, a

phenomenon connected to an unrestrained hepatic glucose output. A predominant insulin action in the liver is the inhibition of gluconeogenesis by a cascade of events that terminates with a diminished PEPCK activity, an occurrence that has been shown to be abolished in diabetes, leading to an uncontrolled hepatic glucose output (Pandey et al. 2011). High fat diet induces the expression of miR-29a in myocytes, an event that impairs the insulin signaling pathway and glucose uptake through a pronounced decrease in insulin receptor substrate 1 (IRS-1), suggesting that upregulation of miR-29a by saturated fatty acids (SFA) is causally associated with the development of muscle insulin resistance (Yang et al. 2014).

miR-106b was associated with muscle insulin resistance and T2D. miR-106b is highly expressed in the diabetic subjects' muscle. High level of this miRNA provokes mitochondrial dysfunction and insulin resistance in C2C12 myotubes by addressing mitofusin-2 (a mitochondrial membrane protein participating in mitochondrial fusion in mammalian cells, induced during myogenesis and involved in the maintenance of the mitochondrial network). Remarkably, expression of miR-106b is improved after treatment with TNF-α, suggesting that its increased expression under chronic low-grade inflammation could be a link between mitochondrial alteration and T2D (Zhang et al. 2013b).

Myocardial Metabolism

An interesting field of research is the pleiotropic regulatory functions of miR-208a, a heart-specific miRNA that also affects glucose metabolism and energy homeostasis. Cardiac muscle tissue helps to regulate systemic energy homeostasis through MED13 (Baskin et al. 2014), a subunit of the Mediator complex, which governs transcription by the thyroid hormone and additional nuclear hormone receptors (Baskin et al. 2015). MED13 level is negatively controlled by miR-208a. Oligonucleotides anti-miR-208 provide resistance to diet-induced obesity and improve glucose tolerance in the mouse model (Grueter et al. 2012).

Role of miRNAs in the Liver

miR-122 is a dominant hepatocyte-specific miRNA representing about 75% of total miRNA expression in hepatocytes with about 135,000 copies, making it one of the highly expressed miRNAs in humans. Levels of miR-122 are controlled by liver-enriched transcription factors (LETFs), including hepatocyte nuclear factor (HNF) 6 and 4a. The miR-122 regulatory network has been involved in many functions in the liver, ranging from cholesterol metabolism, stress responses, viral infection, cancer, and circadian hepatic gene regulation (Szabo and Bala 2013; Tsai et al. 2012). This miRNA also plays a role in metabolic syndrome and other liver disorders, such as alcohol-related liver inflammation, autoimmune processes, and the development of liver fibrosis in both humans and in animal models. Pathological suppression of miR-122 has been identified in hepatocellular carcinoma (Burchard et al. 2010), nonalcoholic steatohepatitis (Cheung et al. 2008), and liver cirrhosis (Szabo and Bala 2013). Due to its role in the metabolism of cholesterol, this miRNA is intensively investigated. Inhibition via antisense of miR-122 in healthy mice results in lower rates of serum cholesterol, LDL and serum triglyceride, increased oxidation of hepatic fatty acids, and decreased expression of key genes involved both in the metabolism of fatty acids and biosynthesis of cholesterol, including the rate-limiting enzyme 3-hydroxy-3-methylglutaryl-CoA-reductase (Esau et al. 2006). Antisense inhibition of this miRNA in chimpanzee results in a reduction in plasma cholesterol supporting its central role in maintaining liver metabolism (Elmen et al. 2008). miR-122 can also be detected in blood, and circulating miR-122 has been suggested as a liver injury biomarker in hepatitis B and C, nonalcoholic fatty liver disease, and drug-induced liver disease (Bandiera et al. 2015).

miR-33, whose coding sequence is embedded within an intron of the SREBP gene, has been shown to regulate cholesterol metabolism, fatty acids metabolism, and glucose metabolism/insulin signaling (Davalos et al. 2011). miRNA

targets include molecules involved both in cholesterol transport to HDL/reverse cholesterol transport and the transport of cholesterol to bile.

Additional miRNAs

miR-27b controls lipid metabolism and is impaired in dyslipidemia, so disrupting both heart and liver functions (Vickers et al. 2013). miR-27a is considered a critical post-transcriptional hub interconnecting different components of the lipid metabolism, being able to target RXRα, ABCA1, FASN, SREBP1, SREBP2, PPARα, PPARγ, ApoA1, ApoB100, and ApoE3 (Vickers et al. 2013).

miR-34a affects hepatic levels of SIRT1, and miR-34a upregulation with a concomitant decrease in Sirt1 levels has been reported in fatty livers of mice with diet-induced obesity (Lee et al. 2010). In addition, miR-370 targets carnitine palmitoyl transferase, a mitochondrial enzyme involved in the transport of long-chain fatty acids across the membrane, and concomitantly controls lipid metabolism (Iliopoulos et al. 2010).

Circulating miRNAs

While miRNAs were first detected in cells, a growing number of miRNAs are found in high concentrations in blood and other body fluids such as in serum, plasma, urine, saliva, and maternal milk (Turchinovich et al. 2011). Stability in blood and body fluids has been questioned in the past (Cortez and Calin 2009), given the ubiquity of nucleases. Nevertheless, this finding stimulated interest in the possibility that changes in cell-free miRNAs could be used as noninvasive biomarkers (Kim 2015). Because of their availability, the most typical miRNA sources are whole blood, serum, and plasma (Grasedieck et al. 2013).

Anti Nuclease Protection

Circulating miRNAs (c-miRNAs) are not, as predictable, naked molecules and two major mechanisms to shield them from nuclease activity have been identified. The first one consists in the formation of complexes of specific proteins, such as Argonaute 2 (AGO-2) (involved in the RNA silencing complex) (Arroyo et al. 2011), with high-density lipoproteins (Vickers et al. 2011), or with nucleophosmin-1 (NPM-1) (an RNA-binding protein involved in the nuclear export of ribosomes) (Wang et al. 2010). The second proposed mechanism stems from the detection of c-miRNAs inside circulating microvesicles or exosomes (Mittelbrunn et al. 2011), originating either from the cell plasma membrane or from the endosomal compartments (Camussi et al. 2011). While a defined mechanism for the release of miRNAs from donor cells remains largely unknown, growing evidence supports the possibility that extracellular miRNAs, organized in either exosomes or protein complexes, can be transferred to recipient cells where they can regulate the translation of the target/s gene/s (Weber et al. 2010).

Circulating miRNA in Obesity, Diabetes and Associated Conditions

Differential c-miRNA profiles have been identified in subjects with obesity and T2D (Guay and Regazzi 2013) and levels of specific c-miRNAs vary from one setting to another. miR-126 is reduced in T2D (Zampetaki et al. 2010); elevated serum levels of microRNAs 192 and 194 are associated with incident T2D (Jaeger et al. 2018); miR-1, miR-21, miR-133a, and miR-208 are enriched in the plasma after myocardial infarction (Zile et al. 2011); miR-122 is increased in hepatic injury and steatosis (Cermelli et al. 2011), in addition to let-7e in hypertension (Li et al. 2011).

A meta-analysis by Zhu and Leung showed that miR-29a, miR-34a, miR-103, miR-107, miR-132, miR-142-3p, miR-144, and miR-375 represent potential circulatory biomarkers for T2D (Zhu and Leung 2015). In the same analysis, miR-199a-3p and miR-223 were found as potential tissue biomarkers of T2D. An additional meta-analysis reported that levels of circulating miR-27a, miR-29a, miR-142-3p, miR-222, miR-320a, and miR-375 were increased and levels of miR-17, miR-20b, miR-197, and miR-652 decreased in individuals with T2D (Villard et al. 2015).

Diabetic subjects are known to exhibit increased platelet activity. Platelet-derived miRNAs could be exploited as biomarkers in inflammatory diseases, including T2D and CVD, given the abundance of platelets in the blood and their wide contribution to the c-miRNAs pool (Pordzik et al. 2018). In a study by Stratz et al. (2014) miRNA relative levels between the T2D cohort and controls were not significantly different in platelets; nevertheless, functional implications of these molecules can be relevant in the pathogenesis of T2D (Pordzik et al. 2019).

Recently, Ghai et al. identified several miRNAs encapsulated in circulating extracellular vesicles that were affected by metformin treatment in T2D patients, suggesting that these miRNAs may serve as possible biomarkers for assessing drug treatment response (Ghai et al. 2019).

Besides, miR-191 was positively associated with glycemic impairment and progression in the high-risk Asian Indian ethnic group; conversely, miR-122, miR-15a, miR-197, miR-320a, miR-423, miR-486 exhibited an inverse relationship with odds for glycemic progression after 2.5 years compared to those who remained stable (Flowers et al. 2015).

Blood Glucose, Blood Pressure and Metabolic Syndrome

In a large population-based study ($n = 871$), levels of miR-144-5p, miR-122-5p, miR-148a-3p, miR-589-5p, and let-7a-5p were associated with glycemic status (Mononen et al. 2019). In the same study, miR-144-5p and miR-148a-3p were linked to glucose levels, while miR-144-5p, miR-122-5p, miR-184, and miR-339-3p were associated with insulin levels and HOMA-IR score. miR-148a-3p, miR-15b-3p, miR-93-3p, miR-146b-5p, miR-221-3p, miR-18a-3p, miR-642a-5p, and miR-181-2-3p were linked to HbA1c levels.

Besides, high blood pressure was associated with circulating miR-130a and miR-195 (Karolina et al. 2012). Changes in circulating miR 23a, miR 27a, miR 130, miR 195, miR 197, miR 320a, and miR 509-5p were associated with metabolic syndrome (Karolina et al. 2012; Deiuliis 2016). c-miRNA profiles showed a sex-specific association with metabolic syndrome (Wang et al. 2013b). Moreover, it was proposed that let-7b, miR-143, and miR-221 control both atherogenic and adipogenic progressions (Hulsmans et al. 2011).

Bariatric Surgery

Ortega et al. identified a significant increase in circulating miR-140-5p, miR-142-3p, miR-222, and decrease of miR-532-5p, miR-125b, miR-130b, miR-221, miR-15a, miR-423-5p, and miR-520c-3p in morbidly obese patients. Bariatric surgery resulted in a significant reduction in circulating miR-140-5p, miR-122, miR-193a-5p, and miR-16-1, and an increase in miR-221 and miR-199a-3p levels (Ortega et al. 2013). Besides, levels of circulating miR-17-5p and miR-132 were decreased in obesity, reflecting the pattern of expression of miRNAs in omental fat from the same group of obese people (Heneghan et al. 2011).

Pediatric Protocols

Differential c-miRNAs signatures occur in overweight/obese children and adolescents as compared to normal weight (Prats-Puig et al. 2013; Iacomino et al. 2016, 2019; Can et al. 2016; Thompson et al. 2017; Iacomino and Siani 2017). Accordingly, our group has reported that a panel of miRNAs is differentially expressed in

overweight/obese European children, miR551a and miR-501-5p resulted upregulated; miR-10b-5p, miR-191-3p, miR-215-5p, and miR-874-3p resulted downregulated (Iacomino et al. 2019). In a further analysis by Oses et al. miR-122 and miR-34a, were overexpressed in obese children and nonalcoholic fatty liver disease (NAFLD) and/or insulin resistance (Oses et al. 2019).

Mounting evidence was also found in newborns, pregestational maternal obesity, and gestational obesity (Carreras-Badosa et al. 2015). Among babies born to obese or lean mothers, the rates of some c-miRNAs, including miR-155, miR-181a, and miR-221, differ significantly. Such miRNAs were also suggested as useful predictors of obesity and increased risk of developing disorders in children born to obese women (Mendez-Mancilla et al. 2018).

Several c-miRNAs were found down- and upregulated in pregestational and gestational obesity; some were associated with pregnancy weight gain, others were closely associated with metabolic parameters during gestation and were independent predictors of pre- and post-natal growing (Carreras-Badosa et al. 2015). Also, levels of some c-miRNAs were associated with gestational diabetes, especially in prepregnancy overweight women (Wander et al. 2017). Recent data showed that the supply of miRNAs in maternal milk was likewise altered in overweight/obese lactating mothers, pointing to a plausible molecular communication between mother and infant through miRNAs (Zamanillo et al. 2019).

Other studies also investigated how diet, exercise, weight loss, and bariatric surgery impact miRNAs profiles in obese patients. A significant modulation of specific c-miRNAs was observed in overweight/obese subjects after low or high glycemic index diet and low-fat diet (Giardina et al. 2019). Moreover, miR-21, miR-126, miR-130b, miR-221, and miR-222 are upregulated in both obese and normal-weight subjects following acute aerobic exercise (Bao et al. 2018). Several studies have shown that gastric bypass deeply impacts c-miRNA levels from the preoperative baseline with time-dependent changes (Alkandari et al. 2018). The combination of gastric bypass surgery with exercise likewise affected the pattern of several c-miRNAs (Nunez Lopez et al. 2017). A summary of several bariatric surgery studies was recently reported in a meta-analysis from Langi et al. (2019).

Translational Considerations

miRNA related drugs have been synthesized and systemically administered for therapeutic purposes, and one of them, the small-interfering RNA (siRNA) agent Patisiran (Onpattro, Alnylam Pharmaceuticals, Cambridge, MA, USA), was FDA approved for a rare polyneuropathy caused by hereditary transthyretin-mediated amyloidosis. Given the ability of miRNA mimics to overexpress the transcript, and of miRNA repressors to silence it, they are well-positioned to modulate peripheral tissues regarding genetic/epigenetic derangements. Indeed, it is estimated that 60% of human protein-coding genes are targeted or regulated by miRNAs. In this sense, several trials are going on to develop additional drugs for benign and malignant diseases, including oncological chemoresistance in certain cancer modalities (Hanna et al. 2019).

Ordinary diabetes and obesity have not been given similar attention, perhaps because there are comparatively simple and well-established treatment options in the market. Nevertheless, applications for metabolic disease screening, prognosis, and early diagnosis of complications are envisaged. As mentioned, selected miRNAs can be detected years before conventional markers become positive. In this sense, miRNA-based predictive algorithms could be adopted in the near future, to improve patient management in the clinical routine (Jiménez-Lucena et al. 2018).

Contents

Abstract

Obesity is a complex disease with multifactorial etiology requiring cause-specific treatment approaches. Among the various causes, obesity due to microbial infections has been reported since 1982, linking several microbes to obesity. Among them, avian adenovirus SMAM-1 and the human adenovirus Ad36 have been extensively studied for the past 25 years. Experimental Ad36 infection causes obesity in animal models, yet paradoxically improves glycemic control. The E4orf1 gene of Ad36 has been shown to be necessary and sufficient for adipogenesis and also responsible for better glycemic control. Animal models show that E4orf1 may be a candidate to treat type 1 or type 2 diabetes or nonalcoholic fatty liver disease. Collectively these studies show a causational and correlational link of Ad36 to animal and human obesity. Overall, developing vaccines to prevent virus-induced obesity and harnessing the antihyperglycemic potential of E4orf1 are the two long-term goals of this line of investigation.

Ad36 virus · Adipogenesis · Viral obesity · Obesity vaccine · E4orf1 gene · Obesity control · Diabetes control

Introduction

The prevalence of obesity worldwide has nearly tripled since 1975 and continues to grow at a pandemic rate (Collaboration NCDRF 2016, 2017). Since 2013, obesity has been recognized as a disease by the American Medical Association (AMA) (Pollack 2013). The AMA declaration makes it more effective to address this complex disease and associated comorbidities, as obesity substantially increases the risk of metabolic diseases (for example, type 2 diabetes mellitus (T2D) and fatty liver disease), cardiovascular diseases (hypertension, myocardial infarction, and stroke), musculoskeletal disease (osteoarthritis), Alzheimer disease, depression, and some types of cancer (breast, ovarian, prostate, liver, kidney, and colon).

The fundamental cause of obesity is considered as an energy imbalance between calories consumed and calories expended. Hence, the core treatment recommendations rely almost exclusively on eating less and moving more to create a negative energy balance for inducing weight loss. However, at the individual level, weight-loss interventions aimed at reducing calorie intake and increasing energy expenditure are frequently not successful in the long term. Besides eating and physical activity, there are several putative factors such as infection, epigenetic changes, increased maternal age, endocrine disruptions, and intrauterine effects that might contribute to obesity (McAllister et al. 2009). This highlights that obesity has a multifactorial etiology, yet its current treatment is not cause-specific. For example, sleep disorders or sleep apnea is linked with obesity (Bayon et al. 2014), so an effective and comprehensive weight-loss treatment should address sleep as well. It is known that infections can influence obesity and obesity can influence susceptibility to or severity of infections (Dhurandhar et al. 2015). This chapter describes a novel translational journey from the identification and characterization of an adipogenic adenovirus Ad36, to exploiting its unique antidiabetic property for therapeutic application.

Infectobesity

Studies from several laboratories over the past 30 years have indicated that certain infections might promote the development of obesity, which is termed as "*Infectobesity*," (Dhurandhar 2011; Akheruzzaman et al. 2019) or obesity of infectious origin. Induction of obesity in mice experimentally infected with canine distemper virus was the first report of *Infectobesity* (Lyons et al. 1982). Since then, several animal and human viruses, bacteria, parasites, and scrapie agents have been reported to cause obesity in insects, chickens, rodents, and nonhuman primate models (Pasarica and Dhurandhar 2007). In a longitudinal birth cohort study, it was shown that infection, but not antibiotic use, during infancy is associated with a risk of childhood obesity (Li et al. 2017). Several additional microbes including *Chlamydia pneumoniae* (Dart et al. 2002), *Selenomonas noxia* (Goodson et al. 2009), *Helicobacter pylori* (Arslan et al. 2009), the gut microflora (Ley et al. 2006), and a collective load of infection with herpes simplex virus 1 or 2, enterovirus and *C. pneumoniae* (Fernandez-Real et al. 2007) are all associated with human obesity. The mechanism by which these microbes impose their adipogenic action varies, ranging from an effect on the central nervous system (canine distemper virus, Borna disease virus), to metabolism (gut microbiota), and adipose tissue (adenoviruses) (Pasarica and Dhurandhar 2007). The only human pathogens causatively and correlatively linked with animal and human obesity, respectively, are adenoviruses that directly influence the adipose tissue.

SMAM-1 Adenovirus

The first adipogenic adenovirus identified was an avian adenovirus, SMAM-1. Experimental SMAM-1 infection of chickens increased adiposity, yet reduced serum cholesterol and triglyceride levels compared to uninfected controls (Dhurandhar et al. 1990, 1992). Another set of uninfected chickens sharing cages with SMAM-1 infected chickens acquired infection and increased adiposity. Screening for the presence of SMAM-1 antibodies as an indicator of past SMAM-1 infection in humans, found 20% seropositivity (Dhurandhar et al. 1997). This was a surprising finding as humans are not considered susceptible to avian adenovirus infection. Phenotypically, the SMAM-1 seropositive subjects had significantly greater body mass index (BMI) as an indicator of adiposity, but lower serum cholesterol and triglyceride levels. The similarities found among animal and human studies suggested a causative role of SMAM-1 for increasing adiposity in humans, without conclusively establishing such a role.

Human Adipogenic Virus: Adenovirus 36

Human adenovirus 36 (Ad36) was the first human adipogenic virus reported, which was earlier isolated from the fecal sample of a girl suffering from enteritis (Wigand 1980). The presence of neutralizing antibodies is an indication of current or past infection with the virus. Compared with other human adenoviruses, Ad36 is antigenically distinct, which generates neutralizing antibodies that are specific to Ad36 infection. This greatly helps in specifically identifying past Ad36 infection in humans. A series of different experiments in animal models including chickens, mice, rats, and marmosets showed that Ad36 increases adiposity (Dhurandhar 2002; Dhurandhar et al. 2000, 2001, 2002; Pasarica et al. 2006; Na and Nam 2012). About 60–100% of the animals experimentally infected with Ad36 develop obesity (adiposity >85th percentile) compared with the uninfected control group. Ad36 infected animals have about 35–60% greater adipose tissue mass, a level of fat gain which is very similar to that increased by many genetic models of obesity (Chida et al. 2006; Butler et al. 2000; Lang et al. 2008). In rodents, Ad36 infection showed significantly greater adiposity in just 4 days post inoculation (Pasarica et al. 2008a), which persisted even 6–7 months later (Pasarica et al. 2006; Dhurandhar et al. 2002). In chow-fed mice, the adipogenic effect of Ad36 is evident; however, in mice on 60% fat diet, Ad36 infection did not increase adiposity over that induced by the high fat diet in control mock, uninfected mice (Krishnapuram et al. 2011). Ad36 infection and obesity can be transferred from an infected set of animals to uninfected recipients, thus fulfilling a Koch's postulate (Dhurandhar et al. 2001).

Ad36 Improves Glycemic Control

Rats experimentally infected with Ad36 gained adipose tissue, yet improved systemic glycemic control by lowering fasting serum insulin levels compared to control, and improved insulin sensitivity as determined by lower HOMA-index (Pasarica et al. 2006). In chow-fed and high-fat-fed mice, Ad36 infection improved glycemic control by lowering fasting serum insulin levels (Krishnapuram et al. 2011). Ad36 in fact inhibited the proximal insulin signaling and yet, increased the distal insulin signaling leading to increased cellular glucose uptake (Fig. 7.1). In adipose tissue, skeletal muscle, and liver, Ad36 infection selectively activated the Ras-PI3K pathway (distal insulin signaling) by increasing the abundance of glucose transporters (GLUT 4 and GLUT 1) in skeletal muscle and adipose tissue and their translocation to the cell membrane. In the liver, Ad36 attenuated GLUT2 expression, which suggested reduced hepatic glucose release.

This in vivo finding supported the in vitro study which demonstrated reduced glucose release in Ad36-infected hepatocytes

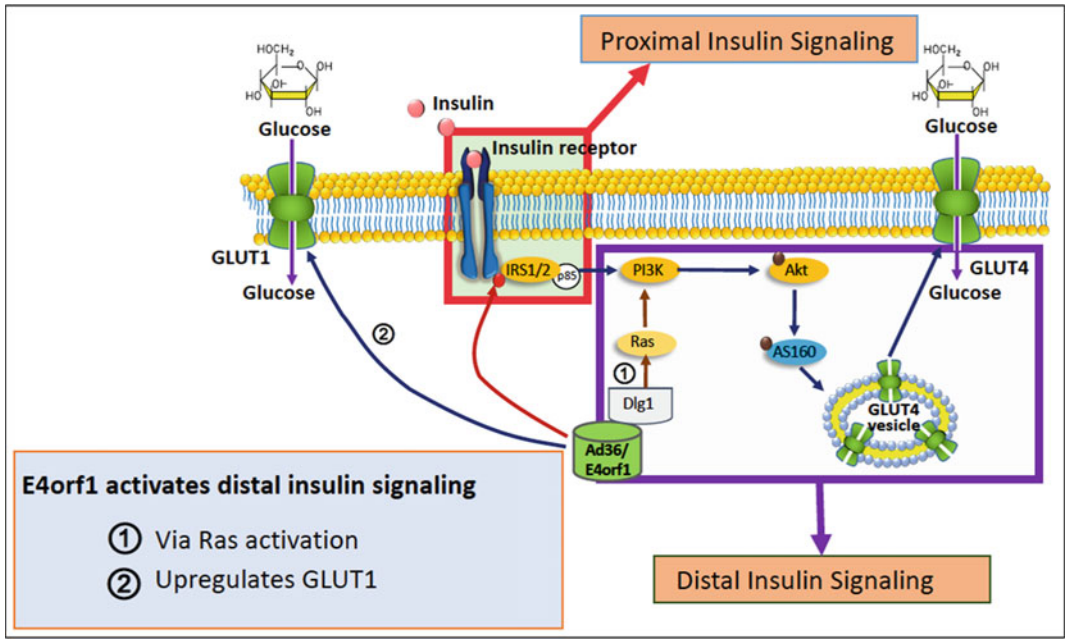

Fig. 7.1 Ad36/E4orf1 enhances cellular glucose uptake independent of insulin signaling. Ad36 and its E4orf1 protein increases cellular glucose uptake by increasing *GLUT1* and *GLUT4* gene expression and protein abundance, which appears to be mediated via *Ras*-activated *PI 3-kinase* pathway and independent of insulin signaling. More specifically, Ad36/E4orf1 expression blocks the proximal insulin signaling by increasing serine phosphorylation of insulin receptor and insulin receptor substrate 1/2 (IRS1/2), while increasing cellular glucose uptake by activating Ras/PI3K mediated phosphorylation of PKB/Akt leading to translocation of Glut4 from the cytoplasm to the cell membrane, collectively known as the distal insulin signaling

(Krishnapuram et al. 2011; Rogers et al. 2008a; Wang et al. 2008). Thus, Ad36 appears to improve systemic glycemic control by increasing cellular glucose uptake in skeletal muscle and adipose tissue, and by decreasing hepatic glucose output, thereby reducing circulating glucose levels. A similar signaling mechanism was observed when human skeletal muscle cells (HSKM) and adipose tissue explants were experimentally infected in vitro (Wang et al. 2008; Rogers et al. 2008b). Interestingly, Ad36-infected high-fat-fed mice significantly lowered hepatic lipid content and increased glycogen compared to control (Krishnapuram et al. 2011) indicating that Ad36 infection protects the liver from hepatic steatosis and inflammation. Ad36 reduced hepatic glucose release, lipogenesis, inflammation (downregulated inflammatory markers IL-6, INFγ, TNF-α), insulin resistance, and fibrosis and upregulated lipid oxidation and export in the livers of mice (Krishnapuram et al. 2011).

Mechanism of Ad36 Action

The adipogenic effect of Ad36 is evident in the visceral adipose tissue of Ad36-infected rats, showing 3–60-fold greater expression of adipogenic genes compared to that in uninfected rats matched for body fat (Pasarica et al. 2006). Studies revealed that Ad36 infects resident stem cells/stromal cells from adipose tissue and induces adipogenic commitment, replication, and differentiation in these cells leading to increased lipid accumulation (Rogers et al. 2008a; Vangipuram et al. 2004; Rathod et al. 2009; Pasarica et al. 2008b) (Fig. 7.2). Thus, Ad36 appears to increase adipose tissue

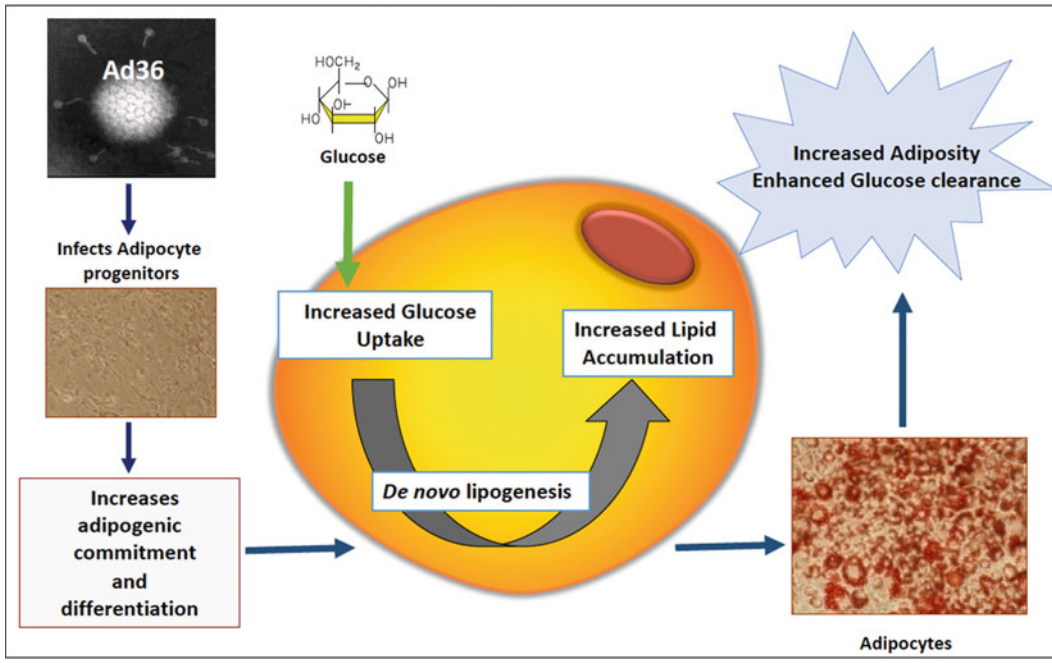

Fig. 7.2 Mechanism of Ad36 action. Ad36 infects resident stem cells/stromal cells (adipogenic progenitors) from adipose tissue and induces adipogenic commitment, replication, and differentiation in these cells, leading to increased glucose uptake, de novo lipogenesis, and lipid accumulation. Collectively this causes increased adiposity accompanied with enhanced glucose clearance

hyperplasia and hypertrophy to increase adiposity—a hypothesis that was indirectly tested in humans. Adipocyte progenitors obtained from human subjects had about eight-fold greater potential to differentiate into adipocytes, when the cells harbored Ad36 DNA in their adipose tissue, compared to their counterparts without the viral DNA (Pasarica et al. 2008b). This indicated an association of Ad36 infection with greater adipogenic potential in humans. Ad36 increases lipid accumulation only in the infected cells as observed in human adipose-derived stem cells (Pasarica et al. 2008b) (Fig. 7.3).

Adenoviral genes are divided into early genes, denoted by the letter E and late genes, denoted by the letter L. The early genes are transcribed earlier in virus replication, and the late genes are for structural proteins. The early gene 4 open reading frame 1 (E4orf1) of Ad36 was identified as to be necessary and sufficient for the Ad36 mediated induction of adipogenesis (Rogers et al. 2008a).

Virus-Induced Obesity: A Causative Role in Humans

Obesity has an insidious onset and progress, which makes it challenging to determine when an individual might have been infected. Also, obesity can have multiple etiological factors, which makes it difficult to identify one single cause. It is possible that for an individual, a combination of infection with other factors may be involved in obesity development. Lastly, while animal experiments convincingly demonstrated that Ad36 increases adiposity, experimental Ad36 infection of humans is not possible due to ethical considerations. For these reasons, it is challenging to establish a causative role for Ad36 in human obesity. Instead, a framework has been proposed to indirectly assess such a role of Ad36 (Dhurandhar 2011).

One key component is to test the hypothesis that humans who are naturally infected with Ad36

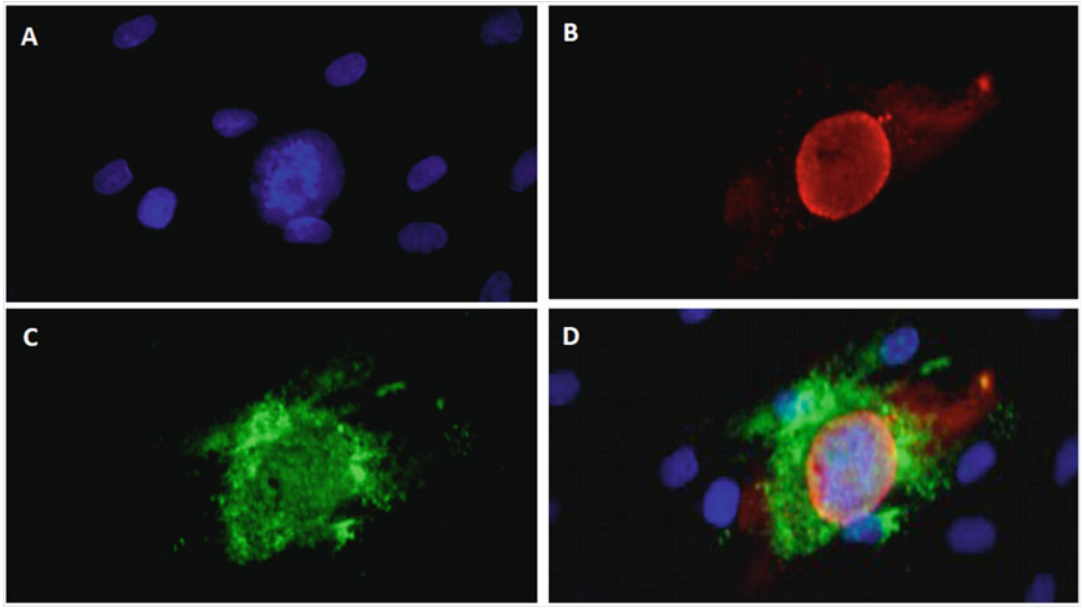

Fig. 7.3 Ad36 infection induces lipid accumulation in human adipose-derived stem/stromal cells (hASC). Lipid accumulation is observed specifically only in Ad36-infected hASC. (**a**) shows DAPI stain for nuclei of multiple cells (blue), and (**b**) Ad36 hexon protein antibodies are seen in one infected cell (red). (**c**) Lipid-specific BODIPY stain shows cellular lipid accumulation (green), (**d**) only in the Ad36-infected cell (merge) 6 days post inoculation

will exhibit a phenotype similar to that observed in animals that are experimentally infected with Ad36. In Ad36 infected animals, the major phenotypic changes include greater adiposity, yet better metabolic profile including lower serum cholesterol and triglycerides, better glycemic control, and less hepatic steatosis (Pasarica and Dhurandhar 2007; Pasarica et al. 2006; Na and Nam 2012; Krishnapuram et al. 2011). Interestingly, natural Ad36 infection appears to mirror associations with these phenotypes in humans. Nearly a dozen studies from Korea (Na et al. 2010, 2012), Italy (Trovato et al. 2009), and the United States of America (Dhurandhar 2011) have reported the association of Ad36 with overweight and/or obesity in adults and children. A study of 1400 Caucasian, Black, or Hispanic men, women, or children from four separate cohorts showed significantly better glycemic control and lower hepatic fat levels in individuals who were naturally infected with Ad36 (Krishnapuram et al. 2011). The association between Ad36 infection and obesity has been conclusively shown in a series of meta-analysis studies. Yamada et al. showed that Ad36 infection was positively associated with significantly higher BMI and obesity (Yamada et al. 2012). Two other meta-analysis studies with 5739 and 10,191 subjects respectively, also showed the association between Ad36 infection and increased risk of obesity (Xu et al. 2015; Shang et al. 2014).

Most twins share very similar body profiles due to their shared genetic makeup. Therefore, twins who are discordant for Ad36 infection could provide evidence about the possible adipogenic role of Ad36 in humans. Twins with natural Ad36 infection had significantly greater BMI and body fat, compared to their co-twins who were uninfected (Atkinson et al. 2005).

Associations do not establish causations. A 10-year follow-up of over 1400 Hispanic men and women, those who were naturally infected with Ad36 at baseline, showed significantly greater percent body fat at baseline and a

Table 7.1 Similarity between animal and human studies of Ad36

Experimental infection	Natural exposure in humans
(a) Adiposity and adipogenesis	(a) Obesity and greater body fat gain
(b) Better glycemic control	(b) Better glycemic control
(c) Less liver fat	(c) Less liver fat

significant gain in adiposity and better glycemic control over 10 years. Natural Ad36 infection was also positively associated with obesity but negatively associated with nonalcoholic fatty liver disease (NAFLD) in Italian populations (Trovato et al. 2009, 2010, 2012) (Table 7.1).

The implications for identifying and characterizing Ad36 induced obesity is that unique prevention and treatment strategies can be identified. Additionally, these strategies could be beneficial for the treatment of other adipogenic pathogens. For example, a long-term goal of this line of investigation is to develop a vaccine to prevent obesity that is specifically caused by Ad36 infection.

Exploiting the Antidiabetic Property of Ad36

In vitro studies identified E4orf1, a 125 amino acid protein of Ad36, as required and essential for the observed beneficial effects with Ad36. In vitro studies show that E4orf1 increases glucose uptake in pre-adipocytes, adipocytes, and myoblasts, while reducing glucose release from hepatocytes (Dhurandhar et al. 2011a). E4orf1 selectively bypasses the proximal insulin signaling and upregulates the distal insulin signaling pathway via increased expression of PI3K, PKB/AKT, and GLUT4 translocation to increase cellular glucose uptake (Na et al. 2016a; Shastri et al. 2018). Inflammatory cytokines generally impair glycemic control. However, E4orf1 improves cellular glucose uptake even in the presence of inflammatory cytokines (Na et al. 2016b). In hepatocytes, E4orf1 reduces glucose output and de-novo lipogenesis, increases complete fatty acid oxidation, and promotes lipid transport, which are considered the key determinants of hepatic lipid storage (Dhurandhar et al. 2012). Collectively, these in vitro studies show that E4orf1 can improve cellular glucose metabolism even in the presence of insulin resistance, impaired insulin signaling, and inflammation.

Cell signaling studies also indicated that E4orf1 reduces de-novo lipogenesis, and promotes fatty acid oxidation and the export of lipid from hepatocytes (Dhurandhar et al. 2012), which may explain its contribution to reduced hepatic steatosis in mice (McMurphy et al. 2017; Kusminski et al. 2015). Functionally, Ad36 or E4orf1 increase glucose uptake in preadipocytes, adipocytes, myocytes, and reduce glucose release from hepatocytes (Dhurandhar et al. 2011a, 2012; Krishnapuram et al. 2013; Na et al. 2013), which likely collectively contributes to better glycemic control induced by E4orf1 in vivo (McMurphy et al. 2017; Kusminski et al. 2015; Hegde et al. 2016).

Ad36 or E4orf1 robustly upregulate the expression of PPAR-gamma and adiponectin in adipocytes, which in turn may help enhance cellular glucose uptake (Rogers et al. 2008b; Dubuisson et al. 2011). However, E4orf1 is capable of enhancing cellular glucose uptake independently of peroxisome proliferator-activated receptor (PPAR) gamma (Dubuisson et al. 2011). Based on what was known about E4orf1 action and our findings, the molecular events that lead to E4orf1-induced glucose uptake can be surmised as follows (Dhurandhar et al. 2011a, b, 2012; Kusminski et al. 2015; Frese et al. 2003; Kong et al. 2014; Kumar et al. 2014): E4orf1 protein is synthesized in a cell, after Ad36 infection, hence it is unlikely to have a cell surface receptor. In its interaction with the insulin signaling pathway, it bypasses proximal insulin signaling, which includes the binding of insulin to its cell receptor and the signal transduction through tyrosine phosphorylation of insulin receptor substrates (IRS). In fact, E4orf1 inhibits the

proximal insulin signaling by reducing tyr-phosphorylation of IRS, and by increasing its ser-phosphorylation. Instead, E4orf1 enters insulin signaling at the level of phosphatidyl inositol 3-kinase (PI3K) activation.

E4orf1 has a PDZ domain-binding motif (PBM) at the C-terminal. Through its PBM, the peptide binds to PDZ proteins, which are scaffolding proteins that facilitate protein–protein interactions. E4orf1 requires its PBM to bind to Dlg (Drosophila disc large)-1 protein. After the binding, the complex travels to the cell membrane, where it activates Ras and subsequently, upregulates PI3K. E4orf1 requires intact PBM for Ras induction, and for the activation of PI3K-AKT signaling, leading to greater membrane translocation of Glut4, and glucose uptake (Fig. 7.1). This understanding prompted efforts to therapeutically exploit the properties of E4orf1.

Possibilities for Therapeutic Administration

Being an exogenous, virus-derived protein, E4orf1 does not have any endogenous cellular receptors, and delivering it in vivo is challenging. Hence, the efficacy of E4orf1 was tested in vivo using different approaches: (1) Retrovirus mediated expression, (2) Adeno-associated vector expressing E4orf1, and (3) Transgenic mice with adipose tissue-specific inducible expression of E4orf1. All three approaches conducted in separate laboratories improved glycemic control in mice models (McMurphy et al. 2017; Kusminski et al. 2015; Hegde et al. 2016).

Retrovirus-mediated expression of E4orf1 in mice reproducibly improved glucose clearance following a glucose challenge despite a high-fat diet (Hegde et al. 2016). Further, E4orf1 also improved tissue-specific molecular signaling in mice, mainly greater protein expression of adiponectin, p-AKT, and glucose transporter Glut4. Hepatic expression of AAV-E4orf1 in a genetic model of diabetes (db/db mice), dietary model of insulin resistance (DIO mice), and normoglycemic animals (wild-type mice), completely alleviated hyperglycemia and robustly improved glycemic control without significantly increasing liver fat accumulation or hepatic steatosis (McMurphy et al. 2016). Transgenic expression of E4orf1 in the adipose tissue of mice upon doxycycline induction improved glucose clearance, despite a high-fat diet challenge, by enhancing the Ras-ERK-MAPK signaling in transgenic adipocytes (Kusminski et al. 2015).

Glucose and insulin responses to glucose load were determined at the same time in these mice, which showed near lack of insulin response in the E4orf1 group, indicating that the enhanced glucose disposal by E4orf1 seems to reduce the need of endogenous insulin (Kusminski et al. 2015). This phenomenon is termed as the "*insulin sparing effect*" of E4orf1 (Dhurandhar 2013). Hydrodynamic gene delivery of E4orf1 with an adipocyte-targeting sequence (ATS-E4orf1) in the liver of high-fat-fed and streptozotocin-injected mice (disease models of type 2 and type 1 diabetes, respectively), improved the ability of these mice to eliminate excess glucose from the blood and ameliorate liver function in both disease models.(Yoon et al. 2017; Voss et al. 2015) Therefore, E4orf1 expression, systemic or tissue-specific, in mice improves glycemic control independent of high-fat diet intake and impaired proximal insulin signaling, by reducing insulin levels in vivo.

This highlights that E4orf1 is not an insulin secretagogue or insulin mimetic, rather it displays endogenous insulin sparing action to clear glucose. This insulin-independent ability of E4orf1and its protection of liver against lipid accumulation makes it a novel and effective therapeutic candidate for type 2 diabetes, type 1 diabetes, and NAFLD.

Summary

Either the E4orf1 protein itself or its small molecule analogs may be useful for developing as therapeutic agent(s) to improve hyperglycemia. An appropriate delivery mechanism, such as nanoparticle-mediated delivery of E4orf1 protein or small molecule analogs, is needed to effectively and specifically deliver E4orf1 to targeted tissues, in order to harness its therapeutic effects.

Contents

Abstract

Based on the genetic etiology, obesity could be divided into two main categories: polygenic and monogenic (syndromic and non-syndromic) forms. The polygenic form of obesity is caused by a combination of environmental factors and several genetic variants, with minor effects. The monogenic forms are caused by mutations in single genes with major effects. We focus on the recent advances and future perspectives in the field of genetic obesity, to provide a comprehensive review covering the underlying mechanisms involved in the development of obesity.

Introduction

Obesity can cause adverse health effects due to its association with several diseases, such as type 2 diabetes (T2D), hypertension, metabolic syndrome, cardiovascular diseases, and some cancers (Garvey et al. 2016; WHO 2019). These comorbidities associated with obesity contribute to reducing lifespan, and are responsible for three million deaths per year (Finucane et al. 2011; De Lorenzo et al. 2016).

Globally, 650 million adults and 124 million children and adolescents (aged 5–19 years) were obese in 2016. Currently, the global prevalence is 13% and will reach 20% by 2025, if the post-2000 trends continue (Garvey et al. 2016; WHO 2019). One of the major contributors to population weight gain is energy imbalance, caused by the ingestion of high-calorie foods that exceeds energy expenditure. However, not all subjects with obesogenic lifestyle develop this disorder, suggesting a strong genetic component (Pigeyre and Meyre 2018). The percentage of obesity that can be attributed to genetics ranges from 40 to 70%, according to previous studies using monozygotic and dizygotic twins (Wardle et al. 2008).

The etiology of obesity is extremely complex, being influenced by multiple interactions among environmental, hormonal, lifestyle, metabolic, nutritional, and genetic factors (De Lorenzo et al. 2016). Common forms of obesity are multifactorial and polygenic, caused by an interaction of environmental factors with multiple genetic variants with minor effects. However, rare monogenic forms were identified in humans and mice, which are caused by mutations with major effects in a single gene (Fig. 8.1) (da Fonseca et al. 2017). Several genes have been associated with human obesity, in which they could be related to either polygenic, monogenic, or both forms (Locke et al. 2015; Saeed et al. 2015; Hasnain 2016; Tunç et al. 2017).

Monogenic Obesity

Monogenic forms of obesity are caused by a loss-of-function mutation in a single gene (Albuquerque et al. 2015). These single-gene disorders result from variants of disturbing genes that encode receptors or ligands involved in appetite and satiety regulation as well as metabolism (da Fonseca et al. 2017). They can be divided into two different groups: syndromic obesity is usually associated with cognitive delay, dysmorphic characteristics and, organ-specific developmental abnormalities; whereas monogenic non-syndromic obesity is associated with intense hyperphagia, early-onset severe obesity and in some cases neuroendocrine dysfunctions. These forms can have a Mendelian autosomal (dominant and recessive) or X-linked inheritance (Pigeyre and Meyre 2018). Although monogenic forms of obesity are rare in humans, the identification of affected individuals allows for personalized clinical management, genetic counseling and, in some cases, specific pharmacological therapy.

Homeostatic Pathways Involved in the Regulation of Appetite and Satiety

In the early 1900s, clinical and experimental studies have postulated the involvement of the hypothalamus in the regulation of satiety, appetite, and body weight. Firstly, mice and cats were submitted to chemical and electrical experiments that damaged their hypothalamus, which result in an increase or loss of bodyweight depending on the size and region of the lesion (Hetherington and Ranson 1940; Anand and Brobeck 1951). In humans, patients with brain tumors in the hypothalamic area can become obese (Daousi et al. 2005). Later, the existence of a specific system in the hypothalamus that can regulate energy homeostasis called leptin-melanocortin pathway was discovered (Fig. 8.2) (Cone 2005; Morton et al. 2006; Larder et al. 2014).

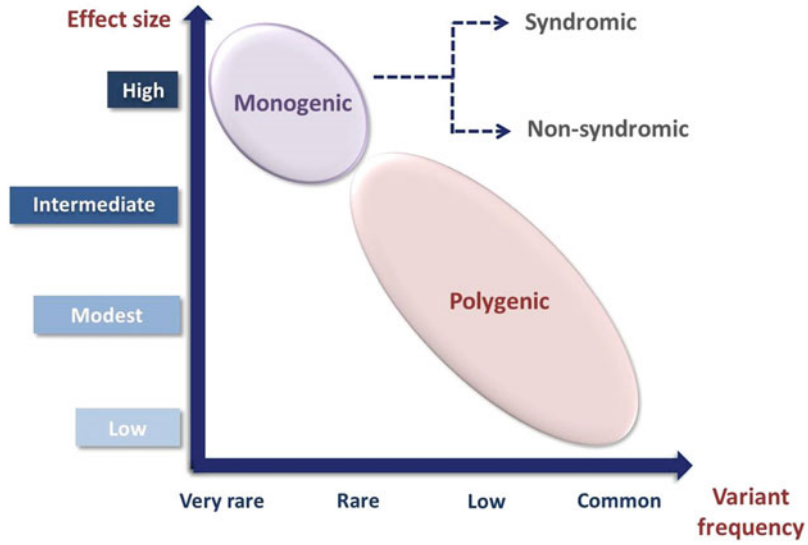

Fig. 8.1 Polygenic obesity occurs due to a combination of multiple genetic variants with common, low, and rare frequency that have to low up to intermediate effect. However, monogenic obesity is caused by rare or very rare mutations with high effects

The brain controls energy balance through obtaining information about the energy stock by peripheral hormones, and then it is used to regulate the neuronal circuit into the hypothalamus (Cone 2005; Larder et al. 2014). During fasting and low energy stock, the stomach secretes ghrelin that binds to its receptor in the orexigenic neurons, stimulating the expression of neuropeptide Y (NPY) and agouti-related protein (AgRP). Orexigenic neurons project from the arcuate nucleus (ARC) to the paraventricular nucleus (PVN) of hypothalamus, stimulating food intake, and suppressing energy expenditure (Cone 2005; Vetter et al. 2010; Sutton et al. 2016). However, leptin is secreted by white adipose tissue when the body accumulates adiposity and/or energy replacement occurs. It crosses the blood–brain barrier and binds to leptin receptor (LEPR), localized in the ARC.

Leptin acts suppressing NPY and AgRP expression as well as inducing the proopiomelanocortin (POMC), cocaine, and amphetamine-related transcript production in anorexigenic neurons (Vetter et al. 2010; Albuquerque et al. 2015; da Fonseca et al. 2017). POMC is cleaved and processed by prohormone convertase 1/3 (PC1/3, encoded by proprotein convertase subtilisin/kexin type 1 [*PCSK1*] gene), which produces α-melanocyte-stimulating hormone (α-MSH) (Freemark 2018). These products bind to the melanocortin-4 receptor (MC4R) in the PVN, resulting in a decreased energy intake and an increased basal energy expenditure (Vetter et al. 2010; Larder et al. 2014; da Fonseca et al. 2017; Freemark 2018). Interestingly, genetic variants involved in leptin-melanocortin pathway have been associated with the development of severe early-onset obesity (Wabitsch et al. 2014; Saeed et al. 2015; da Fonseca et al. 2019b).

Non-syndromic Form of Obesity

Over the past two decades, a large number of different genetic variants in the ligands or receptors, which disrupt the signaling of the leptin-melanocortin pathway were identified, resulting in hyperphagia, severe obesity in early childhood and in some cases, endocrine and immune disorders (Asai et al. 2013; Tunç et al. 2017). All these mutations were found in thirteen genes, including *LEP*, *LEPR*, *POMC*, *PCSK1*, and *MC4R* (Table 8.1). The non-syndromic form of obesity can affect up to 2–5% of the severely obese subjects and is transmitted under Mendelian autosomal recessive or dominant category

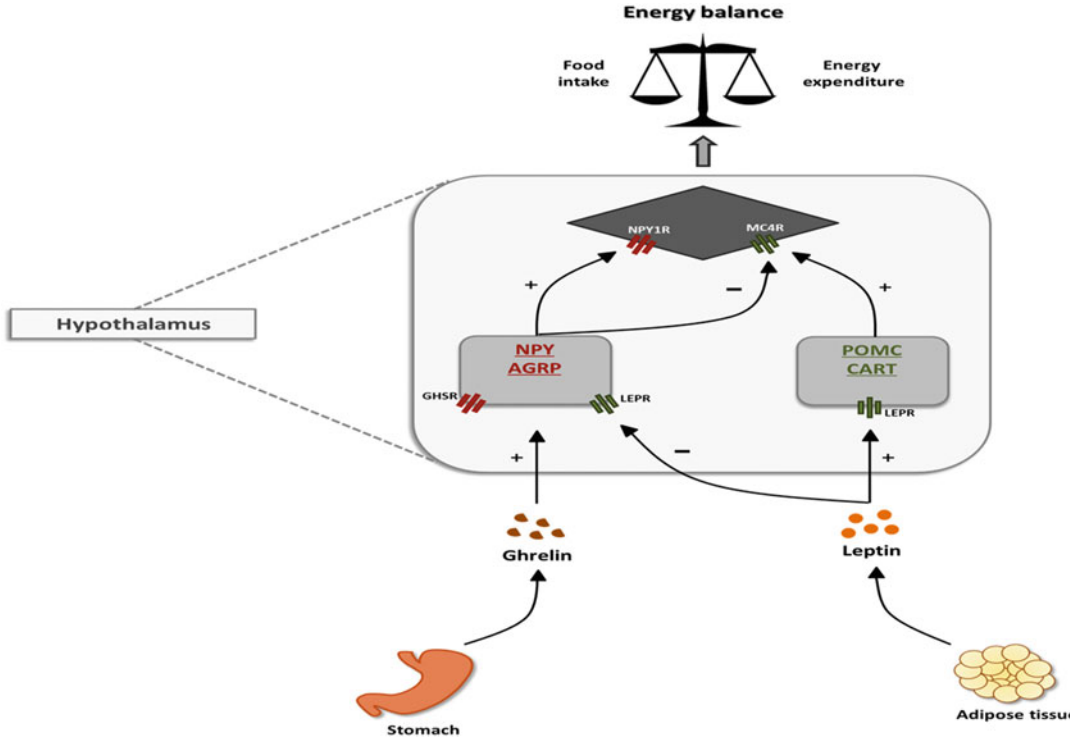

Fig. 8.2 Schematic presentation of hypothalamic leptin-melanocortin pathway. Leptin is secreted by adipose tissue and binds to its receptor located in two sets of neurons in the arcuate nuclei of hypothalamus. Leptin activates the anorexigenic pathway and inhibits orexigenic system, resulting in decreased food intake and increased basal energy expenditure. In contrast, ghrelin is produced by stomach and activates the orexigenic neurons, increasing the caloric intake and suppressing the energy expended. LEPR, receptor of leptin; GHSR, growth hormone secretagogue receptor; NPY, neuropeptide Y; AGRP, agouti-related protein; NPY1R, neuropeptide Y receptor Y1; POMC, proopiomelanocortin; CART, cocaine and amphetamine-related transcript; MC4R, melanocortin-4 receptor

(da Fonseca et al. 2017; Freemark 2018; Saeed et al. 2018).

Leptin Gene Aberrations

Congenital leptin deficiency (OMIM#614962) is a very rare autosomal recessive disorder caused by homozygous mutation in *LEP* gene on chromosome 7q31.3. In 1997, Montague and collaborators described for the first time a human leptin deficiency caused by a frameshift homozygous mutation (c.398delG; p. Gly133_fs*14). This variant was identified in two severely obese children who are cousins, within a highly consanguineous family of Pakistani origin. The same mutation was reported in another two children of Pakistani origin but unrelated to the earlier found patients (Farooqi et al. 2002; Gibson et al. 2004). Eleven other pathogenic mutations have since been reported. These genetic variants were identified in patients from consanguineous families in Colombia, Pakistan, German, Turkey, India, and Egypt and from a non-consanguineous family in Austria. With the exception of two mutations (p. Asn103Lys and p.Arg105Trp), all pathogenic *LEP* variants found are population specific and have not been identified in other ethnic groups (Saeed et al. 2015; Hasnain 2016).

To date, less than 50 subjects have been described to be homozygous for loss-of-function mutations in *LEP* gene. These patients usually exhibit very low or undetectable leptin levels

Note: *NA*, not available

into the circulation as a result of impairment in either synthesis or secretion of this adipocytokine (Saeed et al. 2015; Hasnain 2016). However, Wabitsch and collaborators (2014, 2015) described three probands carrying different homozygous *LEP* mutations (p.Asp100Tyr and p.Asp103Lys) with hyperleptinemia. In these cases, the mutant leptin is produced and secreted but is not functional.

Leptin Receptor Disorders

Leptin receptor deficiency (OMIM#614963) is another autosomal recessive disorder, caused by homozygous/compound heterozygous mutations in *LEPR* gene on chromosome 1p31. Clement and collaborators (1998) reported the first cases of *LEPR* deficiency in three siblings with early-onset morbid obesity from a consanguineous family of Kabilian origin (north of Algeria). After that, several *LEPR* pathogenic mutations have been reported in probands from European, Egyptian, Pakistani, and Turkish origin (Gill et al. 2014; Saeed et al. 2014, 2015; Huvenne et al. 2015).

Gill et al. (2014) have performed whole-exome sequencing in five individuals with extreme obesity of four consanguineous families (four probands and one affected sibling). They identified two novel *LEPR* frameshift mutations (p.His160Leufs*9 and p.Cys186Alafs*27), resulting in a truncated receptor that lacks the domain required for leptin signal transduction. Interestingly, one novel large deletion was observed in six unrelated subjects with early-onset morbid obesity from Reunion Island (Indian Ocean, France), suggesting a founder effect. Due to the high frequency of this large deletion, a quantitative real-time PCR was developed to detect heterozygous carriers in this population (Huvenne et al. 2015).

Clinical Profile

Since *LEPR* deficiency also disrupts leptin signaling, clinical hallmarks of affected patients are similar to those with homozygous *LEP* mutations. These patients had typical features including severe early-onset obesity, hyperphagia, hypogonadotropic hypogonadism, impaired immune system, and neuroendocrine/metabolic dysfunction (Le Beyec et al. 2013; Gill et al. 2014).

Selected LEP-deficient probands could be pharmacologically treated with recombinant leptin (metreleptin/Myalept), leading to reduction in food intake, fat mass, and metabolic and endocrine abnormalities (Wabitsch et al. 2014; Roth et al. 2018). However, the drug is not approved for this indication, just for lipodystrophy.

LEPR deficiency patients usually have elevated circulation leptin concentrations, reflecting the loss of sensitivity of the receptor. There is no evidence that metreleptin could be useful; however, Setmelanotide is currently undergoing advanced clinical trials for such indication, reportedly meeting all defined endpoints (Globenewswire.com 2019).

The Melanocortin Pathway

Proopiomelanocortin Gene

Similarly to *LEP* and *LEPR*, rare pathogenic mutations described in *POMC* and *PCSK1* were associated with severe early-onset obesity, transmitted under Mendelian autosomal recessive. *POMC* gene is located on chromosome 2p23.3 and encodes a complex pro-peptide which is processed post-transcriptionally to produce several bioactive peptides (adrenocorticotropin [ACTH], β-endorphin, and α-,β-, γ- MSH). These peptides bind to melanocortin receptors and act on energy balance, skin pigmentation, adrenal steroidogenesis, and thermoregulation. Alpha- and beta-MSH activate MC3R and MC4R as well as antagonize the action of AgRP, involved in the control of satiety and appetite (Cawley et al. 2016). Homozygous or heterozygous pathogenic mutations have been reported in 17 probands from Netherland, Slovenian, German, Switzerland, Indian, Turkish, Iraqi, and Hispanic origins (Anisimova et al. 2016; Ozsu and Bahm 2017; Çetinkaya et al. 2018).

The first cases of severe obesity due to POMC deficiency (OMIM#609734) were observed in two unrelated children from Germany. The first proband carried compound heterozygote variants

(c.433delC and c.313G>T), which disrupt the corrected synthesis of ACTH and α-MSH, and the second proband was homozygous for a mutation in the splice site (c.-11C>A) that eliminates POMC translation. Both children presented severe early-onset obesity, adrenal insufficiency, and red hair pigmentation. Later, the same group described three new cases with similar clinical phenotype (Krude et al. 2003). The hypopigmentation is due to inadequate activation of MC1R by POMC peptides in the skin. However, Farooqi et al. (2006) identified a novel *POMC* homozygous frameshift mutation (c.206delC) in a 2-year-old male proband with severe obesity, hypocortisolism, and brown hair with dark red roots. This result suggests that patients with severe early-onset obesity and adrenal insufficiency should be evaluated to *POMC* mutations even in the absence of red hair pigmentation (Mendiratta et al. 2011). Despite POMC deficiency being a rare disorder, several studies have reported that the defective allele in the heterozygous state may contribute to the obesity susceptibility (Farooqi et al. 2001; Challis et al. 2002; Lee et al. 2006; Samuels et al. 2013).

Proprotein Convertase Gene

Congenital proprotein convertase (PC1/3) deficiency (OMIM#600955) is caused by loss-of-function mutations in the proprotein convertase subtilisin /kexin type 1 (*PCSK1)* gene located on chromosome 5q15 (Frank et al. 2013; Martín et al. 2013; Härter et al. 2016). PC1/3 is a member of the serine endoproteases family, which is expressed in endocrine and neuronal cells. In the hypothalamus, PC1/3 is involved in the POMC processing, which results in the production of α-MSH (Smith and Funder 1988; Tao 2005; Vetter et al. 2010). Homozygous and compound heterozygous mutations in the *PCSK1* gene were described in several patients with hyperphagia, severe malabsorptive diarrhea, central diabetes insipidus, growth hormone deficiency, primary hypogonadism, and other endocrines abnormalities (Frank et al. 2013; Martín et al. 2013; Wilschanski et al. 2014; Härter et al. 2016). The functional consequences of *PCSK1* mutations may have an important role in the severity and variety of the clinical phenotype (Martín et al. 2013). Interestingly, Philippe et al. (2015) reported a novel nonsense heterozygous mutation in *PCSK1* that was co-segregate with obesity in a French family, following a dominant mode of inheritance. Therefore, rare pathogenic mutations in *PCSK1* may be associated with an autosomal dominant or recessive form of Mendelian obesity (Martín et al. 2013; Philippe et al. 2015).

Melanocortin Receptor Genes

Melanocortin 4 receptor (MC4R) deficiency (OMIM#618406) is the most common cause of non-syndromic monogenic obesity. This disorder is caused by heterozygous, heterozygous compound, and homozygous deleterious variants in *MC4R* gene, located on chromosome 18q21.32 (Doulla et al. 2014; da Fonseca et al. 2017; Drabkin et al. 2018). Several rare pathogenic variants were identified in the *MC4R* gene, which could lead to partial or complete loss of receptor function (Collet et al. 2017). *MC4R* variations are inherited in an autosomal codominant model, with a high degree of expressivity and penetrance in heterozygous carriers (Farooqi et al. 2003; Farooqi 2015). Previous studies have reported that patients with heterozygous mutations have a less severe phenotype compared to homozygous carriers (Farooqi et al. 2003; Drabkin et al. 2018). *MC4R* is expressed in the PVN and is the receptor for α-MSH, regulating appetite and satiety. Consistent with this role, loss-of-function *MC4R* variants are associated with hyperphagia and severe early-onset obesity. Moreover, some patients can also exhibit severe hyperinsulinemia and increased linear growth (Farooqi et al. 2003; Melchior et al. 2012; Doulla et al. 2014; da Fonseca et al. 2019b).

Recently, our group described for the first time a Brazilian case with *MC4R* start lost mutation (p. Met1?). This variant was identified in a 29-years-old female patient with childhood-onset obesity, moderate binge-eating disorder, and high caloric intake (4900 calories per day) (da Fonseca et al. 2019b). Since pharmacological agents are being

developed to treat patients with MC4R deficiency, it is extremely important to assess the sequence of this gene in severe early-onset obesity individuals in order to identify pathogenic variations that would benefit from this treatment (Chen et al. 2015; Collet et al. 2017).

Setmelanotide has entered two phase III clinical trials in 2017, including pro-opiomelanocortin (POMC) deficiency obesity, besides leptin receptor (LEPR) deficiency obesity, with encouraging results (Globenewswire.com 2019).

Other Genes

Besides MC4R protein, BDNF haploinsufficiency has also been associated with severe early-onset obesity. This protein is a member of the nerve growth factor family, involved in the proliferation, survival, and differentiation of neurons (Tapia-Arancibia et al. 2004). A previous study has also indicated that BDNF acts on leptin-melanocortin pathway and may be a downstream target of MC4R signaling (Xu et al. 2003). Gray et al. (2006) reported a child harboring a de novo chromosomal inversion (46, XX, inv (11) (p13p15.3), which disrupts one copy of *BDNF* gene located on chromosome 11p13. Additionally, deletion of entire *BDNF* gene in a mother and a child were associated with severe obesity and developmental delay (Harcourt et al. 2018). However, data regarding point pathogenic mutations in the *BDNF* are scarce in the literature. Recently, Serra-Juhé et al. (2019) have analyzed 463 severe early-onset obese patients and 480 controls from the Spanish population. They identified three rare variants in four patients and none in normal-weight individuals. Two of these mutations were predicted to be pathogenic (p. Ile123Val and p.Cys141Gly) by in silico analyses. These probands presented obesity and mild to severe hyperphagia. Two of these patients also exhibited liver steatosis and insulin resistance with dyslipidemia. None of them showed congenital and behavioral issues.

Syndromic Form of Obesity

Syndromic forms of obesity are used to describe obese subjects with particular phenotypes, such as mental retardation, dysmorphic features, and organ-specific developmental abnormalities. At least four rare syndromes are associated with severe hyperphagia and obesity, caused by chromosomal abnormalities and genetic variations in genes that are involved in appetite and satiety control, suggesting an origin at the level of the central nervous system (Bell et al. 2005). Syndromic obesity includes Prader Willi (OMIM#176270), Bardet-Biedl (OMIM#209900), Alstrom (OMIM#203800), and Cohen (OMIM#216550) syndromes (Albuquerque et al. 2015). The genetic basis of these syndromes is extremely heterogeneous, and may be inherited in either an autosomal dominant or a recessive fashion.

Prader Willi Syndrome

Prader Willi syndrome (PWS) is the most common form (1 in 10,000–15,000 live births), affecting an estimated 350,000–400,000 individuals in the world (Irizarry and Haqq 2018). PWS is an autosomal dominant disorder characterized by peculiar facial features, infantile hypotonia, hypothalamic hypogonadism, short stature, mild mental retardation, and behavioral problems and hyperphagia resulting in severe obesity. Most of the cases are caused by a paternally inherited deletion at the chromosomal region 15q11–q13 (~70%) and less frequently by maternal uniparental disomy 15 (~20–30%). Additionally, rare cases (~5%) are affected by imprinting defects and chromosome 15 translocations or rearrangements (Bell et al. 2005; Butler 2011; Irizarry and Haqq 2018).

The responsible gene(s) for PWS development as well as hyperphagia and obesity phenotype in these patients is still unknown, though several candidate genes have been reported. Interestingly, patients with PWS exhibit high plasma levels of ghrelin at any age, suggesting an interaction among increased appetite, obesity, and leptin-melanocortin pathway (Feigerlová et al. 2008).

However, ghrelin-reducing agents do not diminish hyperphagia or body mass in subjects with PWS (De Waele et al. 2008). Recently, Burnett and colleagues performed an elegant study showing that neuroendocrine PWS-associated phenotypes may be a result of reduced expression of prohormone convertase 1, which impacts on the processing of proinsulin, pro-GH releasing hormone and proghrelin (Burnett et al. 2017). Further studies are necessary to clarify the role of PC1 in PWS cases.

Bardet–Biedl Syndrome

Bardet–Biedl syndrome (BBS) is a rare disorder (1 in 125,000–160,000 in Europe) characterized by early-onset obesity, progressive rod-cone dystrophy, polydactyly, learning disabilities, progressive renal dysfunction, hypogonadism, and genital abnormalities (Irizarry and Haqq 2018). It has a typically a autosomal recessive inheritance, but some families may have a triallelic mode of transmission (i.e., interaction of two or more *loci*) (Beales et al. 2003; Khan et al. 2016). BBS is a genetically heterogeneous disorder caused by mutations in at least 19 *loci* (also called BBS genes), all of which have a key role in ciliary development or intraflagellar transport (Fan et al. 2004; Khan et al. 2016; Irizarry and Haqq 2018).

Previous functional studies in single-cell organisms have shown that certain BBS genes are specific to ciliated cells, which are important for mammalian development, contributing to correctly position the organs in the body. Dysfunction in these ciliated cells may explain the alterations in pigmentary epithelial and structural abnormalities; however, the exact mechanisms leading to the obesity phenotype are still unknown (Irizarry and Haqq 2018). Experimental studies have shown that BBS mice are leptin resistant with decreased expression of POMC, suggesting that BBS genes may have an important role in maintaining leptin sensitivity in POMC neurons localized into the hypothalamus. These results might suggest that BBS genes can impact on the anorexigenic pathway leading to hyperphagia and obesity (Rahmouni et al. 2008).

Alstrom and Cohen Syndrome

Alstrom syndrome (AS) is an extremely rare autosomal recessive disorder caused by mutations in the *ALMS1* gene on chromosome 2p13. As cases exhibit progressive cone-rod dystrophy leading to juvenile blindness, sensorineural hearing loss, and early-onset obesity (Maffei et al. 2017). Screening for *ALMS1* gene in these affected patients showed a strong clustering of pathogenic mutations in exons 8, 10, and 16. Moreover, the majority of disease-causing mutations were nonsense or frameshift, which result in premature protein truncation (Irizarry and Haqq 2018). Similar to BBS, AS is caused by mutations disrupting neuronal cilia function, which may impact on appetite and satiety responses (Davenport et al. 2007).

Finally, Cohen syndrome is also an autosomal recessive disease caused by mutations in *COH1* gene (also called *VPS13B*) located at chromosome 8q22 (Albuquerque et al. 2015). This gene encodes a transmembrane protein that has an important role in the development and function of eye, hematological system, and central nervous system. The mechanism by which abnormalities in this protein lead to the Cohen syndrome phenotype is still unknown; however, the affected patients show mental retardation, obesity, hypotonia and craniofacial, ocular, and limb abnormalities. Pathogenic mutations in *COH1* are rare around the world, but it is overrepresented in some populations, such as Finnish, Japanese, Caucasian, and Jewish (Rodrigues et al. 2018).

Polygenic or Common Obesity

The common form of obesity is multifactorial and polygenic, caused by an association between environmental factors and multiple genetic variants that have a slight effect on body weight. Several approaches have been used to find genetic variants associated with obesity or obesity-related traits, particularly genome-wide association study (GWAS). This approach evaluates a huge number of polymorphisms across the genome in a large

sample and through statistical analysis, it allows identifying the loci associated with shifts of BMI or other anthropometric measurements (for example, the waist–hip ratio [WHR]) (Albuquerque et al. 2015; da Fonseca et al. 2017). To date, GWAS discovered more than 100 obesity-associated loci, in which genetic variants explain only a small portion of heritability in obesity (Speliotes et al. 2010; Locke et al. 2015; Wu et al. 2018).

Recently, Wu et al. (2018) performed GWAS for BMI and WHR using 242 monozygotic and 140 dizygotic twin pairs. A total of 291 loci were nominally associated with BMI-WHR, playing an important role in different pathways, such as homeostasis, olfactory transduction, and platelet production. Despite the robust studies and the vast number of obesity-associated loci, most of the genetic variability in BMI remains unexplained.

Relevant Candidates

Among the loci identified by GWAS, *FTO* gene has been consistently associated with obesity in different populations (Frayling et al. 2007; Albuquerque et al. 2013; da Fonseca et al. 2019a). FTO is a nucleic acid demethylase that has an important role in energy homeostasis, suggesting that this enzyme influences obesity at the epigenetic level (Gerken et al. 2007). Interestingly, polymorphisms in the intron 1 of *FTO* may have an effect on appetite/satiety, food choices, expended energy, and body weight (McCaffery et al. 2012; Qi et al. 2014; Magno et al. 2018; Rivas et al. 2018). Additionally, several common genetic variants of *BDNF* gene were associated with obesity or obesity-related traits (Beckers et al. 2008; Thorleifsson et al. 2009; Speliotes et al. 2010). A polymorphism (rs4074134) near *BDNF* gene was associated with the reduction of BMI and waist circumference in the Northern Han Chinese ancestry (Han et al. 2013). This polymorphism was also associated with obesity in the Japanese population; however, this result was not observed in a Brazilian population (Hotta et al. 2009; da Fonseca et al. 2019a). The discrepancy of the results may be explained by differences in the genetic background of the populations.

Besides *FTO* and *BDNF*, GWAS have also identified other obesity-associated loci that are expressed or known to act in the central nervous system, involved in regulation of food intake and energy expenditure. Several of these genes have been previously associated with severe early-onset obesity (*MC4R*, *POMC*, *SH2B1*, and *BBS4*), suggesting an overlap of the genetic background between monogenic and polygenic form of obesity (Speliotes et al. 2010; Locke et al. 2015).

Ongoing Studies and Future Perspectives

The use of genetic knowledge to predict subjects at high risk of developing obesity, especially in an obesogenic environment, may be useful in preventing this disease (Srivastava et al. 2016). Currently, patients with suspicion of monogenic obesity (syndromic and non-syndromic) can be screened based on diagnostic hypothesis using chromosomal microarray analysis, candidate gene sequencing, whole genome/exome sequencing, conventional cytogenetic, and/or fluorescence in situ hybridization. Theses analyses can contribute to identifying the causal variants allowing molecular diagnosis, clinical management, genetic counseling, and in some cases, specific treatment (Pigeyre et al. 2016).

Obesity treatment based on genotype (personalized medicine) is being pursued in patients with congenital leptin deficiency, and especially leptin receptor deficiency. caused by pathogenic mutations in *LEPR* gene.

The MC4R agonist (Setmelanotide) has been shown to decrease food intake and body weight in patients POMC deficiency as well. This agonist binds to MC4R in these patients, replacing the missing αMSH activity in the leptin-melanocortin system (Kühnen et al. 2016; Collet et al. 2017). Kühnen et al. (2016) have treated two POMC deficient subjects using subcutaneous injection of setmelanotide. Both patients showed a

substantial reduction in hunger and weight loss (patient 1: 51.0 kg after 42 weeks; patient 2: 20.5 kg after 12 weeks), improving their quality of life. In addition, setmelanotide can also reduce body weight in MC4R deficient patients (on average 0.6 kg/week). It is speculated that setmelanotide may be effective in treating other genetic obesity disorders, including PCSK1 deficiency and Prader-Willi syndrome (Kühnen et al. 2016).

The Upstream Environment for the Obesity Epidemic

9

Peter Congdon

Contents

Abstract

While individual behaviour and genetics are major risk factors for obesity, for health prevention it is important also to consider upstream influences on obesity, stemming from the urban physical and social environment. Environmental features such as urban sprawl, food deserts, and varying access to exercise and greenspace, affect both activity and diet, and hence bodyweight. Thus many studies show environmental impacts on obesity, and on related outcomes such as diabetes, with these impacts being socially and spatially differentiated: with worse food and exercise access in lower income areas. Analytical frameworks for the obesity epidemic should reflect wide geographic differences in incidence and prevalence between regions and small areas, including spatial clustering. A case study of changing obesity in US counties shows widening inequalities and persistently high obesity clustering in some regions.

Introduction: The Obesity Epidemic

The obesity epidemic continues across the world, and is now recognised as a major public health issue, though this recognition is only relatively recent (James 2009). In the United States, the prevalence of obesity in 2015–2016 was 40%, affecting about 93 million adults, though the upward trend is irregular (Flegal et al. 2012). The trend extends to the third world, with an estimating doubling in global obesity levels since 1980 (Bhurosy and Jeewon 2014; Fox et al. 2019). Obesity is a major risk factor for cardiovascular disease, diabetes, and hypertension, and hence a major factor for increased health care costs (Biener et al. 2017).

While genetic factors, possibly linked to ethnicity, and adverse health behaviours, influence susceptibility to obesity (Stryjecki et al. 2018; Riveros-McKay et al. 2019), they cannot in themselves account for the rapid increases in obesity. Instead, behavioural changes linked to changes in the food and exercise environments are also relevant to increased obesity (Faith and Kral 2006; Caballero 2007; Cummins and Macintyre 2006; Egger and Swinburn 1997). Physical activity is declining, and sedentary behaviour increasing, both in developed societies, and lower and middle-income countries (Gaskin and Orellana 2018). Dietary changes, such as growing fast food consumption and the "nutrition transition" (Popkin 2015) are also relevant.

Comorbidities of Obesity

Obesity is a risk factor for increased morbidity and mortality, particularly for cardiovascular disease, diabetes, and hypertension, but also for cancer and other chronic diseases, including liver and kidney disease and osteoarthritis. The impact of obesity and overweight on health and mortality is recognised in disease burden studies (Must et al. 1999).

Regarding overall mortality, there is some debate about the impacts of overweight (BMI 25–<30) and grade 1 obesity (BMI 30–<35), with Flegal et al. (2013) reporting excess mortality only at obesity grades 2 and above. However, the study by the Global BMI Mortality Collaboration (2016) reports no mortality benefit from any grade of overweight or obesity, and finds a log-linear increase in mortality as BMI increases compared to a reference BMI of 20–25.

Among the diseases linked to obesity, the recent spread of diabetes has been most evident, and like obesity has been characterised as an epidemic (e.g. Zimmet 2017; Unnikrishnan et al. 2017). The diabetes epidemic affects low and middle-income countries, such as India and China, as well as higher-income developed societies. In the United States, around 9% of adults (or 30 million) have diabetes according to a report by CDC (2017), and similar levels are reported in China (Yang et al. 2010) and India (Health Issues India 2019). In LMIC countries diabetes is generally higher in urban settings, and hence is associated with urbanisation (Gassasse et al. 2017; Ramachandran et al. 1999).

The impact of obesity on the risk of diabetes, particularly type 2 diabetes (T2D), is well-established, though diabetes is multifactorial, and many other risk factors than obesity or BMI per se are relevant. For example, among normal-weight subjects, diabetes incident risk is especially related to waist size (Carnethon et al. 2012). Population ethnic composition is also relevant to variations of diabetes risk. Thus raised diabetes risk among south Asian groups has been attributed to increased insulin resistance, even adjusting for adiposity (McKeigue et al. 1991). There is also increased research on diabetes risk through epigenetic changes that can be transmitted from one generation to another thus reinforcing increases in diabetes.

Despite such qualifications, the majority of T2D subjects are obese, and higher obesity grades elevate the risk of diabetes, as does longer established obesity. Abdullah et al. (2010) report

an overall relative risk (RR) of 7.2 for diabetes among obese persons compared to those of normal weight, and for overweight a RR of 3.0. Among different obesity indices, the waist-to-height ratio may offer better predictions of diabetes risk than waist circumference or BMI (Ashwell and Browning 2011). Potential biophysical mechanisms include:

- Abdominal obesity causing fat cells to release pro-inflammatory reducing sensitivity to insulin.
- Obesity triggering metabolic changes that cause adipose tissue to release increased amounts of fatty acids, glycerol, hormones, and pro-inflammatory cytokines involved in developing insulin resistance.

Environment and Obesity

A major research effort has focused on the impacts on obesity of the urban built environment and its obesogenic aspects. Thus Cummins and Macintyre (2006) refer to the "over-emphasis on the role of individual health behaviours, which has tended to ignore the influence of the complex social and physical contexts in which individual behavioural decisions are made. Such critiques have led to a new focus on 'environmental' exposures that encourage excessive food intake and discourage physical activity". Environmental exposures are partly invoked to explain wide contrasts in obesity prevalence between income groups. Prominent themes in this work are the impacts of urban sprawl, of food deserts and access to healthy food outlets, and of inequity in access to exercise opportunities.

Sprawl

Impacts of the built environment on both physical activity and diet have been framed, especially in terms of neighbourhoods with high walkability and connectivity, as opposed to car-dependent environments associated with urban sprawl. Sprawl relates to land use patterns associated with recent suburban car-dependent development, though the concept has many facets and varying definitions. Thus a literature and conceptual review of sprawl by Galster et al. (2001) found no common definition and relatively few attempts at operationalisation. These authors posit eight distinct dimensions: density, continuity, concentration, clustering, centrality, nuclearity, mixed uses, and proximity.

Thus sprawl is generally characterised as low-density suburban development, with low connectivity, car dependence, low walkability, and discouraged physical activity. This land-use pattern is distinct from that in more central city areas, or in compact mixed-use development, with relatively high connectivity and walkability, and high levels of active commuting (Kashef 2011). As examples of land-use effects on obesity (and diabetes), Creatore et al. (2016) find adverse trends in these outcomes in less walkable Ontario neighbourhoods over the period 2001–2012, but no such trends in the most walkable neighbourhoods; while Flint and Cummins (2016) find obesity linked to car-only commuting.

Food Access

The food environment and access to healthy food outlets are another feature of the urban environment that has been linked to growing obesity, and also to sprawl (Mead 2008; Hamidi 2019). Food type is relevant to the concept of food deserts, typified as areas with low access to supermarkets, and hence to fresh fruit and vegetables, and more likely to be deprived or ethnic majority areas (Fleischhacker et al. 2011). For example, Larsen and Gililand (2008) find low-income residents of inner-city neighbourhoods in London (Ontario) had poorer access to supermarkets than high-income residents, and that inequalities in access to supermarkets had increased.

A concomitant concept is that of "food swamps" (Cooksey-Stowers et al. 2017) whereby low-income areas have food access biased to fast food outlets and convenience stores offering especially foods high in fat, salt, or sugar

(HFSS) (Food Foundation 2019). For child obesity, school location in relation to fast food outlets is therefore potentially important (Aviola et al. 2014).

Consumption of healthy food in deprived areas is also affected by relative costs of healthy food as against HFSS foods (Drewnowski and Specter 2004). Thus Jones et al. (2014) report that since 2002, healthier foods have been consistently more expensive than less healthy ones, with a growing gap between them.

Exercise Access and Physical Activity

Access to exercise opportunities and natural space is associated with greater physical activity and improved health; for example, Angraal et al. (2019) show an adverse impact on cardiovascular mortality of diminished access to exercise opportunities. However, access to such opportunities is socially and spatially unequal. Thus the location of urban green space and parks is typically biased to areas containing higher income and white ethnic groups. In particular, in the United States, nonwhite and low-income groups generally live in the urban core or in inner suburbs where green space is limited and/or poorly maintained, while upper-income groups live on the suburban periphery with more abundant green space (Wolch et al. 2014). Regarding exercise opportunities (and hence levels of physical activity vs. sedentary behaviour), Timperio et al. (2010) show that BMI among older children is reduced by a higher density of public open spaces designated for sport or recreation.

Neighbourhood Social Environment

Neighbourhood impacts on obesity and diabetes extend to the social environment, including area deprivation, social capital, crime perceptions, and neighbourhood safety (Lee et al. 2019a). Thus impacts of area deprivation may occur even after controlling for adverse impacts of lower individual socio-economic status (Diez-Roux et al. 1997), sometimes described as "deprivation-amplification" (Cummins and Macintyre 2006). The widespread adoption of multilevel perspectives is based on a premise that characteristics of communities are potentially related to cardiovascular outcomes, and risk factors, independently of individual-level variables. Hence one should seek to elucidate their independent and combined effects.

Regarding crime, there are plausible pathways through which neighbourhood crime levels influence obesity, with impacts on activity and sedentary behaviour acting as mediating or intermediate variables in the association (Richardson et al. 2017; An et al. 2017).

Regarding social capital, Wu et al. (2018) find that adults with higher network diversity and high generalized trust have lower obesity risk, while social capital also impacts obesity-related behaviours, including smoking, diet, and physical activity. Social capital is generally lower in deprived areas, and social capital may mediate the typically negative relationship between neighbourhood deprivation and self-rated health (Verhaeghe and Tampubolon 2012).

Environment and Diabetes

Given the downstream obesity response to environmental factors, similar environmental impacts on diabetes have been reported, though with some specificity also.

Thus Bravo et al. (2019) consider quality of the built environment as a potential influence on T2D, beyond the usual research focus on food and physical activity access. Environmental quality is likely to mediate the impact of area deprivation on obesity and diabetes prevalence.

Den Braver et al. (2018) also mention urban residence per se (as opposed to rural residence) as a risk factor for diabetes. This may be related to adverse impacts of the urban physical environment, especially pollution, on diabetes risk (Rajagopalan and Brook 2012; O'Donovan and Cadena-Gaitán 2018). Migration to city areas may also enhance diabetes risk (Ruiz-Alejos et al. 2018).

Other studies report similar risk factors in environment-diabetes ecological studies as in environment–obesity studies. Thus Dendup et al. (2018) refer to walkability, physical activity resources, and access to green space as protective factors reducing diabetes risk.

Spatio-Temporal Aspects of Obesity

Trends to higher levels of obesity are highly disparate at subnational levels. For example, at the state level in the United States, adult obesity rates in 2018 range nearly twofold, from 39.5% in Mississippi to 23% in Colorado. Variations at small area scales, such as county or zip code level, are much wider.

In addition, many studies show spatial clustering in obesity (and related outcomes) at small area levels (e.g. Huang et al. 2015; Schuurman et al. 2009), and such spatial concentrations tend to be persistent (Joost et al. 2016). Such spatial clustering reflects clustering in risk factors, namely sociodemographic aspects of different areas (compositional impacts in the terminology of multilevel studies), and contextual effects, such as food and exercise access, and sprawl patterns (Schneider et al. 2017).

From a spatio-temporal perspective, one may be interested in the persistence of high obesity risk in certain areas ((Joost et al. 2016), in future spatial predictions (Guo et al. 2019), and the role of collective vs. individual behaviour in the obesity epidemic (e.g. Gallos et al. 2012).

To exemplify spatial clustering and persistent clustering, we consider obesity prevalence data for 3141 US counties from the Behavioral Risk Factor Surveillance System (BRFSS) for four periods, 2005–2007, 2008–2010, 2011–2013, and 2014–2016. Figure 9.1 maps out obesity prevalence in the final period (for the US continental counties), with break points at quintiles.

We first consider spatial clustering in 2014–2016 using the local Moran statistic as a local index of spatial association or LISA (Anselin et al. 2006). In particular, this assesses which areas can be classed as the centre of "high-high" clusters, whereby both the area itself and the areas surrounding it have significantly raised obesity. Figure 9.2 shows the location of these clusters as well as other possible cluster types under the LISA cluster scheme. Figure 9.2 shows that whereas county clusters with high obesity concentrate in southeast United States, clusters with low obesity tend to be in the west and mountain states.

To exemplify spatio-temporal modelling of the obesity epidemic in the United States, we use a Bayesian disease mapping approach (Lawson and Lee 2017) in BUGS (Lunn et al. 2009). Denote

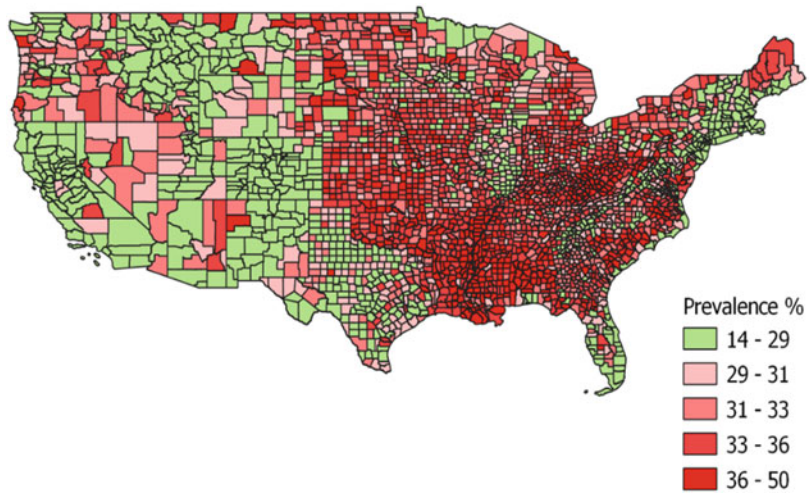

Fig. 9.1 Obesity prevalence, US continental counties (2014–2016)

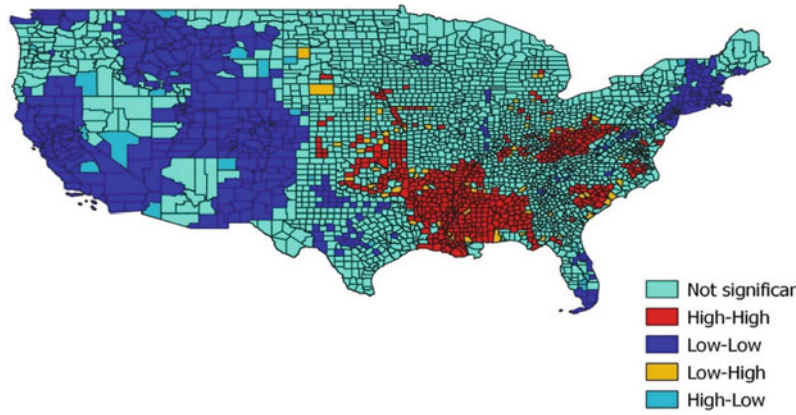

Fig. 9.2 US continental counties, obesity 2014–2016, cluster patterns

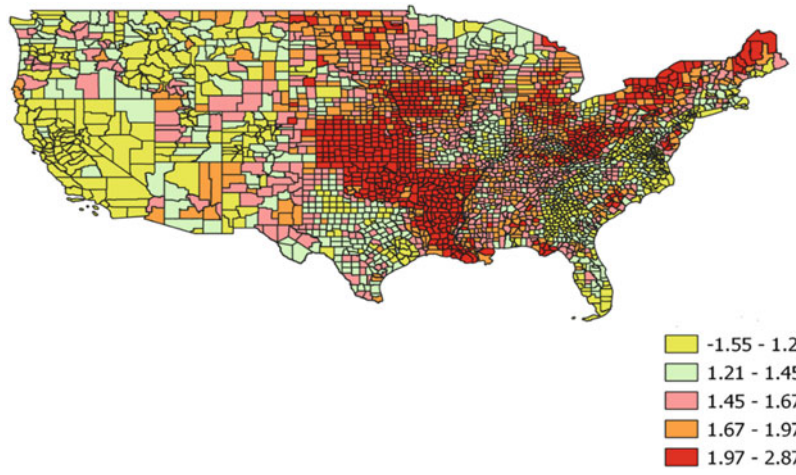

Fig. 9.3 Obesity prevalence growth rates (%), US continental counties, 2005–2007 to 2014–2016

age-standardised obesity rates in county i (=1, . . ., 3141) and period t (=1, . . ., 4) as r_{it}. These are modelled as

$$r_{it} = \beta_0 + s_i + d_i t + u_{it},$$

where β_0 is the intercept, and s_i are spatially correlated effects measuring the obesity level in period 1, as in the scheme of Besag et al. (1991). The d_i are spatially correlated linear growth rates, while the u_{it} are iid normal errors. This is an analogue of the varying intercepts, varying slopes model used in analysing longitudinal and multilevel data, but allows for spatial clustering (as evident in Figs. 9.1 and 9.2).

Figure 9.3 maps out the estimated growth rates d_i, and shows that the highest growth in obesity to be in the same counties which have the highest obesity according to Figs. 9.1 and 9.2. This suggests both persistent spatial inequalities in obesity, and a widening of such inequalities.

Conclusion: Unresolved Issues and Future Perspectives

There is by no means a consensus in the literature about the impacts of the urban environment on obesity and related outcomes, and debate continues. For example, on the fundamental

question of the relative importance of diet and physical activity, some studies emphasize physical activity (Fisher et al. 2013: Blair et al. 2013), while some stress dietary changes (Malhotra et al. 2015; Luke and Cooper 2013).

Regarding debate on specific environmental impacts, and in particular the impact of sprawl, Eid et al. (2008) consider panel survey data on obesity status and particularly the role of propensity to obesity. They characterise the sprawl effect in terms of levels of mixed use, and find a negative correlation between mixed-use and obesity, after controlling for observable individual characteristics. However, they report that "once we take advantage of the panel dimension of our data to control for unobserved propensity to be obese, the correlation between obesity and mixed-use also vanishes". In related work considering self-selection of residential location, Plantinga and Bernell (2007) find that individuals who move to denser locations lose weight, but that BMI affects the choice of a dense or sprawling location, such that dense locations are unlikely to be selected by high BMI individuals.

Regarding food access and location of healthy as against unhealthy food outlets [a supply side influence], sceptical studies have instead focused on the reliance on observational data to establish the role of the food environment (Hall 2018), and on demand differences between income groups. Thus Allcott et al. (2017) considered supermarket location, and concluded that "the causal impact of unhealthful food supply is small, relative to either the overall obesity rate or the nutrition-income relationship." Other studies have reported equivocal findings on the impact of access to fast food outlets, with Fraser et al. (2010) reporting "conflicting results between obesity/overweight and fast food outlet availability". Snowdon (2018) found a lack of evidence to support official policies (in the United Kingdom) to restrict location of fast food outlets near schools. In a review of 74 studies of the relationship between the density and proximity of fast food outlets and the prevalence of obesity, Snowdon reports that only fifteen (20%) found a positive association between the proximity and/or density of fast food outlets and obesity/body mass, while 44 (60%) found no positive association.

Therefore future research has a role in clarifying such unresolved aspects of the environment–obesity nexus. In terms of quantitative analysis of obesity, especially its spatio-temporal aspects, there is more scope to investigate geographic heterogeneity, for example in terms of spatially varying impacts of ecological factors on obesity prevalence and obesity-related mortality (Lee et al. 2019b; Wen et al. 2010). Spatio-temporal modelling might also be used to analyse the varying pace of the obesity epidemic, and the considerable national variation in obesity levels (Hruby and Hu 2015).

Abstract

The pathophysiology of inflammation has emerged as a player in the quest to understand the fundamental functions involved in obesity-enabled diseases. The dysregulated adipose tissue homeostasis and its endocrine function due to the excessive consumption of high-calorie diet, compounded with a modern sedentary lifestyle and predisposing effects of environmental and genetic factors, result in the initiation and the development of low-grade chronic inflammation in obese and overweight patients. The increased inflammatory cytokines and chemokines further complicate the already challenged physiology of the person with obesity and manifest into several associated comorbidities, including T2DM, heart diseases, cancer, and early aging. This chapter discusses the intricate association among obesity, inflammation, and their resultant and associated comorbidities. Additionally, some of the current and conventional therapeutic approaches and potential future interventional strategies targeting newer molecular players are also addressed.

Keywords

Obesity · Chronic low-grade inflammation · High-calorie diet · Comorbidities · Body mass index · Therapeutic targets

Introduction

A sustained high-calorie diet intake leads to the modification of the adipose tissues (AT), where hypertrophy and hyperplasia of the adipocytes are observed (Jo et al. 2009). This modification leads to alteration in the functions of the adipocytes, and contributes to the recruitment of the immune cells, which then secrete inflammatory cytokines and chemokines (Kumari et al. 2019; Kumari and Yadav 2018). Inflammation of adipocytes results in chronic low low-grade local inflammation, which ultimately becomes systemic (Reilly and Saltiel 2017).

Inflammation & Innate Immunity

Inflammation is the defensive reaction of the body in face of toxic effects, in conjunction with a healing process to restore damaged tissue. Several factors like microbial invasion, tissue injury, and many exogenous and endogenous antigens cause inflammation (Takeuchi and Akira 2010). Classically, there are five cardinal signs of inflammation: heat (*calor*), pain (*dolor*), redness (*rubor*), swelling (*tumor*), and loss of tissue function (*functio laesa*). In the fifth century BC, Hippocrates coined terms such as edema (swelling), which are still used to describe inflammation, and also observed inflammation in the early stage of the healing process after tissue damage.

Enhanced vascular endothelium permeability allows serum outflow and immune cell extravasation. Under ideal conditions, the inflammatory response rapidly proceeds and tissue damage is repaired. Nevertheless, if it lasts for an extended period, inflammation could lead to multiple complications and even death.

Inflammation engages immune cells, including macrophages and dendritic cells (DCs) and non-immune cells, including epithelial cells, endothelial cells, and fibroblasts, which play important roles and contribute to innate immunity (Hamada et al. 2019). Proinflammatory cytokines inclusive of tumor necrosis factor-alpha (TNF-α) and interleukin-1 (IL-1), facilitate leukocyte extravasation by growing leukocyte adhesion molecules in endothelial cells. Innate immune cells, including DCs, macrophages, and neutrophils, are

activated at the site of infection or injury, remove foreign particles and host debris by phagocytosis, plus secrete cytokines that activate the slower, lymphocyte-mediated adaptive immune response (Newton and Dixit 2012). Germline-encoded receptors of pattern recognition (PRRs) sense the existence of a structurally conserved area of microbial species known as pathogen-associated molecular patterns (PAMPs). Current findings suggest that PRRs also identify endogenous molecules secreted from damaged cells, called damage/danger-associated molecular patterns (DAMPs) (Singh et al. 2019).

There are currently listed four diverse classes of PRR families. These families are toll-like receptors (TLRs) and C-type lectin receptors (CLRs), which are transmembrane proteins, while the other two are cytoplasmic proteins, retinoic acid-inducible gene (RIG)-I-like receptors (RLRs) and NOD receptors (NLRs). These receptors are found in other nonprofessional immune cells apart from macrophages and DCs. PRR senses PAMPs or DAMPs and upregulates gene transcription involving inflammatory responses, except for certain NLRs. Such genes encode proinflammatory cytokines, chemokines, type I interferons (IFNs), and antimicrobial proteins involved in the regulation of many uncharacterized proteins and signals for PRR. The inducible gene expression patterns differ among activated PRRs. Inflammatory cytokines, for instance, TNF-α, IL-1, and IL-6 control inflammatory response. Such pro-inflammatory mediators are pleiotropic proteins that control inflammatory tissue apoptosis, modify endothelial vascular permeability, use inflamed tissue blood cells, and induce the development of acute-phase proteins (Kim et al. 2016).

Intertwined Relation of Obesity and Inflammation

Elevated levels of proinflammatory adipokines and cytokines including resistin, leptin, IL-6, TNF-α in the visceral adipocytes, and associated immune cells contribute to obesity pathophysiology. Inflammation of the white adipose tissue (WAT) correlates with the obese or overweight phenotype (Ellulu et al. 2017). WAT, a physiological storage site of lipids, is recognized as a dynamic contributor in several physiological and pathophysiological processes such as insulin resistance (IR), decreased glucose tolerance, and diabetes. Obese WAT is infiltrated by macrophages, which may be a significant source of locally produced pro-inflammatory cytokines (Lauterbach and Wunderlich 2017). WAT macrophage infiltration is diminished with a reduction of body weight in obese or overweight patients.

Intestinal Dysbiosis and Obesity

Obesity is also associated with chronic low-grade inflammation and endotoxemia originated in the gut. It is thus akin to a disease state with a complex interaction of genetic and environmental factors. A high-calorie diet has a profound effect on the gut microflora. The lipopolysaccharide (LPS), a pathogen-associated molecular pattern (PAMP), and a principal constituent of the Gram-negative bacterial cell wall, in physiological conditions, is found to be hiked in the intestinal lumen and low or nil in the plasma (Gnauck et al. 2016). In case the LPS concentration increases in the plasma, it has a direct effect on the gut barrier function, enhancing tight junction permeability in the enterocyte cells of the intestine by expression and localization of CD14 and TLR-4 in the plasma membrane of those epithelial cells (Guo et al. 2013). Further, LPS-induced tight junction permeability has been reported to act via LPS/TLR-4/FAK/MyD88 signaling axis (Guo et al. 2015). Thus, being an endotoxin, LPS mediates gut barrier dysfunction via incorporation of focal adhesion kinase (FAK) and MyD88 adapter proteins.

TLRs are upregulated with inflammation in the tissues, and in addition to intake of dietary lipids that are influenced by the action of the gut microflora, help in stimulating the innate immune response arm (Schoeler and Caesar 2019). There is evidence that inflammation caused by the gut microbiota can help in the activation of the signaling pathways of IKKβ, JNK, and PI3K,

thereby regulating the progression of obesity, inflammation of the AT, and resistance to insulin (Hullar and Fu 2014; Miro-Blanch and Yanes 2019; Ramos-Molina et al. 2019).

High-Calorie Diet and Inflammation

High-calorie Western diets have also been reported to induce residential immune cells of the gut, specifically macrophages, and alter their phenotype from tolerogenic to inflammatory. This phenotype change has further been implicated in the loss of Tregs cell population and function (Bain and Schridde 2018; Wang et al. 2019). The immune cells of the innate immune system are prone to transcriptional and epigenetic modulation in order to show a trained immune response, thus enhancing the immune response. The same is true even in the case of a sterile immunogen derived from a high-calorie diet (Netea et al. 2016).

Nonbacterial Dietetic Immunogens and Inflammation

Plenty of sterile bioactive molecules are now known that activate the innate immune response such as oxidized LDL, urate crystals, and cholesterol crystals. A high-calorie diet is linked to increased levels of oxLDL in circulation (Chatauret et al. 2014). In a study, Bekkering et al. showed that peripheral blood monocytes from healthy individuals, when treated with exogenous oxLDL, had a modulation in their function and phenotype. Furthermore, these cells showed a foamy appearance with enhanced production of cytokines such as TNFα, IL-6, IL-8, and IL-18 (Bekkering et al. 2014). This observation was further confirmed by Varghese et al., who implicated the role of a transcription factor sterol regulatory element-binding protein-1 or SREBP-1 in the enhancement of proinflammatory and foam cell phenotype of the U937 monocytes-derived macrophages (Varghese et al. 2019).

The oxLDL has also been implicated to modulate the innate immune response and generate a proinflammatory phenotype through the activation of the NLRP3 inflammasome (Liu et al. 2014; Sheedy et al. 2013; Singh et al. 2019). Inflammasomes are critical immune sensors that perceive environmental agents in the form of PAMPs and DAMPs and cause a release of proinflammatory cytokines. Uric acid and cholesterol crystals could activate the NLRP3 inflammasome complex and ultimately, the release of the proinflammatory cytokines (Beydoun et al. 2018; Stodle et al. 2018). Christ et al. have recently shown that the high-calorie diet sets off an innate immune response in *Ldlr*$^{-/-}$ mice, via NLRP3 inflammasome complex activation. The infiltration of myeloid cells like monocytes in the obese adipocytes, specifically the WAT, indicates the same fact (Christ et al. 2018). The infiltrating monocytes and their site-specific differentiation into macrophages are yet another cause of an inflammatory phenotype evident in obese people (Bai and Sun 2015) (Fig. 10.1).

Factors Responsible for Inflammation in Obesity

Genetic and Epigenetic Factors

In modern civilizations, where high-calorie food consumption and lack of physical activity, along with controlled climate encourages weight gain, polygenic obesity is the most prevalent modality (Alam et al. 2012; Heo et al. 2018; Raffan et al. 2016). However, in early severe obesity in children, monogenic forms are not uncommon. Even though genetic and epigenetic mechanisms mostly respond to nonspecific inflammatory changes, a more direct contribution is envisaged for epigenetics (Raghuraman et al. 2016), possibly involving gut microbiota (Ramos-Molina et al. 2019).

MicroRNAs

MicroRNAs (miRNA) are endogenous small single-stranded noncoding RNA molecules

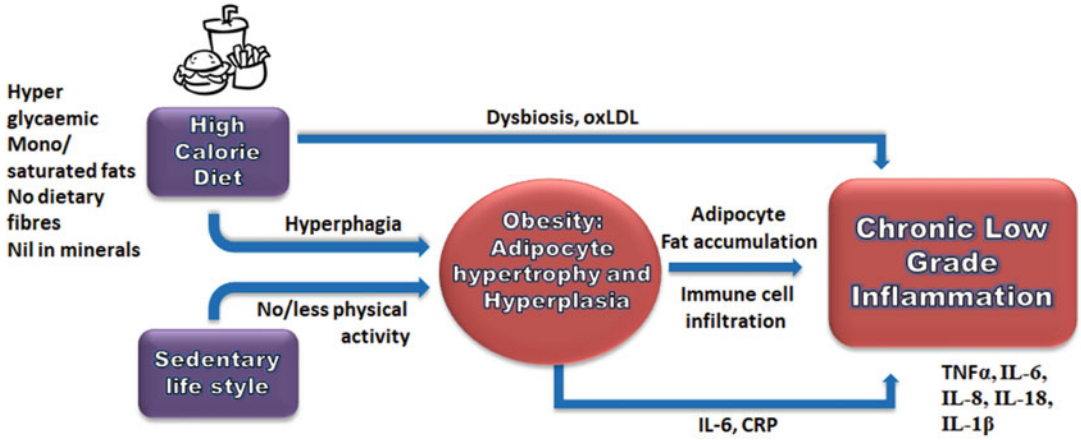

Fig. 10.1 Schematic representation of High-calorie diet-induced obesity and chronic low-grade inflammation. Development of an obese/overweight phenotype occurs upon chronic consumption of a high-calorie diet and leads to development of chronic low-grade inflammation in the body

(containing ~22 nucleotides), and their function is to regulate gene expression post-transcriptionally. They have also been involved in obesity and diabetes, by targeting various pathways of the metabolic function or adipocyte differentiation. miR-21 functions in the human AT and is related to BMI. miRNAs can act as modulators of the inflammatory reaction by selectively suppressing NF-kB pathway components. miR-146b-5p, which is known to regulate inflammatory signaling cascades, is reduced in obese and Type 2 diabetes mellitus (T2DM) individual monocytes. miR-107 inhibition caused by toll-like receptor 4 (TLR4) is dysregulated in obesity, resulting in an increased inflammatory response in macrophages (Olivieri et al. 2013). In peripheral blood mononuclear cells, gene overexpression for miR-103 and miR-143 was shown in a T2DM rat model (Vatandoost et al. 2015).

Both miRNAs were related to dysregulated adipogenesis, affecting (AT) development in the case of abundance of substrates, and miR-193b regulated adipocyte secretion of chemokine CCL2, reflecting a pathway seen in macrophages. LncRNA E33 overexpression was connected with the increased expression of several pro-inflammatory genes in RAW 264.7 cells, while the silencing of lncRNA E33 reversed these effects (Reddy et al. 2014).

Cellular Links Between Obesity and Inflammation

AT includes various types of cells, including pre-adipocytes, adipocytes, fibroblasts, and endothelial cells. The cell–cell cross talk that takes place, both locally with associated immune cells, and also systemically with other organs, is mediated not only by intercellular contact, but also by cytokines, chemokines, and other biomolecules (Liu and Nikolajczyk 2019).

Adipocytes

During obesity, the distance between adipocytes and AT vasculature increases due to adipocyte enlargement, potentially resulting in hypoxia. Hypoxia leads to the activation of hypoxia-inducible factor 1 (HIF-1) expression in adipocytes, to protect the AT from hyperplasia-related programmed cell death. It also causes the secretion of differentiation cues for the resident immune cells. When macrophages infiltrate these hypoxic ATs to clear the apoptotic and necrotic cells, they further amplify the inflammatory response via the production of IL-6 and TNF-α locally. Hypoxic ATs release differential signals acquired by residential or infiltrating

macrophages, resulting in an overall change from the M2 anti-inflammatory pattern, to M1 pro-inflammatory macrophage cells.

An elevated M1-like macrophage count and their secretome are found to be positively correlated with IR during obesity. AT inflammation has also been associated with a change in the T lymphocytes (Dam et al. 2016). The T lymphocyte subpopulation change includes an activation state of the $CD8^+$ T cells, a reduction of the Tregs and Th2 cells, an elevation in the number of Th1 and Th17, all being the hallmark of proinflammatory milieu shift. During obesity-induced hypoxic conditions, it has been reported that the Th17/Treg ratio gets modulated (Liu and Nikolajczyk 2019). One of the proposed mechanisms is the proteasomal degradation of Foxp3, that leads to the activation of RORγt protein, an essential molecule for Treg development. Thus, Treg cells' development gets suppressed aiding in the inflammation of the adipocytes. HIF-1 also induces IFNγ secretion from Th1 cells. This is followed by an activation event of transcription factors such as STAT3. STAT3 is further reported to be a major transcription factor for TH17 activity (Raphael and McGeachy 2018).

Activation of $CD8^+$ T cells is also an occurrence in the inflammatory response to obesity that results in activation/infiltration of M1-like macrophage in AT. The population of both effector $CD8^+$ T cells and memory cells is found to be increased in visceral adipose tissue (VAT), in comparison to subcutaneous adipose tissue. Under the hypoxic WAT microenvironment, the influx of $CD8^+$ T cells is related to enhanced expression of HIF-1. This information indicates that hypoxic adipocyte microenvironment regulates an infiltration of $CD8^+$ T cells before M1 phenotype changes in the macrophages.

Treg Cells

Tregs cells are anti-inflammatory T cells that are comparatively common in lean and their numbers decrease with the development of obesity. VAT-resident Tregs express IL-10, which prevents proinflammatory IL-6, RANTES (Regulated on activation, normal T Cell produced and secreted), SAA-3 (Serum amyloid A3) and MMP-3 (Matrix metalloproteinase-3) from being produced via TNF-α. IL-10 also establishes the phosphorylation of insulin receptor substrate (IRS)-1 and thus recovers glucose transporter GLUT4 expression in adipocytes, following TNF-α administration. In VAT, IL-33 receptor regulates IL-33 ligand Tregs-ST2 (also known as IL1RL1 and IL-1 IL1RAP receptor accessory protein). IL-33 also contributes to the stimulation of innate lymphoid cells type 2 (ILC2) and eosinophilic aggregation in murine VAT, indicating that these functions work in tandem with VAT-associated Treg anti-inflammatory impact (Han et al. 2015; Kolodin et al. 2015; Liu and Nikolajczyk 2019; McLaughlin et al. 2014).

Adipocyte lipid metabolites, stressed by growing fatty acids content in obesity, deliver antigens present in CD1 lymphocytes, which stimulate iNKT cells to reduce AT inflammation. Adipose iNKTs can also help Tregs by supplying IL-2, consistently with the results that CD1d knockout mice lowered the production of IL-2 in AT, and it was related to lean AT Tregs during interim high-fat diet (HFD) eating (Park et al. 2018; Satoh and Iwabuchi 2018).

γδ T Cells

γ-T cells express the surface T cell receptor (TCR) genes, and are mostly found among intestinal intraepithelial lymphocytes. In mice fed a HFD to induce obesity, there is a reduction in both ordinary αβ and γδ lymphochytes. Diet-induced weight loss restores both categories, and also improves outcome in experimental colitis. Thus both types of lymphocytes seem to enhance inflammation, when underexpressed in obesity.

The Treg population in AT is negatively regulated by IL-17, which originated from M1 macrophages and lymphocytes. IL-17 and other pro-inflammatory cytokines, including interleukin-1β (IL-1β), tumor necrosis factor α, and IL-6 which are associated with the progression of simple obesity toward metabolic syndrome. Cytolytic functions, involving $CD8^+$ T cells, may also help

prevent malignancy in obesity (Le Menn et al. 2018; Singh et al. 2016).

B Lymphocytes

B cells are known to infiltrate the growing AT, where they secrete cytokines and autoreactive antibodies (IgG), that interfere in the inflammatory microenvironment. B cell subtypes comprise B1 and B2 cells, which are subdivided additionally into unknown regulatory B cells (Bregs)/B10 subsets. The development of IL-10 and a variety of surface markers also define them. Each of these subpopulations of B cells has been involved in AT inflammation associated with obesity (Liu and Nikolajczyk 2019). The secreted antibodies from the B cell subsets have different functions: B1 cells are found to secrete anti-inflammatory or natural antibodies (IgM) and B2 cells the proinflammatory autoreactive IgG.

Natural antibodies are in reverse association with circulating levels of MCP-1 (CCL2). MCP-1 is related to Th2 response and controls the chemotaxis of macrophages, thereby regulating chronic inflammation (Engin 2017; Frasca and Blomberg 2017; Lu et al. 2019).

B cells provide antigens to T cells and thereby trigger macrophages as well as DCs. Even though B cells' secretion of obesity-related cytokines is less, their participation in inflammation is enhanced by having unique antigen concentration capability, via epitope-targeted acceptance/processing to control the function of T cells. Also, in obesity/T2DM, B cells regulate anti-inflammatory Treg cells. B cell-knockout mice on HFD show rare $CD4^+$ and $CD8^+$ T cells generating IFNα, indicating that other mechanisms may affect the consequence of B–T cell signaling in obesity (Liu and Nikolajczyk 2019).

Myeloid Cells

Myeloid dendritic cells and macrophages are the most capable antigen-presenting cells (APCs). At first, local AT macrophages network with naive $CD4^+$ T cells through Class II MHC molecules. Subsequently, a defined inflammatory milieu brings $CD11c^+$ macrophages into AT which, in effect, stimulates traditional T cells to multiply and thus maintain adaptive immune response, which leads to AT inflammation. Chronic high-calorie diet intake leads to the modulation of the adipocyte functioning further, interfering with β catenin and PPARγ, important protein responsible for adipocyte homeostasis. It was shown that a reduction in the expression levels of PPARγ and β-catenin in conventional DCs of AT leads to the prevalence of a proinflammatory state (Macdougall et al. 2018).

Molecular Mediators of Obesity and Inflammation

TNF-α

The chronic low-grade inflammation, features release of proinflammatory cytokines such as TNF-α, IL-6, and IL-1β, along with the dysregulated secretion of proinflammatory adipokines such as resistin and lipocalin-2 from the adipocytes. These are risk factors for the development of type 2 diabetes as well (Saltiel and Olefsky 2017).

In obese individuals, specifically in males, the level of TNF-α has been found to be elevated in plasma (El-Haggar and Mostafa 2015). TNF-α is known to enhance the phosphorylation of insulin receptor substrate (IRS)-1 and aggravate IR. Further, in the visceral adipocytes, TNF-α triggers IR via activation of JNK1/2 and its cross talk with the IRS signaling pathway (Fernández-Veledo et al. 2009). Since peripheral IR also characterizes T2DM in skeletal muscle, AT and liver, the prevalence of chronic low-grade inflammation in these organs may lead to IR, metabolic syndrome, and diabetes (Honka et al. 2018).

IL-1β

Obesity induces danger signals such as glucose and free fatty acids, and causes defective cell

organelle function such as that of mitochondria, which ultimately result in reactive oxygen species (ROS) generation. The increased level of ROS activates NLRP3 inflammasome complex in the peripheral tissues such as adipocytes, skeletal muscle, islets cells, and also in macrophages (Sharma et al. 2018). IL-1β is released, contributing to IR. Further, IL-1β induced expression of suppressor of cytokine signaling protein further suppresses insulin-dependent β cell survival.

There are several factors associated with obesity-linked inflammation, which include cytokines and adipokines, which propel the development of cardiovascular diseases, diabetes, neurodegenerative diseases, and several types of cancer (Han and Lean 2016).

Adiponectin and Leptin

Adiponectin prevents atherosclerosis owing to its protective action on the function of the endothelial cells. Since it is evident that reduced bioavailability of endothelial NO synthase (eNOS) causes an increased leukocyte adhesion and platelet activation, it ultimately leads to compromised endothelial cell barrier function (Siragusa and Fleming 2016). It was shown that adiponectin induced NO production in the endothelial cells via AMPK mediated expression of the eNOS gene, thus improving the endothelial dysfunction in cardiovascular diseases (Deng et al. 2010).

Leptin induced expression of TNF-α and IL-6 is thought to promote endothelial cell dysfunction and ultimately cardiovascular diseases (Tahergorabi and Khazaei 2015). In a study by Lee et al. of this cascade, IL-6 and TNF-α were implicated in oxidative stress-induced coronary endothelial cell dysfunction in obese rodents (Lee et al. 2017).

Secreted Frizzled-Related Protein 5

Secreted frizzled-related protein 5 (Sfrp5) is a soluble anti-inflammatory adipokine. Similar to adiponectin, the expression of Sfrp5 has also been found to diminish in obesity and cardiovascular diseases (Tong et al. 2019). Sfrp5 is a negative modulator of the secreted Wnt proteins, specifically Wnt5a, which is known to induce macrophages to produce proinflammatory cytokines. However, non-canonical Wnt5a-mediated JNK1 signaling cascade is suppressed, maintaining a Th2 type anti-inflammatory profile. Wnt5a has been found to promote inflammation in the endothelial cells and found present in atherosclerotic lesions, and Sfrp5 could participate in retarding obesity, IR, and atherosclerosis. It is questioned whether Wnt5A noncanonical signalling pathways are the only ones, as the canonical β-catenin pathway can also be activated with receptor availability. Inflammation is a common substrate of obesity, T2DM, and CVD, which makes it possible for Sfrp5 to be at the crossroad between such conditions (Wang et al. 2020).

Obesity, Inflammation and Cancer

Liver Cancer

Elevated levels of TNF-α/IL-6 during obesity and consequent low-grade chronic inflammation promote the IKK/JNK and AMPK/TORC-1 signaling cascades that underlie the obesity-induced inflammatory liver damage. Along with other insults, engaging diet and microbiome aberrations, the development of nonalcoholic fatty liver disease and nonalcoholic steatohepatitis embodies a dysfunctional state of the hepatocytes, which then ultimately die due to the prolonged insult, and trigger the regeneration mechanism of the liver (Kholodenko and Yarygin 2017). Thus, the obese phenotype and accumulation of resultant pro-inflammatory cytokines released by the adipocytes and infiltrated immune cells via a portal vein in the liver, may ultimately lead to the development of hepatocellular carcinoma (HCC). Moreover, the same low-grade inflammation with the constant buildup of adipokines, cytokines, and growth factors can fuel tumorigenesis in the peripheral tissues.

Pancreatic Cancer

Cohort-based studies have directly implicated an increased mortality rate of obese individuals with pancreatic ductal adenocarcinoma (PDAC) (Genkinger et al. 2015). Bariatric surgery could be protective in such patients (Xu et al. 2018). Owing to the chronic low-grade inflammation in obese individuals, elevated levels of IL-6 and TNF-α (Kern et al. 2018) and other cytokines and chemokines are found in the circulation. IL-6 is known to be the activator of JAK-STAT (signal transducers and activator of transcription) pathway. Development of obesity-induced IR via accumulation of visceral fat and inflammation is thought to be via IL-6/JAK/STAT signaling. PDAC is thought to involve KRAS oncogene expression, which further activates STAT3 and NF-κB signaling cascades leading to the development of PDAC (Ling et al. 2012; Pramanik et al. 2018). Furthermore, STAT-3 activation is implicated to be necessary for the development of PDAC (Fukuda et al. 2011; Lesina et al. 2011). Moreover, obesity-induced recruitment of Tregs cells in the pancreas with neoplasia causes the suppression of the immune clearance of the malignant cells and promotes tolerance of neoplastic cells aiding to PDAC complications (Cox and Olive 2012).

Colorectal Cancer

Obesity is associated with colorectal cancer (CRC), most common form of malignancy in men and women (White et al. 2018). The connecting link could be partly related to adipokine and cytokine levels, specifically that of adiponectin, leptin, IL-6, and TNF-α, even though the participation of dysbiosis and gut epithelial barrier dysfunction should not be overlooked. Adiponectin, being anti-inflammatory, is also an anticancer in nature (Monks et al. 2019). Adiponectin-knockout mice were found much more susceptible to inflammation-induced CRC as compared to their wild-type counterparts (Saxena et al. 2012). Mechanistically it is known to suppress mTOR protein via AMPK activation and thus reduces cell growth in human colorectal cancer cells. Leptin, a pro-inflammatory adipokine that is overexpressed in obese individuals, induces cell proliferation and anti-apoptotic properties via p42/44 mitogen-activated protein kinase (MAPK) and PI3K/Akt/mammalian target of rapamycin (mTOR) axis. In colorectal cancer specimens, leptin receptor (LEPR) expression was associated with tumor stage, neoangiogenesis index, regional and distant metastases (Vuletic et al. 2019).

IL-6 is a potential driver of several malignancies, including IL-6 driven PDAC, and also involves CRC. It is overexpressed in both obese and CRC patients (Zeng et al. 2017). TNF-α is overexpressed in animal models of high-fat diet-induced obesity (Wu et al. 2016). The role of TNF-α in IL-6 production and development of CRC has been anticipated (Chung et al. 2017) (Fig. 10.2).

Therapeutic Approaches for Obesity and Inflammation

The therapeutic approaches currently in practice involve pharmacological approaches, probiotic/prebiotics, phytochemicals, gene therapy and stem cell-based therapy. Some of these approaches are discussed below briefly.

Probiotics and Phytochemicals

Some *Lactobacillus sps* (*L. rhamnosus*, and *L. plantarum*) and *Bifidobacterium* (*B. infantis* and *B. longum*) are being used in probiotic formulations for obesity treatment. Some species of probiotic bacteria, including *Lactobacillus* and *Bifidobacterium* genera have the capabilities to

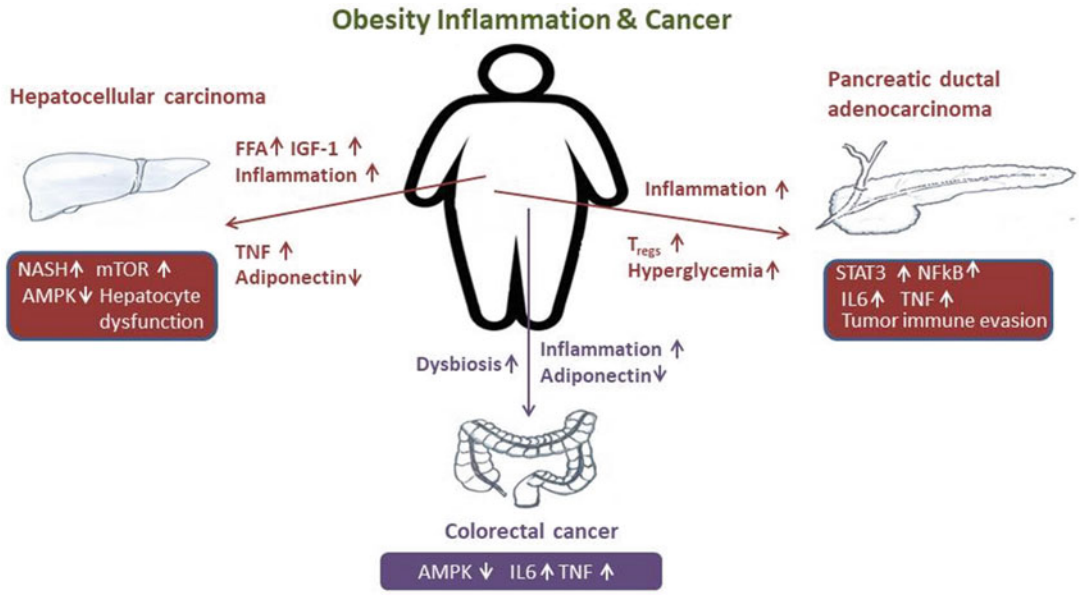

Fig. 10.2 Schematic representing association of obesity, chronic low-grade inflammation, and cancer. Several mechanisms are involved in the development of different forms of cancers owing to obesity and chronic low-grade inflammation (*FAA* free fatty acid, *IGF-1* Insulin-like growth factor-1, *TNF* tumor necrosis factor, *AMPK* adenosine monophosphate-activated protein kinase, *IL-6* Interleukin-6, Signal transducer and activator of transcription 3, T_{regs} T regulatory cells)

decrease body weight while other species might have deleterious effects. Prebiotics and probiotics are endowed with antiobesity and antidiabetic properties as shown in multiple animal models. However, outcomes of human trials are still not sufficiently robust to be endorsed in official guidelines and recommendations (Cerdó et al. 2019).

Plant-derived phytochemicals are also promising as anti-inflammatory molecules in the treatment of obesity. Curcumin experimentally modulates different cellular pathways and could act as an anti-inflammatory agent in obesity and associated comorbidities (Kandhari et al. 2018; Balaji et al. 2016; Firdous 2014. Nevertheless, a meta-analysis failed to confirm benefits for inflammatory markers in various contexts, including metabolic syndrome (White et al. 2019). Resveratrol has been shown to reduce levels of COX-2, IL-6, and TNF-α in adipocytes. Other flavones like apigenin and luteolin can reduce the TNF-α induced expression of NF-κB, and thus can be potential drugs in decreasing inflammation in obesity-related and other metabolic complications (Koh et al. 2018).

Cell-based Therapy

Cell-based approaches including brown adipose tissue transplantation, cell lysates, exosomes, and stem cell administration are currently being investigated in the treatment of obesity and related complications (Payab et al. 2018). Immunomodulatory potential of adipose tissue stem cells (ASCs) derived exosomes were also analyzed in one study on C57BL/6 male obese mice. ASCs derived exosomes polarized macrophages to M2 phenotype and further decreased inflammation in WAT. In one study, mice treated with adipose tissue-derived stem cells (ADSCs) exhibited lower WAT inflammation and obesity progression (Shang et al. 2015; Zhao et al. 2018). Mesenchymal stem cells isolated from human AT were helpful in regulating metabolic dysregulation induced by a high-fat diet in obese mice (Shree et al. 2019).

11 Crosstalk Between Adipose Tissue, Macrophages, and Other Immune Cells: Development of Obesity and Inflammation-induced Metabolic Diseases

Rohit Patel, Johnna Francis Varghese, and Umesh Chand Singh Yadav

Contents

Abstract

During metabolic disorders, the adipocytes increase in number and size along with the alteration in their functions. They secrete various types of chemical factors which contribute to inflammation and various physiological dysregulations. The adipose tissue acts as a reservoir of the immune cells such as macrophages, T-cells, and B-cells that

maintain the homeostasis of body's metabolic processes. However, the dysfunctional adipocytes and overpopulated immune cells secrete various cytokines and chemokines which promote low-grade chronic inflammation in the body causing the development of several metabolic diseases including diabetes, vascular diseases, and cancer.

Keywords

Adipose tissue · Obesity · Insulin resistance · Inflammation · Macrophage · Adipocytokines

Introduction

The adipose tissue comprises of resident preadipocytes which differentiate into mature adipocytes throughout their lifespan, and thus keep expanding the adipose tissue based on nutritional status and increased storage requirements. Mature adipocytes have a tendency to expand in size to accommodate storage demands and in overnutrition situation, they become hypertrophic. Adipocytes lack uniformity and vary in terms of size and population based on the localization in the body, capacity to secrete adipocytokines, as well as the cellular compositions, number of immune cells, blood vessels, and stromal cells forming it (Coelho et al. 2013).

Adipose tissue is both morphologically and physiologically differentiated, for example, mammalian adipose tissue is present in two forms: white adipose tissue (WAT) and brown adipose tissue (BAT). Mostly, the WAT is represented as a reservoir of energy whereas BAT is widely present in human neonates and is involved in regulating the body temperature via thermogenesis (Villarroya et al. 2019). WAT comprises of preadipocytes (adipocytes that are not yet lipid-loaded), fibroblasts, endothelial cells, and leukocytes, most importantly macrophages. WAT has a range of functions, which include release of hormones such as resistin, visfatin, and adiponectin. Along with this, cytokines such as interleukin (IL)-6 and tumor necrosis factor-α (TNF-α) released from WAT are involved in modifying insulin sensitivity and inflammatory processes, WAT also releases leptin and angiotensin which participate in controlling the nutritional uptake (Coelho et al. 2013).

Apart from these, several micro RNAs (miRs) have been found dysregulated in WAT during obesity, and establish a close association with metabolic disorders associated with obesity. The miRs are small noncoding around 20–22 nucleotide long RNA sequences, which bind to their target mRNA at 3'UTRs and regulate the translation of mRNA. Some miRs are also involved in regulating inflammation in WAT. For example, miR-221 and miR-222 have been reported to have a positive correlation with the expression of TNF-α released by WAT. The exosomal release of the miRs from adipose tissues such as miR-99b also regulates the metabolism of other tissues. MiR-99b induces suppression of hepatic Fgf21 by binding to its 3'UTR. Fgf21 is primarily involved in maintaining the metabolic regulation in obese and diabetic models by increasing insulin sensitization and lowering glucose levels (Tezze et al. 2019).

Brown adipocytes are comparatively smaller than WAT. They are abundant with cytoplasmic content, possess varied cytoplasmic lipid droplets and numerous mitochondria which are involved in release of heat via oxidation of stored fatty acids. BAT is characterized by extensive vascularization, and the blood vessels assist the delivery of components for storage and oxidation, as well as disperse the heat generated to different parts of the body (Coelho et al. 2013). Under obese conditions, release of exosomal miRs from BAT such as miR-325 and miR-743b is presumed to target the uncoupling protein 1 (UCP-1) expression, and miR-98 targets peroxisome proliferator-activated receptor-gamma coactivator alpha (PGC1α), both these proteins are involved in adaptive thermogenesis. They contribute towards the metabolic syndrome by whitening of the BAT (Tezze et al. 2019).

Adipose Tissue as a Source of Inflammation

Obesity influences the quantity, nature, and subtypes of the immune cells that are harboured in adipose tissue and thus the later has emerged as an active immunological organ (Grant and Dixit 2015).

Adipose tissue secretes a variety of adipokines and cytokines which may be both pro- (TNF-α and IL-1β) and anti-inflammatory (IL-10) in nature. Approximately 30% of circulating IL-6, a proinflammatory cytokine, originates from adipose tissue. With increased adiposity, the level of IL-6 increases, and is further stimulated by TNF-α and IL-1β (Grant and Dixit 2015). In obese condition, adipose tissue is poorly oxygenated due to proportional reduction of blood flow. This hypoxic condition activates HIF-1α and NF-κB followed by alteration in the expression of several proinflammatory adipokines (Ge et al. 2014). These molecules have the ability to affect insulin sensitivity of adipose tissue and promote insulin refractoriness, participating in the development of type-2-diabetes mellitus (T2DM), cardiovascular diseases (CVDs) and other metabolic disorders.

Tumor Necrosis Factor α

Adipocytes synthesize a 26 kDa transmembrane protein pro-TNF-α, which upon stimulation by various oxidative and inflammatory stimuli gets cleaved by matrix metalloproteinases (MMPs) into a soluble and active form of TNF-α, a 17 kDa protein, and released into circulation. It is known to increase serum glucose concentrations and induce insulin resistance in *in vivo* experimental models of obesity. TNF-α is also a potential activator of NF-κB-mediated proinflammatory signaling pathway, which is implicated in numerous inflammatory diseases. Increased levels of TNF-α, have been attributed to the presence of adipose tissue-residing macrophages especially the M1 type. As shown in Fig. 11.1, insulin impairment in the presence of TNF-α is mediated via activation of c-Jun-N-terminal kinase (JNK) or inhibitor of NF-κB kinase (IKK) and increased expression of suppressor of cytokine signaling (SOCS3), which then inhibits the signaling via insulin receptor substrate (IRS).

MiR-155 expressed in obese individuals inhibits the transcripts of proteins which act as repressors of TNF- α (Fig. 11.1). Transgenic mouse models with an overexpression of miR-155 exhibit enhanced production of TNF-α. Similarly, under hyperglycemic conditions, an increased expression of miR-155 and miR-146a is responsible for activation of TNF-α/TGF-β1/NF-κB proinflammatory signaling pathway (Marques-Rocha et al. 2015). Another regulatory pathway for TNF- α production involves miR-145-mediated activation of p65, an integral part of NF-κB complex. Along with this miR-145 downregulates the expression of protease ADAM17, leading to an increased membrane bound fraction of biologically active form of TNF-α (Marques-Rocha et al. 2015).

Interleukin-6

IL-6 along with the other proinflammatory cytokines is secreted by the NK cells residing in the adipose tissue (Lu et al. 2016). Elevated

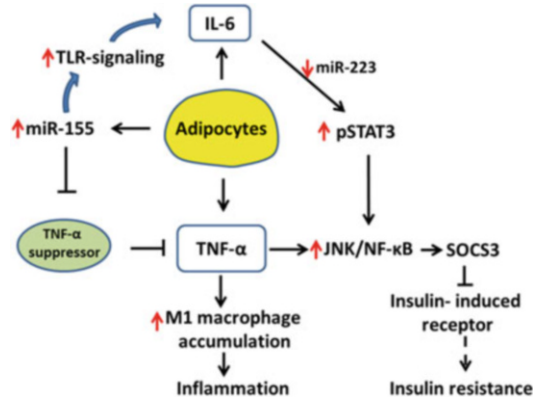

Fig. 11.1 Schematic diagram showing cytokines production from adipocyte and its effect on inflammation and insulin resistance. Adipocytes during obesity secrete proinflammatory cytokines (TNF-α and IL-6) which induce inflammation via accumulation of macrophages and insulin resistance via JNK/NF-κB-mediated SOCS3 activation. Adipocytes also express miR-155 that regulates the release of both TNF-α and IL-6. Further, decreased levels of miR-223 during obesity results in increased IL-6-mediated STAT signaling leading to activation of NF-κB

circulating level of IL-6 in obese subjects is strongly correlated with insulin resistance (Varghese et al. 2018). IL-6 levels also positively correlate to the body mass and plasma free fatty acids in the patients with T2DM. IL-6 participates in glucose homeostasis and regulation and activation of the immune system (Kurauti et al. 2017). IL-6 directly inhibits the signal transduction of insulin receptor thereby inhibiting insulin activity, leading to insulin resistance (Zand et al. 2017). IL-6 acts on the insulin signaling by upregulating SOCS3 expression, which impairs the insulin-induced receptor and phosphorylates the IRS-1 in hepatocytes and adipocytes (Fig. 11.1). It is also actively involved in regulation of insulin-degrading enzyme (IDE), an important molecule involved in insulin clearance in the body. Low level of IL-6 leads to decreased expression and activity of IDE which could result in hyperinsulinemia (Kurauti et al. 2017).

Blocking the IL-6 signaling leads to depreciation of larger adipocytes replaced by smaller adipocytes. In addition to this, IL-6-mediated signaling promotes the chemotaxis and infiltration of macrophages into the adipose tissue as well as their polarization into the M1 type (Kraakman et al. 2015). As observed in TNF-α regulation, miR-155 also plays an important role in mediating increased expression of IL-6 by potentiating TLR signaling, via negatively regulating SH2 domain-containing inositol-5-phosphatase 1 (SHIP1) and suppressor of cytokine signaling 1 (SOCS1) (Marques-Rocha et al. 2015). IL-6/STAT3 (signal transducers and activators of transcription 3) is responsible for complex inflammatory pathways, where IL-6 promotes phosphorylation and activation of STAT3. IL-6 promotes STAT3 by inhibiting miR-223, a negative regulator of STAT3 (Marques-Rocha et al. 2015).

Monocyte Chemoattractant Protein-1 (MCP-1)

A member of CC chemokine superfamily, this cytokine recruits and activates circulating monocytes during angiogenesis and acute inflammation. MCP-1 levels are augmented in obese individuals, and gene expression of MCP-1 is elevated in both visceral and subcutaneous adipose tissues. Elevated MCP-1 attracts more leukocytes to the inflammatory site, which further aggravates inflammation by secreting excessive levels of TNF-α and IL-6, contributing to insulin refractoriness and diabetes. Infiltration of monocytes into the adipose tissue is also contributed by the adipocytes, i.e., by secreting MCP-1 along with macrophage inflammatory protein-1α (MIP-1α), macrophage colony-stimulating factor (M-CSF), macrophage migration inhibition factor (MIF-1), and chemokine CCL5 (RANTES), thereby facilitating the diversification and maturation of monocytes into macrophages (Fig. 11.2) (Coelho et al. 2013). Thus, inclining the polarization of macrophages into M1 type, increased plasma levels of MCP-1 via CCR2 stimulate the phosphorylation of ERK1/2. Activated ERK is then responsible for decreased tyrosine phosphorylation of IR-β and increased serine-based phosphorylation of IRS-1, leading to insulin resistance in hepatocytes and skeletal muscles (Chen et al. 2015).

When elevated, miR-467b is found to target and inhibit MCP-1 and TNF-α via downregulating lipoprotein lipase. However, downregulated expression of miR-467b in macrophages under obese conditions leads to an enhanced expression of MCP-1 (Tian et al. 2012). Another miR identified to target MCP-1 secretion in macrophages is miR-125-5b-5p, which is

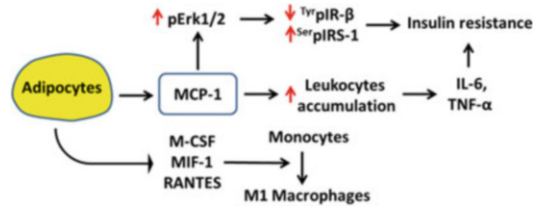

Fig. 11.2 Schematic representation of MCP-1-mediated pathway in adipocyte. MCP-1 released from adipocyte during obesity causes leukocyte accumulation, which further leads to IL-6 and TNF-α production. MCP-1 also activates Erk1/2 signaling leading to insulin resistance. Further, adipocytes also cause M1 macrophage accumulation via M-CSF, MIF-1, and RANTES production

also found to be downregulated under obese conditions. This miR targets beta lactamase protein (LACTB), an active-site serine protein, involved in maintaining metabolic circuit thereby regulating the levels of MCP-1. However, the downregulation of miR-125-5b-5p leads to upregulation of LACTB, followed by increased MCP-1 secretion in macrophages (Lu et al. 2016).

Adipocytokines: A Linking Mediator Between Adipose Tissue, Inflammation, and Immunity

Adipocytokines encompass molecules like leptin, resistin, visfatin, and adiponectin. Other cytokines released by the adipose tissue (IL-1, IL-6, MCP-1, and TNF-α) are not considered as adipocytokines, even though taking part in the immune modulation. Granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-4, and IL-13, which induce proliferation of macrophages, should also be added to the list (Braune et al. 2017), as certain chemokines including CCR5, C-X-C motif chemokine 12 (CXCL12), and semaphorin 3E promote macrophage infiltration and recruitment.

Blocking IL-6-induced signaling cascade does not completely abrogate insulin resistance or obesity-induced weight gain (Kraakman et al. 2015). This indicates the role of other cytokines and adipokines in the obesity-related pathogenesis. Further, IL-6 signaling also assists the retention of macrophages by macrophage-adipocyte adhesion, and this inhibits conversion of WAT to beige adipose tissue (Chung et al. 2017), thus continues to promote adipose tissue-mediated inflammation.

Normal vs. Sick Fat

Adipocytes from lean individuals, akin to normal fat, preferably secrete adipokines that are anti-inflammatory in nature, which include *transforming growth factor beta* (TGF-β), IL-10, IL-4, IL-13, and IL-1 receptor antagonist. In contrast to this, adipose tissue from obese individuals, sick fat, secretes proinflammatory cytokines such as TNF-α, visfatin, resistin, plasminogen activator inhibitor 1, leptin, and IL-6, which promote inflammatory condition and pathogenesis (Ouchi et al. 2011). The proinflammatory adipokines modulate insulin sensitivity directly or indirectly via stimulation of inflammatory pathways which affects insulin-mediated signaling. For example, phosphorylation of serine residue of the IRS by the adipokines through the JNK and I-kappa B kinase β (IKKβ)/NFκB pathway, disrupts the insulin signaling leading to insulin resistance.

Orchestration of Inflammatory Responses

Inflammation in the adipose tissue induces upregulation of proinflammatory adipocytokines. The connection between adipocytokines and miRs appears to be reciprocal where cytokine signaling has an impact on the miRs production. Likewise, the miRs also target mRNA of cytokines and cytokine signaling. For example IL-1β and TNF-α are critical stimulators of miR-155 and miR-146a while IL-6-mediated suppression of miR-200c directs the indispensable activation of inflammatory signaling cascade (Marques-Rocha et al. 2015). In general miR-185, miR-103, miR107, and miR143 get downregulated in obese individuals whereas they are upregulated in lean subjects (Marques-Rocha et al. 2015).

Immune Cell Recruitment

Neutrophils, eosinophils, basophils, mast cells, B and T cells infiltrate and reside in the adipose tissue. The immune cell population and their associated response may vary based on various factors such as diet, cold exposure, body weight, feeding and fasting (Grant and Dixit 2015). The *in vivo* experiment in mice model showed that in high-fat diet (HFD) fed animals, adipose tissues were infiltrated by neutrophils within 3 days, followed by macrophages in 2 weeks, and recruitment of B and T cells by the end of 4 weeks (Winer et al. 2011; Talukdar et al. 2012).

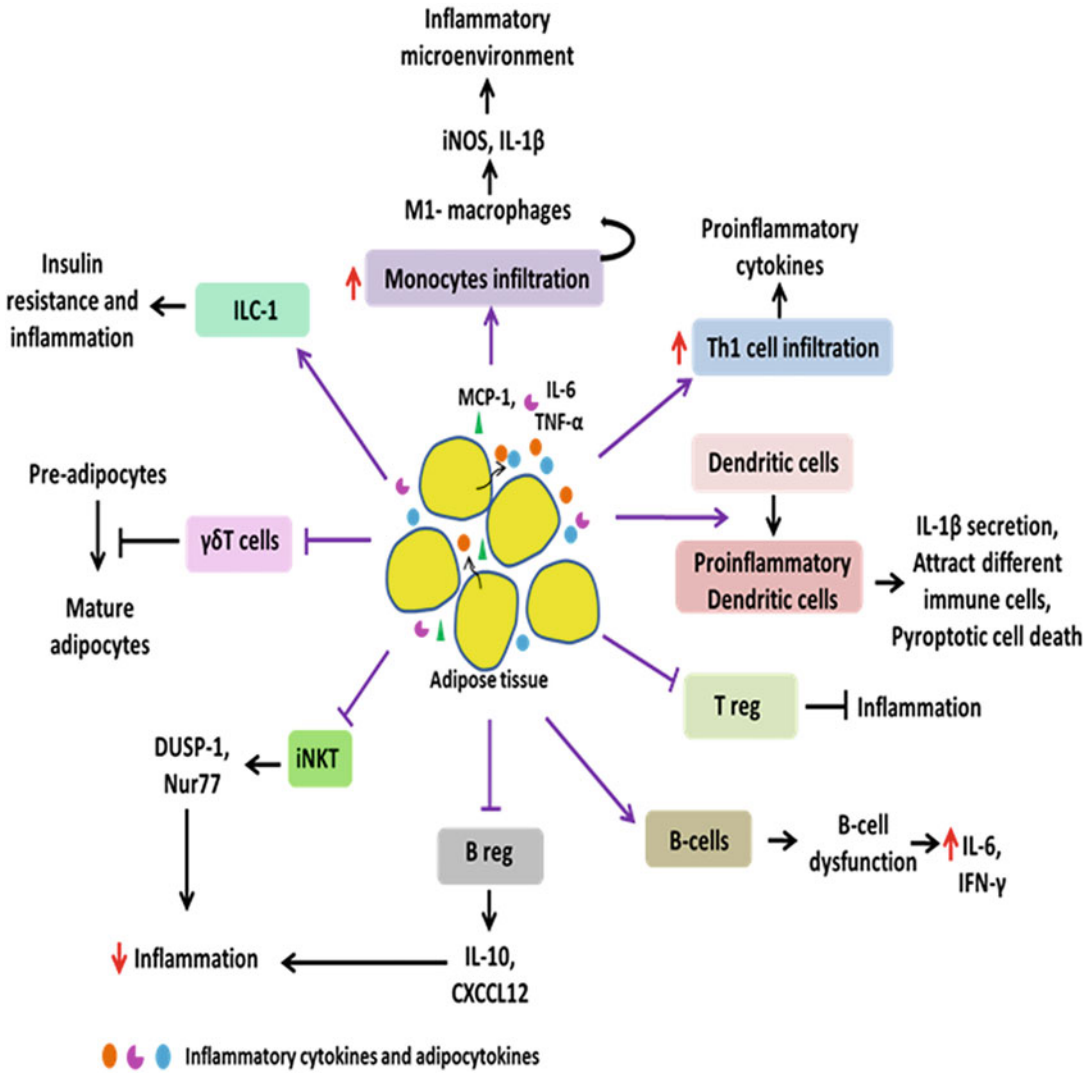

Fig. 11.3 Schematic diagram showing interaction of macrophages and other immune cells with adipose tissue. Various adipocytokines (IL-6, MCP-1, IL-1β, TNF-α) released from adipocytes and adipose-residing immune cells during obesity increases inflammation-mediated metabolic dysregulation. These inflammatory mediators attract and activate various immune cells which further secrete various chemokines and cytokines causing excessive inflammation and metabolic complications

The cells tend to change their number and characteristics based on different conditions and microenvironment in the tissue. Insulin resistance and obesity are certain conditions that have the ability to skew the adipocyte-residing immune cells, from anti-inflammatory subtype to the proinflammatory type. This also includes the macrophage polarization where M2 type of cells transform into M1 type, which is also accompanied by the loss of regulatory T cells (Fig. 11.3).

Macrophages

Approximately 50% of the immune cells residing in the obese adipose tissue are macrophages, while in lean individuals it accounts for about 10%. The tissue macrophage population is directly correlated to the total adiposity and adipose cell size and are involved in secreting the majority of inflammatory cytokines. Chemokines secreted by the adipocytes such as MCP-1,

MIF-1, chemokine CCL5 (RANTES), and M-CSF, attract and facilitate the infiltration of monocytes into the adipose tissue where they eventually transform into macrophages (Coelho et al. 2013). As observed in the obese mice models, macrophages when infiltrated in the adipose tissue, undergo transformation of phenotype from M2 type with cluster of differentiation (CD)-206, arginase (Arg)-1, and CD301 markers, to proinflammatory M1 phenotype with expression of nitric oxide synthase (NOS)2, TNF-α, and integrin alpha X chain protein (Itgax) (Appari et al. 2018; Rondini and Granneman 2020).

The M1 type prominently expresses inducible nitric oxide synthase (iNOS), IL-1β, and CD11c on the cell surface whereas the M2 macrophages express IL-10, Arg, and chitinase-like protein Ym-1. This switching of macrophages from M2 to M1 type is at the very core of adipose tissue. In obese conditions, the presence of M1 type of adipose tissue macrophages reflects the futile clearance of dead adipocytes. Generally, efficient efferocytosis is accompanied with the presence of M2 type of macrophages, establishing an anti-inflammatory microenvironment (Boutens and Stienstra 2016). Under obese conditions, it is the M1 macrophages that populate the adipogenic clusters, facilitating adipogenesis and angiogenesis as well as activation of the proinflammatory signaling needed for efficient adipogenesis (Boutens and Stienstra 2016).

The adipose tissue inflammation and resultant resistance to insulin, lipid oxidation, and mitochondrial biogenesis are regulated by PPARγ and PPAR coactivator-1β (PGC1β). Knockdown of PPARγ specifically exacerbates the inflammation in macrophages and promotes HFD-induced obesity (Odegaard et al. 2007). Adipose tissue-residing macrophages derived from obese mice have the tendency to induce systemic glucose tolerance and insulin resistance by downregulating PPARγ (Ying et al. 2017). Obesity induces lysosome biogenesis in macrophages residing in the adipose tissue and inhibition of the lysosome function impairs the lipid metabolism in the cells thus, reducing the whole adipose tissue lipolysis (Xu et al. 2013).

Increased content of lipids in the cells and alteration in lipid metabolism are associated with a low-grade inflammation during obesity (Xu et al. 2013). One of the critical signaling pathways that controls lipid metabolism in the macrophages is AMPK. It is an antagonist of the biosynthetic pathways, i.e., it suppresses fatty acid synthesis as well as increases their oxidation via phosphorylation of acetyl-CoA carboxylase (ACC) (Pearce and Everts 2015). The AMPKβ1-deficient macrophages lead to increase in the levels of diacylglycerol and inflammatory markers, and suppress the expression of mitochondrial enzymes and phosphorylation of ACC. This conducts to increased lipid accumulation (Galic et al. 2011).

In AMPKβ1$^{-/-}$ mice, administration of HFD enhanced inflammation of adipose tissue residing macrophages, with subsequent insulin resistance (Galic et al. 2011). Presence of saturated fatty acids such as palmitate instigates the signal transduction pathways pertaining to inflammation and lipid metabolism. These saturated fatty acids bind to cell surface receptors such as TLRs followed by proinflammatory signaling cascade activation, excessive inflammatory cytokine production, and internalization of palmitate. This is subsequently followed by activation of p62 and PPARγ proteins, which promote the metabolic phenotype of macrophages (Kratz et al. 2014). Studies state that deficiency of fatty acid synthase (FAS) prevents the recruitment of macrophages in the adipose tissue. It is also associated with the retention of cholesterol in the plasma membrane and disruption of Rho GTPase trafficking, which modulates cell adhesion, activation, and migration (Wei et al. 2016).

Macrophage transcriptome studies indicate that adipose tissue-residing macrophages in the obese adopt a peculiar metabolic program, which includes glycolysis and oxidative phosphorylation (Boutens et al. 2018). Inflammation-induced excessive glycolysis in macrophages contributes to increased production of inflammatory cytokines. Inhibition of glycolysis with 2-deoxyglucose (2-DG) reduced lactate production and glucose oxidation by macrophages (Boutens et al. 2018).

Dendritic Cells (DCs)

In obese mice models depletion of adipose-residing DCs resulted in recovering the insulin sensitivity and decrease in the levels of proinflammatory cytokines (Zand et al. 2017). High-fat diet skews the DCs towards the proinflammatory phenotype with an increase in the secretion of IL-1β and expression of IL-1R, toll-like receptor (TLR) 4 and caspase-1. The proinflammatory phenotype of DCs and their secretions attract more inflammatory immune cells into the adipose tissue. Further, increased levels of caspase-1 and IL-1β promote pyroptotic cell death, releasing more danger molecules in the milieu which add significantly to ongoing onslaught of inflammatory bursts. Unlike the conventional type, the plasmacytoid DCs (pDCs) possess a low capacity of processing soluble antigen. pDCs recruitment in the adipose tissue induces obesity and insulin resistance, whereas its depletion is followed by reduced metabolic complications (Ghosh et al. 2016; Hannibal et al. 2017).

The cDCs residing in the visceral adipose tissue (VAT) have the ability to acquire a tolerogenic phenotype, i.e., antigen-specific activation of T-cell tolerance. This phenomenon in cDCs is attributed to the activation of *peroxisome proliferator-activated receptor gamma* (PPARγ) and β-catenin pathways (Macdougall et al. 2018). Inhibition of the β-catenin and PPARγ pathways does not affect the phenotypical features of the animal such as adipose tissue content, food intake, or weight gain, however it aggravates the local inflammatory responses and obesity-induced insulin resistance (Macdougall et al. 2018). Tolerogenic properties of adipose tissue-residing cDCs serve as inflammation check points. cDCs are likely to undergo phenotypical and functional changes based on the level of obesity, providing a foundation to authenticate the role of cDCs in obesity and associated metabolic disorders.

Lymphocytes

Genes of lymphocytes involved in recombination and diversity for antibody production are metabolically active. Recombination-activating gene (RAG)-1-deficient mice tend to develop insulin resistance (Winer et al. 2009). Approximately 5–10% of the total immune cell population is composed of T cells which mainly reside in the subcutaneous and visceral adipose tissue, and act as a major hub for memory T cells inducing proliferation and effectiveness (Han et al. 2017). In obese mice, the population of T cells increases specifically when the subset $CD8^+$ population is greater than the $CD4^+$ in the adipose tissue. Insulin resistance is attributed to the presence of $CD8^+$ cells. Infiltration of these cells into adipose tissue is followed by the recruitment and accumulation of macrophages. Genetic depletion of $CD8^+$ T cells depreciates inflammation of adipose tissue and ameliorates insulin resistance (Nishimura et al. 2009).

Regulatory T (Treg) Cells

Treg population keeps a check on the inflammation in the adipose tissue. These cells are generally found in fat depots in normal states and their numbers tend to strikingly reduce under the obese conditions. Apart from the role of T cells, B cells also play a significant role in adipose tissue. Depleting B cells in HFD-fed mice improved tolerance towards glucose as well as reduced adipose tissue inflammation (Winer et al. 2011). B cells tend to secrete more proinflammatory cytokines such as interferon gamma (IFN-γ), IL-6, and IL-8, than anti-inflammatory cytokines which include IL-10 and IL-5. B cells exert detrimental effects by producing pathogenic IgG type of antibodies.

Nutrient rich microenvironment in the adipose tissue instigates Treg cells to take up lipids. This property is generally not seen in the conventional or lymphoid-residing Treg cells. The PPAR-γ-mediated fatty acid metabolism is a critical factor that regulates the phenotype of adipose tissue-residing Treg cells, depicting a PPARγ-dependent expression of forkhead box P3 (Foxp3) and GATA3 (Cipolletta et al. 2012). Lipid metabolism gets augmented in Treg cells in the presence of pioglitazone, a synthetic agonist of PPARγ. This

leads to an increase in the expression of fatty acid transporters CD36, enzymes involved in fatty acid synthesis (Slc27a2, Stearoyl-CoA desaturase (Scd) 1 and Lipe), triglyceride synthesis (Dgat1), fatty acid oxidation (Cpt1a), and lipid droplet-associated protein (Plin2) (Cipolletta et al. 2012). Thus, it is possible that Treg cells could store lipids by regulating the lipolysis to generate free fatty acids for both anabolic and catabolic purposes. These findings go hand in hand with the fact that Tregs preferably utilize lipid oxidation for energy in comparison to effector T-cells that utilize the energy generated from glycolysis (Michalek et al. 2011).

Treg cells are attuned to the local microenvironment while residing in the adipose tissue, and this affects the metabolic profile, function, and phenotype. However, some features of adipose Treg cells are similar to Treg cells residing in other microenvironments. For example, signaling pathway that controls the Treg metabolism is mediated via the lipid phosphatase (PTEN) (Newton et al. 2016). Native $CD4^+$ T-cells undergo transformation into Treg cells when PTEN is overexpressed, leading to the formation of $Foxp3^+$ Treg cells in adipose tissue (Kalin et al. 2017). Studies state that deletion of PTEN leads to a hyper-glycolytic state, which disrupts the Treg lineage affecting the CD25 and Foxp3 expression.

A subtype of B cells, i.e., adipose tissue regulatory B (Breg) cells, are observed to restrain the inflammation of adipose tissue and positively affect the insulin sensitivity. These cells are involved in the survival and homeostasis of the adipose tissue by releasing IL-10, CXCL12, and free fatty acids (Nishimura et al. 2013).

Unconventional Lymphocytes

Unconventional lymphocytes include the invariant natural killer cells (iNKT), γδ T cells, mucosal-associated invariant T (MAIT) cells, and innate lymphoid cells.

iNKT Cells

A significant number of invariant natural killer cells (iNKT) are present in the adipose tissue. These are innate T cell types and represent 15–20% of the entire T cells. Mice that lack iNKT cells show metabolic derangements including weight gain, insulin resistance, larger adipocytes, and fatty livers. Increasing the number of iNKT cells improves the condition of weight loss and metabolism. iNKT cell-mediated amelioration of insulin sensitivity is attributed to its association with Th2 type cytokine production (Lynch et al. 2012). Adipose iNKT cells have a unique transcriptional signaling with an overexpression of mitogen-activated protein (MAP) kinase phosphatase Dusp1 and Nur77, a nuclear transcription factor, which then regulates inflammation, cell growth, glucose metabolism, and insulin resistance (Lynch et al. 2015).

Unlike iNKT cells that are found in other tissues and express poxvirus finger transcription factor, the adipose tissue iNKT cells express the basic leucine zipper transcription factor E4 promoter-binding protein 4 (E4BP4) which controls the production of IL-10. Enrichment of regulatory iNKT cells in adipose tissue controls inflammation and maintains it in quiescent state, and regulates the homeostasis of other anti-inflammatory immune cells such as Treg and M2 macrophages (Lynch et al. 2015).

γδ T Cells

These are unconventional type of T cells and represent 1–10% of the entire circulating T cells, in mice as well as humans. They are reduced in obese patients and have a negative correlation with the body mass index (Costanzo et al. 2015). They inhibit the differentiation of preadipocytes 3T3-L1 to mature adipocytes, and impair glucose uptake in mature adipocytes (Zuniga et al. 2010). These cells are preferably accumulated in the adipose deposits of the inguinal, colon, and small intestine.

Innate Lymphoid Cells (ILCs)

ILCs have a classic lymphoid morphology, however they are identified by the expression of cytokines and functional molecules released by them (ILC1 and ILC2) (Artis and Spits 2015). During obesity and T2DM, the ILC2 in VAT secretes IL-5 and IL-13, which regulate the levels of eosinophils and alternatively activated

macrophages, thereby controlling insulin resistance and HFD-induced obesity (Hams et al. 2013; Molofsky et al. 2013). Adipose tissue in obese subjects exhibited a reduced number of ILC2s (Brestoff et al. 2015). Anti-inflammatory cytokine IL-25 elicited ILC2 response regulates metabolic homeostasis, by controlling lower weight gain when subjected to HFD (Hams et al. 2013).

In contrast, IFN-γ induces the ILC to polarize towards ILC1 type, where they contribute towards insulin resistance in HFD-induced obesity (O'Sullivan et al. 2016). Decreasing their number results in reduced cytotoxicity via alteration in the conversion of proinflammatory macrophages to anti-inflammatory population. Metabolic disorders are exacerbated in cases where there is an adoptive transfer of ILC1 population of cells (Boulenouar et al. 2017).

In mouse models, HFD appreciably increases the number of neutrophils and macrophages. Expression of neutrophil-derived elastase and myeloperoxidase increases when a HFD is administered along with neutrophil infiltration.

Metabolic Regulation of Adipose Tissue-residing Immune Cells in Different Disease Conditions

In adipose tissue of obese organisms, macrophages with a much more complex immunophenotype are observed which does not conform to the traditional M1 and M2 polarization type (Kratz et al. 2014). This morphology is induced by external stimuli such as glucose, insulin, and palmitate that get elevated during metabolic disorders. Metabolic markers follow, such as Perilipin 2(Plin2) and ATP-binding cassette transporter (Abca) 1, along with release of proinflammatory cytokines TNF-α and IL-1β (Kratz et al. 2014). Dead adipocytes capable of inducing the expression of IL-1β and IL-6, are cleared by the macrophages, with inhibition of inflammation in obesity (Coats et al. 2017).

Since macrophages are smaller than adipocytes, they clear the adipocytes via lysosomal exocytosis, driven via NADPH oxidase 2 (Coats et al. 2017). Lysosomes biogenesis occurs during obesity, and inhibition of the macrophage lysosome function may increase the lipid content in macrophages, reducing adipocyte lipolysis (Xu et al. 2013). Macrophages contribute towards dysregulated lipid metabolism independent of their phenotype.

Arterial Hypertension

Many hypertensive patients are not obese, however they present the features of metabolic dysregulation. Visceral adipose tissue (VAT) inflammation can be identified, partaking in the pathogenesis of vascular dysfunction (Mikolajczyk et al. 2016). Loss of protective function of the VAT triggers a loss of endothelium-dependent vasodilation and leads to stiffness of blood vessels (Nosalski and Guzik 2017). Morphological alterations induce a more proinflammatory VAT, which dedifferentiates and becomes metabolically active. Increased levels of resistin and visfatin and decreased levels of adiponectin and leptin can be observed. Additionally, increased production of chemokines such as RANTES or CXCL10, a key molecule for recruitment of activated $CD8^+$ T cells, monocytes, and macrophages, are also implicated (Nosalski and Guzik 2017).

Atherosclerosis

Augmented levels of adipokines such as vaspin, leptin, visfatin, and chemerin due to VAT dysfunction are associated with the development of atherosclerosis. At the early stages, immune cells such as macrophages, dendritic cells, and T cells infiltrate the adipose tissue that surrounds the vasculature (Skiba et al. 2017). This is followed by endothelial dysfunction and induction of oxidative stress. Endothelial dysfunction is a critical event in the atherosclerotic plaque formation (Patel et al. 2019). These conditions, however, can be reversed by targeting metabolic functions of proteins such as Angiotensin (Ang) 1–7 (Skiba et al. 2017). Adipose tissue inflammation is continuously observed over various stages of the

disease. Aged ApoE$^{-/-}$ mice showed high number of leukocytes in the aorta, which is indicative of advanced atherosclerosis. Along with this, T cell population could be correlated with the lesion size, as their depletion has been shown to prevent atherosclerosis (Meng et al. 2016). Epicardial adipose tissue is a depot of paracrine-acting adipokines and can contribute towards vascular atherogenesis.

Insulin Resistance and Diabetes

Elevated numbers of M1 type macrophages affect insulin signaling, and are attributed to the increased $CD8^+/CD4^+$ ratio and a decrease in Treg cells. This population tilt is mediated via the regulation of signal transducer and activator of transcription3 (STAT3) signaling (Priceman et al. 2013). Neutrophils, though present in small numbers, can impair insulin signaling as well. Neutrophil elastase induces glucose intolerance and insulin resistance via increased degradation of insulin receptor substrate-1. Inhibition or genetic knockdown of this enzyme reverses the adversity. Its inhibition also ameliorates the inflammation in adipose tissue by decreasing TLR4-dependent expression of proinflammatory markers (Talukdar et al. 2012).

During obesity and diabetes, mast cells secrete IL-6 and IFN-γ, which also promote and contribute to proinflammatory effect. The pathogenic response receptors such as TLR4, and the NLR family inflammasome such as cryporin/NLRP3, induce the secretion of active IL-1β and IL-18 in macrophages that recognize the ligands upregulated during obesogenic conditions (Varghese et al. 2019). The downstream effect of this activation includes the regulation of inflammatory intracellular lipids such as ceramides and sphingolipids, which are then responsible for inducing insulin resistance and diabetes (Summers 2010).

Acknowledgments Senior Research Fellowship to Dr. Patel from SERB, DST, Govt. of India and to Dr. Varghese from GSBTM, Govt. of Gujarat, India are thankfully acknowledged. The grant support to Dr. Yadav from GSBTM (sanction no.GSBTM/MD/PROJECTS/SSA/5050/2016-17) and SERB (sanction no.ECR/2015/000266) is highly acknowledged.

Diabetes Forecasts and Statistics for the Coming Decades

12

Alexandre Assuane Duarte and Olga Golubnitschaja

Contents

Abstract

Diabetes has become one of the foremost diseases worldwide, even though growth and prevalence are geographically heterogeneous, according to such variables as ethnic profile, diet, and selected lifestyle variables. Traditionally a concern of the affluent Western society, it is rapidly spreading to developing societies, with potentially disastrous public-health consequences. In recent decades, the regions with the steepest elevation of prevalence were the Eastern Mediterranean, Africa, and South

East Asia. In contrast, Europe and particularly the USA, perhaps on account of long experience and more abundant healthcare resources, have achieved more success in curbing the epidemic. Both modifiable and nonmodifiable risk factors are operative. Obesity and unhealthy lifestyle are prominent in the first modality, whereas aging deserves attention among nonmodifiable precipitants, as the world population is becoming older. Given the possibility of 600 million diabetics in 2045, from current 422 million, the need for implementation of preventive policies cannot be overemphasized.

Introduction

Diabetes mellitus (DM) affects 422 million people in all continents (WHO 2019). The outlook is becoming worse, as regions and age brackets that were relatively free from the disease, especially children, are progressively becoming involved, in tandem with lifestyle changes and longer life expectations (Fig. 12.1). A relevant example is children and teenagers, whose glucose homeostasis deteriorates in parallel with overweight and obesity (Golubnitschaja 2013). Such young patients will eventually pay a high price in the form of cardiovascular disease, cancer, neurological disorders, and premature death (Golubnitschaja 2013).

Global Profile of the Diabetes Epidemic

A worldwide evaluation encompassing 34 years (1980–2014) (World Health Organization 2016) revealed that few regions were able to curb disease growth (Fig. 12.2). Growth accelerates most in less-affluent areas like the Eastern Mediterranean, with a 2.3 times jump in prevalence between 1980 and 2014, and Africa, with a similar proportion of elevation. (Duarte et al. 2018)

South-East Asia region does not come far behind, with a 2.1 times stronger prevalence in 2014. In contrast, the illness is nearly under control in Europe, with a comparatively modest 1.4

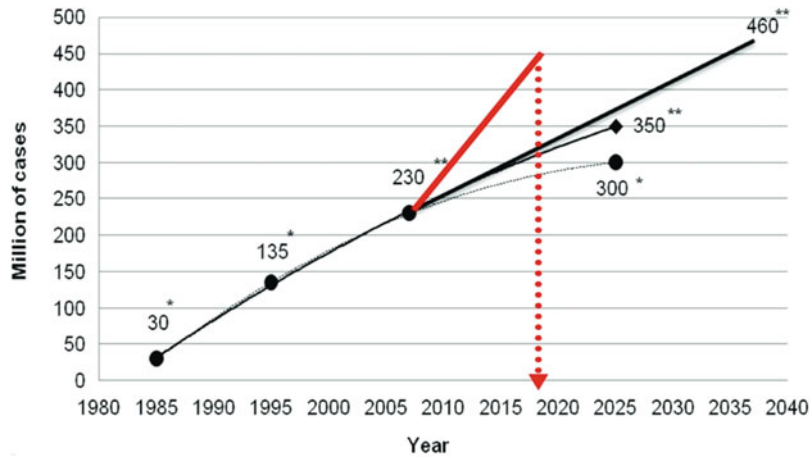

Fig. 12.1 Single asterisks are applied to prognoses from the 1980s, and double ones for those of the early 2000s. Actual prevalence figures, collected in recent years (in red) are even more worrisome (Golubnitschaja 2013). Reprinted with Permission from Duarte AA, Mohsin S, Golubnitschaja O. Diabetes care in figures: current pitfalls and future scenario. EPMA J 2018; 9(2): 126–131

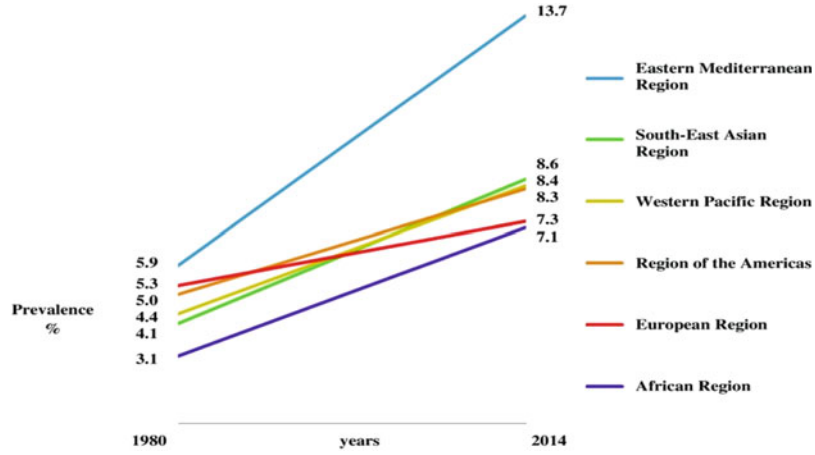

Fig. 12.2 Prevalence of DM on a global scale: retrospective comparative analysis in the period of time from the year 1980 to 2014 (NCD Risk Factor Collaboration (NCD-RisC) 2016). times elevation in the observed period. Differently from Latin America, the Caribbean, and Canada, where the increase is robust, thus influencing the global profile of the Americas, the USA featured a reduction in the incidence of diabetes in the last decade. According to certain authors, this could be due to immigration of younger populations (Benoit et al. 2019).

Decreased Diabetes Incidence in the USA

The announcement comes from the Centers for Disease Control and Prevention (CDC). After peaking in 2009, with 1.7 million new cases a year, the incidence of diabetes in the USA shrunk by 35%, to 1.3 million in 2017. Prevalence remained stable during this period, a finding attributed to longer survival for such populations (Benoit et al. 2019; Media Relations 2019).

Does that mean that at least in the context of richer countries, with countrywide diabetes prevention programs, the tide of diabetes can be stemmed? There are both favorable and ominous evidence. All-cause and cardiovascular mortality in Americans with diabetes are following the same positive trend (International Diabetes Federation 2017). In turn, obesity spread is unrelenting,

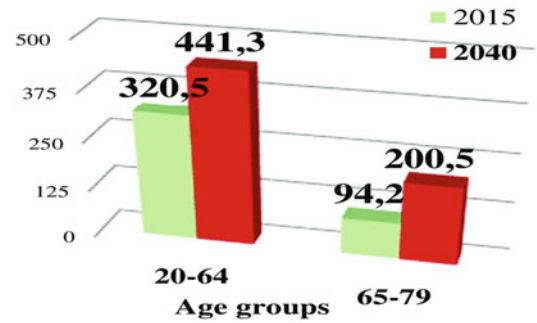

Fig. 12.3 The entire DM patient's pool (in million of patients) stratified by the age as registered in the year 2015; prognostic estimations for the corresponding age-groups are made for the year 2040 (International Diabetes Federation 2015). Reprinted with Permission from Duarte AA, Mohsin S, Golubnitschaja O. Diabetes care in figures: current pitfalls and future scenario. EPMA J 2018; 9(2): 126–131

among nearly all social classes and age groups, which strongly impacts the future of type 2 diabetes (International Diabetes Federation 2017).

The Elderly Population

Life expectancy is improving in most countries, a finding consistent with more diabetic cases (World Health Organization 2016). The 2.1 times anticipated growth of the condition in the

old-age population (65–79 years) till 2040, actually exceeds by 50% of the prognosis for those in the 20–64 age bracket (Fig. 12.3) (International Diabetes Federation 2017). Younger people are currently the clear majority, however, the opposite is predicted for 2040, with more than two-thirds of that population being represented by the elderly people (68.8%) (International Diabetes Federation 2017).

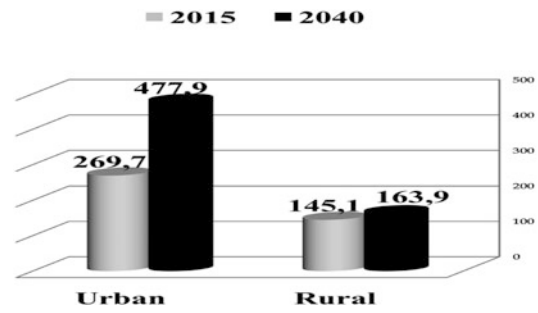

Fig. 12.4 DM patient distribution profiles (in million) between the urban and rural areas as documented for the year 2015 and prognosed for the year 2040 (World Health Organization 2016; International Diabetes Federation 2017, 2015). Reprinted with Permission from Duarte AA, Mohsin S, Golubnitschaja O. Diabetes care in figures: current pitfalls and future scenario. EPMA J 2018; 9(2): 126–131

Gender and Social/economic Profiles

Type 2 diabetes (DM2) is a multifactorial disorder, driven by both genetic and environmental factors. The impact of obesity is the most highlighted, with its accompanying array of sedentarism, lack of physical exercise, and high-fat (Western) diet, yet other predisposing factors point toward diabetes. Besides aging, as alluded to, smoking and alcohol addiction should be mentioned (Luo et al. 2018). The alluded to epigenetic factors could act in the aging process and therefore contribute to the diabetes predisposition (Luo et al. 2018). Differences in prevalence regarding gender and financial income, partially reflect the summed-up effects of the mentioned circumstances.

Fig. 12.5 Gender-related patient distribution profiles (in million): actually (year 2015) registered patients versus prognoses for the year 2040 (International Diabetes Federation 2017). Reprinted with Permission from Duarte AA, Mohsin S, Golubnitschaja O. Diabetes care in figures: current pitfalls and future scenario. EPMA J 2018; 9(2): 126–131

Demographic Patterns

Demographic patterns of diabetes are still conflicting in the literature, depending on geography, ethnic background, economic status, and other characteristics, yet a global forecast for 2040 addressing the living environment has already been outlined (Fig. 12.4) (International Diabetes Federation 2015).

Such a progressive concentration of the disease in the city milieu is consistent with the global urbanization trend, even though rural obesity is not a novelty anymore. Indeed, pediatric obesity rates in certain peripheral locations can be higher than in urban areas (Hosseini and Yilmaz 2019).

Significantly, gender shifts in the diabetes trend for the next two decades are unlikely (International Diabetes Federation 2017). Even though data on diabetes registered a higher prevalence among men (Fig. 12.5), women were more obese or overweight than men. Only in the age group of 70–79 women have a higher prevalence of diabetes than men (International Diabetes Federation 2017). The higher the income of the country, the higher were the rates of overweight and obesity, which are strong well-known risk factors for diabetes (World Health Organization 2016).

Current (2017) statistics reveal a higher and increasing prevalence of the disorder in populations aged 20–64 years. The prognosis for

the prevalence of diabetes in the range of 65–79 years of age will be more than double in 2045, with a prevalence shift toward the elderly population (International Diabetes Federation 2015).

Worldwide Estimations for 2040

In most of the Western Asia-Pacific and South-East Asia regions, until just a couple of decades ago, diabetes was a secondary concern (Duarte et al. 2018). Now it is forecasted that they will carry the largest burden on the planet, at least in absolute numbers, responding for 56% of the diabetes population (World Health Organization 2016).

Projections are less ominous for Europe, and even less for the USA, as already signaled (World Health Organization 2016). Yet the region of North America and the Caribbean will continue to deteriorate, predominantly on account of the contribution of Mexico, but also of Canada and some Caribbean islands (World Health Organization 2016; Benoit et al. 2019).

Concerning expansion compared to current burden, no area will suffer more than Sub-Saharan Africa, followed by North Africa, and Middle East, with 3.0 and 2.4 elevation, respectively, until 2040 (Duarte et al. 2018) (Fig. 12.6).

Public Health Challenges

As emphasized in Table 12.1, the USA and Western European countries still have to deal with large numbers of diabetics, requiring major financial and labor investments (Statista 2019). Yet the speedometer is moving faster in the South and East of the planet, with non-Western countries being predominantly overwhelmed by the epidemic (International Diabetes Federation 2015). This could partly be due to the susceptibility of South Asians, and possibly Asians in general, to lesser degrees of obesity, acquiring precocious comorbidities, particularly type 2 diabetes (Pomeroy et al. 2019). Atavic low lean mass is an ethnic feature of some of these populations,

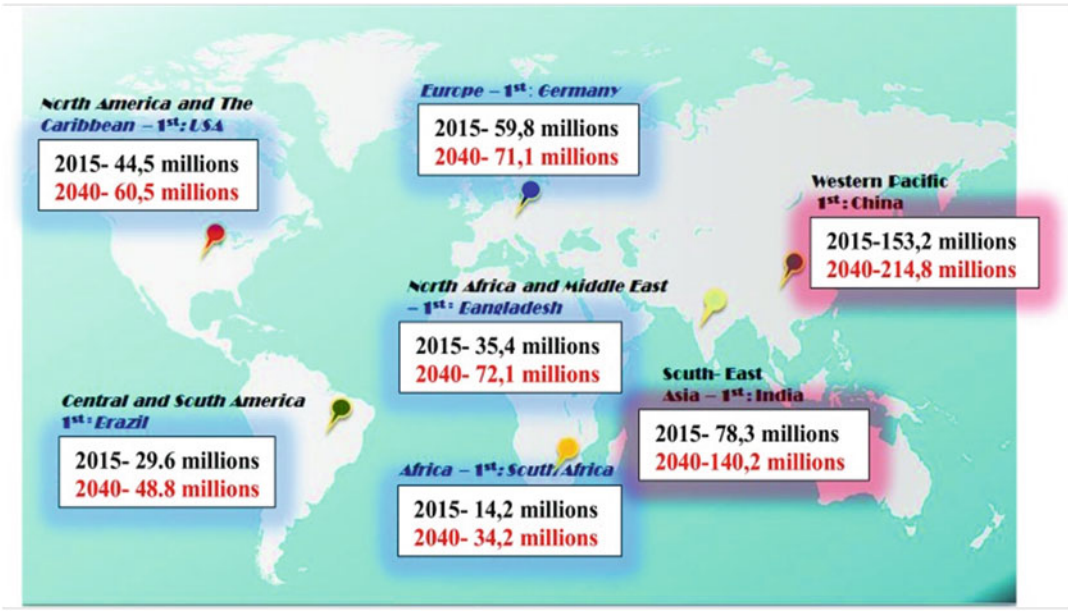

Fig. 12.6 Prognosis of diabetes prevalence in 2040 (International Diabetes Federation 2017, 2015). Reprinted with Permission from Duarte AA, Mohsin S, Golubnitschaja O. Diabetes care in figures: current pitfalls and future scenario. EPMA J 2018; 9(2): 126–131

Statista (2019)

and could underlie early deterioration of glucose homeostasis, when exposed to the Western diet and lifestyle (Pomeroy et al. 2019).

The unrelenting demands for massive diabetes-related budgets in those regions, potentially threatening the whole healthcare economy, are illustrated by Chinese figures. In 1993, only 0.07% of the gross domestic product (GDP) was channeled to diabetes. Figures 15 years later underwent a 300% jump (0.21% of GDP in 2008) (Mao et al. 2019). Specifically for China, this was no calamity, as the period coincided with an excellent industrial performance of the country (Mao et al. 2019). For nations with fragile economies and less impressive GDP growth, consequences can be more unsettling.

Diabetes Complications

Micro- and macrovascular troubles are notorious, along with neurodegenerative and oncological comorbidities (International Diabetes Federation 2017). Retinopathy potentially leading to blindness, and nephropathy with attending needs for hemodialysis and transplantation in advanced cases, can further contribute to heavy acute as well as lifelong expenses (International Diabetes Federation 2015). Chronic leg ulcers and impaired wound healing, besides demanding occasional surgery and amputation, further interfere with health budgets and quality of life (WHO 2019).

Ischemic heart disease is traditionally listed as one the most frequent, and remains among the most costly complications, both in Western and Eastern countries (Gerdtham et al. 2009; Ward et al. 2014; ADA 2018). Fatal myocardial infarction incurs a USD 4067 bill in Taiwan (Cheng et al. 2018). Less common, however, expensive disorders include ischemic stroke, with an annual event cost of 42,119 USD in the USA (Ward et al. 2014), end-stage renal disease, reaching 28,551 dollars annual costs in Australia (Clarke et al. 2008), and leg amputation, with annual expenditures of 14,949 euros in Sweden (Gerdtham et al. 2009) and USD 7677 in Taiwan (Cheng et al. 2018). It has been estimated that complications respond for 25% and 45%, respectively, of the expenses of treating diabetes in emergency and nonemergency settings (ADA 2013).

Direct and Indirect Costs

Another way of financially analyzing the impact of diabetes on society is by adding indirect costs, to the better known disbursements involving screening, diagnosis, therapy, and long-term management of the illness and its direct complications (Seuring et al. 2015). Such less prominent, however, no less tangible items

Table 12.2 Per capita diabetes-related direct and indirect costs

Country	Direct	Indirect
USA	4221–9346	518–4050
Spain	907–4690	556–3379
Italy	4588	208
Netherlands	2780	195

In US dollars (Seuring et al. 2015)
[a]Estimated range for the entire region

encompass absenteeism, reduced productivity for the labor sector, as well as for those unemployed, however, active in household and other informal activities, disease-related disability, and premature deaths triggering lost productivity (Seuring et al. 2015).

As displayed in Table 12.2, estimates significantly differ among countries, as a consequence of disparate cost- of- living, healthcare practices, and computed variables, such as just drug consumption, or also hospitalization, diagnostic work-up, and rehabilitation, among direct costs for instance (Seuring et al. 2015). Nevertheless, the numbers are almost always substantial, notably for poor countries. The most striking discrepancies concern indirect costs, as there is less consensus about how to define and quantify those values. Usually lower than direct costs, in some studies, they come out higher (Seuring et al. 2015).

In the USA, diabetes-related costs including medical expenses and diminished productivity were roughly 300 billion USD in 2010. A 71% increase until 2025 (514 billion USD) is anticipated, more conspicuous than expected inflation or GDP shifts in the period (ADA 2013). The same growth curve, projected for 2040, would render a USA bill of 772 billion, and a worldwide expense of 8.5 trillion, assuming 650 million diabetics at that time (Duarte et al. 2018). Such values are unfeasible, particularly in the developing world, forecasting a crisis in the management of the diabetes population.

According to the American Diabetes Association (ADA), not less than USD 237 billion direct and 90 billion indirect costs, were incurred by the USA in 2017 with the disease (ADA 2018). This amounts to one-fourth of the healthcare budget for total expenditures, or half as much for specific diabetes costs (ADA 2018)

In other words, each diagnosed patient requires a total disbursement around USD 16,750 per year, and 57% corresponds to specific diabetes costs (USD 9600 per capita) (ADA 2018). Such outcomes exceed the average results obtained by Seuring et al. (2015), and displayed for that country in Table 12.2.

Outlook for the Next 30 Years

The growth of obesity continues uncurbed in the entire world, including the USA. This means that despite the respite in the American diabetes epidemic (Benoit et al. 2019; Media Relations 2019),

the future for much of the planet still looks bleak. The increase in lifespan is another negative variable concerning diabetes, as old age is detrimental to pancreas physiology, consistent with an elevation of new-onset cases. At the same time, as existing diabetics live longer, prevalence will be impacted, even if incidence remains the same. As a consequence, the number of diabetics in the USA could double or triple till 2050, affecting as many as one-third of the population, from 10% of current population (CDC 2019).

In synthesis, there is no way of avoiding the fact that type 2 diabetes is a catastrophic enemy, one that has eluded eradication, even though responding to an arsenal of glucose-lowering drug and lifestyle therapies. One death in seven is attributed to the disease, which is also behind the majority of instances of blindness (<75 years of age), renal failure, and nontraumatic lower limb amputations (CDC 2019).

The same way that in politics, the price of liberty is eternal vigilance, diabetes explosive growth will only be curtailed employing sensible, incremental steps, aiming to act on preventive and predictive strategies, avoiding complications and promoting quality of life, possibly benefiting from advances in artificial intelligence, machine learning, databanks, microbiomics, and all other omics (multi-omics), integrated into the innovative concept of predictive, preventive, and personalized medicine (3PM or PPPM) (Golubnitschaja 2013).

Improved Screening, Diagnosis, and Prognosis

In 2019, Issa et al. investigated a possible predictive marker for the risks and complications of DM2, namely angiopoietin-like protein-8 - (ANGPTL-8) (Issa et al. 2019). The role that this liver-secreted amino acid plays has been subject of investigation, controversy, and lack of consensus in the past decades (Issa et al. 2019). This study confirmed that high ANGPTL-8 levels are a risk factor for having DM2 (four times risk [OR 4.03 unadjusted; 6.26 adjusted]). Another interesting finding was a strong correlation between ANGPTL-8 levels and impaired kidney function, possibly predicting diabetic nephropathy. Larger follow-up studies are needed to validate this association (Issa et al. 2019).

Wang et al. (2019) developed in Central China an affordable and personalized method to predict the diabetes risk of patients and to analyze the relationship between the studied risk factors and DM2. The 3-year cohort was composed of 5557 nondiabetic patients, with a validation cohort of 1870 (Wang et al. 2019). The so-called nomogram was based on age, blood pressure, blood sugar, and cholesterol levels. Simple instruments like these can generate large scale identification of individuals at-risk in a suboptimal health status (SHS) (Wang et al. 2019; Ge et al. 2019). Therefore, health policies are better implemented and resources can be wisely used in a targeted manner for a specific population. The above-mentioned method can be easily implemented in multiple countries creating immense databanks that can be further useful globally (Wang et al. 2019).

China is the country with the highest absolute number of individuals with DM2, and urban disease increase in the last two decades (Ge et al. 2019). Ge et al. (2019) used a screening questionnaire assessing the suboptimal health status condition which is characterized by fatigue and lack of energy for 3 months or more, through such variables as fatigue, organ systems, and mental status (suboptimal health status questionnaire-25, SHSQ-25), indicating that SHS could be a strong predictor of DM2 (Ge et al. 2019). Unhealthy lifestyle habits and physical inactivity were definitive factors contributing to a worse suboptimal health state.

The most prominent approach to reverse current trends in the diabetes epidemic is the innovative concepts of predictive, preventive, and personalized medicine (PPPM or 3PM), promoted by EPMA and EPMA Journal (Golubnitschaja 2013). This translates into predictive diagnostics, targeted prevention, and person- tailored treatments in the context of so-called suboptimal health status,

which is the state before the onset of the disease, thus preventing complications of NCDs (noncommunicable diseases) and particularly diabetes (Golubnitschaja 2013; Duarte et al. 2018).

Acknowledgment This chapter was based on the original article "Diabetes care in figures: current pitfalls and future scenario" published by Duarte et al. (2018).

Abstract

Langerhans published in 1869, the thesis entitled "Contributions to the microscopic anatomy of the pancreas" (translated from German). In a healthy adult man, the islet mass is usually 1–2% of the pancreas mass, and can reach 500,000–1 million islets with 50–250 μm of diameter. Nowadays, at least five types of cells were identified in the pancreatic islets, which are responsible for the secretion of hormones: alpha, beta, delta, PP, and epsilon cells. Although pancreatic progenitor cells can be differentiated from stem cells, progenitor cells treated with some combinations of signaling factors can generate different cell types. Beta-cells are hard to produce, and people should be informed on how important it is to have a healthy lifestyle, in order to avoid exposing beta cells to the toxicity of sustained hyperglycemia. In the future, beta-cell neogenesis could repopulate the injured islets of the diabetic individual.

Alpha-cell · Beta-cell · Diabetes · Obesity · Insulin signaling

The Pancreatic Islet

The year of 2019 corresponds to the 150th anniversary of the description of the pancreatic islet by Paul Langerhans (1847–1888). In February 1869, Langerhans presented his thesis entitled "Beiträge zur mikroskopischen Anatomie der Bauchspeicheldrüse" (Contributions to the microscopic anatomy of the pancreas) (Langerhans 1869), in which he described the presence of "islets" of clear cells throughout the gland, with staining properties different from the surrounding tissues. However, Langerhans did not suggest any function, except for the erroneous assumption that the islets might be like lymph nodes (Barach 1952). After 150 years, the pancreatic islets are better known, and cell composition and secretions in physiological and pathological situations were determined (Mandarim-de-Lacerda 2019).

It was Gustave-Edouard Laguesse (1861–1927) in Lille who named in 1893, the "islets of Langerhans," and postulated that they could act in digestion. Laguesse also hypothesized that the model of diabetes found in the pancreatectomized dog could be explained by the absence of these islets, which suggests their intervention in an internal secretion. Laguesse created the term "endocrine" (*endo* = inside, and *krino* = I secrete), to designate this type of cells pouring in the circulating blood to their product of synthesis (Wémeau et al. 2018).

A thin layer of connective tissue surrounds the islets, and separates them from the exocrine pancreas. In mature mammals, the islet mass is usually 1–2% of the pancreas mass and, in a healthy adult man, that can mean 500,000 to 1 million islets, with 50 to 250 μm in diameter (Hellman 1959a). The tail of the pancreas concentrates a higher density of islets than the head and body of the pancreas (Hellman 1959b).

Cytoarchitecture, Vascularization, Innervation, and Paracrine Interactions

The human and rodent islets differ substantially by several characteristics, including architecture, cell composition, gene expression, and some aspects of insulin secretion. Pancreatic islets of mice are highly vascularized, with endothelial and endocrine islet cell interactions essential for islet cell differentiation and function. Human islets have five times fewer vessels per island than islets of mice (Brissova et al. 2015).

Five types of cells could be identified in the pancreatic islets, responsible for the secretion of hormones. Considering rodent islets, we can find the following subsets of endocrine cells: (Kim et al. 2009)

1. Alpha-cells (releasing glucagons), correspond to 20%;
2. Beta-cells (insulin and amylin / islet amyloid polypeptide), cosecreting these molecules with an amylin-insulin ratio of 1: 100, (Adeghate and Kalasz 2011) correspond to 70%;

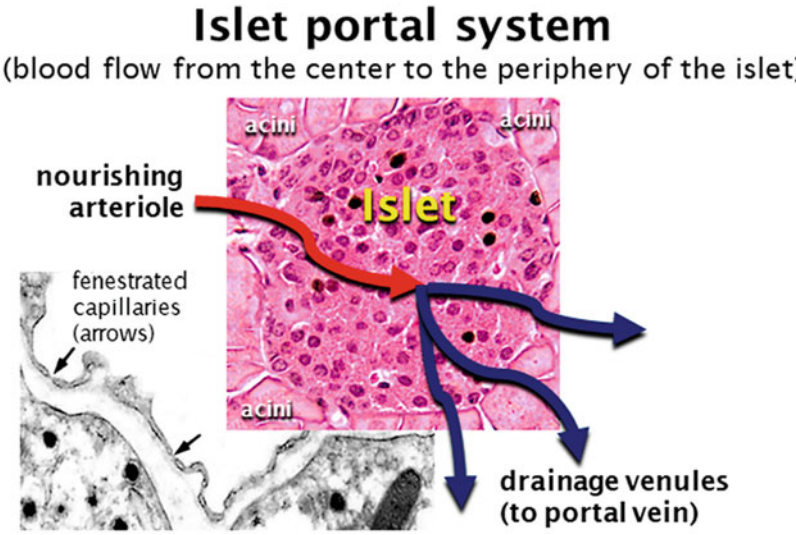

Fig. 13.1 The vascularization of the pancreatic islet. Arterial branches ultimately derived from the celiac artery reach the pancreas, and one or more arterioles nourish the islet from its central part, subsequently undergoing capillarization (the capillaries of this region are fenestrated). The blood is collected by small venules that eventually reach the portal vein (modified from Leung 2010)

3. Delta-cells (producing somatostatin), represent less than 10%;
4. Epsilon-cells (generating ghrelin) amount to less than 1%;
5. PP cells (also known as gamma-cells or F cells, providing pancreatic polypeptide), represent less than 5%;
6. Additionally, serotonin-producing enterochromaffin cells are present in pancreatic islets of mammals, at least at a given stage of development (Wierup et al. 2014).

The human islets have insulin-immunoreactive beta-cells, glucagon-immunoreactive alpha-cells, and somatostatin-containing delta cells dispersed in the islet (Brissova et al. 2005; Folli et al. 2018). Rodent islets exhibit a predominance of insulin-producing beta-cells located in the islet core, while the periphery has some numbers of alpha-, delta-, and PP cells (Abdulreda et al. 2016). The human islets contain proportionately fewer beta-cells and more alpha-cells. In human islets, most beta-, alpha-, and delta-cells are aligned along the blood vessels, without any order or arrangement, indicating that islet microcirculation probably does not determine the order of paracrine interactions (Fig. 13.1) (Cabrera et al. 2006; Leung 2010).

In smaller human islets (<60 μm diameter), beta-cells are in the islet core, while alpha-cells are peripherally located, parallel to the vessels. In larger human islets, alpha-cells are also found along the vessels that enter and branch within the islets. A three-dimensional analysis showed that the islet cells are distributed in an organization of trilaminar epithelial plaques, surrounded by vessels on both sides. In the islet core, the ratio between beta- and alpha-cells is higher than in the periphery, and decreases with increasing islet diameter (Bosco et al. 2010). In epithelial plaques, beta-cells are frequently located in a central position, however, generally display cytoplasmic extensions between peripheral nonbeta-cells (Baetens et al. 1979).

The vascularization and innervation of the islet are highly interconnected, and are essential for intercellular communication. Both participate in control of blood flow, a vital role for endocrine secretion (Penicaud 2017). Sympathetic innervation is necessary for the formation of pancreatic islets, as well as their functional maturation. Ablation of sympathetic innervation or beta-adrenergic signaling during development, results in a change in islet architecture with reduced insulin secretion, and impaired glucose tolerance in mice (Borden et al. 2013).

The beta-cells in the islet show excellent communication with each other via gap junctions, and with other cell types via diffusible chemical

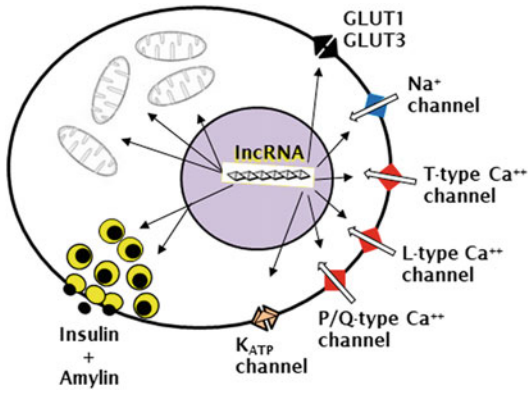

Fig. 13.2 The beta-cell. Schematic representation of the beta-cell, highlighting the channels and membrane receptors that act on cell function, and the production of insulin and amylin. We see that three types of Ca^{++} channels are present (T-type or low-voltage, L-type or voltage-dependent, and P/Q-type or high-voltage). All are controlled by long noncoding RNAs (lncRNAs) that play epigenetic regulatory roles in key molecular processes (gene expression, genetic imprinting, histone modification, chromatin dynamics), interacting with all kinds of molecules (modified from Esguerra and Eliasson 2014)

messengers (Benninger and Hodson 2018). The islet endocrine cells use a sophisticated system of endocrine, paracrine, and autocrine signals to synchronize their activities, which allows rapid and accurate control not only of hormone release, but also of cell differentiation and survival. Moreover, the different categories of paracrine/autocrine signals are complemented by neurotransmitters and neuropeptides, which are controlled by long noncoding RNAs (lncRNA transcripts with lengths exceeding 200 nucleotides, not translated into protein) (Esguerra and Eliasson 2014) (Fig. 13.2).

Like neurons, endocrine cells synthesize, accumulate, and release neurotransmitters in the islets, and have receivers capable of decoding these signals (Di Cairano et al. 2016). Several neurotransmitters have been proposed to function as islet paracrine signals, but most of them have not yet met the criteria to be considered authentic paracrine signals, especially in human islets (the results of other species cannot be directly translated into the human context) (Caicedo 2013).

Postnatal Pancreas

During fetal and early postnatal life, rapid beta-cell proliferation results in daily doubling of their population, associated with vascular growth (Nikolova et al. 2006). In the human fetus, beta-cells already secrete insulin in response to secretagogues (Adam et al. 1969), however in rodents, this occurs only after birth (Kervran et al. 1979). At birth, the islet architecture appears similar to adult animals, while their total population continues to increase. Beta- and alpha-cells continue rapidly growing between days 4 to 10 after birth, until day 28, due to demand for insulin. Most islet cells develop in the tail and the dorsal pancreas (Dhawan et al. 2007).

Apoptosis, as well as proliferation, modulates the development of the endocrine pancreas. Apoptosis of beta-cells is rare during embryogenesis, however not after birth, with islet remodeling and changes in beta-cell maturation. The frequency of apoptotic beta-cells in adult rats is approximately 0.5%, with reduction until 6 months after birth (Scaglia et al. 1997).

Mitochondria play a role in islet protection, preventing apoptosis against oxidative stress. Also, insulin-like growth factor 2 (IGF2), a survival factor that potentiates beta-cell growth, maturation, and function, is another growth factor that prevents apoptosis of beta-cells, expressed in beta-cells at the beginning of rodent life (Reusens and Remacle 2006). Besides, neuropeptide Y (NPY) receptors play a role in the control of beta-cell mass. Activation of the NPY receptor functionally protects the islets, by restoring glucose reactivity after chemical-induced damage. Thus, NPY receptor activation might attenuate beta-cell apoptosis, preserving functional beta-cell mass, and lessening hyperglycemia phenotype in a low-dose streptozotocin diabetes model (Franklin et al. 2018).

There is a balance between the growth of new beta-cells and the loss of old beta-cells, which can be evaluated through the assessment of the total mass (Marinho et al. 2019a). There are various sources for the endogenous production of new beta-cells from existing cells. Beta-cells, long

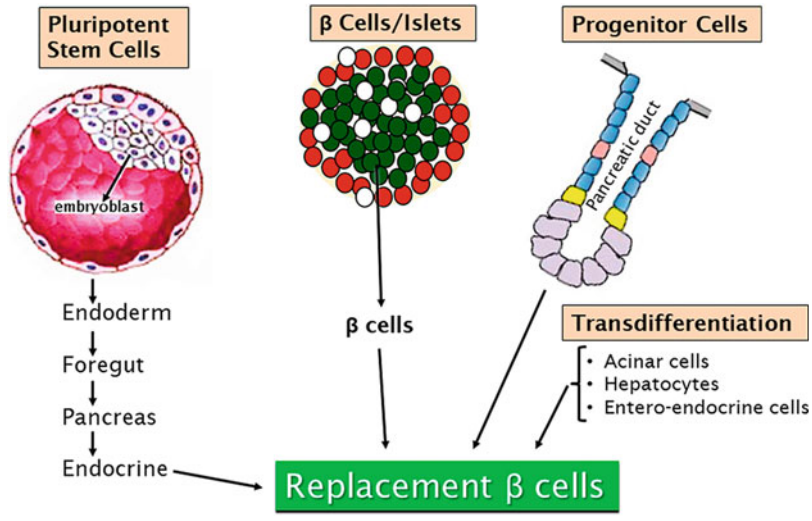

Fig. 13.3 Expansion of the beta-cell mass in adults: possible mechanisms (modified from Nichols et al. 2014)

considered postmitotic, have demonstrated the potential for regenerative capacity. Likewise, the presence of facultative endocrine progenitor cells of the pancreas has been established. Also, the malleability of cell identity has enabled the generation of beta-cells from other differentiated cell types (Nichols et al. 2014).

The expansion of the beta-cell mass in adults continues, as their ability to regenerate decreases with age, and involves three possible mechanisms: (Soggia et al. 2011) (a) the proliferation of preexisting beta-cells; (b) neogenesis from progenitor cells or undefined adult stem cells; (c) transdifferentiation from end-stage cells (especially in association with conditions such as obesity and pregnancy) (Fig. 13.3).

Role of Nonbeta Islet Cells

Alpha-cells usually produce glucagon, however when beta-cells are damaged, alpha-cells also provide glucagon-like peptide type 1 (GLP-1), a beta-cell growth and survival factor (Habener and Stanojevic 2013). In the mouse, some glucagon-producing alpha-cells and somatostatin-producing delta-cells become insulin-expressing cells, after the ablation of insulin-secreting beta-cells, thus promoting the recovery from diabetes. Therefore, islet nonbeta-cells (alpha-cells and polypeptide-producing gamma-cells) can be reprogrammed by transcription factors, to produce and secrete insulin in response to glucose. Once transplanted into diabetic mice, converted human alpha-cells reverse diabetes and continue to produce insulin, even after 6 months (Furuyama et al. 2019). Also, transformed alpha-cells acquire the electrophysiological characteristics of beta-cells, and conduct insulin secretion stimulated by glucose. Pathways regulated by aristaless-related homeobox (Arx) protein, and by DNA methyltransferase-1 (Dnmt1) enzyme, are enough to achieve the targeted generation of beta-cells from adult pancreatic alpha-cells (Chakravarthy et al. 2017).

Beta-cell Proliferation

About 1–2 g is the beta-cell mass in the adult human pancreas, essential for glucose homeostasis (Saisho et al. 2013). In early life, beta-cells are primarily derived from precursor cells, after which the proliferation of beta-cells speeds up to generate functional beta-cell mass (Jiang et al. 2018). Increment of beta-cell mass is noted to peak within the first 2 years of life, and then to rapidly decrease in childhood (Mezza et al. 2014).

After birth, approximately 3% of beta-cells are in the active cell cycle, whereas in adults, human beta-cell proliferation is low (Mezza et al. 2014).

Transforming growth factor-beta (TGFbeta) isoforms are potent regulators of growth and differentiation. Moreover, TGFbeta receptor signaling pathway is involved in pancreatic development (Daneshmandi et al. 2017), promoting endocrine cell differentiation and maturation, and inhibiting acinar cell growth in embryogenesis. Beta-cell proliferation might occur after pancreatic duct ligation, depending on infiltrating macrophages releasing TGFbeta1 to upregulate SMAD 7 protein, an antagonist of the TGFbeta receptor signaling pathway. The inflammation-induced beta-cell proliferation is linked to the enhanced levels of Cyclin D1 and Cyclin D2 proteins, as well as nuclear exclusion of p27 protein (regulated by SMAD 7) (Xiao et al. 2014). TGFbeta1, SMAD 2, and SMAD 3 are expressed in adult islets, while SMAD 7 is not observed in insulin, glucagon, and somatostatin cells in healthy individuals; however, it is overexpressed after pancreatic injury (Xiao et al. 2016).

Figure 13.4 illustrates the canonical TGFbeta/SMAD signaling pathway. On the cell membrane, TGFbeta binds to type II receptors, recruiting type I receptors, then it phosphorylates SMAD 2 and SMAD 3. Notably, translocation from the cytoplasm to the nucleus regulates downstream gene expression, after forming a complex with SMAD 4 (Jiang et al. 2018). Besides, the TGFbeta receptor signaling pathway interferes on noncanonical pathways, involving mitogen-activated protein kinase (MAPK) pathways, and

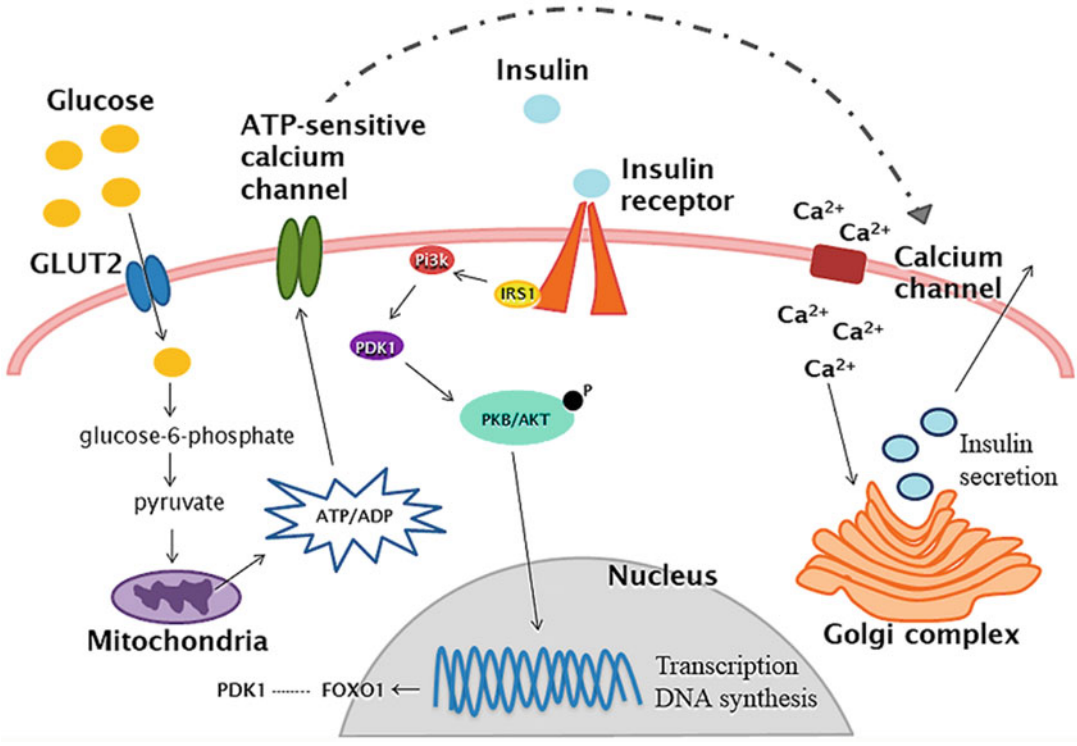

Fig. 13.4 PI3K / AKT insulin signaling pathway in pancreatic beta cells. Physiologically, in the postprandial period, insulin binds to its receptor on the alpha subunit, leading to the phosphorylation of its membrane receptor beta subunit. The phosphorylation of tyrosine residues activates IRS1, leading to AKT phosphorylation and FOXO2 transcription, which in turn triggers PDX1 transcription. In fasting periods, AKT-p promotes FOXO1 transcription, which inhibits PDX1 transcription. Abbreviations: AKT, protein kinase B; FOXO2, human Forkhead box protein O2; IRS1, insulin receptor substrate 1; PDX1, pancreatic and duodenal homeobox 1

the phosphatidylinositol 3′-kinase (PI3K)/protein kinase B (AKT) pathway (Hamidi et al. 2017).

The WNTs are part of a family of secreted signaling proteins, that perform their functions through autocrine and paracrine mechanisms. These proteins interact with receptors and trigger a cascade reaction, resulting in the accumulation of beta-catenin in the cytoplasm. The postnatal activation of beta-catenin in beta-cells, results in increased proliferation of this cell type, whereas increased expression of Axin 2 (WNT/beta-catenin pathway antagonist) has an opposite effect (Rulifson et al. 2007).

Insulin Synthesis

Preproinsulin is a high molecular weight molecule, consisting of four different domains: C-peptide, A and B chains (insulin), and a signal peptide, which is responsible for its rapid penetration into the endoplasmic reticulum (Suckale and Solimena 2010). In the rough endoplasmic reticulum, the preproinsulin undergoes cleavage of its signal peptide, giving rise to proinsulin. The proinsulin molecule consists of two chains, the alpha-carboxyterminal and the beta-aminoterminal, joined by peptide C. The alignment of the disulfide bonds that bind the two chains is the primary function of peptide C, allowing adequate molecular folding and cleavage. Microvesicles transport proinsulin to the Golgi complex, an ATP-dependent process (Vakilian et al. 2019).

Within the Golgi complex, up to the formation of secretory granules, proinsulin is converted into insulin by cleavage of the C-peptide (predominantly at the junction with the beta chain), by specific endopeptidases (proconvertases 2 and 3), and an exopeptidase (carboxypeptidase H) (Liu et al. 2014). Once separated, insulin and C peptide are packed into secretory granules. Insulin molecules, in the presence of zinc and acidic pH, aggregate and form hexamers, initiating the crystallization process. Under normal conditions, 95% of the secreted hormone is insulin, and 5% proinsulin (Fig. 13.5) (Liu et al. 2018).

Insulin Output Modulation

The beta-cell can modulate the synthesis and secretion of insulin according to metabolic demand. Increases in the extracellular concentration of glucose, neurotransmitters, nutrients, and hormones stimulate the synthesis of proinsulin; however, glucose concentration does not affect its conversion into insulin. The glucose threshold to enhance insulin synthesis is between 2 and 4 mmol/L and, to boost its secretion, 4–6 mmol/L. Among the nutrients that can stimulate insulin synthesis, ribose, and some amino acids like leucine are involved (Suckale and Solimena 2010).

Growth hormone, cortisol, glucagon, GLP-1, gastric inhibitory polypeptide (GIP), secretin, cholecystokinin, gastrin, situations such as pregnancy and obesity stimulate insulin synthesis. Somatostatin and epinephrine inhibit insulin secretion, but somatostatin does not affect proinsulin synthesis. In the case of excessive production of insulin by the beta-cell, the granules are degraded by lysosomes, through proteolytic action, a process that is known as crinophagia (Liu et al. 2014).

Signaling Pathways Related to Insulin

There are several pathways of insulin signaling: the phosphatidylinositol 3-kinase (Pi3k) pathway, with formation of the CAP/Cble complex, and the RAS pathway—Mitogenic Activated Protein Kinase (RAS-MAPK). The Pi3k path is the most important, leading to metabolic actions such as glucose transport, glycolysis, glycogen synthesis, lipid metabolism, and protein synthesis, besides cell growth and inhibition of apoptosis. Inhibition of Pi3k blocks almost all metabolic responses stimulated by insulin (Saad et al. 1992).

Pi3k is an enzyme composed of two subunits, one regulatory (p85) and one catalytic (p110). The catalytic subunit is unstable and only detected in association with the regulatory subunit. It plays an essential role in cell differentiation and mitogenesis. The regulatory subunit

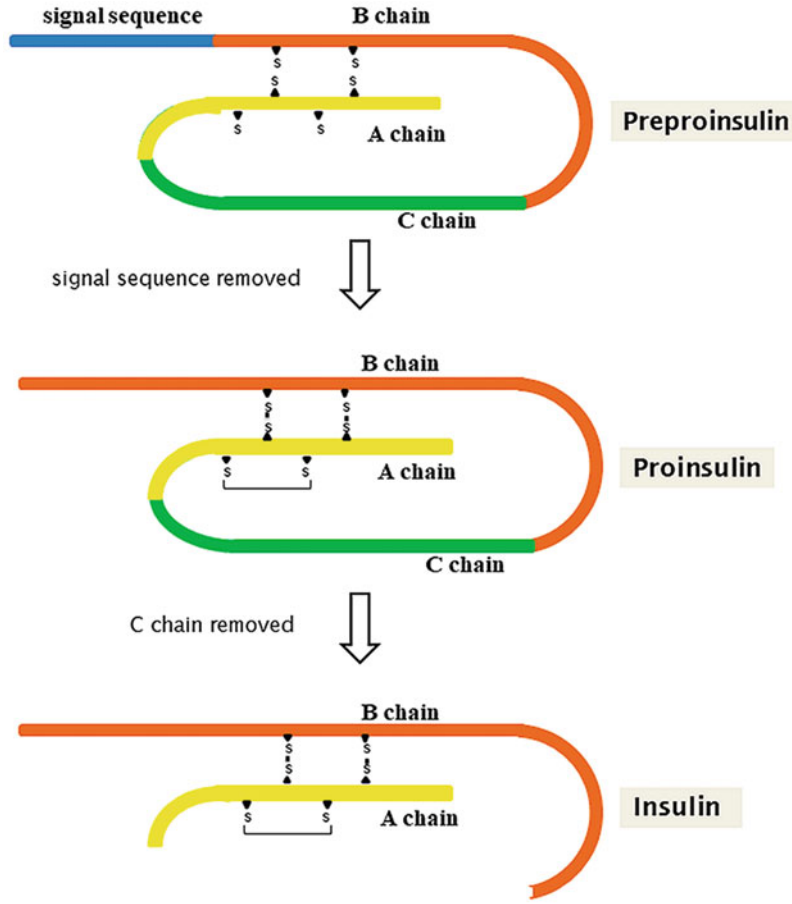

Fig. 13.5 Insulin synthesis and processing. The mature insulin hormone is produced from the processing of its preprohormone, called preproinsulin. The initial cleavage of a 23 amino acid amino-terminal amino acid, called the signal sequence, and the formation of hydrogen bridges, culminating in the production of proinsulin. The removal of C peptide (C chain) by proteolysis produces insulin with its A and B chains

contains two SH2 domains, which allow its binding to the YMXM and YXXM sites (Y = tyrosine, M = methionine, and X = any amino acid), phosphorylated by the insulin receptor substrate (IRS) proteins, activating the associated catalytic domain (Lietzke et al. 2000). The enzyme catalyzes the phosphorylation of phosphoinositides at the 3-position of the inositol ring, producing phosphatidylinositol-3-phosphate, phosphatidylinositol-3,4-diphosphate, and phosphatidylinositol-3,4,5-triphosphate (PIP3).

PIP3 recruits other serine/threonine kinases for the plasma membrane, such as phosphoinositol-dependent kinase 1 (a protein homologous to the murine thymoma v-AKT viral oncogene) (Kim and Park 2018). In pancreatic beta-cells, insulin and insulin growth factor 1 (IGF-1) activate AKT in a manner dependent on the activation of Pi3k. In the Pi3k/AKT insulin pathway, the insulin receptor substrate type 1 (IRS1), is the primary substrate of the insulin receptor in the beta-cells. When IRS1 expression decreases in insulin resistance, this substrate can be partially offset by the increase of IRS2 (Kim et al. 2007).

The binding of insulin to the alpha subunits of its membrane receptor activates the beta subunits, promoting autophosphorylation, which in turn enables the intrinsic tyrosine kinase function that catalyzes the phosphorylation of IRS1, which interacts with Pi3k, stimulating the recruitment of the significant molecule of the cascade, AKT (Brunet et al. 1999). The AKT protein, once phosphorylated, positively regulates Forkhead transcription factors (FOX), whereas FOXO2 inhibits FOXO1 (Katoh and Katoh 2004). With the decrease of AKT expression, FOXO2 drops

and FOXO1 is more expressed, with consequent reduction of the pancreatic and duodenal homeobox 1 transcription factor (PDX1), controlled by the earliest identified gene in the embryonic development of the pancreas, characterizing a state of cellular dysfunction (Kitamura et al. 2002). PDX1 is a crucial transcription factor, that is expressed at several stages of pancreatic development and in the process of differentiation of beta-cells. The expression of PDX1 is linked to the preservation of pancreatic beta-cell function, and clinical studies have shown a decrease in PDX1 expression during insulin resistance (Yang et al. 2012).

Glucose Transporters

Glucose transporters (GLUT) are also critical factors in the response of insulin secretion. In physiological conditions, GLUT2, present in the cytoplasm of pancreatic beta-cells, is stimulated to translocate into the plasma membrane by the increased concentration of extracellular glucose, allowing the entry of glucose into the cell, with the consequent participation of this molecule in energy metabolism (Beamish et al. 2017). Glucose serves as a substrate in the glycolysis pathway, producing pyruvate molecules that participate in the tricarboxylic acid cycle, and the electron transport chain in the mitochondria, generating adenosine triphosphate (ATP—), the chief energy coin that leads to the closure of voltage-dependent potassium channels.

These in turn act by causing depolarization of the plasma membrane over the calcium channels, leading to the influx of this ion into the cytoplasm, which promotes the conversion of proinsulin into insulin, regulating the secretion of this hormone (Dai et al. 2012). The CAP/Cbl pathway is also required for insulin to stimulate glucose transport (Cbl is a proto-oncogene, which is associated with CAP adapter protein). The CAP-Cbl complex is phosphorylated, migrates to the cell membrane, and promotes a second signal for the translocation of GLUT4, parallel to the Pi3k pathway (Fig. 13.6) (Chiang et al. 2001).

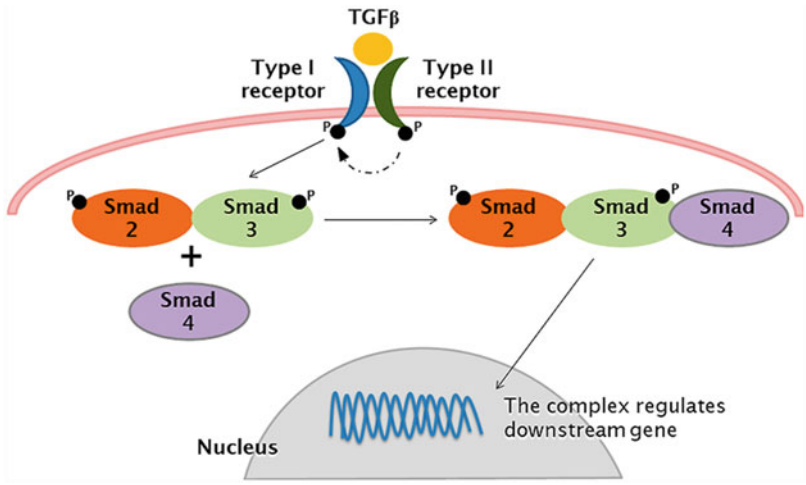

Fig. 13.6 Canonical TGFβ/SMAD signaling pathway. On the cell membrane, TGFβ binds to type II receptors, recruiting type I receptors, then phosphorylates SMAD2 and SMAD3 to form a complex with SMAD4. The complex translocates to the nucleus, regulating downstream gene expression. Abbreviations: SMAD, refer to the homologies to the *C. elegans* SMA ("small" worm phenotype) and *Drosophila* MAD ("Mothers Against Decapentaplegic") family of genes; TGF, transforming growth factor

Islet Transplantation and Stem-cell Differentiation

Insulin-secreting beta-cells and glucagon-secreting alpha-cells cooperate to regulate blood glucose levels. Destruction or dysfunction of beta-cells is known to lead to diabetes, and hence problems with insulin production. Unfortunately, no treatment yet can permanently stop the progression of diabetes and its various complications, even though relatively prolonged remission is possible with intensive lifestyle interventions, as well as bariatric/ metabolic surgery in a proportion of cases (Taylor et al. 2019).

Islet transplantation can often normalize blood glucose levels for several years, and thus prevent complications from diabetes, in insulin-dependent patients (Wojtusciszyn et al. 2019). The procedure is minimally invasive or mini-surgical, involving purified islets which are infused through the portal vein of the liver. The procedure often needs to be repeated, so that the individual no longer needs long-term insulin.

Stem Cell Sources

Pancreatic islets for transplantation are scarce. Stem cell-derived cells could be an alternative. Differentiation of stem cells into mature alpha-cells and beta-cells is one of the principal challenges, besides subsequent isolation, purification, and arrangement in islet-like structures for transplantation (Anazawa et al. 2019).

Stem cell unicellular RNA sequencing (scRNA-seq) at each stage of differentiation, helps in the identification of the types of subsequently generated cells, thus guiding the progression of pancreatic progenitor cells into specific cell lines (Schiebinger et al. 2019). Efficiency of current approaches to achieve the desired aims is not ideal because of cell heterogeneity, and insufficient knowledge of all the necessary molecular signaling factors (Theis and Lickert 2019).

Pancreatic progenitor cells can be differentiated from stem cells, and subsequently to hormone- and nonhormone-expressive cell types (Veres et al. 2019), confirming that parental cell specification is the key to produce the targeted cell types. The desired endocrine cell subtypes should be isolated, purified, and then reassembled into pseudo-islets, to provide mature stem cell-derived islet cells. A simple dissociation and reassembly procedure, can remove most nonendocrine proliferative cells from cell culture (Balboa et al. 2019). Stem cell-derived pancreatic progenitor cells have already been transplanted to patients with type 1 diabetes. However, they need to further differentiate into beta-cells and insulin, upon glucose stimulation (Clinicaltrials 2017). Alpha-cells should be transplanted as well, as they control hormone secretion, and contribute to glucose regulation (Veres et al. 2019).

Alpha-cell Plasticity

Insulin production is stimulated in nonsmoothed alpha-cells, when the combination of beta-cell loss or inhibition of insulin signaling, and gamma cell inactivation or mild inhibition of alpha-cells occurs (Chera and Herrera 2016). Animal studies have shown that after ablation of almost all beta-cells in the pancreas of adult mice, 1–2% of alpha-cells expressing glucagon, and gamma cells expressing somatostatin, spontaneously secrete insulin, leading beta-cell mass to significant regeneration and normoglycemia (Chera et al. 2014). The mechanism that fully controls insulin expression is unknown; however, studies have identified insulin signaling pathways in alpha-cells and surprisingly also in gamma cells, as regulators of alpha-cell identity and conversion into insulin-producing cells (Thorel et al. 2011).

It seems that maintaining cellular identity is an active, constant process mediated by repressive signals, that are released by neighboring cells, and prevent cells from differentiating after adulthood (Thowfeequ 2007). Half a century of research into the determination and maintenance of cell identity, has revealed that adult cells are not terminally differentiated but retain some potential for plasticity, even in higher organisms (Chera et al. 2014). The spontaneous conversion

of adult cells is considered a sporadic event, which is highly regulated and activated exclusively after injury, and whose efficiency correlates with mechanisms that preserve a specific cellular identity. In contrast, knowledge of the regulation of "brake signals" responsible for maintaining the integrity of adult cells is still limited (Thowfeequ 2007).

Regenerative Medicine

The fate of a cell and its functionality are regulated by genetic and epigenetic factors, that become "blocked" due to self-regulatory feedback, or through the action of regulatory signals from the microenvironment in which the cells reside, namely neighboring cells and extracellular matrix (Chera and Herrera 2016; Chera et al. 2014). Thus, it is these factors that determine the plasticity of a cell. Changes in the identity of adult cells, mainly if triggered by stress responses, are a basis for regenerative medicine (Jessen et al. 2015). Studies with stem cells have helped to clarify what happens inside and outside the cell, for this plasticity to occur (Chakravarthy et al. 2017).

Massive beta-cell damage may lead to the release of local signals, that act as modulators of change or maintenance of alpha-cells, causing a small amount of these cells to assume the function of lost cells (Pagliuca et al. 2014). Thus, the stability of cellular identity is context-dependent, and has several levels of control over changes in phenotype (Thorel et al. 2011). Maintaining cellular status is an active process of repressive signals released from neighboring cells, blocking an intrinsic tendency of cells to modify their phenotype and functional characteristics (Holmberg and Perlmann 2012).

The Beta-cells Mass

In insulin-resistant states, pancreatic islets often respond by increasing insulin secretion to maintain normoglycemia, a process called beta-cell compensation (Zimmet et al. 2001), and it is evident from rodent studies that both the expansion of beta-cell mass, and the increased function of these cells are essential (Korc 2019). In experimental studies, it is possible to quantify beta-cell mass and monitor pancreatic islet injury or recovery (Mandarim-de-Lacerda 2019; Marinho et al. 2019a). Stimulating factors related to beta-cell mass development include increased nutrient supply (mainly glucose and fatty acids), insulin, and other growth factor signals, and increased levels of sensitivity to incretin hormones such as GLP-1 (Chen et al. 2016). Increasing the enteric nutrients, particularly in the form of fat, may also result in the expansion of beta-cell mass, by increasing GLP-1 produced from L cells in the gut (Nauck and Meier 2018).

Beta Cell Mass Increase

As mentioned (Fig. 13.3), a variety of sources can originate the endogenous production of new beta-cells from existing cells: (a) beta-cells (long thought to be postmitotic) are now considered to have potential for regeneration, (b) pancreatic facultative endocrine progenitor cells, and (c) generating beta-cells from other differentiated cell types (Nichols et al. 2014). In mice, alpha and delta cells can be lineage-traced and reprogrammed by the transcription factors PDX1 and MAFA, to produce and secrete insulin in response to glucose (Furuyama et al. 2019).

Pancreatic Islets in Obesity and Intermittent Fasting

The prevention of obesity-induced type 2 diabetes mellitus (T2D) by dietary modifications, including daily calorie restriction and intermittent fasting, has been described in human clinical trials (Tuomilehto et al. 2001). Caloric restriction regimens are still the most common dietary strategies, reducing energy intake by 20–50% of the needs (Omodei and Fontana 2011). Figure 13.7 illustrates the islet modification due to obesity and intermittent fasting.

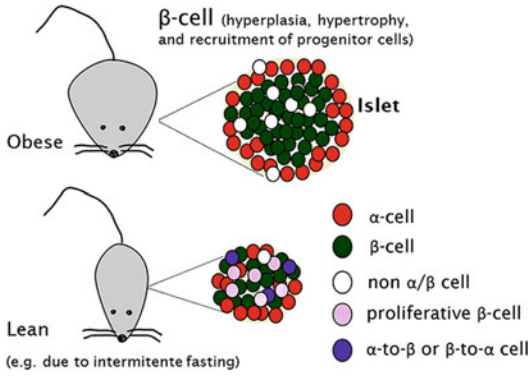

Fig. 13.7 Adaptation of the pancreatic islet and cells. Obesity represents a stress factor for the pancreatic islet, which increases in size, and the beta-cell is stimulated to produce more insulin to maintain blood glucose control. The beta-cell undergoes hyperplasia, hypertrophy, and progenitor cells are recruited. With time and established insulin resistance, there is depletion of beta-cells. Weight loss improves pancreatic islet stress, which tends to regain cell arrangement and function

For many, intermittent fasting seems to require less effort than ordinary calorie restriction diets, is cost-effective, and is a useful tool in promoting weight loss and maintenance (Das et al. 2007). Intermittent fasting has shown promise in achieving weight loss goals, and can prevent and cure rodent models of T2D (Mattson et al. 2017). Intermittent fasting differs from caloric restriction, as it only requires an individual to restrict energy 1–3 days to a week, and allows for free food consumption on the nonrestriction days (Varady 2011). When C57BL/6 mice are fed a high-fat diet *ad libitum,* they develop hyperinsulinemia, obesity, and systemic inflammation (Fraulob et al. 2010), all of which are prevented by intermittent fasting (Marinho et al. 2019b). Interestingly, the antidiabetic effect is not due to caloric restriction, because mice of the intermittent fasting group consume the same amount of food as control mice fed *ad libitum* (Mattson et al. 2017).

Fasting and Glucotoxicity

Beta-cells are highly sensitive to nutrient availability. They are endowed with a low rate of replication, and neogenesis rarely occurs in the adult pancreas. Thus, beta-cell depletion and the consequent loss of insulin secretion, represent a severe stage of diabetes (Meier et al. 2008). In islets of mice with T2D, irreversible beta-cell damage can be elicited by chronic exposure to supraphysiological glucose concentrations (glucotoxicity) (Robertson et al. 2003).

The cellular and molecular mechanisms by which intermittent fasting treats diabetes involve increased sensitivity of insulin receptor signaling. Thus, insulin more readily stimulates glucose uptake by muscle, hepatocytes, and other cell types, including neurons (Sequea et al. 2012). Different signaling pathways might be affected by intermittent fasting: (a) reductions of mTOR signaling and up-regulation of cAMP-responsive element-binding protein (Hatori et al. 2012); (b) improved mitochondrial function (Descamps et al. 2005); (c) stimulation of mitochondrial biogenesis (Cheng et al. 2016); (d) brain-derived neurotrophic factor (Yuen and Sander 2014); (e) autophagy pathways (Longo and Mattson 2014).

Cellular Effects

Another feature of diabetic beta-cell failure is the dedifferentiation of beta-cells, which results in increased nonhormone-producing cells within pancreatic islets (i.e., cells producing neither insulin nor glucagon, known as nonalpha/beta) (Talchai et al. 2012). Intermittent fasting can improve the markers of transitional alpha-to-beta or beta-to-alpha-cells that coexpress both alpha- (i.e., glucagon) and beta biomolecules (i.e., PDX-1 and insulin). Also, differentiated or committed cells can be diminished, followed by the induction of transitional cells, and significant increases in the proliferation and quantity of insulin-generating beta-cells (Cheng et al. 2017).

Neurogenin 3 (NGN3—expressed by 2–10% of acinar and duct cells in the healthy adult human pancreas), is a marker for progenitors giving rise to beta-cells, and intermittent fasting preserves or restores beta-cell function, once NGN3-driven beta-cell regeneration occurs in diabetic mice

(Wei et al. 2018). Also, autophagic flux causing cell death is enhanced, stimulating progenitor, or other cells to regenerate beta-cells in order to reverse the beta-cell loss, despite continued high-fat intake in an experimental model, thus improving glucose tolerance by enhancing glucose-stimulated insulin secretion and NGN3 expression (Liu et al. 2017).

Fasting and Refeeding Sequence

Intermittent fasting promotes FOXO-1 and its transcriptional targets in pancreatic islets, transitionally inducing the expression of progenitor cell marker NGN3+ upon refeeding, which leads to beta-cell regeneration, and changes in a wide range of cytokines associated with beta-cell recovery (Chakravarthy et al. 2017; Cigliola et al. 2018). Thus, intermittent fasting and refeeding generate the complex and highly coordinated conditions, required for the generation of stable insulin-producing beta-cells, and reversion of severe beta-cell depletion (Cheng et al. 2017). It not only suppresses the circulating cytokines associated with beta-cell damage (e.g., TNF-alpha and IL-12), but also increases those associated with regeneration (e.g., IL-2 and IL-10) (Dirice et al. 2014). Inflammation decreases, and a cytokine profile beneficial for the restoration of insulin secretion and the reversal of hyperglycemia is achieved (Cheng et al. 2017).

Conflict of interest There is no conflict of interest in this manuscript.

Funding Conselho Nacional de Desenvolvimento Científico e Tecnológico (Brazil) (CNPq, Grant No 302.920/2016-1 to CAML, and 305.865/2017-0 to MBA), Fundação Carlos Chagas Filho de Amparo à Pesquisa do Estado do Rio de Janeiro (Faperj, Grant No E-26/202.935/2017 to CAML, and E-26/202.795/2017 to MBA). These foundations had no interference in the accomplishment and submission of the manuscript.

Abstract

Options currently being used for the treatment of obesity abound, however, few have successfully and sustainably reversed the disease and its comorbidities. This has led to the search for alternative approaches. Targeting of the signaling of the soluble and endogenous secretory receptors for advanced glycation end products (sRAGE and esRAGE) could be the cornerstone, in the management of obesity and its associated complications. This chapter critically reviews available evidence and interventions in this field.

Keywords

Obesity · Metabolic dysfunction · Receptor for advanced glycation end products · Advanced glycation end products · Nutrition

Abbreviations

AGEs	Advanced glycation end products
$A\beta_{1-42}$	Amyloid β1-42
esRAGE	Endogenous secretory receptor for advanced glycation end products
IKKβ	Inhibitory kappa B (IκB) kinase β
MAPKs	Mitogen-activated protein kinases
MCP-1	Monocyte chemoattractant peptide 1
NFκB	Nuclear factor kappa-light-chain-enhancer of activated B cells
NADPH-oxidase	Nicotinamide adenine dinucleotide phosphate oxidase
RAGE	Receptor for Advanced Glycation End products
Ros	Reactive oxygen species
sRAGE	Soluble receptor for advanced glycation end products
TNF- α	Tumor necrosis factor alpha
T2DM	Type 2 diabetes mellitus
4-HNE	4-hydroxy-nonenal

Introduction

Few therapies have been able to reverse obesity and its complications (Eleazu et al. 2019). Given the increasing rates of this condition (Chowdhury et al. 2016), different avenues have been pursued. Targeting of the signaling of the soluble and endogenous secretory receptors for advanced glycation end products (sRAGE and esRAGE) could be promising (Eleazu et al. 2019).

Concept of Obesity

Obesity results in hyperplasia and hypertrophy of the adipocytes (Eleazu et al. 2019), engaging endogenous and environmental mechanisms (Emami et al. 2016; Eleazu et al. 2019).

Type 2 Diabetes Mellitus

One of the closest associations for excess body fat is the risk of type 2 diabetes mellitus (T2DM), also known as "diabesity" (Leitner et al. 2017). Obesity induces increased release of free fatty acids (FFAs) and secretion of proinflammatory cytokines, such as interleukin 6 and TNF-α from visceral fat, with a high lipolytic rate, and possibly abdominal adipose depots as well, which trigger insulin resistance, desensitizing cells to insulin response following hepatic glucose production, and leading to increased rate of glucose production. On the muscle, the increased free fatty acids also inhibit pancreatic insulin secretion and derange glucose uptake (Boden, 2008). A BMI as low as 22 kg/m^2 can induce diabetes (Someya et al. 2019).

Hypertension, Dyslipidemia, and Cardiovascular Disease

A BMI above 26 kg/m^2 can be followed by 2–3 times more risk for hypertension. An elevation in stroke volume, along with hypertrophy of the left ventricle, can aggravate cardiovascular morbidity and mortality. With systemic vascular resistance unchanged or elevated, blood pressure rises. Insulin resistance can also enhance sympathetic tone, andrenal sodium, and water reabsorption. Genetic risk is also worth mentioning (Dlamini et al. 2019).

Atherosclerotic Cardiac Disease

Visceral adipose tissue is linked with increased plasma triacylglycerol (TAG), decreased HDL cholesterol, increased production of VLDL cholesterol, impaired clearance of TAG rich lipoproteins, and higher lipolysis in the adipose tissue. Lipolysis can also precipitate fatty liver (Sarwar et al. 2018).

Insulin resistance favors expression of proinflammatory adipokines including interleukin-6, IL-1β, and tumor necrosis factor-α, further worsening insulin resistance, promoting increased flux of FFAs into the liver, mitochondrial dysfunction, reactive oxygen species production, hepatic inflammation, and fibrogenesis (Lambertucci et al. 2018; Divella et al. 2019).

Cancer

At least one cancer in five is more frequent among the obese (Wolin et al. 2010; Roberts et al. 2010), perhaps as a consequence of insulin resistance and systemic inflammation, along with fatty liver disease (Divella et al. 2019). Disturbed sex steroid signaling, along with insulin/insulin-like growth factors are also related to cell proliferation (Roberts et al. 2010).

Other Comorbidities

Kidney disease (Navarro et al. 2016) and premature death, primarily from cardiovascular diseases are currently well recognized in obesity. Overweight carries a milder danger (Kyrouu et al. 2018). BMI is obviously a major determinant of metabolic syndrome (He et al. 2014; Miranda et al. 2017; Miranda et al. 2018), whereas visceral fat seems more relevant for cardiovascular risk than BMI (Ferrier 2014; Eleazu et al. 2019).

Lifestyle, Pharmacotherapy, and Surgery

Lifestyle and pharmacotherapy are standard approaches for milder cases (Ferrier 2014; Eleazu et al. 2019, Apovian et al. 2015), contrasting with bariatric surgery, reserved for class II or III obesity. (Ferrier 2014; Eleazu et al. 2019).

The Advanced Glycation End Products (AGEs)—Receptor for Advanced Glycation End Products (RAGE) System

AGEs are toxic compounds that are formed through nonenzymatic glycoxidation reactions, induced by the nucleophilic addition of free amino groups from proteins, lipids or nucleic acids to the carbonyl groups of monosaccharides (Yamagishi et al. 2015; Nowotny et al. 2015; Eleazu et al. 2019). The Maillard reaction leads to the generation of reversible Schiff base adducts that spontaneously rearrange to form more stable, covalently bound Amadori products, which progress to AGEs (Nowotny et al. 2015; Kehm et al. 2019; Eleazu et al. 2019). AGEs can be derived from sugars, lipids, and amino acids (Uribarri et al. 2015) (Fig. 14.1).

Cross-linked products between AGEs in basement membrane of extracellular matrix (ECM) and AGE-RAGE binding can damage collagen, vitronectin, and laminin, potentially inducing vascular stiffening and myocardial dysfunction (Cheng et al. 2017).

Oxidative Damage

Nuclear factor kappa-beta (NFκB) and nicotinamide adenine dinucleotide phosphate oxidase (NADPH-oxidase) can be part of the negative response, with elevated oxidative stress (Luevano-Contreras and Chapman-Novakofski 2010; Vlassara and Uribarri 2014). Further inflammation, apoptosis and metabolic dysfunction can be the result (Cheng et al. 2017; Yang et al. 2018) (Fig. 14.2).

Dietary Imbalance

Diet supplies not only substrates, but also AGEs themselves (carbohydrates, lipids, and proteins). About 10% of exogenously derived AGEs are

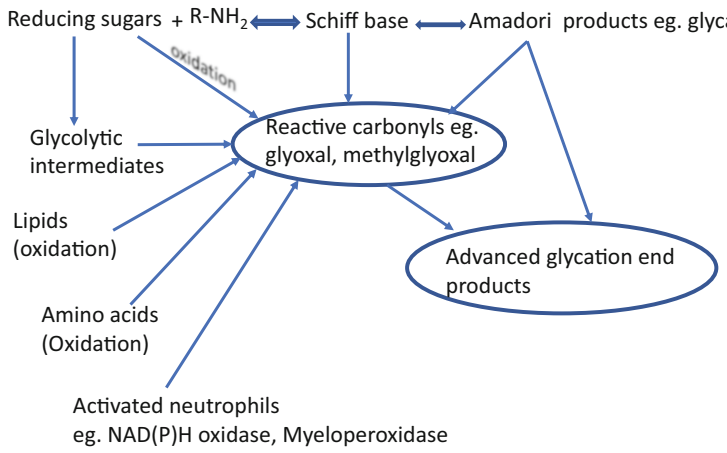

Fig. 14.1 Formation of advanced glycation end products (AGEs) from different pathways. AGEs are formed through the initial reaction between reducing sugars and the free amino group of a protein going through the stages of Schiff base and Amadori product formation. Other pathways through lipid oxidation or activated neutrophils may also lead to the formation of AGEs, even in the absence of glucose. Sources: Mostafa et al. (2007), Uribarri et al. (2015), Eleazu et al. (2019)

absorbed, and two-thirds are retained (Yamagishi et al. 2015). Lipoxidation and glycation are features of excessive body weight, including malondialdehyde (MDA), acrolein, 4-hydroxy-nonenal (4-HNE), and glycation products (glyoxal and methyl glyoxal) (Aldini et al. 2007). Insulin resistance and diabetes are negatively impacted (Eleazu et al. 2019; Vasudevan et al. 2011).

The RAGE Family

RAGE is a cell-surface immunoglobulin, including soluble molecules, full spelling RAGE (F-RAGE), (Chiavaroli et al. 2012) and soluble RAGE (sRAGE) (D'Adamo et al. 2011). RAGE, is considered as a pattern-recognition receptor (PRR), linking with AGEs, amyloid β-peptide, DNA-binding protein high mobility group box-1 (HMGBl)/amphoterin), and S100/calgranulins (Eleazu et al. 2019; Chuah et al. 2013).

RAGE occurs in kidney, neurons, skin, and lungs (Eleazu et al. 2019; Chuah et al. 2013), promoting transduction of kinases, and inducing oxidative stress via NFκB and NADPH-oxidase (Kehm et al. 2019). Increased ROS also increases AGEs formation, which further activates NFkB, and cytokines, which could form a vicious cycle for AGEs (Nowotny et al. 2015; Chiavaroli et al. 2012; Giannini et al. 2012; Pierine et al. 2014; Miranda et al. 2018; Eleazu et al. 2019) (Fig. 14.2).

esRAGE and sRAGE Signaling

Soluble receptors for AGEs attract extracellular RAGE ligands (Yang et al. 2018), inhibiting RAGE formation via "decoy receptors". This phenomenon along with RAGE antagonists or antibodies could antagonize deleterious clinical developments (Eleazu et al. 2019; Miranda et al. 2018). Less AGE binding to full length receptor (F-RAGE) (Lue et al. 2009) counteracts RAGE formation (Younessi and Yoonessi 2011; Eleazu et al. 2019).

Correlation with Comorbidities

In the experience of Falcone et al. (2005) reduced sRAGE could signal cardiovascular disease. According to D'Adamo et al. (2011), low esRAGE and sRAGE were markers of fatty liver in prepubertal obesity. Low esRAGE coexists

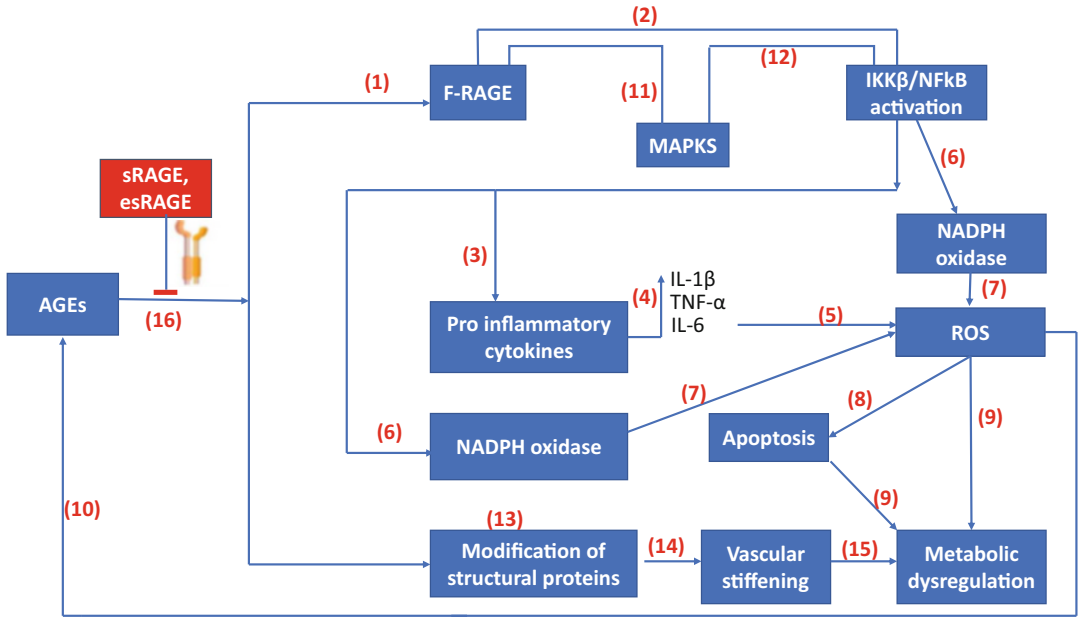

Fig. 14.2 Mechanism of action of advanced glycation end products (AGEs) and interaction between AGEs and soluble receptor AGE (sRAGE). F-RAGE- Full Length RAGE; sRAGE-soluble receptor for advanced glycation end products, esRAGE-endogenous secretory receptor for advanced glycation end products; MAPKS-Mitogen-activated protein kinases. (1) Binding of AGEs to full spelling (F-RAGE), (2) triggers the activation of IKKβ/NFkB pathway. (3) Activation of NFkB further transcribes and activates other (4) inflammatory cytokines including interleukin-1 beta, interleukin-6, tumor necrosis factor, (5) leading to the formation of ROS or (6) it activates NADPH oxidase, (7) generating reactive oxygen species in the process. (8) Increased ROS formation could affect the integrity of the membrane, triggering apoptosis, (9) leading to metabolic dysregulation. (10) Increased ROS also increases AGEs formation through a feed forward mechanism, which further activates NFkB. This activation increases the expression of proinflammatory cytokines such as interleukin-6, tumor necrosis factor alpha (TNF- α), and in addition to RAGE itself, thereby intensifying the inflammatory response and leading to metabolic dysregulation. (11) Activation of F-RAGE can also promote the activation of phosphatidyl inosito-3-kinase (PI3K)/protein kinase B (Akt) and the mitogen-activated protein kinase (MAPKs), (12) generating inflammatory mediators, ROS, apoptotis, and metabolic dysregulation. (13) AGEs formation could also promote the modification of structural proteins like collagen, vitronectin, and laminin, weakening the integrity of vascular structure and leading to vascular stiffening (14), myocardial dysfunction, and (15) metabolic dysregulation. (16) Endogenous secretory receptor for AGEs (esRAGE) and soluble receptor for AGEs (sRAGE) bind to AGEs, removing them from circulation and making them unavailable for binding to full length RAGE to trigger AGE-RAGE proinflammatory signaling and pathological effects. By this, they downregulate the expression of RAGE and attenuate AGEs/RAGE-mediated metabolic dysfunction (Nowotny et al. 2015)

with depressed adiponectin and higher thromboxane-dependent platelet activation, which can lead to elevated cardiovascular and metabolic risk (Vazzana et al. 2012).

sRAGE concentrations point toward metabolic syndrome components in male, however, not in female subjects (He et al. 2014; Eleazu et al. 2019). Also Guclu et al. (2016) found a negative relationship between sRAGE level and metabolic syndrome.

Obesity and Diabetes

Diminished sRAGE and T2DM are a recognized pattern (Miranda et al. 2017), analogously to excessive body weight (Dozio et al. 2017; Miranda et al. 2017; Miranda et al. 2018). Total sRAGE is endowed with similar properties (Dozio et al. 2017; Miranda et al. 2017; Miranda et al. 2018). During weight loss esRAGE values recover (Miranda et al. 2018).

Therapeutic Interventions

RAGE and sRAGE agonists have been used in Alzheimer's disease combined with diabetes/insulin resistance. Azeliragon (vTv Therapeutics, High Point, NC, USA) crosses the blood-brain barrier (Bongarzone et al. 2017), antagonizing the linking of sRAGE to amyloid β1-42 ($A\beta_{1-42}$). An ongoing trial addresses Alzheimer's disease and high HbA1c.

Many other potential applications have been envisaged in cell and animal models encompassing diabetic vascular dysfunction, cardiovascular disease, some modalities of cancer, rheumatoid arthritis, inflammatory bowel disease, endotoxemia, and shock (Hudson and Lippman 2018); however, clinical studies are lacking so far.

Anti-incretin Effect: A Missing Link between Obesity, Diabetes, and Metabolic Surgery

15

Theocharis Koufakis, Spyridon N. Karras, and Kalliopi Kotsa

Contents

Abstract

The exact changes in physiology of individuals undergoing metabolic surgery are still under investigation. According to the foregut hypothesis, surgical bypass of certain parts of the gastrointestinal (GI) tract leads to the downregulation of biological factors that are secreted by the upper GI system, and compete against incretin actions (anti-incretins). Those molecules have a negative effect on insulin secretion, action, and sensitivity. Various biological factors have been hypothesized to exert anti-incretin properties, including dopamine, ghrelin, enterostatin, and oxyntomodulin. Disruption of the balance between incretins and anti-incretins could be considered as a pathway leading to the development of obesity and insulin resistance.

Introduction

Incretins are gut hormones which play a key role in the preservation of glucose homeostasis in humans. Gastric inhibitory polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) amplify the glucose-dependent secretion of insulin by the pancreatic beta-cells, presenting at the same time extrapancreatic actions. GLP-1 is known to inhibit postprandial glucagon secretion and delay gastric emptying, duodenal, and small intestine motility, thus resulting in delayed sugar absorption (Seino et al. 2010; Karras et al. 2012). Incretins mediate the well-described incretin effect, according to which orally digested glucose triggers a stronger insulin response than that resulting from the intravenous administration of the same amount of glucose (Rehfeld and Stadil 1973). The incretin effect has been recognized to be reduced in people with type 2 diabetes (T2D) compared with healthy controls, although it is debated whether this is a cause or a consequence of the diabetic state (Knop et al. 2007).

Changes in incretin biodynamics have been recognized as part of the mechanisms explaining the positive effects of metabolic surgery on obesity and T2D. Several studies have established increased concentrations of both GLP-1 and GIP after bariatric surgery procedures (Bose et al. 2010; Honka et al. 2018), related to improved insulin secretion and lower insulin resistance (IR). However, the exact changes in the physiology of individuals undergoing metabolic surgery are still under investigation and intensive research is currently being conducted to elucidate the full spectrum of the implicated mechanisms (Karras et al. 2019).

According to the foregut hypothesis (Rubino and Gagner 2002), surgical bypass of certain parts of the gastrointestinal (GI) tract leads to the downregulation of biological factors that are secreted by the upper GI system, and compete with incretins actions (anti-incretins). Those molecules have a negative effect on insulin secretion, action, and sensitivity (Rubino and Amiel 2014).

The Anti-incretin Theory

The anti-incretin theory suggests that the presence of food in the GI tract, apart from activating the cascade of incretin-related biological actions, also stimulates a negative feedback adaptation, which is the release of anti-incretins (Kamvissi et al. 2010). Anti-incretins aim to balance the glucose-lowering effects of incretins, in order to prevent excessive insulin release, potentially leading to hypoglycemia (Rubino and Gagner 2002; Kamvissi et al. 2010; Rubino and Amiel 2014).

Incretins also stimulate beta-cell proliferation (Lavine and Attie 2010; Lindqvist et al. 2014). A similar phenomenon occurs with modern GLP-1 analogues such as liraglutide, which inhibits beta-cell apoptosis through stimulation of PI3-kinase-dependent AKT

phosphorylation (Kapodistria et al. 2018). Albeit protective (Lavine and Attie 2010), these responses might be potentially harmful in case of unlimited proliferation, due to the absence of appropriate regulatory mechanisms. Animal studies have showed that Roux-en-Y gastric bypass (RYGB) results in increased beta-cell mass postoperatively (Lindqvist et al. 2014), suggesting that RYGB abolishes gut-derived signals that prevent excessive growth of beta-cells, in face of elevated incretins (Rubino and Gagner 2002; Holst 2007; Rubino and Amiel 2014).

Early Response to Dysglycemia after Bariatric Surgery

Up to 89% of bariatric patients experience early T2D remission (Wickremesekera et al. 2005). As this appears during the first postoperative days, weight loss cannot play a significant role. Surgical exclusion of specific parts of the GI tract from nutrient transit, could abolish anti-incretin signals, thus resulting in improved insulin action and sensitivity (Rubino and Gagner 2002; Kamvissi et al. 2010; Rubino and Amiel 2014).

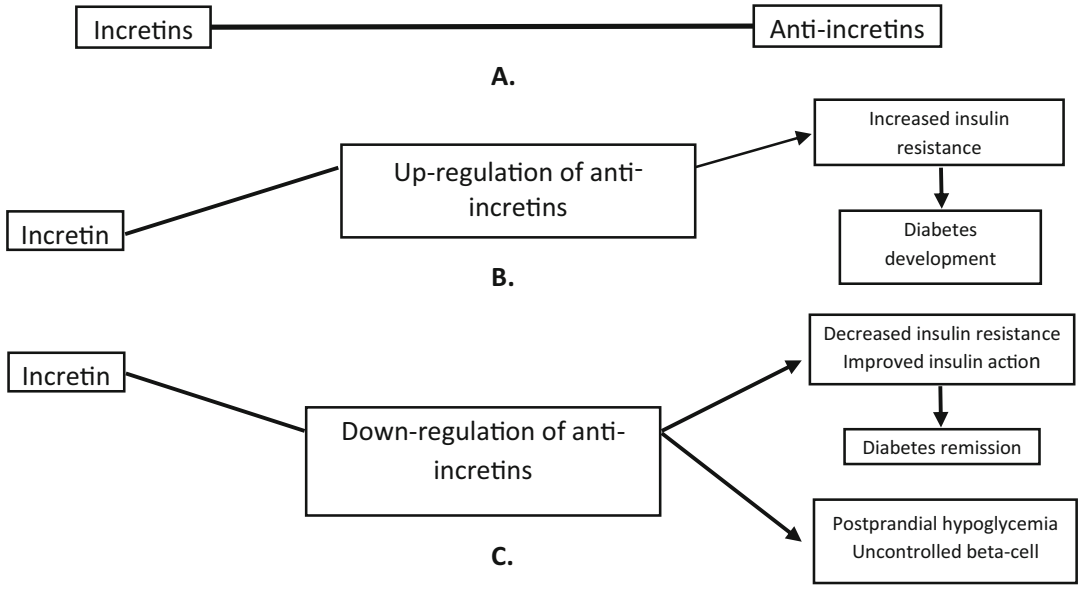

Fig. 15.1 A schematic overview of the balance between incretins and anti-incretins. (**A**) The normal state, in which the balance between the two mechanisms results in the preservation of normal glucose homeostasis, (**B**) Type 2 Diabetes, where an exaggeration of the anti-incretin effect could contribute to the development of insulin resistance and hyperglycemia, (**C**) Following metabolic surgery, where down-regulation of anti-incretins could lead to diabetes remission, and rarely to postprandial hypoglycemia and unrestricted beta-cell growth

Post-bariatric Hypoglycemia

On the other hand, postprandial hypoglycemia possibly linked to unrestrained beta-cell proliferation, occasionally occurs after RYGB (Cummings 2005). It is also postulated that Western-pattern diets or food additives might promote the overexpression of anti-incretins and through this pathway, to deteriorate beta-cell function and sensitivity (Rubino and Gagner 2002; Kamvissi et al. 2010). Figure 15.1 summarizes current knowledge about these shifts.

Potential Pathways and Molecules

Any anti-incretin should gather a number of features, including: (a) downregulation of insulin production and release from the pancreatic beta-cells, (b) production by an enteroendocrine source as a result of exposure to nutrients, and c. response to fasting or carbohydrate restraint (Alfa et al. 2015).

Dopamine

Dopamine exerts regulatory effects on glucose metabolism, given that it has the ability to downregulate incretin-mediated enhanced glucose-dependent phosphoprotein signaling procedures, as well as to inhibit *in vitro* GLP-1-promoted islet and beta-cell proliferation (Maffei et al. 2015). Tyrosine hydroxylase, the rate-limiting enzyme of dopamine synthesis, is highly expressed in parietal and ileal epithelial cells, as well as Lieberkuhn crypts (Kozicz and Arimura 2002). Of note, D2-like receptors which are believed to be the key mediators of dopamine-related suppression of insulin secretion, are expressed in beta-cells (Rubi et al. 2005). As shown in a study conducted with a rodent beta-cell line (INS-1 832/12), insulin secretion was amplified following the knock-out of the aforementioned receptors (Wu et al. 2008), further supporting the implication of dopamine in an autocrine circuit of neurotransmitter regulation, which acts as a limiting factor of glucose-

stimulated insulin secretion (Chaudhry et al. 2016). There is an experimental evidence that diet-derived tyrosine, a precursor of L-DOPA and dopamine, participates in postprandial glucose homeostasis. This circuit could be involved in protection against hypoglycemia via inhibition of glucose-stimulated β-cell insulin secretion, a response consistent with the anti-incretin hypothesis (Korner et al. 2019).

Ghrelin

Ghrelin has been also postulated to play an anti-incretin role, albeit relevant data are more limited here. Ghrelin has been demonstrated to prevent GLP-1-mediated stimulation of cyclic adenosine monophosphate signaling and insulin secretion in beta-cells (Damdindorj et al. 2012), and suppress the production of adiponectin (Cummings 2009), whereas synthetic ghrelin administration in humans can restrain insulin secretion (Tong et al. 2010). However, the effect of metabolic surgery on ghrelin is controversial, with both increase and stability being observed (Cummings 2009).

Other Molecules

The amino acid sensor G protein receptor 142 (GP142) integrates anti-incretin properties, since it stimulates pancreatic glucagon secretion, but also exerts adjusting effects on insulin-mediated glucose uptake in fat and muscle, and hepatic glucagon-mediated glucose production (Lin et al. 2018).

Oxyntomodulin has been also reported to upregulate glucagon secretion both *in vitro* and *in vivo* (Baldissera et al. 1988), having at the same time the ability to decrease glucagon secretion through the activation of the GLP-1 receptor (Holst et al. 2018a, b). Those GP142 and oxyntomodulin actions could be considered as part of the physiological response antagonizing incretin-induced hypoglycemia and preserving normal glucose levels, through the modulation of glucagon hepatic production, peripheral glucose utilization, and perhaps other mechanisms (Karras et al. 2019).

Correlation with Diabetes and Obesity Remission Following Metabolic Surgery

Salinari et al. (2017) investigated the impact of metabolic surgery (biliopancreatic diversion) on glucose homeostasis variables. Participants with obesity exhibited lower insulin sensitivity, whereas in normal individuals, insulin sensitivity was lower during oral compared to intravenous glucose administration. The more robust difference between oral and intravenous insulin sensitivity in obese individuals was attenuated following biliopancreatic diversion. It was predicted that hypoglycemia would occur during an OGTT, in case insulin sensitivity remained in the range of intravenous glucose administration, particularly in case of obesity and IR. According to the anti-incretin model, postprandial amplification of IR protects against hypoglycemia, following the elevation of insulin levels as a result of food intake.

In an experimental study (Salinari et al. 2014), nonobese, diabetic Goto-Kakizaki rats were subjected to resection or bypass of various intestinal segments. Duodenal-jejunal bypass (DJB) as well as jejunectomy, although improving insulin sensitivity, did not have an impact on GIP and GLP-1 concentrations, indicating no role for elevated incretin levels. Downregulation of specific duodenum- and jejunum-derived molecules that negatively affect insulin sensitivity might be responsible instead. It could also be hypothesized that an exaggerated anti-incretin effect is a component of T2D pathophysiology, even in the absence of obesity.

Enhancement of Pancreatic Beta-cell Mass

Lindqvist et al. (2014) achieved improvements in glycemic homeostasis following RYGB in a porcine model, driven by an increase in beta-cell

mass, islet number, and number of extra islet beta-cells, suggesting that the operation resulted in the suppression of signals that inhibit beta-cell proliferation. This is in agreement with the anti-incretin theory, albeit different studies have failed to demonstrate an increased beta-cell mass after bariatric procedures (Meier et al. 2006). Inappropriately, improved beta-cell function, rather than changes in beta-cell mass, might explain the post-operative hypoglycemia occasionally seen in people subjected to RYGB.

A different study (Salinari et al. 2013), assessed the effects of protein extracts, derived from the duodenum-jejunum conditioned-medium (CM) of diabetic rodents on insulin sensitivity, both *in vitro* and *in vivo*. Jejunal proteins negatively affected muscle insulin signaling, through promotion of Akt ^{473}Ser phosphorylation in L6 cells, possibly via mTOR Complex 2 (mTORC2) or TSC activation, and Akt recruitment to plasma membrane. The authors indicated the proximal small bowel of animals with diabetes as a source of diabetogenic factors that have the potential to impair peripheral insulin sensitivity; however, these interesting findings need to be replicated by studies in humans.

Future Perspectives

The idea that T2D and obesity could be effectively managed or even put into remission following metabolic surgery is gaining popularity, due to increasing evidence supporting the effectiveness of surgical approaches, not only in reducing weight loss and improving glucose outcomes (Batterham and Cummings 2016), but also in preventing obesity-related macrovascular complications (Yan et al. 2019). The exact mechanisms mediating the effects of bariatric surgery are still hotly debated, as these are complex and involve interactions between numerous physiological and pathogenetic pathways (Karras et al. 2019).

The anti-incretin theory provides an alternative theoretical framework to explain the mechanisms behind the effects of metabolic surgery on T2D, and highlights the significance of the GI tract in the homeostatic regulation of food intake and energy balance in humans. Disruption of this two-way feedback loop, could be considered as an additional pathway leading to the development of obesity and IR.

Obviously, the anti-incretin theory should be studied in the context of other mechanisms that explain the impact of bariatric surgery on metabolic outcomes. For example, changes in incretin bioavailability (Holst et al. 2018a, b), differentiation of the vagus nerve anatomy (de Lartigue et al. 2014), altered expression of bile acids (Penney et al. 2015), and modified gut microbiome (Liou et al. 2013), have been all shown to contribute to the metabolic benefits of bariatric surgery.

Anti-incretin molecules and pathways, as well as genetic, molecular or biochemical markers able to monitor such phenomenon in obesity and diabetes, are worthwhile topics for future research (Karras et al. 2019).

Abstract

Obesity has a strong inherited component (40–75% of the risk is driven by genetic factors), including monogenic syndromic or not, oligogenic, and polygenic modalities. Monogenic nonsyndromic/oligogenic genes in the leptin-melanocortin pathway are analyzed, as well as their role in energy balance. Early genetic testing along with traditional and ongoing attempts to clinically handle several relevant categories is similarly addressed.

Keywords

Obesity · Monogenic · Leptin/melanocortin pathway · Genetic testing · Mereleptin · Setmelanotide

Introduction

Obesity is a serious pandemic and an often neglected concern (NCD Risk Factor Collaboration (NCD-RisC) 2017). It has nearly tripled in a few decades to reach 650 million adults and 124 children in 2016 (NCD Risk Factor Collaboration (NCD-RisC) 2017). Practically, all ages and socioeconomic groups are affected. The disease is associated with the development of multiple comorbidities: depression, sleep apnea, osteoarthritis, diabetes, hypertension, cardiovascular disease, and some cancer (Apovian 2016). Obesity and its many comorbidities result in poorer quality of life and reduced disability adjusted life years and life expectancy (Ng et al. 2014). Current treatments are useful for selected groups; however, they did not effectively change the obesity epidemic (Bray et al. 2016). This modest success in treating obesity may be attributed to a "one size fits all" management and may not be in the best interest of patients who come from diverse ethnic, socioeconomic, and health backgrounds (Bruce et al. 2007).

In 2010, Auffray et al. proposed the concept of P4 (predictive, preventive, personalized, and participatory), also known as precision medicine (Auffray et al. 2010). Precision medicine is a move away from standardized treatment, to the one that adapts therapies to achieve the best outcomes for individual patients (Auffray et al. 2010). Precision medicine proposes to make use of an array of biological and 'multi omics' information, such as patient genome, epigenome, transcriptome, proteome, and microbiome, to cite a few, for more precise prevention and care (Auffray et al. 2010). This concept of treatment may apply successfully to the management of complex disorders such as obesity (Blakemore and Froguel 2010).

Obesity is multifactorial in essence (Reddon et al. 2016). Environmental risk exposures include poor diet, lack of exercise, altered sleep patterns, psychosocial stress, endocrine disruptors, pharmaceutical iatrogenesis, and controlled ambient temperatures (McAllister et al. 2009), while biological factors such as *in utero* programing, demographic variables, and comorbidities such as depression, gut microbiome, epigenetics, and genes also influence susceptibility to obesity (Pigeyre et al. 2016). Up to 40–75% of genetic propensity toward fat accumulation emerges from twin, family, and population studies (Stryjecki et al. 2018; Yang et al. 2015a), and an array of monogenic (i.e., Mendelian) syndromic, nonsyndromic, oligogenic, and polygenic transmissions are identified (Pigeyre et al. 2016; Tam et al. 2018; Kaur et al. 2017).

At the individual level, nature and nurture contribute to obesity in varying degrees, from

predominantly environmental (e.g., Sumo wrestlers) to purely genetic (e.g., monogenic condition) origins (Kanehisa et al. 1998; Lunsky and Meyre 2019). Nonsyndromic monogenic adiposity could represent excellent targets for the application of precision medicine (Blakemore and Froguel 2010). Not only do monogenic defects cause striking body weight gain, but also their simple biological origin (i.e., partial/complete inactivation of one gene) allows for actionable and effective treatments for a subset of patients (Blakemore and Froguel 2010; Lunsky and Meyre 2019).

Leptin Deficiency

Leptin controls appetite and calorie balance. Leptin deficiency is a rare autosomal recessive disorder, registered in different parts of the world (Pigeyre and Meyre 2018; Yupanqui-Lozno et al. 2019). Homozygous or heterozygous compound loss-of-function mutations (*LEP*) are observed in human populations. Truncated transcription and virtual absence of leptin can be the result (Montague et al. 1997; Haglund et al. 2018). Nonfunctioning protein without altering circulating levels is another possibility (Haglund et al. 2018; Wabitsch et al. 2015a). Hyperphagia and severe early obesity are typical of complete leptin deficiency (Montague et al. 1997; Kohlsdorf et al. 2018). T-cell compromise and immune deficiency are also featured (Farooqi et al. 2002). Late puberty and aberrant hormonal cycles can be observed (Strobel et al. 1998). Heterozygous carriers of *LEP* mutations can also display increased body fat (Farooqi et al. 2001).

Leptin Receptor Deficiency

Loss-of-function coding mutations in the leptin receptor (*LEPR*) gene have been documented in human populations as leptin deficiency (Pigeyre and Meyre 2018). LEPRb is the longest of the six leptin isoforms coded by *LEPR* and most commonly contains the mutations triggering obesity (Wasim et al. 2016). Disorders include severe and precocious weight gain, along with immune deficiency, hormonal changes, stunted growth, and diabetes (Clement et al. 1998; Farooqi et al. 2007a; Hannema et al. 2016; Armagan et al. 2019; Niazi et al. 2018). Mutations in *LEPR* can be relatively common among families with a high inbreeding rate (Saeed et al. 2015). Heterozygous mutations in *LEPR* are followed by comparable BMI; however, body fat mass is more abundant than that in control population (Farooqi et al. 2007a).

Proopiomelanocortin Deficiency (POMC)

In certain circumstances, *POMC* is not translated, or derived hormones (ACTH, α-MSH, and β-MSH) are incorrectly formed (Krude et al. 1998; Clement et al. 2008; Farooqi et al. 2006). Both homozygous and compound heterozygous cases are described in literature (Pigeyre and Meyre 2018; Hilado and Randhawa 2018). Excessive weight gain is often detected shortly after birth, along with diabetes and multiple hormonal dysfunctions (Krude et al. 1998; Clement et al. 2008; Farooqi et al. 2006; Ozsu and Bahm 2017). Red hair, noticed in Caucasian individuals with light skin (Clement et al. 2008; Cirillo et al. 2012), is putatively connected with the α-MSH pathway. Excessive adiposity in heterozygotes has also been reported (Farooqi et al. 2006; Challis et al. 2002; Lee et al. 2006; Dubern et al. 2008).

Proprotein Convertase 1 Deficiency (PC1)

Failure of PC1 can be linked to major weight gain after birth, deranged glucose homeostasis, intestinal function and circulating hormones including POMC (O'Rahilly et al. 1995). An initial affected case was confirmed as heterozygous compound for the *PCSK1* gene encoding the PC1 protein (Jackson et al. 1997), followed by additional subjects (Pigeyre and Meyre 2018). *PCSK1* is therefore admitted as a monogenic recessive

mechanism of uncontrolled weight gain, within the PC1 pathway, triggering protean hormonal and nonhormonal derangements (Jackson et al. 1997, 2003; Farooqi et al. 2007b; Martin et al. 2013; Frank et al. 2013). PC1 mutations impair important hormone cascades; consequently, heterozygous mutations in *PCSK1* precipitate both oligogenic and monogenic dominant cases of elevated body mass index (BMI) (Creemers et al. 2012; Philippe et al. 2015).

Melanocortin 3 Receptor Deficiency (MC3R)

From Singapore (Lee et al. 2007, b) to Poland (Demidowich et al. 1863), however not in the USA (Ehtesham et al. 2019), partial or complete mutations related to MC3R have been associated with obesity, with a threefold elevation of the risk on aveage (Ehtesham et al. 2019), consistent with experimental results (Chen et al. 2000; Butler et al. 2000). MC3R functions differently from the melanocortin 4 receptor (MC4R), depending on kinases including ERK1 and ERK 2 (Yang et al. 2015b).

Melanocortin 4 Receptor Deficiency (MC4R)

Mutations in the *MC4R* gene are the most often recognized (0.2–5.8%) among cases with excessive body weight (Lunsky and Meyre 2019). Food intake is controlled via α-MSH and agouti-related peptide (Farooqi and O'Rahilly 2008), involving signals from POMC neurons (Farooqi and O'Rahilly 2008). β-arrestin and MAPK are equally emphasized in this context (Lotta et al. 2019). Homozygous and heterozygous compound cases suffer from hyperphagia, preference for high-fat instead of high-sucrose food, and major shifts in body composition and arterial pressure (Lunsky and Meyre 2019). Heterozygotes suffer from less obvious repercussions, depending on clinical and environmental circumstances (Stutzmann et al. 2008; Drabkin et al. 2018; Saeed et al. 2015).

Kinase Suppressor of Ras 2 Deficiency (KSR2)

This biomolecule modulates a number of kinases, (Frodyma et al. 2017) encompassing AMPK, which is relevant for energy homeostasis (Costanzo-Garvey et al. 2009; Guo et al. 2017). Reduced energy expenditure despite hyperactivity, insulin resistance, and glucose intolerance is observed in fully deficient laboratory animals (Costanzo-Garvey et al. 2009; Brommage et al. 2008; Revelli et al. 2011), with less robust responses upon milder deficiency (Revelli et al. 2011). Brain knockout conducts to similar however milder consequences than in systemic knockout mice (Guo et al. 2017). Usual features of *KSR2* human mutation carriers encompass weight gain shortly after birth, glucose homeostasis changes, and diminished consumption of energy substrates (Pearce et al. 2013).

Melanocortin 2 Receptor Accessory Protein 2 (MRAP2) Deficiency

This predominantly brain protein is relevant for MC4R and other receptors (Chan et al. 2009). In mice, a codominant form of obesity is elicited by the deficiency (Asai et al. 2013). Several *MRAP2* mutations including E24X variant lead to advanced obesity in humans (Asai et al. 2013). Heterozygous carriers can be at risk as well (Schonnop et al. 2016). The Q174R mutation diminishes MC4R signaling *in vitro* (Schonnop et al. 2016). Large-scale sequencing of *MRAP2* exons along with functional assessment of 23 rare *MRAP2* variants confirmed that loss-of-function heterozygous mutations precipitate monogenic hyperphagic childhood and adult obesity, hyperglycemia, and hypertension (Baron et al. 2019).

Adenylate Cyclase 3 (ADCY3) Deficiency

Common variants in the *ADCY3* gene have been associated with body mass index variations in diverse human populations (Speliotes et al.

2010; Wen et al. 2012; Monda et al. 2013). A missense mutation in *Adcy3* is associated with body weight variation in rats (Keele et al. 2018). Whereas Adcy3 deficiency in rodents favors excessive adiposity, gain-of-function mutation has the opposite effect (Pitman et al. 2014; Tong et al. 2016). Homozygous loss-of-function mutations in *ADCY3*, hyperphagia, and severe obesity were confirmed in humans (Saeed et al. 2018). A founder essential splice mutation in *ADCY3* also resulted in higher BMI (Grarup et al. 2018). Homozygous mutations in *ADCY3* are not very rare in certain obese populations (Saeed et al. 2018; Grarup et al. 2018; Bjerregaard and Jorgensen 2013). ADCY3 colocalizes with MC4R, and impairment is recognized as a factor for weight gain (Siljee et al. 2018).

Steroid Receptor Coactivator-1 (SRC-1) Deficiency

SRC-1 is secreted in the hypothalamus and enhances *POMC* transcription via the STAT3 pathway (Yang et al. 2019). Complete SRC-1 deficiency in mice leads to reduced energy expenditure and significantly higher weight gain upon high-fat diet (Picard et al. 2002). Concordantly, deletion of SRC-1 leads to decreased *POMC* expression, increased food intake, and high-fat diet induced obesity (Yang et al. 2019; Wang et al. 2006). Fifteen heterozygous missense mutations in *SRC-1* were found in cases with obesity at young age. Dysfunction of the STAT3 and POMC reporter pathways was detected (Yang et al. 2019). In contrast, four missense mutations found in nonobese controls did not impact SRC-1 function (Yang et al. 2019). In an experimental model of SRC-1 mutation (p.L1376P), exaggerated adiposity coincided with defective POMC response (Yang et al. 2019).

Semaphorin 3 Signaling Deficiency

Class 3 Semaphorins (SEMA3A-G) and their receptors (PLXNA1-4; Neuropilin (NRP1-2)) are linked to GnRH neurons in the central nervous system (Alto and Terman 2017). SEMA3 signaling contributes to melanocortin circuits and energy balance (van der Klaauw et al. 2019). In mouse models and also *in vitro*, it was found that SEMA3s acting via NRP2 direct the development of POMC projections in deep brain nuclei (van der Klaauw et al. 2019). Deletion of NRP2 receptors in POMC neurons of mice disrupted POMC projections, causing reduced energy expenditure and weight gain (van der Klaauw et al. 2019).

Experimental evidence confirms the role of energy homeostasis of genes in the SEMA 3 signaling pathway (van der Klaauw et al. 2019). Among a cohort of European ancestry, 40 rare variants of 13 genes related to SEMA3 signaling were found in 573 cases with severe BMI elevation at young age (van der Klaauw et al. 2019; Hendricks et al. 2017). Different molecular mechanisms were identified (van der Klaauw et al. 2019). Very rare (minor allele frequency $<0.025\%$) variants were prominently featured by affected cases in this large series (van der Klaauw et al. 2019).

An Overview of Current Treatments of Obesity in Child and Adult Populations

Lifestyle Modifications

Research has found that dietary changes along with exercise are associated with less adiposity in children and adults with high BMI (Dombrowski et al. 2014; Peirson et al. 2014, 2015a). Lifestyle modifications also have a beneficial impact on cardio-metabolic outcome, lipid profile, and glucose homeostasis (Ho et al. 2013; Baillot et al. 2015). A significant problem with these methods is poor adherence, which ultimately hinders treatment effectiveness

(Burgess et al. 2017). If weight loss is achieved following lifestyle modifications, another challenge is to maintain this benefit in the long run (Peirson et al. 2015b).

Behavioral Modifications

Behavioral interventions involve patients learning to self-monitor nutrition and exercise, identifying barriers to weight loss and supporting one another on their journey (Jin 2018). These interventions often last for 1–2 years and have shown moderate treatment effects in terms of lowering BMI (Peirson et al. 2015a; Jin 2018). Furthermore, pairing these approaches with lifestyle modification has shown to increase adherence to the program and modestly improve weight loss outcomes in children and adults (Dombrowski et al. 2014; O'Connor et al. 2017). A benefit of these treatments is that they involve minimal side effects and as such can be easily applied into care settings (Peirson et al. 2015a; O'Connor et al. 2017). Another advantage is the possibility to use media devices to promote behavioral changes, even though the efficacy of eHealth interventions has yet to be demonstrated (Hutchesson et al. 2015). A notable concern is that behavioral intervention effects may not been maintained in the long run (Peirson et al. 2015a).

Pharmaceuticals

Orlistat prevents the uptake and digestion of triglycerides. It is a widely used agent with a good safety profile and has been shown to provide clinically significant and ongoing decreases in BMI when used in conjunction with a slightly hypocaloric diet and exercise (Khera et al. 2016). Common side effects of orlistat are steatorrhea (i.e., excess of fat in feces) and diarrhea, caused by the body's limited absorption of dietary fats in response to the drug (Bansal and Al Khalili 2019). Other side effects include abdominal pain and fecal spotting (Smith et al. 2013). Phentermine-topiramate is a drug combination prescribed to severely obese adults. Phentermine acts as an appetite suppressant, stimulating norepinephrine and epinephrine release, while topiramate increases the effect on gamma-aminobutyric acid-A receptors, altering sensations of satiety (Allison et al. 2012). Common adverse outcomes include dry mouth, constipation, dysgeusia (i.e., distortion of the sense of taste), and insomnia (Allison et al. 2012). Overall, the pair demonstrates beneficial dose-dependent effects on weight outcomes in obese adults after 1 year (Allison et al. 2012). Liraglutide is an efficacious drug used to treat both obesity and type 2 diabetes (T2D). It is a glucagon-like peptide 1 receptor agonist, suppressing appetite and energy intake in addition to delaying gastric emptying (Astrup et al. 2009). The drug was found to be more effective than orlistat in reducing weight outcomes and blood pressure at all doses in addition to decreasing the prevalence of prediabetes in patients (Astrup et al. 2009). Adverse events aside from nausea and vomiting were often short-lived with users of liraglutide, highlighting its efficacy over others as a treatment for obesity (Astrup et al. 2009). Lorcaserin is another drug that acts on serotonin 5-HT2C receptors in the central nervous system to inhibit appetite in obese individuals (Fidler et al. 2011). Dizziness, headaches, and nausea are common adverse effects of the medication. Lorcaserin administered alongside a lifestyle modification program was found to provide the best weight outcomes in adults (Fidler et al. 2011).

Bariatric Surgery

While these interventions are invasive and have potential for mortality, this risk is relatively low (0–1.5%) (Arterburn and Courcoulas 2014). Information from randomized clinical trials has shown bariatric procedures to be more effective than other nonsurgical interventions (Noria and Grantcharov 2013). Some studies also cite improvements to quality of life measures in those who were surgically treated (Moulla et al. 2018). Another benefit of bariatric surgery is its ability to improve various obesity-associated

comorbidities (Picot et al. 2009). Many patients with T2D have reported normal levels of plasma glucose following their surgeries and lowered cardiovascular risk (Noria and Grantcharov 2013; Moulla et al. 2018; Picot et al. 2009). Even though increasingly popular, this modality is still not available to many candidates (Arterburn and Courcoulas 2014; Noria and Grantcharov 2013; Moulla et al. 2018; Picot et al. 2009).

Diagnosis and Treatments of Mendelian Forms of Obesity

Diagnosis of Nonsyndromic Monogenic Obesity

Both dysmorphic, intellectually disabled and normal cases can be seen (Pigeyre and Meyre 2018). *LEP* and *LEPR* mutations are associated with more severe and precocious diseases, contrasting with much more benign heterozygous *MC4R* mutations (Kohlsdorf et al. 2018; Vazquez-Moreno et al. 2019). In contrast, adults with heterozygous *MC4R* mutations present higher BMI than nonmonogenic obese adults (Stutzmann et al. 2008). Targeting children and adults with moderate to extreme obesity is a priority. Clinical and biochemical features along with family assessment may guide the genetic diagnosis (Pigeyre and Meyre 2018). Hypopigmentation of hair and skin, intestinal dysfunction, and a Mendelian recessive pattern of inheritance for obesity may signal the presence of homozygous/heterozygous compound mutations in the *POMC* and *PCSK1* genes (Choquet and Meyre 2010). Leptin, ACTH, and cortisol should be monitored. Leptin is low in congenital deficiency and can substantially increase in mutations in *LEPR*. (Montague et al. 1997; Clement et al. 1998; Farooqi et al. 2007a). Inactive "normal" leptin levels are possible in some circumstances (Wabitsch et al. 2015b, c). ACTH deficiency including clinical symptoms is a possibility in *POMC* and *PCSK1* mutations. Tailored metabolic and hormonal panels are being designed for some of these cases, with wider coverage and reduced costs (Shabana 2016).

Genetic sequencing, preferably addressing complete exome panels, is the advised approach in possibly monogenic cases. Major targets are *LEP, LEPR, POMC, PCSK1, MC4R, MC3R, ADCY3*, *MRAP2*, and *KSR2*, and explanatory algorithms are available at www.acmg.net and other sites. Variant prediction and pathogenicity tools are also available (Creemers et al. 2012; Vazquez-Moreno et al. 2019; Tarnanas et al. 2015). *In vitro* and *in vivo* functional experiments, while labor- and resource-intensive, remain the gold standards to assess the biological consequences of mutations (Creemers et al. 2012; Richards et al. 2015). Importantly, they often provide divergent conclusions from *in silico* prediction tools used alone (Heikkinen et al. 2009). For monogenic obesity genes contributing to an important burden of disease (e.g., *MC4R*), it may be relevant to assess *in vitro* the functional consequences of all possible missense variants once and for all, as has been recently performed for the *PPARG* gene (Meyre et al. 2019). Testing of other family members to establish cosegregation with obesity is recommended, especially when a new pathogenic variant is discovered.

Personalized Management of Nonsyndromic Monogenic Forms of Obesity

Lifestyle attention is crucial in monogenic obesity mutation carriers. *MC4R* and *POMC* heterozygous loss-of-function mutations are initially responsive, even though a high risk of relapse should be accounted for (Majithia et al. 2016; Reinehr et al. 2009; Santoro et al. 2006). The environment can contribute to penetrance (Stutzmann et al. 2008). Better socio-economic status is protective in some countries (Morell-Azanza et al. 2019). However, this association is

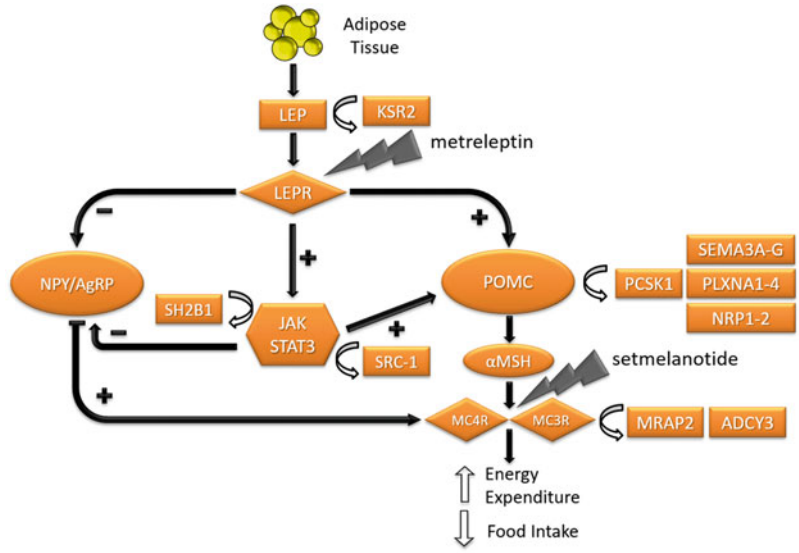

Fig. 16.1 Genes located in the leptin-melanocortin pathway, which have been associated with monogenic/oligogenic obesity

not observed in *MC4R* heterozygous mutation carriers, suggesting that higher education is not always beneficial for lifestyle (Stutzmann et al. 2008). Biologically driven hunger can be overpowering (Newton et al. 2017).

Classic anti-obesity drugs such as sibutramine, liraglutide, or serotonin and noradrenaline reuptake inhibitor induce weight reduction and improve cardiometabolic health risks in *MC4R* mutation carriers (Kleinendorst et al. 2017; Hainerova and Lebl 2013). Other targeted agents are being evaluated as well (Fig. 16.1). Complete POMC deficiency can respond to setmelanotide (Iepsen et al. 2018), similar to *LEPR* homozygous and *MC4R* heterozygous mutations (Kuhnen et al. 2016; Clement et al. 2018; Collet et al. 2017).

Bariatric Surgery in Monogenic Obesity

Homozygous *LEPR* and compound heterozygous *MC4R* mutations (Le Beyec et al. 2013; Huvenne et al. 2015; Aslan et al. 2011a; Jelin et al. 2016) could be valid surgical candidates, as well as heterozygous *MC4R* functional mutations, even though with less favorable outcomes (Meyre et al. 2014; Moore et al. 2014; Censani et al. 2014; Bonnefond et al. 2016; Elkhenini et al. 2014; Hatoum et al. 2012; Aslan et al. 2011b).

Funding Sources DM holds a Canada Research Chair in Genetics of Obesity.

Declarations of Interest The authors declare that they have no competing interests.

Abstract

Diabetic kidney disease (DKD) is a microvascular complication of progressive renal decline in patients with diabetes, which is the leading cause of end-stage renal disease (ESRD) globally. Early epidemiological and genetic studies demonstrated that DKD is a heritable condition, indicative of an underlying genetic component for its increased susceptibility. Since then, significant work has been conducted to unravel causal genes implicated in DKD development and progression. With the advancement of genomic technologies, genome-wide association studies (GWASs) and next-generation sequencing (NGS) approaches continue to expand our knowledge of the genetic architecture of DKD and uncover novel biological pathways implicated in disease pathogenesis. Additionally, the establishment of large international collaborations has led to significantly increased cohort sizes to improve overall statistical power to detect novel associations.

Diabetic kidney disease (DKD) · End-stage renal disease (ESRD) · Diabetes · Genetics · Genome-wide association studies (GWAS) · Rare variants

Introduction

The rise in incidence of diabetes and its micro- and macrovascular complications, including diabetic kidney disease (DKD), have become a financial and healthcare burden globally. DKD is a progressive, microvascular complication that affects 30–40% of patients with type 1 (T1D) or type 2 (T2D) diabetes and is the leading cause of end-stage renal disease (ESRD) (Gu, 2019, Alicic et al., 2017, Li and Pezzolesi, 2018, Reutens, 2013). DKD initiation and progression arise through metabolic dysregulation associated with diabetes, e.g., hyperglycemia and hyperlipidemia, and activation of the renin-angiotensin system (Reidy et al., 2014, Alicic et al., 2017). Prescribed medications, such as angiotensin-converting enzyme inhibitors (ACEi) and angiotensin II receptor blockers (ARBs), in conjunction with intense glycemic control interventions, can improve overall clinical outcomes (Brenner et al., 2001). Despite the near universal implementation of renoprotective therapies, there has been little reduction in the rate of DKD and ESRD, and DKD continues to be associated with excess morbidity and premature mortality in patients with diabetes.

Early epidemiological studies demonstrated that DKD is a heritable condition shown to aggregate in families, which thereby provided a foundation for studies aimed at examining the genetic factors underlying its susceptibility (Borch-Johnsen et al., 1992, Quinn et al., 1996, Seaquist et al., 1989, Fioretto et al., 1999, Faronato et al., 1997). Current estimates of the contribution of genetics to the overall risk of DKD (i.e., heritability or h^2) range from 0.3 to 0.49 (Freedman et al., 2007, Sandholm et al., 2017), suggesting that genetic variation may contribute up to 49% of the risk of DKD. Completion of efforts to sequence the human genome, through the Human Genome Project (Lander et al., 2001), and characterization of a haplotype map of the genome, through the International HapMap Project (Altshuler et al., 2005), enabled investigators to begin examining sources of genetic variation, such as single nucleotide polymorphisms (SNPs), at a genome-wide scale using genome-wide association studies (GWASs).

Early GWASs of DKD focused on the role of common variation (i.e., SNPs with a minor allele

frequency (MAF) > 5%) and identified several SNPs strongly associated with DKD. More recently, large-scale collaborative efforts have led to improved GWASs of DKD, which include larger sample sizes, and facilitated studies that are better powered to detect robust and more reproducible genetic signals. In addition to common variation, which likely explains only a fraction of the associated risk of DKD, next-generation sequencing (NGS) studies involving whole genome sequencing (WGS) and whole exome sequencing (WES) are emerging to help explain some of the 'missing heritability' of DKD (Manolio et al. 2009).

Pathophysiology of DKD in T1D and T2D

DKD patients present with numerous histological and clinical phenotypes that vary with the type and duration of diabetes. With regard to renal histology in T1D DKD, glomerulopathy is apparent with an expansion of the mesangium, basement membrane thickening, and podocyte loss, along with tubular atrophy and tubulointerstitial fibrosis (Alicic et al., 2017; Reidy et al., 2014; Fioretto et al. 2008). Furthermore, increasing proteinuria and decreasing estimated glomerular filtration rate (eGFR) occur in T1D DKD patients with advanced glomerulopathy. Contrarily, renal histology in T2D DKD patients is varied and occasionally does not manifest the T1D DKD phenotype. A subset of patients presents similar histological patterns observed in T1D DKD patients; others may, however, present with just some or absent glomerulosclerosis.

Nondiabetic Kidney Deterioration

Early reports of nondiabetic forms of kidney disease (i.e., NDKD), including immunoglobulin A (IgA) nephropathy, focal segmental glomerulosclerosis, and other glomerulopathies, have been reported in < 10% of T2D proteinuric patients (Fioretto et al. 2008) yet, recent estimates from multiple centers report the incidence of NDKD in T2D patients from 33% to 73% (Anders et al., 2018). Unfortunately, the only way to distinguish DKD from NDKD in patients with diabetes is through kidney biopsy and histological analysis. This process is the "gold standard" for diagnosing DKD, albeit physicians rarely perform kidney biopsies on diabetic patients.

Instead, clinical biomarkers are used to assess renal damage and functional decline in patients with diabetes. By measuring urinary albumin excretion and serum or urinary creatinine, physicians can monitor the severity of renal injury and functional impairment to renal insufficiency, respectively. Measurements of progressive renal damage include calculations of urinary albumin-creatinine ratios (ACRs) and renal decline with eGFR, where persistent macroalbuminuria/proteinuria is defined as ACR > 300 mg/g and severe kidney damage is defined by an eGFR < 30 mL/min/1.73m^2 (Reutens, 2013).

Disease Trajectory

The natural history of DKD is thought to proceed first with normal glomerular function or hyperfiltration and then with urinary microalbuminuria progressing into macroalbuminuria, which is accompanied by decreasing eGFR and, ultimately, results in ESRD (Alicic et al., 2017, Macisaac et al., 2014, Reutens, 2013) (Fig. 17.1). However, it is difficult to determine the degree of renal decline by the presence of albuminuria alone. Progressive renal impairment can occur without albuminuria in T1D DKD patients who have advanced glomerular lesions (Caramori et al., 2003). In T2D DKD patients, the absence of the transition from microalbuminuria to macroalbuminuria and albuminuria without renal decline can occur (Retnakaran et al., 2006, Gaede et al., 2004). Additionally, individuals can revert to normoalbuminuric status and still have renal insufficiency (Perkins et al., 2010).

For extreme phenotypes, overt macroalbuminuria indicates sustained renal damage and a likely progression to ESRD. Because of

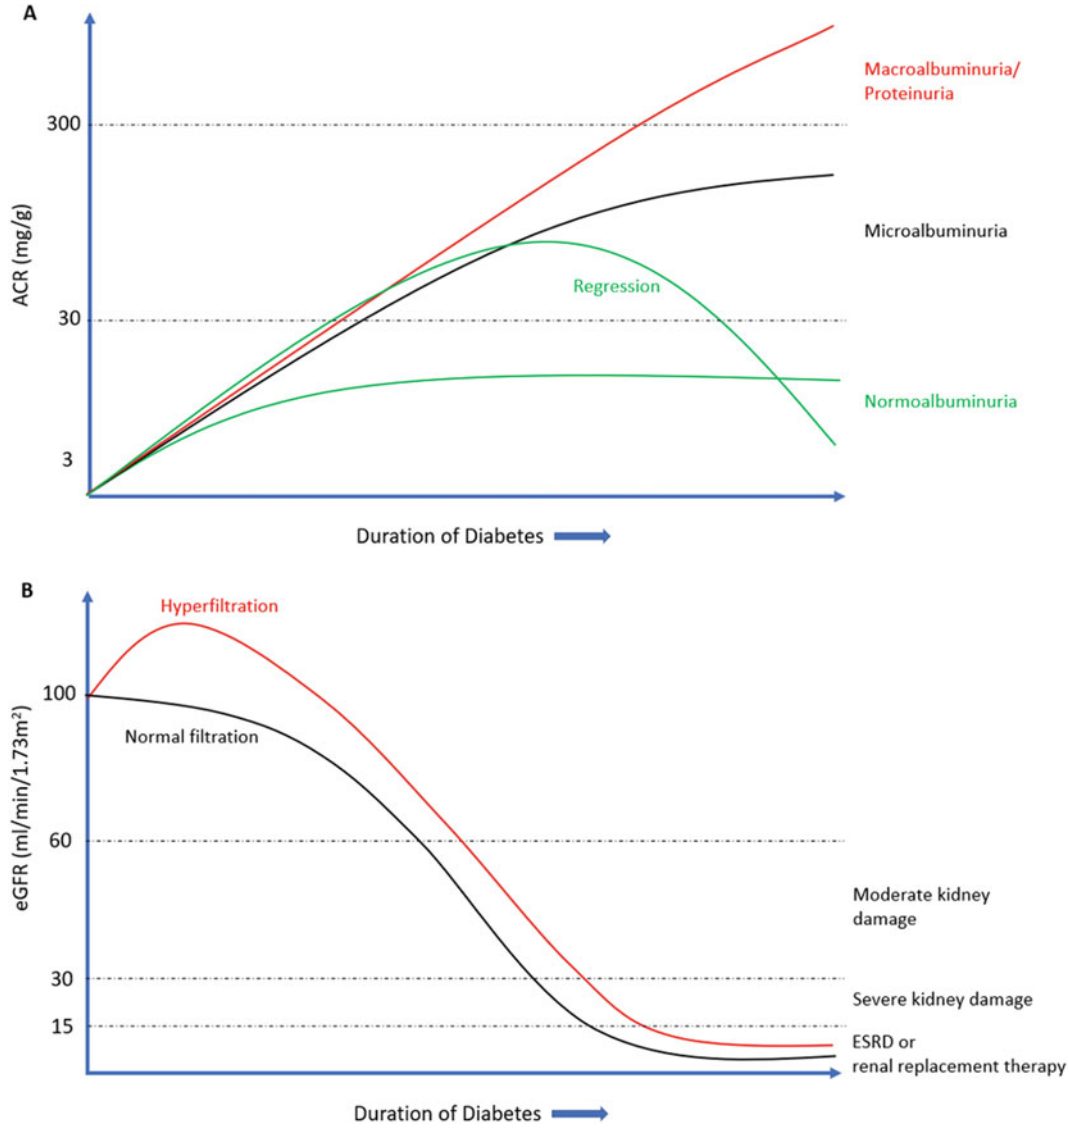

Fig. 17.1 Natural History of DKD. Graphical representations demonstrating the progression of DKD using clinical markers of (**A**) renal injury (albumin-creatinine ratio, ACR) and (**B**) renal function decline (estimated glomerular filtration rate, eGFR) in patients with diabetes. Macroalbuminuria/proteinuria is defined as ACR $>$ 300 mg/g and severe kidney damage eGFR $<$ 30 mL/min/1.73m^2. Regression from microalbuminuria to normoalbuminuria illustrates an example of the phenotypic heterogeneity that can occur with DKD

the dynamic presentation of albuminuria, eGFR and its longitudinal trajectory (i.e., rate of renal function decline) are considered better predictors of progression of DKD (Skupien et al., 2012). Importantly, patients with poor glycemic control do not always progress or ever develop DKD, suggesting that other influences, such as individual genetic risk, may play a role in both susceptibility and progression (Reidy et al., 2014).

When designing genetic studies of DKD, researchers primarily rely on ACR and eGFR measurements to define cohorts and examine the association of various albuminuria- or eGFR-

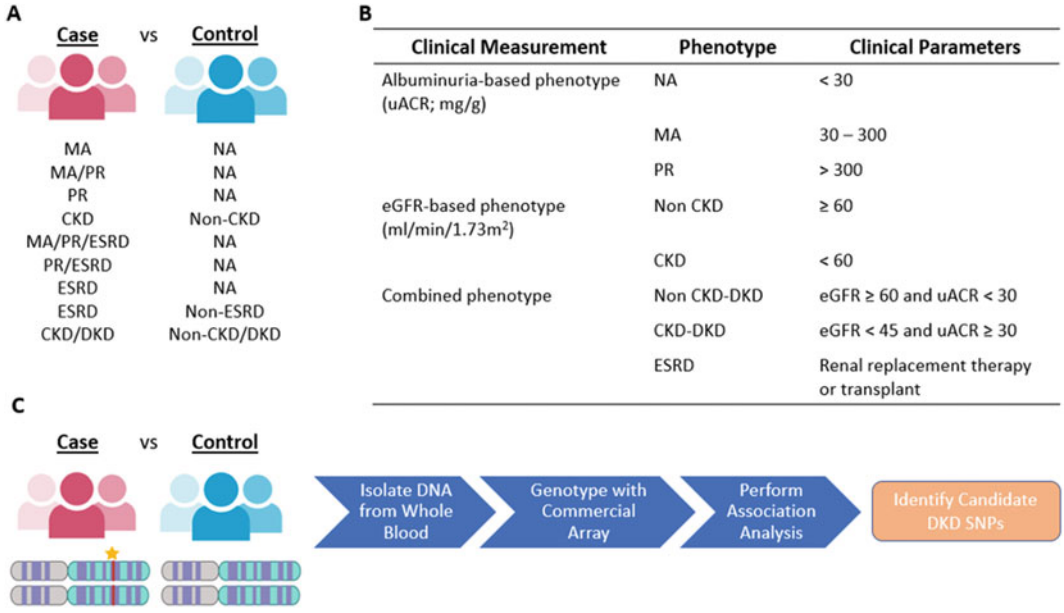

Fig. 17.2 GWASs of DKD. (**A**) Dichotomous phenotypes examined in case-control-based approaches with presented clinical parameters for each ACR-based, eGFR-based, or combined phenotype in (**B**). based phenotypes with genetic variants (i.e., SNPs) (Fig. 17.2). Genetic studies typically dichotomize patients based on these phenotypes and perform case-control association analyses. For example, DKD 'case' subjects could be defined as those who have proteinuria or ESRD, and the frequency of SNPs observed in these patients could be compared with frequencies observed in diabetic 'control' patients with normoalbuminuria. Studies may also examine associations between SNPs and quantitative traits for ACR or eGFR, instead of dichotomizing cases and controls for association analyses. Unfortunately, no genetic analysis of renal function decline has been conducted to date (Li and Pezzolesi, 2018).

The Genetic Architecture of DKD through GWASs

While early genetic studies employed positional cloning and linkage analysis to identify potential causal regions for DKD susceptibility, current genetic approaches utilize GWASs to identify susceptibility markers. GWASs detect associations between the frequency of different alleles of SNPs and a disease trait within a given population and have been very powerful in complex, common disease genetics. Generally, GWASs analyze common SNP variation within the genomes of unrelated individuals. Here, we present the major findings from recent GWASs of T1D and T2D DKD patients (Table 17.1).

Early GWASs of DKD were primarily performed on T1D DKD cohorts, as there are less compounding risk factors compared to T2D DKD, such as cardiovascular health and age,

which can increase phenotypic heterogeneity. One of the first T1D DKD GWASs identified *FRMD3* and *CARS* in 820 diabetic cases with either persistent macroalbuminuria or ESRD (Pezzolesi et al., 2009b). The original discovery cohort signals did not reach genome-wide significance (defined as a *P*-value $< 5 \times 10^{-8}$), most likely due to its modest sample size. Associations at these loci were reproducible in a cohort composed of patients from the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Study (DCCT/EDIC) (Pezzolesi et al., 2009b).

Another early GWAS analysis and a subsequent replication study identified another reproducible candidate DKD gene, *ELMO1*, in both T2D and T1D study cohorts (Shimazaki et al., 2005, Pezzolesi et al., 2009a). As genetic associations at both *FRMD3* and *ELMO1* were independently replicated, the functional roles of both genes in DKD susceptibility have been examined further. In a study by Martini et al., one SNP located in the promoter region of *FRMD3* was computationally and functionally demonstrated to show increased binding of transcription factors, which might downregulate FRMD3 expression and lead to increased DKD susceptibility (Martini et al., 2013). Interestingly, for *ELMO1*, most functional studies have demonstrated that increased renal expression of ELMO1 occurs in DKD mice, overexpression of ELMO1 can promote increased expression of extracellular matrix proteins *in vitro,* and increased expression can cause pathological features of DKD such as glomerular changes and urinary excretion of albumin (Shimazaki et al., 2005, Hathaway et al., 2016). Contrarily, another study challenged the role of ELMO1 in DKD, demonstrating that introducing additional ELMO1 mRNA in PDX1 morphant diabetic zebrafish is renoprotective, by restoring structural integrity in the pronephros (Sharma et al., 2016).

Since these early genetic studies, realizing that common variants have modest impact on disease risk (e.g., odd ratio (OR) typically 1.10–1.40) and that larger sample sizes can improve detection of these signals, collaborative efforts from investigators across the world have empowered larger GWASs. In 2012, the Genetics of Nephropathy—an International Effort (GENIE) consortium—identified two genome-wide significant loci for associations with ESRD (an intronic SNP rs7583877 in *AFF3* and an intergenic SNP rs12437854 located between *RGMA* and *MCTP2*), in a meta-analysis of >12,000 individuals (Sandholm et al., 2012). Additionally, although not genome-wide significant, a strong association with diabetic nephropathy (defined as persistent macroalbuminuria or ESRD) was also seen (intronic SNP rs7588550 in the *ERBB4* gene).

In addition to increasing sample sizes, to overcome limitations of these early GWASs due to imprecise and variable phenotypic heterogeneity, Sandholm et al. analyzed a range of ACR- and eGFR-based subphenotypes, which span different stages and severities of DKD in a meta-analysis of 4 large cohorts (Sandholm et al., 2017). However, despite being well-powered to detect variants with a MAF $\geq$ 10% and an OR $\geq$ 1.55, no SNPs reached genome-wide significance in this study. Suggestive associations for ESRD-based phenotypes ("ESRD vs. no DKD" and "CKD + DKD vs. eGFR >60, normoalbuminuric") were detected in *CNTNAP2* (rs1989248), *PTPN13* (rs61277444), and *AFF3* (rs7562121). As many of the samples included in this study overlap with those in the previous GWAS from the GENIE consortium, this suggestive association at *AFF3* does not provide independent replication of the previously reported association. Interestingly, independent replication was observed in this study for signals reported at *ELMO1* (Shimazaki et al., 2005), the *MYO16-IRS2* locus on chromosome 13q (Pezzolesi et al., 2009b), and *SIK1* (Sambo et al., 2014).

Combined Databases

Following a study design similar to that of Sandholm et al. (Sandholm et al., 2017), the SUrrogate markers for Micro- and Macrovascular hard endpoints for Innovative diabetes Tools (SUMMIT) consortium performed the largest T2D DKD GWAS composed of > 20,000 T2D

patients using eight dichotomous and quantitative DKD subphenotypes (van Zuydam et al., 2018). To further increase sample size, a combined T1D and T2D meta-analysis that included samples of European and Asian ancestry was performed. In total, the sample size of this analysis exceeded 40,000 subjects. Despite this, the yield for discovery of novel loci was modest. One SNP, rs2206136 in *PLCB4*, reached significance with the "CKD" phenotype (P-value $= 2.1 \times 10^{-8}$) in discovery GWAS but not in replication analyses. A novel signal at rs9942471, a position 7 kb upstream of *GABRR1*, was associated with increased microalbuminuria risk in European subjects. Additionally, the combined meta-analysis for eGFR identified a new genome-wide association mapping near *SSB*. Interestingly, as the authors note, while this study aimed to overcome some of the limitations of earlier studies, its significantly larger sample size came with increased phenotypic and, likely genetic, heterogeneity that may have impacted its ability to detect additional genetic associations.

Coding vs Noncoding Variants

SNPs included in these studies mostly map to nonprotein coding regions, which limits the interpretation of the candidate SNP's role in disease susceptibility. Similarly, identified SNPs may be in linkage disequilibrium with causal variants some distance from the identified association, e.g., a causal variant may localize to a gene several hundred kilo-basepair away from the detected association, thereby complicating investigations into the functionality of an associated SNP. Importantly, completion of the National Heart, Lungs, and Blood Institute's Exome Sequencing Project led to the development of a new generation of commercially available genotyping arrays that, in addition to common noncoding variation, now includes coding or 'exome' variants with MAFs as low as 0.5% across the genome (Auer et al., 2016).

Using this technology, the Juvenile Diabetes Research Foundation funded Diabetic Nephropathy Collaborative Research Initiative (JDRF-DNCRI) recently performed the largest T1D DKD GWAS, with 19,406 T1D individuals with and without kidney disease, and identified 16 novel genome-wide significant associations with various dichotomous phenotypes (Salem et al., 2019). The strongest association (rs55703767, a common missense variant in *COL4A3*) was a protective variant against DN, linked to lower glomerular basement membrane thickness. In contrast to the SUMMIT study, which included T1D and T2D individuals of European and Asian ancestry from 16 different studies genotyped on various platforms, the JDRF-DNCRI study benefited from uniform genotyping, quality control procedures, and standardized phenotype definitions. Adoption of this study design, coupled with an increased sample size, helped foster the discovery of several novel associations with DKD in this study.

Ethnic Patterns

Although the majority of genetic studies of DKD have focused on subjects of European ancestry, several studies have included individuals of different ethnicities and demonstrated potential population-specific signals. The majority of these efforts have, however, been in patients with T2D. In the only trans-ethnic meta-analysis of T2D DKD patients, conducted as part of the Family Investigation of Nephropathy and Diabetes (FIND) study, Iyengar et al. identified SNP rs955333, located between *SCAF8* and *CNKSR3*, among patients of American Indian, Europeans, and Mexican ancestries (Iyengar et al., 2015). No SNP reached genome-wide significance in African American T2D patients, although suggestive associations were seen in *APOL1* and *MYH9* genes. As *APOL1* is a well-known ESRD susceptibility locus in African Americans, this signal may be due to nonDKD influences.

In addition to early GWASs that first reported associations at *ELMO1*, a more recent GWAS in T2D DKD Japanese patients identified a genome-wide significant association with rs56094641 in *FTO* as a susceptibility marker for DKD (Taira et al., 2018). The *FTO* locus has repeatedly been

reported to be associated with obesity; however, its association with DKD was not affected by adjustment for BMI in this study. Interestingly, this association was not replicated in European T2D DKD patients. Many studies of T2D attributed ESRD in African Americans have reported additional significant loci, including *SLITRK3*, *ENPP7*, *GNG7*, *SFI1*, and *LIMK2* (Guan et al., 2019, Palmer et al., 2014). With regard to T1D DKD, there have not been any studies to date to address the genetics of T1D DKD in African Americans; intense effort is needed to expand this area of research.

Contributions of Low Frequency and Rare Variations in DKD Patients

Similar to other common, complex diseases, most of the variants identified through GWASs of DKD only explain a small proportion of its overall risk. It has been proposed that some of this 'missing heritability,' which is not accounted for by common variation, may be attributed to additional risk conferred by low frequency ($0.5\% \leq$ MAF $< 5\%$) and rare (MAF $< 0.5\%$) variation (Lee et al., 2014; Manolio et al. 2009). Although next-generation GWASs are beginning to explore their role in DKD susceptibility, challenges for investigating low frequency and rare variation persist in all complex disease genetics. Among these, the sample size requirement needed to detect a robust association with low frequency and rare variation remains a major hurdle.

Statistical Challenges

For single variant association tests, the sample sizes to achieve 80% power (at a significance level of 5×10^{-8} with an OR $= 1.4$) would need to be 6400, 54,000, and 540,000 for variants with MAFs $= 0.1$, 0.01, and 0.001, respectively (Lee et al., 2014). Unfortunately, current DKD cohorts do not exceed 50,000 patients. Additionally, while newer commercial genotyping arrays do include as many as 200,000–250,000 low frequency and rare variants, these arrays are limited to the variants included in the array's design, such that novel variants and those not selected for inclusion cannot be assessed. Finally, while NGS-based approaches (e.g., WES and WGS) are ideal for discovering and interrogating low frequency and rare variation, these approaches still remain costly at scale, despite their continuous declining cost and, thereby, have had limited utility in the field.

Despite these challenges, WES and GWASs including low frequency and rare variants have been utilized with some success to explore the contribution of these classes of variants in DKD. In 2017, Sandholm et al. performed WES in 997 T1D DKD subjects (Sandholm et al., 2017). While no variants reached exome-wide significance (P-value $< 2.5 \times 10^{-7}$) for single variant and gene aggregation tests, nominal (P-value $< 9 \times 10^{-5}$) associations with rare missense alleles were identified; the strongest association was observed at an intronic SNP within *NVL* (rs188427269, MAF $= 0.2\%$, and P-value $= 3.3 \times 10^{-7}$). Importantly, the lack of exome-wide significance in this study is likely due to its modest sample size, as 997 patients may not be enough to detect significant associations with rare variants. In the T1D DKD GWAS from the JDRF-DNCRI, Salem et al. reported several associations with low frequency variants included on a commercial genotyping array associated with ESRD, microalbuminuria, and DN (Salem et al., 2019). The lowest P-value was observed at low frequency intronic variants in *PAPLN* (rs113554206, MAF $= 1.2\%$, and P-value $= 5.39 \times 10^{-7}$).

Given the excess rate of ESRD in African Americans relative to European Americans, Guan et al. evaluated the impact of low-frequency variants in 47 candidate genes involved in kidney structure (e.g., podocyte, glomerular basement membrane, and renal tubular cell genes) with ESRD in approximately 5000 African American subjects (Guan et al., 2016). After excluding carriers of *APOL1* risk alleles, statistically significant associations were observed at two missense variants, located in *CLDN8* and *COL4A3*. A subsequent exome-wide association study by the same group

identified suggestive associations at *OTUD7B*, *IFITN3*, and *DLGAP5* (Guan et al., 2018).

While these studies are the first to begin investigating the role of low frequency and rare variants in DKD, these associations should be interpreted with caution due to an overall lack of genome-wide significance due to their limited sample sizes. These studies may suggest that low frequency or rare variants do not contribute significantly to the underlying genetic component of DKD, as would be seen in monogenic conditions, but may still modestly impact its susceptibility.

From Genetic Causes of DKD to Personalized Therapies

Although progress in personalized therapeutics in DKD has been limited, genetic studies in DKD have shown promise toward translating robust findings to improved patient care. Pharmacogenomics examines how genetic variation can impact beneficial or adverse reactions to therapies and, using genetic data to predict therapeutic response, is beginning to emerge in clinical practice (Roden et al., 2019). This approach has been applied to evaluate reactions to therapies for DKD patients.

One of the earliest studied pharmacogenomic loci in DKD is the insertion-deletion polymorphism of the *ACE* gene (rs4646994), where the insertion (*I*) or deletion (*D*) of a 287 basepair Alu repeat in intron 16 of *ACE* affects patient responses to angiotensin converting enzyme (ACE) inhibitors, a first-line treatment for DKD. In T1D DKD patients, early reports indicated that individual homozygous for the deletion allele (*DD*) was more likely to progress to ESRD and lacked a response to renoprotective therapies. However, a study from the Steno Diabetes Center demonstrated that there is no difference in the renoprotective effects in either *II* or *DD* individuals (Andersen et al., 2003).

Angiotensin Modulators

These conflicting results in T1D DKD patients could result from the modest sample sizes of these studies or the efficacies of the drugs examined. More recently, Wang et al. investigated the renoprotective efficacy of valsartan, an angiotensin receptor blocker (ARB), in T2D patients carrying the *ACE I/D* polymorphism and reported an increased risk of developing DKD among carriers of the *D* allele (Wang et al., 2016). They also observed a beneficial decrease in albuminuria levels for patients with the *ID* and *DD* genotypes when treated with valsartan. This observation is likely due to decreased plasma ACE activity in patients carrying this polymorphism.

While no genetic studies of DKD have reported a significant association with *CYP2C9*, two coding polymorphisms, *2 (Arg144Cys, rs1799853) and *3 (Ile359Leu, rs1057910), can influence CYP2C9 metabolism of ARBs. As ARBs can improve renal function in DKD patients, some studies have examined pharmacological responses with these variants. Lajer et al. described that patients without the CYP2C9*3 polymorphism had a significant change in systolic blood pressure after 4 months compared to *3 carriers. However, both *3 and non*3 carriers had no significant difference in urinary albumin excretion during the study period (Lajer et al., 2007).

Future Directions

Overcoming DKD's phenotypic heterogeneity has proven to be among the most challenging. As a progressive disease, the lack of consistent findings across studies can, in part, be attributed to the array of clinical definitions established by different studies. Since most genetic approaches are inherently cross-sectional, investigators typically examine multiple phenotypes that span all stages and presentations of renal disease. This

approach has drawbacks, as a patient's renal status could change over time (i.e., a microalbuminuric patient reverts to normoalbuminuria or, alternatively, progresses to proteinuria or ESRD), leading to misclassification. Misclassification bias then could result in a significant number of false-negative associations. Indeed, longitudinal investigations of DKD have shed new light on the natural history of this disease and its heterogeneous nature (Perkins et al., 2010, Skupien et al., 2012, Krolewski and Bonventre, 2012, Krolewski, 2015). Additionally, the rate of renal function decline varies widely among DKD patients; perhaps, genetic factors influence whether this decline is slow, where ESRD is reached after decades of diabetes, or decline is rapid and progression to ESRD occurs in as little as a few years after the onset of diabetes (Skupien et al., 2012, Krolewski and Bonventre, 2012, Krolewski, 2015). Because of the heterogeneity of the subphenotypes of DKD, considering such disparate patients simultaneously likely poses challenges to uncovering the genetic basis of DKD.

Additionally, it is possible that a subset of DKD patients have nondiabetic kidney disease (NDKD) coincident with diabetes or concurrent DKD and NDKD. Renal biopsies from patients with diabetes and kidney disease suggest that as many as 30–80% of patients diagnosed with DKD actually had kidney disease attributed to nondiabetic causes (Haider et al., 2011, Sharma et al., 2013, Zhuo et al., 2013). Importantly, this has major implications in terms of patient care, monitoring, and family planning, as well as for research studies aimed at understanding the factors that contribute to DKD. To begin investigating this, we have recently shown that a subset of 'DKD' patients carry rare pathogenic variants indicative of NDKD, e.g., variants in *COL4A3* (associated with focal segmental glomerulosclerosis, thin basement membrane nephropathy, and Alport Syndrome) and *REN* (associated with autosomal dominant tubulointerstitial kidney disease) (Lazaro-Guevara et al., 2020).

Large research consortiums are now bringing together investigators across the globe to combine resources and enhance the cohort sizes of current genetic studies, such as the Juvenile diabetes research foundation-Diabetic nephropathy collaborative research initiative (JDRF-DNCRI) most recent T1D DKD GWAS. Even though establishing large cohorts increases statistical power, how many samples are sufficient to accurately identify all of the contributing genetic variation underlying DKD? Is there a sample size threshold that diminishes any further efforts of larger GWASs?

Epigenomics

In addition to variation at the DNA sequence level, increasing research shows that epigenetic and epigenomic mechanisms, i.e., heritable changes in gene expression, including DNA methylation and histone modifications, which do not alter the sequence of DNA, are involved in DKD pathogenesis (Kato and Natarajan, 2019). Nucleic acid and chromatin histone complex modifications elicit changes in gene expression by affecting the binding of potential transcriptional regulators. It has been demonstrated that "metabolic memory" of previous metabolic dysregulation exists, where patients with long-standing diabetes can still experience complications even after intense glucose control, highlighting prolonged modification of gene expression patterns in DKD risk (Reidy et al., 2014). Therefore, identifying epigenetic signatures could lead to new treatments and diagnostic biomarkers for DKD initiation and progression.

Epigenetics and Chronic Inflammation: Role in Early Detection of Type 2 Diabetes

18

Meenu Ghai

Contents

Abstract

Low-grade inflammation initiates even before type 2 diabetes (T2D) is diagnosed. As a response to change in inflammatory profile of cells and tissues, epigenetics modifications such as DNA methylation (DNAm) and noncoding RNAs provide early cues about forthcoming discord in the bodily system. Thus, targeting epigenetic alterations that occur in the initial phases leading to T2D can provide therapeutics, which will prevent or halt the cascade of T2D and associated long-term complications. New biomarkers need to be identified for prediction and monitoring the progression of T2D. Early detection of

diabetes or prediabetes will also protect individuals from undesirable effects of chronic inflammation and metabolic memory.

Keywords

Type 2 diabetes · Chronic inflammation · DNAm · Noncoding RNAs · Metabolic memory

Introduction

The risk factors of type 2 diabetes (T2D) include genetic predisposition, age, and ethnicity; however, environmental factors should similarly be taken into account. T2D is characterized by hyperglycemia and combination of insulin resistance and/or insufficient insulin production by beta cells, which leads to metabolic derangements and widespread complications (Rawshani et al. 2017; Sladek 2018).

Chronic inflammation plays a role in T2D, sometimes even before disease onset, even though it is not clinically prominent in most cases (Reddy et al. 2019; Tsalamandris et al. 2019). It is characterized by increased pro-inflammatory cytokines, histological changes, and immune shifts (Gregor and Hotamisligil 2011; Hotamisligil 2017). "Self-"antigens can emerge and promote autoimmune activation. Insulin secretion and hyperglycemia can also be further impaired.

Metabolic Memory

Prolonged low-grade inflammation could mediate metabolic memory (Ceriello 2009; Testa et al. 2017) (Fig. 18.1). Intensive glycemic control is often recommended for the management of glucose homeostasis and microvascular complications (Holman et al. 2008; Gaede et al. 2008).

Demonstrated genetic variants are not responsible for more than 10% of the heritable risk for T2D, while rare variants, gene–environment interactions, gene–gene interactions, and epigenetic factors (Kirchner et al. 2013) could be underestimated. Epigenetic mechanisms such as DNA methylation (DNAm) and noncoding RNAs regulate inflammatory gene expression and should deserve much attention (Naidoo et al. 2018).

Adipose Tissue Changes and Cytokine Expression

Obesity leads to changes in tissue cell distribution and inflammatory activity, including pro-inflammatory cytokines and chemokines (Esser et al. 2014) (Fig. 18.1).

Both subcutaneous adipose tissue (SAT) and visceral adipose tissue (VAT) are associated with metabolic risk profile; however, the role of VAT is far more relevant (Kwon et al. 2017).

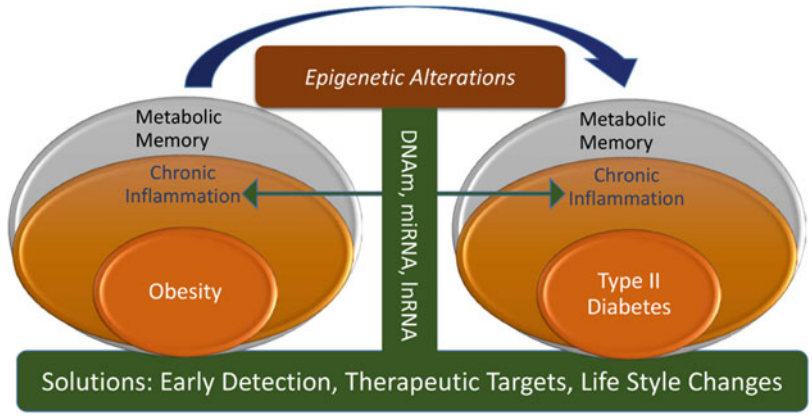

Fig. 18.1 Simplified depiction of development of chronic inflammation and "undesirable" metabolic memory in obesity and T2D. Epigenetic alterations provide early cues to metabolic imbalance and hence can be an ideal target for early detection of chronic inflammation in obesity and T2D

Macrophages, mast cells, neutrophils, and T and B lymphocytes in VAT seem to be key players (Mraz and Haluzik 2014). Adipose tissue (AT) macrophages exhibit intense pro-inflammatory (M1) characteristics (Verboven et al. 2018).

Macrophage activation in AT could precipitate insulin resistance (IR), along with M1 macrophage- or B-cell-mediated inflammation (Russo and Lumeng 2018), with little interference by subcutaneous fat (Verboven et al. 2018).

Chronic Inflammation and Insulin Resistance

Chronic inflammation is associated with insulin resistance in the primary insulin target organs, mainly adipose tissue, muscle, and liver (Gregor and Hotamisligil 2011; Reilly and Saltiel 2017). Inflammatory cytokines compromise insulin signaling in adipocytes by inducing inflammatory pathways (Lee 2013). Dysregulation of preadipocyte/adipocyte functions promotes ectopic fat deposition and insulin resistance (Samuel and Shulman 2012; Wu and Ballantyne 2017). Communication between M1 and M2 macrophage polarizing is detected in this context, with predominance of the alternatively activated macrophage (M2) phenotype and activation of transcription molecules nuclear factor-kappa beta (NF-κB) and activator protein 1 (AP1). Insulin resistance-mediated epigenetic changes are recognized in monocytes and macrophages (Reddy et al. 2014; Hanson and Godfrey 2015).

Epigenetics of T2D

At least 144 genetic variants (not completely independent) at 129 loci, identified by means of genome wide association studies (GWAS), are associated with T2D (Morris et al. 2012; Flannick and Florez 2016). Novel 39 common variants and 4 rare variants should be added (Xue et al. 2018). Gene expression of three genes, which play a role in T2D pathogenesis, namely, *CAMK1D*, *TP53INP1*, and *ATP5G*, was regulated by DNAm associated with genetic variants (Xue et al. 2018).

Age, obesity, diet, physical activity, and fetal and early postnatal development are among the environmental drivers that should not be overlooked. Epigenetics modifications comprise DNAm, histone modification, and noncoding RNA, which regulate gene expression in a tissue specific manner. Environmental influences and DNA sequence variations or single nucleotide polymorphisms (SNPs), such as CpG-SNP, structural variations, and gene–gene interactions, also deserve to be mentioned.

Hyperglycemia and Epigenetics

Hyperglycemia can induce a variety of epigenetic changes that can even persist after the normalization of glucose levels, mainly through the involvement of inflammatory genes (Reddy et al. 2015; Al-Haddad et al. 2016). Hyperglycemia can alter the activity of DNA methyltransferases (DNAmet), with irreversible changes over time. Epigenetic modifications may explain the long-term harmful effects of metabolic memory (Reddy et al. 2015).

DNAm is a well-characterized epigenetic modification. Unlike genotypic variation, DNAm intensity patterns are liable to change over time, with age or following disease or other exposure. Naidoo et al. (2018) elaborately reviewed cell and tissue specific methylation changes associated with inflammation and T2D.

Investigations in Twins

Monozygotic twins present an ideal model to study epigenetic contributions to the disease, as they are genetically the same and genetic influences on epigenetic variations can be ruled out. Because of tissue specificity of epigenetic regulation, it is essential to investigate a homogenous tissue or cell type from a target organ, which is influenced by alterations due to diabetes. Ribel-Madsen et al. (2012) investigated global DNAm

differences in skeletal muscle and subcutaneous adipose tissues from 12 monozygotic twins, discordant for type 2 diabetes. A total of 26,850 cytosine-guanine dinucleotide (CpG) sites in the promoters of 14,279 genes were analyzed. Small intratwin pair methylation differences between diabetic and nondiabetics occurred; however, promoters of genes *PPARGC1A* in muscle and *HNF4A* in adipose tissue showed increased methylation in type 2 diabetes.

Increased expression of genes involved in inflammation and glycan degradation was observed in diabetes discordant monozygotic twins, with most differentially expressed genes being *ELOVL6*, *GYS2*, *FADS1*, *SPP1* (OPN), *CCL18*, and *IL1RN* (Nilsson et al. 2014). Significant DNAm differences were modest; however, 1410 sites showed differential DNAm. Also 15,627 sites, representing 7046 genes including *PPARG*, *KCNQ1*, *TCF7L2*, and *IRS1*, showed differential DNAm in adipose tissue.

Genome-wide methylated DNA immunoprecipitation sequencing (MeDIP-seq) in monozygotic twins reported hypermethylated DMRs in diabetic groups, with high hypermethylation in promoter of the *MALT1* gene, involved in insulin and glycemic pathways and related to taurocholate levels in blood (Yuan et al. 2014). Liu et al. (2015) conducted bioinformatics analysis of DNAm differences in muscle tissues of monozygotic twins, observing 38 differentially methylated genes, including Sirtuin 1, N-acetyltransferase 6, phospholipase A2 group XIIB, and nuclear factor of activated T cell calcineurin-dependent 1. Hwang et al. (2018), reported *ELOVL5* as an epigenetic biomarker for diabetes risk.

Epigenetic Wide Association Studies

Epigenetic modifications can precede disease manifestation or occur as a result of disease diagnosis, and hence, prospective studies are better suited for studying casual changes. In the large epigenetic wide association study (EWAS) by Demerath et al. (2015), 37 variable methylation sites in leucocyte DNA were associated with body mass index (BMI) and one with waist circumference (WC), including sites in genes *CPT1A*, *ABCG1*, and *SREBF1*. Cross-tissue association study using adipose tissue DNA revealed wide agreement in BMI– and WC–methylation associations. Replication using blood DNA was similarly achieved for 37 BMI probes and one WC probe. Sixteen of these sites also replicated in adipose tissue, including 15 novel methylation findings near genes involved in lipid metabolism, immune response/cytokine signaling, and other diverse pathways, including LGALS3BP, KDM2B, PBX1, and BBS2, among others. Additional EWAS showing link between DNAm and T2D has also been reported (Yuan et al. 2014; Nilsson et al. 2014; Dayeh et al. 2014)

In a recent study, Cardona et al. (2019) identified 15 novel methylation variable positions (MVPs) with significant associations with incident and prevalent T2D and also confirmed three previously identified MVPs. The study used whole blood DNA collected at baseline, up to 11 years before T2D onset, to investigate early epigenetic changes and their role in onset of T2D. The research was an incident T2D case-cohort study from the European Prospective Investigation into Cancer and Nutrition (EPIC)-Norfolk cohort. Integration of genome –wide genetic data with methylation data revealed one MVP, cg00574958 at *CPT1A*, which could possibly play direct casual role in T2D. Interestingly, none of the genes with identified MVPs had been identified by genetic association studies, thus indicating use of novel mechanisms/pathways for epigenetic alterations.

Noncoding RNA

Noncoding RNAs do not translate into proteins but bring about epigenetic changes and function to regulate gene expression at the transcriptional and posttranscriptional level. Several microRNA (miRNA) and long noncoding RNA (lncRNA) have been implicated in beta cell development, insulin sensitivity/resistance, insulin production/secretion, and insulin signaling. Noncoding RNAs are actively involved in early inflammation

of the visceral adipose tissue and regulate inflammatory profiles of TNF-α, IL-1, IL-6, IL-18, intercellular adhesion molecule 1, VCAM-1, and plasminogen activator inhibitor 1 (Hamar 2012; Marques-Rocha et al. 2015).

MicroRNAs in Type 2 Diabetes and Inflammation

miRNAs are linked with obesity and inflammation, either directly or indirectly (through regulatory elements such as transcription factors) (Arner and Kulyté 2015). Microarray analysis of human WAT tissues revealed several potentially relevant miRNAs (Heneghan et al. 2011; Keller et al. 2011; Arner and Kulyté 2015).

To state few examples, miR-103 and miR-107 have been implicated in glucose homeostasis and insulin sensitivity (Trajkovski et al. 2011); miR-107 may also play a role in proinflammatory events (Foley and O'Neill 2012); miR-221 promotes white adipose tissue inflammation and decreases insulin sensitivity (Peng et al. 2018). miR 122 is implicated in liver steatosis and elevation in plasma cholesterol levels, circulating miR-122 is strongly associated with metabolic syndrome and T2D (Willeit et al. 2017), miR-146a expression is negatively correlated with fasting blood glucose (FBG), HbA1c, insulin resistance, proinflammatory signals such as TRAF6 and NFκβ mRNA levels, and also proinflammatory cytokines TNFα and IL-6 (Balasubramanyam et al. 2011), and finally, decreased serum level of miR-146a is a sign of chronic inflammation in T2D patients (Baldeón et al. 2014).

A detailed literature survey by Yaribeygi et al. (2018) reports different noncoding microRNAs related to glucose metabolism and pathophysiology of T2D. The authors propose four mechanisms via which miRNAs may alter glucose metabolism: beta cell development, insulin sensitivity/resistance, insulin production/secretion, and insulin signaling. Gottmann et al. (2018) combined QTL, miRNA prediction, and transcriptomics to design a computational framework (miR-QTL-Scan) to identify miRNAs that are regulated in obesity and T2D. The study discovered 170 miRNA regulative elements in human adipose tissue and blood cells.

Long Noncoding RNA in Type 2 Diabetes

Human β-cell transcriptome analysis has shown dynamic regulation and abnormal expression of lncRNAs in T2D (Saeidi et al. 2018). A recent study addressed expression level of lncRNAs in peripheral blood mononuclear cells (PBMCs). Significantly increased levels of lncRNAs HOTAIR, MEG3, LET, MALAT1, MIAT, CDKN2BAS1/ANRIL, XIST, PANDA, GAS5, Linc-p21, ENST00000550337.1, PLUTO, and NBR2 were observed in T2D patients. lncRNA expression patterns of THRIL and SALRNA1 diminished in T2D. The majority of altered lncRNAs were positively correlated with poor glycemic control, insulin resistance, and transcriptional markers of senescence (Sathishkumar et al. 2018).

Circulating lncRNA GAS5 less than 10 ng/μl was found to predict twelve times higher odds of having diabetes (Carter et al. 2015). Wang et al. (2017) identified 55 lncRNAs and 202 mRNAs to be differentially expressed in the blood samples from T2D group. miRNAs were mainly associated with immune regulation, inflammation, and insulin resistance. Newly emerged research interestingly indicates the use of exosomes miRNA and lncRNAs as potential biomarkers for detection or treatments of diabetes and diabetic complications (Chang and Wang 2019). Noncoding RNAs present an attractive target for T2D detection at early stages and may serve as clinical biomarkers.

Noncoding RNAs as Therapeutics Targets

Several studies have reported the inhibition of miRNAs for therapeutic purposes (Nunez Lopez et al. 2016; Nigi et al. 2018; Jiménez-Lucena et al. 2018). Inhibition of miRNAs by antisense

oligonucleotides in mice models has proved to improve glucose homeostasis and insulin sensitivity.

Inhibition of miR-103 and miR-107 by antisense oligonucleotides in liver and in adipose tissue of obese mice improved glucose homeostasis and insulin sensitivity. In contrast, injections in liver of an adenoviral vector expressing miR-107 resulted in elevated fasting blood glucose and insulin levels, impaired glucose tolerance, decreased insulin sensitivity, and increased hepatic glucose production (Trajkovski et al. 2011). Antisense oligonucleotides also demonstrated the potential therapeutic effects of liver-specific miR-122 inhibition and downregulation of miR-181a (Esau et al. 2006; Zhou et al. 2012). Lucia La Sala et al. (2019) demonstrated microRNA-21 as a biomarker for early detection of prediabetes and glucose imbalances. There was upregulation in impaired glucose tolerance (IGT) and in T2D subjects. Inhibition of miR-200c and miR-21 has also been suggested against T2D (Geach 2015; Seeger et al. 2014).

Tissue-specific miR-199a-3p and miR-223 are potential tissue biomarkers for pancreas and liver, respectively, in the context of T2D (Zhu and Leung 2015).

High Fat Diet and Polyphenols

Dietary modifications have also been shown to indirectly modulate miRNA expression (Parra et al. 2010). Experimental high fat diet increased the expression of miR-103 and miR-107, with reversal by plant-derived polyphenols. Dietary polyphenols fed with high fat diet also decreased the expression of miR-122, reduced weight gain, liver steatosis, and insulin resistance (Joven et al. 2012).

Beta Cell Dysfunction

In the relationship between Insulin sensitivity and Cardiovascular disease (RISC) cohort, biomarkers of IGT/reduced β-cell glucose sensitivity were mainly adiponectin, alpha-1-antitrypsin (known to regulate adiponectin levels), endocan, miR-181a, miR-342, and miR-323. The proteins identified were adiponectin, endocan, and sialoadhesin (Belongie et al. 2017).

Despite success in animal models, techniques for *in vivo* specific delivery of "therapeutic" miRNAs will need to be tested and optimized, in order to restore physiological levels of a miRNA deregulated in a specific tissue. miRNA combination therapy could be necessary to address multiple dysregulated miRNAs associated with T2D.

Early Detection/Relative Risk Tests

The International Diabetes Federation (IDF) has estimated that among 642 million cases by 2040, half of them will not be diagnosed (Ogurtsova et al. 2017). Early detection tests/screening of the general population are very important to facilitate risk identification and to curb the damage at early stages. Selective or targeted screening of T2D is performed in high risk cohorts selected by age, body weight, or ethnic origin. Opportunistic screening is conducted by health care professionals, for any other reason, during routine appointments. The most useful glucose homeostasis test is still debated (Vatandoost et al. 2015).

According to Barry et al. (2017), glycated hemoglobin A1c (HbA1c) was neither sensitive nor specific for prediabetes; fasting glucose was specific however not sensitive. Divergence between the criteria of the American Diabetes Association and WHO leads to identification of different populations with limited overlap. The study also suggested that "screen and treat" policies alone are unlikely to halt the epidemic of type 2 diabetes. In the experience of Laiteerapong et al. (2019), newly diagnosed diabetes and an unstable initial 10-year HbA1c predisposed to microvascular complications, even after adjusting for HbA1c control in year 1.

Repeated measurements of fasting plasma glucose seem to better predict diabetes than a single

Table 18.1 List of ongoing clinical trials on T2D and epigenetics

Title of the study	Type of study	Stage/ No. of participants	Major outcomes(epigenetics)	Location (Country)
Epigenetic Contribution to the Pathogenesis of Diabetic Nephropathy in Qatari Population	Observational/ prospective	Recruiting N =240	Assessment of DNA methylation in monocytes, Assessment of urinary micro-RNAs	Qatar
Network-based Epigenome-Wide association Study in Obesity precision Medicine: NEWTON Clinical Trial	observational / Case control/ prospective	Not yet Recruiting N =100	(a) A disease module containing the crucial differentially methylated genes in obese patients and obese patients with T2D compared to controls. (b) Identification of differentially expressed micro-RNA and mRNA	Italy
Sex-specific Relationship of Epigenetic-Based Modifications in the Saliva and Blood With the Occurrence of Type 2 Diabetes	Observational/ Prospective	Recruiting N =224	Correlation of miRNAs in the saliva with the amount of intrahepatic liver fat, ectopic lipids in the heart, and skeletal muscle.	Austria
Unravelling the Role of Mitochondrial DNA Methylation in Type 2 Diabetes	Observational/ Prospective	Recruiting N=36	Mitochondrial DNA methylation and D-loop changes in insulin resistant states such as obesity and type 2 diabetes	United States
Impact of Metabolic Health on Sperm Epigenetic Marks in Humans.	Interventional/ Nonrandomized	Recruiting N =40	Changes in epigenetic markers (DNA methylation and noncoding RNAs) in overweight men with type 1 or type 2 diabetes with a 3 month lifestyle intervention program.	United States
Perturbation of Interactome Through MicroRNA And Methylome Analyses In Diabetes Endophenotypes: the PIRAMIDE Study Design	Observational/ case-control/ Prospective	Recruiting N =35	(a) Identification of differentially methylated genes in both CD4+ and CD8+ cells from T2D patients and controls. (b) Identification of differentially expressed microRNA and mRNA target in both CD4+ and CD8+ cells isolated from T2D patients and controls. (c) Putative epigenetics interactions in the presence or absence of T2D-related cardiovascular dysfunction.	Italy
Investigating the Underlying Mechanisms of Exercise Resistance in Individuals With Type 2 Diabetes	Interventional/ nonrandomized.	Active N=33	Relationship between the basal promoter methylation status of key genes involved in fuel metabolism and activated by exercise in skeletal muscle tissue and cells.	United States
The Interaction Between Protein Intake, Gut Microbiota, and Type 2 Diabetes in Subjects With Different Ethnic Backgrounds (MICRODIET)	Interventional/ Randomized	Recruiting N =120	Epigenetic modifications in monocytes of patients at baseline and end of dietary intervention	France

(continued)

Table 18.1 (continued)

Title of the study	Type of study	Stage/ No. of participants	Major outcomes(epigenetics)	Location (Country)
Who Will Benefit From Bariatric Surgery for Diabetes? Using Fat Distribution Measurement, Gut Hormone Profiles, and Genetic Data to Predict Diabetes Remission	Observational/ prospective	Recruiting N =210	Epigenetic changes in visceral adipose tissue of T2D patients on mixed meal remission, who underwent Roux-en-Y gastric bypass surgery	United Kingdom
Consequences of Hypoglycemia on Cardiovascular and Inflammatory Responses (HCIR)	Interventional, nonrandomized, clinical trial	Recruiting N =112	Epigenetic modifications due to hypoglycemia in the promoter regions of the pro-inflammatory cytokines in monocytes	Netherlands
Association Between Urinary and Serum Levels of miRNA 192 and miRNA 25 and Glomerular Filtration and Albuminuria in Patients With and Without Type 2 Diabetes.	Observational/ retrospective	Recruiting N =300	Urine and serum expression of miRNA192 and miRNA 25	Italy
Prognostic Predictors of Response to Hypoglycemic Therapy	Interventional, randomized	Recruiting N =800	Serum level of microRNA-126, microRNA-21, microRNA-27, miRNA-125, and miRoRNA-155 from baseline to 6 and 12 months after intervention	Russia

test (Inoue et al. 2012). In the opinion of Jackson et al. (2017), a 50-g oral glucose followed by 1-h glucose measurement is superior to other screening tests. If abnormal, an oral glucose tolerance test could follow. Such strategy could be cost effective in high risk populations.

Feldman et al. (2017) were able to diagnose diabetes 4.6 years earlier, by screening asymptomatic individuals, and these cases had a more favorable clinical course than clinically detected diabetes after diagnosis. Screening for both T2D and prediabetes should begin at age 45–50, with follow-up every 5 years, and targeted screening appears to be more cost-effective compared to routine evaluation (Einarson et al. 2017).

Ongoing Clinical Trials

Table 18.1 depicts a few ongoing clinical trials on T2D and epigenetics. The recent research will accelerate the interventions into clinical practice and improve early detection of T2D and arrest of associated complications.

Abstract

Childhood obesity is reaching alarming rates in many countries, posing an urgent and serious challenge. Adipose tissue is a key endocrine organ that releases several pro- or anti-inflammatory adipokines that are involved in the pathogenesis of obesity complications. Moreover, it is suggested that gut microbiota is also involved in the development of these complications, including obesity-related liver disease and metabolic syndrome.

Metabolomics has recently started to pave the way to a better pathomechanistic understanding of hepatometabolic complications, leading to a more efficient diagnosis and better therapeutic approaches. Several metabolites and metabolic pathways contribute to a complex metabolic fingerprint of obesity, metabolic syndrome, and obesity-related non-alcoholic fatty liver disease (NAFLD). Indeed, these conditions seem to have different salivary and urinary metabolomic signatures. The aim of this chapter is to provide an overview of these signatures, metabolomic-driven findings, and perspectives for obesity and obesity-related condition diagnoses and treatments.

Keywords

Pediatric obesity · metabolic syndrome · non-alcoholic fatty liver disease · metabolomics

Introduction

Obese children and adolescents are at high risk of developing several metabolic disorders that were previously considered to be "adult" diseases, including insulin resistance (IR), metabolic syndrome (MetS), type-2 diabetes mellitus (T2DB), hypertension, dyslipidemia, obstructive sleep apnea (OSA), and non-alcoholic fatty liver disease (NAFLD) (Kumar and Kelly 2017; WHO 2016; Morales Camacho et al. 2019; Dietz and Robinson 2005; Lakshman et al. 2012). This is the first time in human history that we are meeting these phenomena in pediatric populations, and the effects on subsequent adulthood are not easily predictable (Rosenbaum 2018).

Adipose tissue is a key endocrine organ that releases several pro- or anti-inflammatory adipokines, which are involved in the pathogenesis of obesity complications. Moreover, it is suggested that gut microbiota is also involved in the development of these complications, including obesity-related liver disease and obesity itself (Vajro et al. 2013a).

NAFLD is a clinical–pathological condition characterized by abnormal lipid deposition in hepatocytes in the absence of excess alcohol intake. It includes a disease spectrum ranging from isolated hepatic steatosis to more severe forms (Non-alcoholic Steatohepatitis, NASH) with inflammation, liver fibrosis, cirrhosis, and eventually hepatocellular carcinoma (HCC) (Tiniakos et al. 2010).

The majority of patients with NAFLD are obese: the obesity-related chronic mild systemic inflammation blocks insulin signaling pathways and leads to insulin resistance, which plays a likely role in the liver disease pathomechanism (Sanyal et al. 2001; Fabbrini et al. 2010).

NAFLD is now considered as the hepatic manifestation of MetS,(Abenavoli et al. 2017; Buzzetti et al. 2016) that is essentially characterized by the clustering of metabolic abnormalities such as glucose intolerance, obesity, dyslipidemia, and hypertension (Hosseinpour-Niazi et al. 2019; Bussler et al. 2017).

While the pathogenesis of MetS and the role of each of its components is complex and not completely elucidated (Fig. 19.1), abdominal obesity and insulin resistance are considered important causative factors (Alberti et al. 2006).

The International Diabetes Federation (IDF) provided the Worldwide Consensus definition of MetS, identifying abdominal obesity (defined as waist circumference) as a prerequisite of MetS (Alberti et al. 2006; Zimmet et al. 2007). In addition, diagnosis is defined by the presence of at least two of the following features: high blood triglycerides (TG), reduced HDL cholesterol

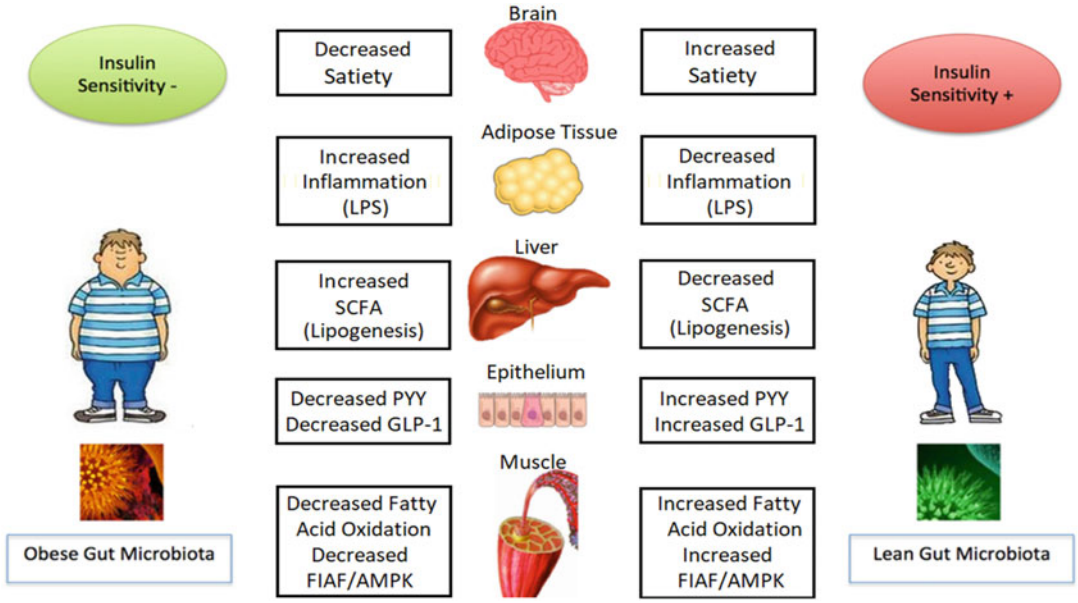

Fig. 19.1 Pathophysiological changes related to insulin resistance in various organs

(HDL-C), increased blood pressure, or increased fasting blood glucose (FBG) (Zafar et al. 2018).

Although there is no agreement on a MetS definition for children and adolescents (Bussler et al. 2017), prevalence is approximately 30%. A current MetS definition in pediatric population is based on the presence of 3 or more of following criteria: (1) TG $\geq$ 110 mg/dL or (WHO 2016); HDL-C $<$40 mg/dL (Morales Camacho et al. 2019) ;FPG $\geq$ 100 mg/dL (Genuth et al. 2003); (Dietz and Robinson 2005) Systolic blood pressure or diastolic blood pressure $\geq$ 90th percentile for sex, age, and height; and (Lakshman et al. 2012) WC $\geq$ 90th percentile for age and sex (Hosseinpour-Niazi et al. 2019; Kelishadi et al. 2007).

MetS severity in childhood has been associated with type-2 diabetes and cardiovascular disease (CVD) in adulthood; therefore, it is necessary to implement, during childhood, interventions for a healthy lifestyle (Lakshman et al. 2012; Eckel et al. 2005).

Metabolic profile analysis, also known as metabolic phenotyping, can be useful to characterize metabolic patterns of cells, tissues, organisms, and biological fluids. It allows the identification of specific features (or biomarkers) of obesity and MetS, in order to assess and track metabolic risk. A good understanding of the biochemical mechanisms underlying obesity and NAFLD is required, to develop suitable screening strategies (Spruijt-Metz 2011; Troisi et al. 2017; Bervoets et al. 2018).

Metabolic Features of Pediatric Obesity and MetS

Significantly different metabolome signatures were identified in normal-weight and obese adolescents' biofluids. Using combined untargeted and targeted metabolomics, it has been demonstrated that inflammation-driven insulin resistance, ammonia toxicity, and oxidative stress could represent crucial metabolomic signatures in obese adolescents (Troisi et al. 2019; Cho et al. 2017a).

A complex metabolic fingerprint characterizes obesity, especially visceral obesity and obesity-related NAFLD (Troisi et al. 2017). Pathogenesis of MetS possibly depends on the interaction

between obesity, insulin resistance, and inflammation (Wittcopp and Conroy 2016).

Accumulation of free fatty acids (FFA) in the liver of pediatric obese subjects is responsible for impaired insulin signaling and consequently insulin resistance, reducing its effect on suppression of glucose production (D'Adamo et al. 2009). The consequence is hyperinsulinemia that induces the liver to produce fat, therefore causing hypertriglyceridemia. In addition adipocytes, because of insulin resistance, induce an increase in lipolysis, raising non-esterified fatty acids (NEFA) levels in blood (Das et al. 2014).

Differences in metabolites observed in obese children with and without NAFLD (Miccheli et al. 2015), could also be related to the microbiota and the gut–liver axis (GLA).

Different metabolites and their pathways derived from mammalian and gut microbial co-metabolism have been associated with phenotypes of MetS, including diabetes, hypertension, and obesity (Dumas et al. 2014). It is widely believed that gut microbiota plays an important role in obesity, MetS, and fatty liver by increasing energy harvesting, when a condition of intestinal dysbiosis, and more rarely when some instances of small intestinal bacterial overgrowth (SIBO) occur (Rutigliano et al. 2017; Tresaco et al. 2005). Changes in the abundance or composition of bacterial species of the gastrointestinal tract are reported in obesity and other metabolic conditions (Vajro et al. 2013a). A damaged intestinal barrier due to local or systemic inflammation could establish a condition known as "leaky gut," in which the GLA can amplify the common interactions between intestinal bacteria/bacterial products and hepatic receptors (Nejatinamini et al. 2015), promoting the portal flow of a large number of metabolites (Goodson et al. 2014).

Gut microbiota deeply changes among individuals, and its composition varies with different conditions. In particular, obesity is associated with significant variations in the structure of intestinal microbiota (Fig. 19.2), in experimental circumstances changing the ratio between the major bacterial phyla Bacteroides and Firmicutes (Turnbaugh et al. 2006). Moreover, the gene richness of the intestinal microbiome and MetS are correlated (Le Chatelier et al. 2013) and can be modulated by diet, reinforcing the role of intestinal ecology quality.

A class of metabolites, known as methylamines, are produced by gut microbiota via bacterial degradation of choline into trimethylamine (TMA), later metabolized into trimethylamine-N-oxide (TMAO) by flavin-containing monooxygenase 3 (FMO3) and other isoforms. This class of metabolites includes TMA, TMAO, and dimethylamine (DMA), identified as markers of NAFLD in murine models (Dumas et al. 2006; Cobbold et al. 2009). In addition, elevated values of homeostatic model assessment-insulin resistance (HOMA-IR) (Tresaco et al. 2005) and of serum uric acid (UA) (Nejatinamini et al. 2015) are associated with MetS and/or hepatic steatosis.

Elevated urinary/blood levels of aromatic amino acids (AAAs) and branched-chain amino acids (BCAAs) occurred in samples from obese patients, and appear to be correlated with IR and the risk of developing obesity-related MetS (Miccheli et al. 2015; Wiklund et al. 2014; Wurtz et al. 2012; Newgard et al. 2009).

Also pertinent to NAFLD, gamma-glutamyl dipeptides indicate increased glutathione (GSH) synthesis as part of an oxidative stress response (Soga et al. 2011).

Lipid metabolism, tyrosine (Jin et al. 2016), alanine, and the urea cycle (Martos-Moreno et al. 2014), acylcarnitine catabolism with and without changes in nucleotides, lysolipids, and inflammation markers are also reported in obesity and related disorders (Butte et al. 2015).

MetS and obesity share a pro-inflammatory state (Wisse 2004; Dandona et al. 2005). Insulin features anti-inflammatory properties, and insulin resistance could contribute to elevated mediators such as TNF-alpha, C-reactive protein, and IL-6 in MetS (Wahba and Mak 2007).

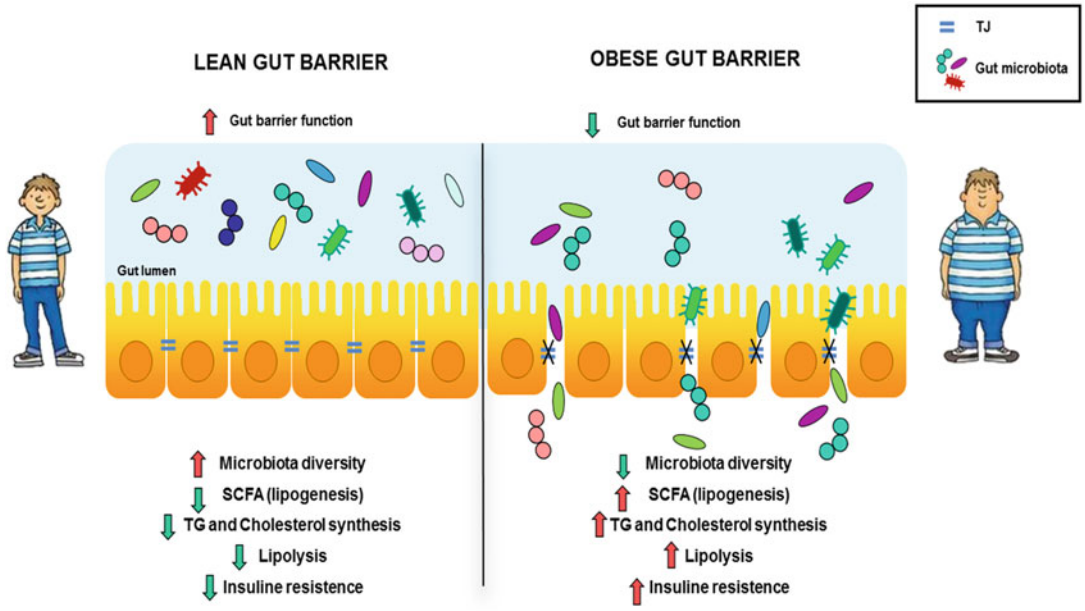

Fig. 19.2 Pictured are the differences in the gut barrier of lean and obese individuals

Urine and Salivary Pathways and Biomolecules

Saliva Production

Saliva is an exocrine solution in which water represents almost 99%, while the remaining 1% consists of a variety of electrolytes and proteins (de Almeida et al. 2008). It is also made up of a complex mixture of secretory products (organic and inorganic molecules) that originated from the salivary glands. Saliva compounds come from the oropharynx, upper airways, gastrointestinal reflux, gingival sulcus fluid, food deposits, and blood-derived compounds (Dodds et al. 2005). The inorganic part includes weak and strong ions (Na^+, K^+, Cl^-, Ca^{2+}, HCO^3, Mg^{2+}, and NH_3); the organic part contains components such as body secretion molecules (urea, uric acid, and creatinine), lipids like cholesterol and fatty acids and more than 400 types of protein. The most important proteins have a glandular origin (alpha-amylase, lysozyme, mucins, and proline-rich proteins) or are plasma-derived (albumin, secretory immunoglobulin A, and transferrin) (Hofman 2001).

Saliva is a mirror of the normal internal characteristics and disease state of an individual (Pfaffe et al. 2011; Nunes et al. 2015; Desai and Mathews 2014; Garrett et al. 1998; Chiappin et al. 2007) and can be defined as a natural filtrate of blood containing potentially diagnostic and prognostic "omic" features such as small molecules, metals, proteins, and DNA.

It can be conveniently and noninvasively collected, it is easy to store, and its collection, compared to that of other biological fluids, such as blood, are not expensive.

Urine Production

Urine production involves two processes: renal–glomerular filtration and tubular reabsorption, commanded by systemic hydration, and electrolyte balance. The glomerulus represents the site of formation of the primary urine while the tubule is involved in the transformation of pre-urine in urine (Ogobuiro and Tuma 2019).

Salivary and Urinary Metabolome

Salivary Metabolome

Pediatric obesity, its related liver disease, and MetS seem to have different salivary metabolomic signatures. The differences can be primarily found in metabolites involved in energy, amino acids, and organic acids metabolism, along with intestinal bacteria metabolism, all of which could be influenced by diet, microbiota, and intestinal mucins (Troisi et al. 2019).

Salivary metabolic distinguish children with reduced numbers of MetS criteria, from those with many indexes, who are at higher risk of hepato-metabolic complications (Troisi et al. 2019).

A partial least squares discriminant analysis (PLS-DA) model can be devised to classify the patient classes based on their salivary metabolomic signature, paving the bases for their use for both early disease diagnosis and monitoring in those with MetS (Troisi et al. 2019). Moreover, it is shown that salivary testing of uric acid (UA), glucose, insulin, and HOMA together with selected anthropometric parameters, may help to noninvasively screen obese children with hepatic steatosis and/or having MetS components (Troisi et al. 2018). Similarly to adults (Goodson et al. 2014; Mussavira et al. 2015; Fekete et al. 1993) and adolescents (Hartman et al. 2016), glucose and insulin are higher in the saliva of obese subjects with or without MetS than in healthy controls. Insulin resistance (IR) is associated with the components of MetS among obese children and adolescents (Nejatinamini et al. 2015; Cho et al. 2017b), and seems superior to glucose for MetS characterization (Costa et al. 2012).

In addition, data of salivary HOMA index (calculated by substituting the glucose and insulin serum values with the corresponding salivary values), indicated that values for obese subjects were higher than those for controls, and the trend is amplified when obesity was complicated by a fatty liver rather than by the number of MetS components.

Even though salivary UA levels were higher in obese patients, no differences were observed with or without a fatty liver. A close relationship seems to exist between UA levels and MetS; in fact, despite hyperuricemia not representing one of the components of MetS, it is demonstrated that UA levels tend to increase in parallel with the number of MetS components. Saliva of obese children had higher levels of palmitic acid, myristic acid, urea, N-acetyl galactosamine, maltose, gluconic acid and isoleucine, and lower levels of hydroxybutyric acid and malic acid, which appear prevalent in patients without steatosis. On the other hand, lauric acid, maltose, and methyl maleic acid were featured by those with steatosis (Troisi et al. 2019).

The levels of valine, mannose, acetopyruvic acid, palmitic acid, triethylene glycol, gluconic acid, citric acid, scyllo-inositol, deoxyglucose, psicopyranose, myoinositol, and cycloserine were higher in obese patients. On the contrary, normal-weight patients showed higher levels of 1,2,3-butanetriol, 2-oxovaleric acid, 2-palmitoylglycerol, di-n-octyl phthalate, itaconic acid, methyl galactoside, stearic acid, 2-piperidinone, maltose, 2-deoxy-D-ribose, pentane dioic acid, glycerol, pentitol, glyceric acid, methyl maleic acid, 2-deoxypentofuranose, β-hydroxy pyruvic acid, 2-hydroxy-methylcyclopentanol, and L-serine. In obese patients with steatosis elevated D-glucuronic acid γ-lactone, 2-deoxy-ribolactone, 2-hydroxyisocaproic acid, pyroglutamic acid, and propanoic acid occurred. In the absence of steatosis butanoic acid, maltose, thiamine, glucopyranose, 2-hydroxybutyric acid, and mannose predominated (Troisi et al. 2018).

The network of salivary molecules that are differently produced in lean and obese patients, with or without MetS/NAFLD comorbidities, was also characterized by higher levels of palmitic acid and myristic acid, which are two saturated fatty acids, generally elevated in patients with steatosis (Troisi et al. 2019). Myristic acid seems to be associated with obesity but not with MetS (Takato et al. 2017).

An increase in activity of C16 Δ9-desaturase and C18 Δ9-desaturase with a decreased Δ5-desaturase activity can be responsible for altered fatty acid metabolism (Kang et al. 2017).

The correlation among lipid profile, glucose, and insulin levels suggests a conserved ability in adapting to a caloric challenge, compared with metabolically unhealthy subjects (Badoud et al. 2015; Aristizabal et al. 2016). Important advances notwithstanding, the predictive performance of these salivary markers remains unsatisfactory (Troisi et al. 2018).

In conclusion, different salivary metabolites and metabolic pathways are involved in a complex metabolic fingerprint of obesity, obesity-related NAFLD, and obesity-related MetS (Magge et al. 2017). Table 19.1 reports a summary of the principal papers about metabolomics application in pediatric obesity.

Urinary Metabolome

Urinary metabolome analysis similarly detects typical obesity-related dietary behavior as well as GLA alteration (Troisi et al. 2017). Intestinal permeability, small intestine bacterial overgrowth (SIBO), and diet preferences can be relevant in this context.

Lower urinary xylitol and phenylacetic acid (PAA) was noticed in the obese population.

Xylitol is not endogenously produced by humans, but it can be found in several types of fruits and vegetables. Its intake can be considered important in preventing the development of obesity and MetS. Amo et al. (2011) demonstrated that long-term intake of xylitol is able to suppress the accumulation of visceral fat, and contextually increase insulin and lipids levels in the plasma of rats fed a high-fat diet.

Xylitol is more elevated in normal-weight patients, supporting the idea that it could protect against obesity-related liver damage (Troisi et al. 2017).

Also, PPA was lower in obese children (Troisi et al. 2017). PPA is synthesized from the amino acid phenylalanine (PA) via phenylpyruvate; phenolic acids are generally associated with beneficial effects for human health (Pandey and Rizvi 2009), whereas low urinary levels of PPA can be related to an unhealthy diet due to a low intake of plant fibers.

Furthermore, Troisi et al. (2017) reported higher urinary glucose levels in obese children than in the normal-weight controls. This evidence is in accordance with findings in both obese children (Urakami et al. 2007) and adults (Elliott et al. 2015).

Methyl histidine concentration in urine was elevated, especially in patients with NAFLD, contrasting with low levels of xylitol (Troisi et al. 2017). Moreover, this metabolite has previously been associated with BMI in obese individuals (Elliott et al. 2015). The same association was found with 4-cresyl sulfate (PCS) that can be considered directly linked to gut microbial activity (Elliott et al. 2015). Consistently, urinary PCS was elevated in obese children without NAFLD and showed a negative correlation with the presence of SIBO.

There is an inverse relationship between BMI and urinary 3-hydroxymandelate, a metabolite of the alpha-adrenergic agonist p-synephrine (Stohs et al. 2011) that is strictly related to tyrosine metabolism.

Indeed, pseudouridine (PSI) level in urine was higher in obese individuals, especially in those with steatosis. It represents a measure of protein turnover, a metabolic process that may be targeted by oxidative DNA stress that is common in pediatric obesity, obesity-related NAFLD, and in other conditions of high dietary energy intake (Topp et al. 2008).

GLA dysfunction, which plays a role in obesity and obesity-related hepatic complications, is responsible for typical signals of metabolome signature, especially in obese children with NAFLD (Troisi et al. 2017). In particular, increased intestinal permeability (IP), gut microbiota dysbiosis, and SIBO have been extensively associated with severity of obesity-related liver damage (Guercio Nuzio et al. 2017; Boursier et al. 2016).

Table 19.1 Principal studies regarding the metabolomics application in pediatric obesity

Author	Population	Sample	Platform	Statistical analysis	Outcome
Topp et al. (2008)	44 normal-weight children (3–18 years old)	Urine	HPLC (targeted approach)	Wilcoxon Mann Whitney	Close relationships between whole-body RNA and protein degradation and metabolic rate. The relationship between 8-oxodG excretion and metabolic rate, however, is less strong suggesting that factors other than metabolic rate considerably affect the oxidative stress to DNA.
Pastore et al. (2014)	63 NAFLD patients	Plasma	HPLC (targeted approach)	Kolmogorov-Smirnov tests	Data demonstrated a defective hepatic sulfur metabolism in children with NAFLD, and that high levels of Hcy and Cys probably correlate with a pattern of more severe histological liver damage, due to mechanisms that require further studies.
Butte et al. (2015)	353 normal weight (NW) Hispanic children and 450 obese children	Plasma	GC-MS (untargeted approach)	PCA and ANOVA	Global metabolomic profiling in nonobese and obese children showed increased BCAA and acylcarnitine catabolism and changes in nucleotides, lysolipids, and inflammation markers. Strong signature of reduced fatty acid catabolism and increased steroid derivatives.
Jin et al. (2016)	39 Hispanic-American, obese adolescents aged 11–17 years (30 had hepatic steatosis $\geq$ 5% and 9 were matched controls with hepatic steatosis $<$ 5%)	Plasma	UPLC-Q/Orbitrap (untargeted approach)	Manhattan plots and t-test	Metabolic pathways of several amino acids are significantly disturbed in adolescents with elevated hepatic steatosis. This is a novel finding and suggests that these pathways may be integral in the mechanisms of NAFLD.
Cho et al. (2017a, b)	91 nonobese and 93 obese adolescent subjects	Urine	UPLC-Q/ToF (untargeted approach) DI-Q/ToF (targeted approach)	PCA, Wilcoxon signed ranks test, Pearson correlation, and linear regression	Increase of inflammation-related metabolites is a crucial metabolomic signature of obesity compared with normal weight in adolescents. These metabolites may be useful for predicting cardiovascular risk. Furthermore, the metabolomic differences observed in this study suggested that adolescent obesity induces impending insulin resistance, ammonia toxicity, and oxidative stress.

(continued)

Table 19.1 (continued)

Author	Population	Sample	Platform	Statistical analysis	Outcome
Gawlik et al. (2016)	87 obese children with and without insulin resistance (IR)	Urine	GC-MS (targeted approach)	K-means clustering and ANOVA	The steroidal metabolomic signature of IR in obese children is characterized by enhanced secretion of steroids from all three adrenal pathways.
Bervoets et al. (2018)	65 obese and 37 normal-weight children	Plasma	NMR spectroscopy (untargeted approach)	PLSDA	Increased levels of lipids, N-acetyl glycoproteins, and lactate. • Decreased levels of several amino acids, α-ketoglutarate, glucose, citrate, and chlorinated phospholipids as compared with normal-weight children.
Troisi et al. (2017)	22 obese children and 14 NW	Urine	GC-MS (untargeted approach)	PLSDA	Obese children had: • Higher levels of glucose/1-methylhistidine • Lower levels of xylitol, phenyl acetic acid, and hydroquinone The metabolic pathways of BCAA and/or their metabolites correlated with an excess of visceral fat centimeters.
Goffredo et al. (2017)	78 obese adolescents with and without insulin resistance (IR)	Plasma	LC-Q/Trap (targeted approach)	Random Forest analysis	Dysregulation of BCAA metabolism characterizes obese adolescents with NAFLD independently of obesity and insulin resistance.
Leal-Witt et al. (2018)	35 prepubertal children with obesity enrolled 6-month-long lifestyle intervention program	Plasma	UPLC-Q/ToF (untargeted approach)	PCA	A sphingolipid metabolism-related signature was identified as the major contributor.
Troisi et al. (2019)	23 obese and 18 NW children	Saliva	GC-MS (untargeted approach)	PLSDA	Differences in metabolites involved in energy, amino and organic acid metabolism.

Small Intestinal Bacterial Overgrowth

A direct relationship was also observed between BMI and urinary excretion of leucine, valine, and isoleucine; branched-chain amino acids (BCAAs) and/or their metabolites showed a correlation with visceral fat, increased IP and SIBO (Troisi et al. 2017). SIBO-positive children had elevated levels of glycolic acid and mannose while in controls valine, PCS, butyrate, and adipic acid were more abundant (Troisi et al. 2017). In addition, urinary cysteine levels were found to be elevated, in accordance with the data obtained from plasma of obese children (Pastore et al. 2014) and adults (Kalhan et al. 2011) with NAFLD.

Finally, the increase in the concentration of both N-methyl nicotinate and hydroquinone (HQ) in urine appears to be protective against hepatic steatosis, probably due to their cytoprotective role (Jin et al. 2016; Dinkova-Kostova and Wang 2011). Glucose and xylitol metabolism, tyrosine metabolism, nicotinate and nicotinamide (vitamin B3) metabolism, and the pentose-6-phosphate pathway are among the most prominent in pediatric obesity (Troisi et al. 2017).

Potential Targets for New Drug Development

It is suggested that nutritional behaviors characterized by elevated fruit and vegetable intake and high monounsaturated fats intake are inversely associated with MetS, and they could improve this condition, especially regarding blood lipids, IR, and liver performance (Kushner 2014; Patti et al. 2015; Pitsavos et al. 2007; Esposito et al. 2007; Camacho and Camacho 2017).

Phytotherapeutic Agents

In many disease models polyphenols exert beneficial effects (Tenore et al. 2014). Annurca apple flesh polyphenols have shown significant hypolipidemic potential due to their ability to reducing cholesterol and low-density lipoproteins (LDL), and increasing apolipoprotein A1 (ApoA1) expression, the major protein component of high-density lipoproteins (HDL) in plasma (Tenore et al. 2014).

The molecules of polyphenolic extract that exert a hypolipidemic effect are procyanidrins. In vitro and in vivo experiments have provided evidence of their potential role in reducing postprandial hypertriglyceridemia by pancreatic lipase inhibition (Tenore et al. 2014). This mechanism induces the suppression of triglyceride absorption (Tenore et al. 2011).

Chlorogenic acid is a phenolic compound from the hydroxycinnamic acid family (an apple-derived polyphenol) that seems to protect against liver injury (Santana-Gálvez et al. 2017). It has been observed to have an impact on many transcription factors and enzymes which are involved in lipid metabolism, being associated with positive effects on obesity and dyslipidemia (Santana-Gálvez et al. 2017). It significantly reduced body weight, visceral fat mass, plasma leptin, and insulin levels, triglycerides in liver and cholesterol in adipose tissue (Cho et al. 2010). In addition, chlorogenic acid appears to be involved in the prevention of weight gain and in liver lipid accumulation reduction, delaying liver steatosis onset and blocking high-fat diet-induced IR (Ma et al. 2015) (Fig. 19.3).

Patti et al. (2015) evaluated the effect of a mixed supplement that contains chlorogenic acid, *Curcuma longa*, silymarin, guggul, and inulin on MetS in humans, reporting significant reductions in body weight, body mass index, waist circumference, fasting glucose, and total cholesterol. Within the same context, Annurca flesh polyphenols could play a beneficial role in MetS prevention and treatment (Tenore et al. 2014).

Gut Microbiota Interventions

Another possible strategy could be based on the administration of probiotics or prebiotics, or fecal transplantation (Saint-Georges-Chaumet and Edeas 2015). Probiotics and related dietary supplements which are employed to enhance and fortify gut microbiota do not have a simple nutritive value (Ewaschuk and Dieleman 2006). Indeed, they are able to change the resident gut microbiota composition and the gut lumen, favoring an anti-inflammatory environment, and improving gut barrier integrity. Similarly, the concept of "prebiotics" is referred to some fermentable carbohydrates that, through their metabolism by gut microorganisms, selectively modulate the composition and/or activity of the gut microbiota (Bluemel et al. 2016; Vajro et al. 2013b).

Ongoing Studies

Urine and saliva have a high diagnostic potential in obesity and MetS, especially in pediatric population, and could make blood sampling unnecessary in a number of circumstances (Troisi et al. 2017, 2018; Belmonte et al. 2017; Pierri et al. 2018). On this basis, an interesting clinical study has been proposed by the University of Salerno: "N.a.p.o.l.i. Study" (Non-invasive Approach for Pediatric Obesity Liver and metabolic Involvement) that aims to achieve a solution for obesity

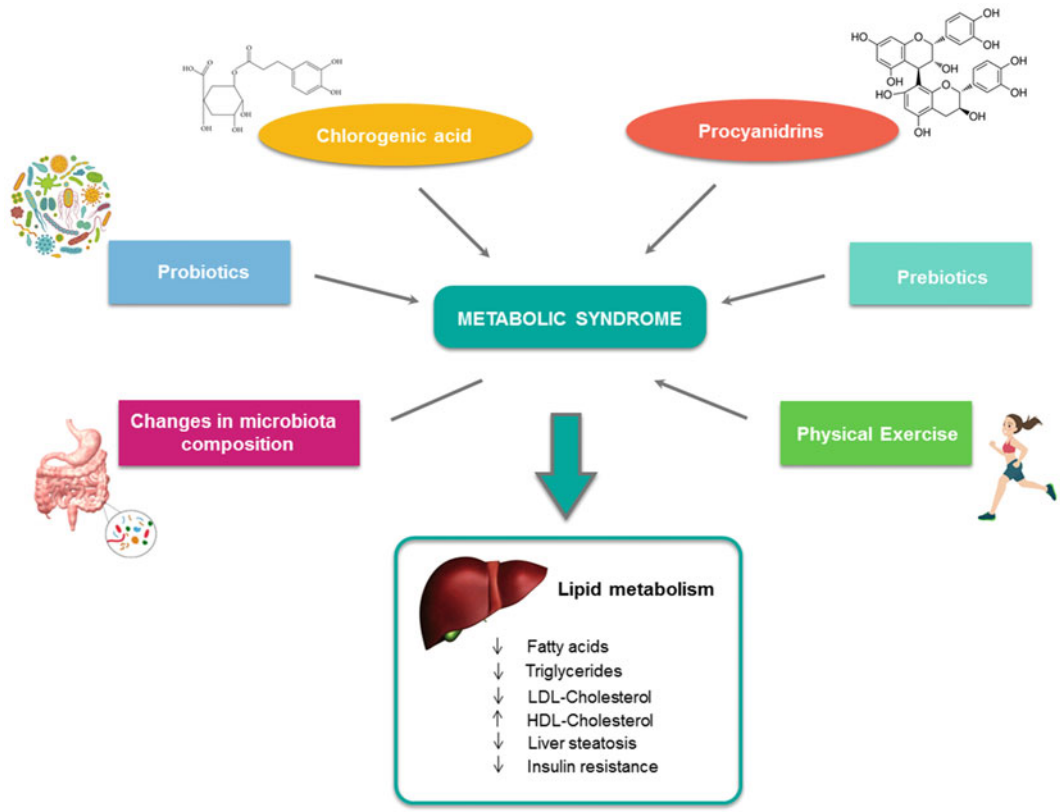

Fig. 19.3 Factors influencing the development of metabolic syndrome and the implications of metabolic syndrome on lipid metabolism

management and monitoring in a pediatric population (Napoli Study 2019). The goal is to develop an integrated system that is able to minimize obesity incidence during the pediatric age, and specifically to monitor comorbidities related to obesity and overweight (hepatic steatosis and MetS). The objectives are (1) Designing and validating a noninvasive system able to identify basal metabolic conditions in pediatric subjects, and to characterize a metabolic profile that is generally related to hepatometabolic conditions; (2) Designing and prototyping a decision support system able to manage the enrollment, the profiling, and the personalization of a diet-therapeutic plan, based on annurca apple supplementation in pediatric subjects.

The study expects to enroll 1000 pediatric patients (500 overweight or obese and 500 normal weight) from different countries in Europe. The inclusion criteria are age between 5 and 16 years; normal weight (BMI percentile between 5th and 85th), overweight (BMI $>$ 85th) or obesity (BMI $>$ 95th) conditions; adherence to the study and signature of informed consent. The exclusion criteria are history of chronic or acute not obesity-related diseases, and/or pathologies that do not allow saliva collection.

Other ongoing studies include Science and Technology in childhood Obesity Policy (STOP) (2019) the EPHORT Childhood Obesity Project (2016), and Childhood Obesity Research Demonstration (CORD) 3.0. (2019) STOP is working to identify policy changes that will address childhood obesity across Europe, until May 2022. It will assess from before birth through childhood, the key components of becoming obese, while putting emphasis on vulnerable and socially disadvantaged children. The goal is to have effective and sustainable solutions for childhood obesity to be implemented in the EU.

The EPHORT Childhood Obesity Project is taking place from 2014 to 2020. Eight areas of action have been identified: (1) Support a healthy start in life, (2) Promote healthier environments, especially in schools and pre-schools, (3) Make the healthy option the easier option, (4) Restrict marketing and advertising to children, (5) Inform and empower families, (6) Encourage physical activity, (7) Monitor and evaluate, and (8) Increase research. The first task for this project was to identify the prevalence of obesity per country in the EU. Then referring to the Areas of Actions, policies, and activities were made. After this, each country was evaluated to see if the actions had been taken, and the prevalence of obesity was measured. Task three included an overview of the engagement of the relevant states, the Commission, and the international organizations. Once this was complete the team is proceeding to assess the Action Plan and make recommendations for the second half-period.

CORD 3.0 will be funded by Massachusetts General Hospital, The Miriam Hospital, Stanford University, University of Nebraska, and Washington University in St. Louis from 2019 to 2024. The goal of the project is for these five research teams to focus on adapting, testing, and packaging effective programs to reduce childhood obesity among children in lower-income families.

'State-of-the-Art' Metabolomics Investigations of Type 2 Diabetes

20

Benita Percival, Justine Leenders, and Martin Grootveld

Contents

Abstract

Metabolomics represents the global investigation of complex biomolecular patterns in living systems, i.e. in organs, cells, tissues or biofluids, and the understanding of how clinically significant deviations from such patterns may facilitate our knowledge of the pathogenesis of human diseases. This now widely expanded research area has been extensively applied to the prognostic monitoring of type 2 diabetes (T2D), particularly in human biofluids. The achievements of T2D metabolomics investigations include the identification of key biomarkers in human biofluid samples, which may also be employed for determining individuals at risk of this condition. T2D biomarkers arise from disturbed

metabolic pathways, which include those distinct from glycolysis and lipid metabolism. Additionally, prognostic fingerprints and biomarkers of insulin resistance have been explored using metabolomics analysis, and these strategies have been critically evaluated for their possible future 'point-of-care' uses in clinical settings. The potential advancement for such 'bedside' metabolomics tests and the future direction of metabolomics in T2D is discussed in detail.

Keywords

Diabetes biomarkers · Plasma metabolome · Saliva metabolome · Urine metabolome · Diabetes metabolic pathways · Diabetes prognostic fingerprints · Bedside metabolome

The Role of Metabolomics

Although the metabolome was first explored centuries ago, through organoleptic tasting analysis and smell of urine as a means of diagnosing diseases, applications of bioanalytical techniques to simultaneously analyse more than one class of biomolecules in urine were first performed by Pauling et al. (1971), and the human metabolome was first described by Oliver et al. (1998). Over the last 20 years, the metabolome itself and means for the utilisation of multianalyte bioanalytical techniques that can be applied to it, have been further defined by others such as Nicholson and Lindon (2008), and many developments have been explored in the literature, with a progressive history of techniques employed for these studies, along with their establishment as key investigatory tools (documented by Kell and Oliver (2016)).

The Normal and Pathological Metabolome

The study of the metabolome allows for the monitoring of metabolic processes within a system by assessment of low-molecular-mass metabolites within biofluids, tissues, cells or other biosamples. Indeed, the metabolome can be affected by many biological processes. These can either be through external stimuli such as medical intervention, i.e. medication, diet or an exercise regimen, or through internal stimuli. An internal stimulus can be introduced by the modification of gene expression using techniques such as cell transfection, both *in vivo* and *in vitro*. Moreover, metabolomics techniques assess these changes by providing a 'snapshot' of the status of biological processes occurring at a specific point in time. This responsive information can provide a high level of detail regarding cellular metabolic processes, may facilitate phenotypic evaluations, and therefore yields an overall 'picture' or 'fingerprint' of a disease's chemopathological status.

Even more valuably, metabolomics is able to probe changing disease status, e.g. the effects of metformin therapy or the regression of inflammatory conditions, in type 2 diabetes (T2D), as can the influence of dietary or physical exercise interventions. Hence, these strategies may be successfully employed to monitor disease severity and progression, information which further increases our understanding of the aetiology, manifestation and progression of particular conditions (German et al. 2005). A combination of metabolomic strategies has been previously applied to pre-diabetes (Zeng et al. 2017), type 1 diabetes (Haukka et al. (2018)), T2D and gestational diabetes (Bentley-Lewis et al. 2015).

Targeted vs. Untargeted Approach

Leading metabolomics techniques are largely untargeted ones and aim to simultaneously detect all possible metabolites present in biological samples. This multicomponent quantitative bioanalytical approach differs from targeted metabolomics investigations, which focus on the analysis of only limited numbers or classes of metabolites that are linked via specific biochemical pathways. Typical techniques include nuclear magnetic resonance (NMR) and liquid chromatography-mass spectrometric (LC-MS)

analyses, which are readily applicable to a wide range of biosamples (Zhang et al. 2012). Briefly, high-resolution NMR analysis is able to detect and quantify metabolites in a high-throughput, simultaneous, non-destructive manner requiring minimal sample preparation. LC-MS strategies, however, can target specific metabolites more sensitively than NMR, whilst lacking the specificity of the latter for absolute metabolite determinations (Sandlers 2017). Therefore, a combination of both LC-MS and NMR methodologies is important for a global understanding of metabolic effects involved in disease processes, and can be essential for thorough determinations of the metabolic status of biofluids and tissue biopsies. Alternative analytical techniques include Fourier transform infrared (FTIR) and Raman spectroscopies (Lindon et al. 2011).

Biomarkers of Type 2 Diabetes

One of the first diagnoses of diabetes was performed in fifth/sixth century BC using a urine sample, and this arose from a physician, Sushruta, acknowledging frequent urination in subjects with this condition, and ants being attracted to the urine (Sharma and Chandola 2011). This knowledge is still applied today in rural areas in different parts of the world, for example in Vietnam (Mull, Nguyen and Mull 2001). Diabetes mellitus became the designated terminology for these patients, which is Latin for abundant flux (of urine) and 'honeyed' or 'sweet,' respectively.

Currently, common biomarkers that are detected in clinical settings include glucose and ketone bodies in urine and plasma, as well as glycosylated haemoglobin A1c (HbA1c) in whole blood. HbA1c reflects the success of therapeutic control by T2D patients self-administering injectable insulin or oral hypoglycaemic agents such as metformin, throughout a 6–8 week period.

However, there are many more markers that can provide further information regarding the status of T2D, e.g. ketone bodies and branched-chain amino acids (BCAAs). These alternative biomarkers can provide valuable information regarding the early detection of T2D, i.e. prior to its full onset, a development which can give rise to improved outcomes for patients.

To date, a combination of biofluids and tissues has been investigated in animals and humans, including blood serum (Drogan et al. 2015; Floegel et al. 2013), blood plasma, urine and saliva. Table 20.1 provides insight into biomarkers that have been suggested to be clinically significant, regarding T2D diagnosis in serum or plasma, urine and saliva.

Serum and Plasma Biomarkers

One of the largest metabolomics studies exploring diabetes was performed with samples collected during the European Prospective Investigation into Cancer and Nutrition (EPIC) (Floegel et al. 2013; Drogan et al. 2015). Floegel et al. (2013) used flow injection analysis mass spectrometry/mass spectrometry (FIA-MS/MS) to determine serum metabolites from control (n = 1482) and T2D (n = 800) participants. The global metabolome of this cohort was monitored over a mean 7-year period to observe the increased or decreased risk of T2D form the status of biomolecular analytes. Upregulations in hexose, phenylalanine and diacyl-phosphatidylcholines (C32:1, C36:1, C38:3 and C40:5), along with downregulations in glycine, sphingomyelin (C16:1), acyl-alkyl-phosphatidylcholines (C34:3, C40:6, C42:5, C44:4 and C44:5) and lysophosphatidylcholine (C18:2) were observed in T2D patients. Drogan et al. (2015) observed 300 individuals who provided serum samples at the beginning of a trial, and also after a median of 6 years, in an untargeted LC-MS investigation. Significant metabolite markers included lysophosphatidylcholine (demethyl 16:0) and phosphatidylcholine (oleoyl-20:0/oleoyl-20:0), which were all downregulated in T2D. As expected, hexose sugars such as glucose were elevated in T2D plasma. In another protocol, glyoxylate was observed to be upregulated

Abbreviations: NMR, Nuclear Magnetic Resonance; MS, Mass Spectrometry

using GC-MS, and recommended it as early marker for T2D (Nikiforova et al. 2014).

Amino Acids and Phospholipids

^{1}H NMR analysis has also been applied to serum metabolites in T2D patients (n = 26) and controls (n = 7) (Coco et al. 2019). Serum alanine, glutamine, glutamate, leucine, lysine, methionine, tyrosine and phenylalanine were all downregulated in T2D participants (Coco et al. 2019). Interestingly, these biomarker findings contrast with those established by other researchers (Table 20.1).

Similar findings to Drogan et al. (2015) were observed in a LC-MS and GC-MS metabolomics investigation, and significantly elevated fructose, α-hydroxybutyrate, alanine, proline, phenylalanine, glutamine, leucine, isoleucine, valine, mysterate, palmitate and stearate levels were observed, together with diminished pyroglutamate, glycerophospholipids and sphingomyelins, in the serum of groups of

patients with either impaired fasting glucose levels or T2D (Xu et al. 2013).

Menni et al. (2013) observed 447 metabolites from fasted plasma samples from females with T2D (n = 115), individuals with impaired fasting glucose (n = 192) and controls (n = 1897) using ultraperformance liquid chromatography–mass spectrometry (UPLC-MS). Of 447 metabolites analysed, 42 were observed to be significantly different on comparison of these two groups (Menni et al. 2013), as noted in Table 20.1.

Prognostic Metabolites

Aloha-Ollie et al. (2019) quantified over 229 metabolites, including amino acids, fatty acids, glycolysis-related metabolites and lipoproteins using ^{1}H NMR analysis in 11,896 individuals, including T2D (n = 293) and controls (n = 11,603) from four Finnish cohorts. The biomarkers that were identified as the strongest indication for this condition included elevated aromatic amino acids, vLDL particles and triacylglycerols (TAGs). Biomarkers shown to be significant for individuals at risk of T2D included elevated glycerol and mono-unsaturated fatty acids and 'acute-phase' glycoproteins. Proposed biomarkers associated with a lower risk of developing T2D included glutamine, linoleate and HDL-triacylglycerols.

Liu et al. (2017) used a combination of liquid chromatography-mass spectrometry (LC-MS), and NMR combined with a least absolute shrinkage and selection operator regression approach, to identify biomarkers that were present in T2D blood samples (n = 349), compared to age-matched controls (n = 3998). In the 14 year follow-up study, similar findings to those of Aloha-Ollie et al. (2019) were found. There were clear disturbances in amino acid metabolism, including pathways featuring isoleucine and tyrosine. Further metabolic differences included those in triacylglycerols (TAGs), lactate, glycerol, pyruvate and vLDL-TAGs.

Some of the markers for insulin resistance include glucose, mannose, α-hydroxybutyrate (α-HB) and α-tocopherol, in addition to selected amino acids and 1-linoleoyl glycerophosphocholine (Peddinti et al. 2017). Elevated α-hydroxybutyrate (HB) is also a marker of glucose intolerance (Peddinti et al. 2017). Branched-chain amino acids (BCAAs) are particularly important since they have been demonstrated to predict T2D 12 years prior to its onset (Wang et al. 2011).

Saliva

Saliva is often proposed as an ideal biofluid for non-invasive analysis of diseases in view of its easy sample collection and its ability to reflect the contents of blood (Yousri et al. 2015; Barnes et al. 2014). Glucose is one of the metabolites that is elevated in the saliva of T2D patients (Gupta et al. 2014; Kadashetti et al. 2015). To determine salivary metabolites, Gupta et al. (2014) collected postprandial, unstimulated whole saliva. Participants were requested to rinse with water thoroughly and not to swallow for a period of 5 min before spitting into a sterile container. Kadashetti et al. (2015) collected fasting salivary samples, also requesting participants to wash their mouths with water. Yousri et al. (2015) collected salivary samples ~2 hr. post-prandially, and critically evaluated the limitations of non-fasted samples in their investigation.

Acetone and Lactate

Acetone has been determined as significantly increased in patients with diabetes in ketoacidosis (Fuji et al. 2014). Other metabolic changes that have been observed include the ratio of D- to L-lactate levels in dried salivary spots from controls (n = 68), pre-diabetic (n = 30) and T2D (n = 5) patients, in which T2D participants had a significantly higher ratio (Numako et al. 2016). The levels of D- and L-lactate were targeted in view of an upregulation of its methylglyoxal precursor, which arises from diabetic complications (Numako et al. 2016). The D- to L-lactate ratio showed good agreement with Hba1c values of blood in patients with diabetes;

however, the correlation of Hba1c values with D- to L-lactate ratio was poor in pre-diabetic samples (Numako et al. 2016). As in the study by Yousri et al. (2015), salivary samples were collected ~2 h. post-prandially (Numako et al. 2016).

Other Biomolecules

Additional disturbances have been observed in glycated proteins, electrolytes, albumin and enzymes (e.g. amylase (Abd-Elraheem et al. 2017), lysozyme and peroxidase) (Negrato and Tarzia 2010), however, and not using NMR and MS metabolomics-based approaches described here. Using an MS strategy, Yousri et al. (2015) found three significant metabolites in diabetic saliva including downregulations in pyroglutamine and 1,5-anhydroglucitol (1,5-AG). Some disturbances in unidentified metabolites in saliva were also documented as part of this investigation (Yousri et al. 2015). Significant salivary metabolites might present as a viable option for point-of-care sampling in a clinical setting.

Oral Diseases and Other Confounding Factors

Dental hygiene status can, of course, markedly influence salivary results, and periodontal diseases show some significant differences in salivary profiles when compared to healthy controls (Aimetti, et al. 2012). Epidemiological studies have shown that periodontitis was observed to be 3 times higher in diabetes patients, specifically poorly controlled individuals (Mealey and Ocampo 2000). Nevertheless, an investigation showed that controls with/without periodontitis and diabetic patients with/without periodontitis all have unique metabolomic profiles when assessed using GC-MS/LC-MS (Barnes et al. 2014). Moreover, Barnes et al. (2014) detected significantly different levels of 1,5-AG, glucose and α-hydroxybutyrate in the salivary profiles of T2D participants from those of healthy controls. These levels had larger fold-changes than those observed in the plasma profiles. Significant alterations were observed in saliva samples with diabetes and gingivitis as a co-morbidity when compared to diabetes patients without gingivitis, and predominantly increased salivary levels of fatty acids and sphingomyelins, along with changes in purine degradation and antioxidant status (Barnes et al. 2014).

Sample Contamination

Food debris, nasal mucus and traces of blood severely impact metabolomics results, if samples are not carefully collected. The overall outlook for salivary metabolomics does, however, show much potential, as patients are much more comfortable providing this sample type of sample than others involving more invasive collection regimens.

Urine

Urine is also very easy to collect and provides high sample volumes. Moreover, this biofluid contains many hundreds of metabolites that are readily detectable.

LC-MS investigations have been performed on urinary samples of T2D (Svingen et al. 2016), with downregulation of betaine, dimethylglycine and sarcosine characteristic of T2D samples. ^{1}H NMR investigations also found T2D downregulations of betaine and dimethylglycine, as well as of acetoacetate, acetate, n-butyrate, 3-hydroxybutyrate, dimethylamine, N-methylnicotinate (NMN) amide and N-acetyl aspartate (NAA), along with downregulated creatinine, N-acetyl functions, nicotinamide mononucleotide acid (NMN), aminohippurate, phenylacetylglycine (PAG), hippurate, allantoin, fumarate and succinate. Twelve control participants provided 7 samples each (total n = 84 samples) and 30 T2D participants provided 1–3 samples (total n = 50 samples). Figures 20.1 and 20.2 demonstrate how the metabolite information can be simultaneously obtained, in a typical diabetic urine sample, using NMR analysis with both 1D and 2D profiling approaches. In a different investigation, urinary betaine concentrations have also been demonstrated to be lower in participants with T2D; this metabolite was determined by LC-MS/MS analysis (Svingen et al. 2016), and this observation is consistent

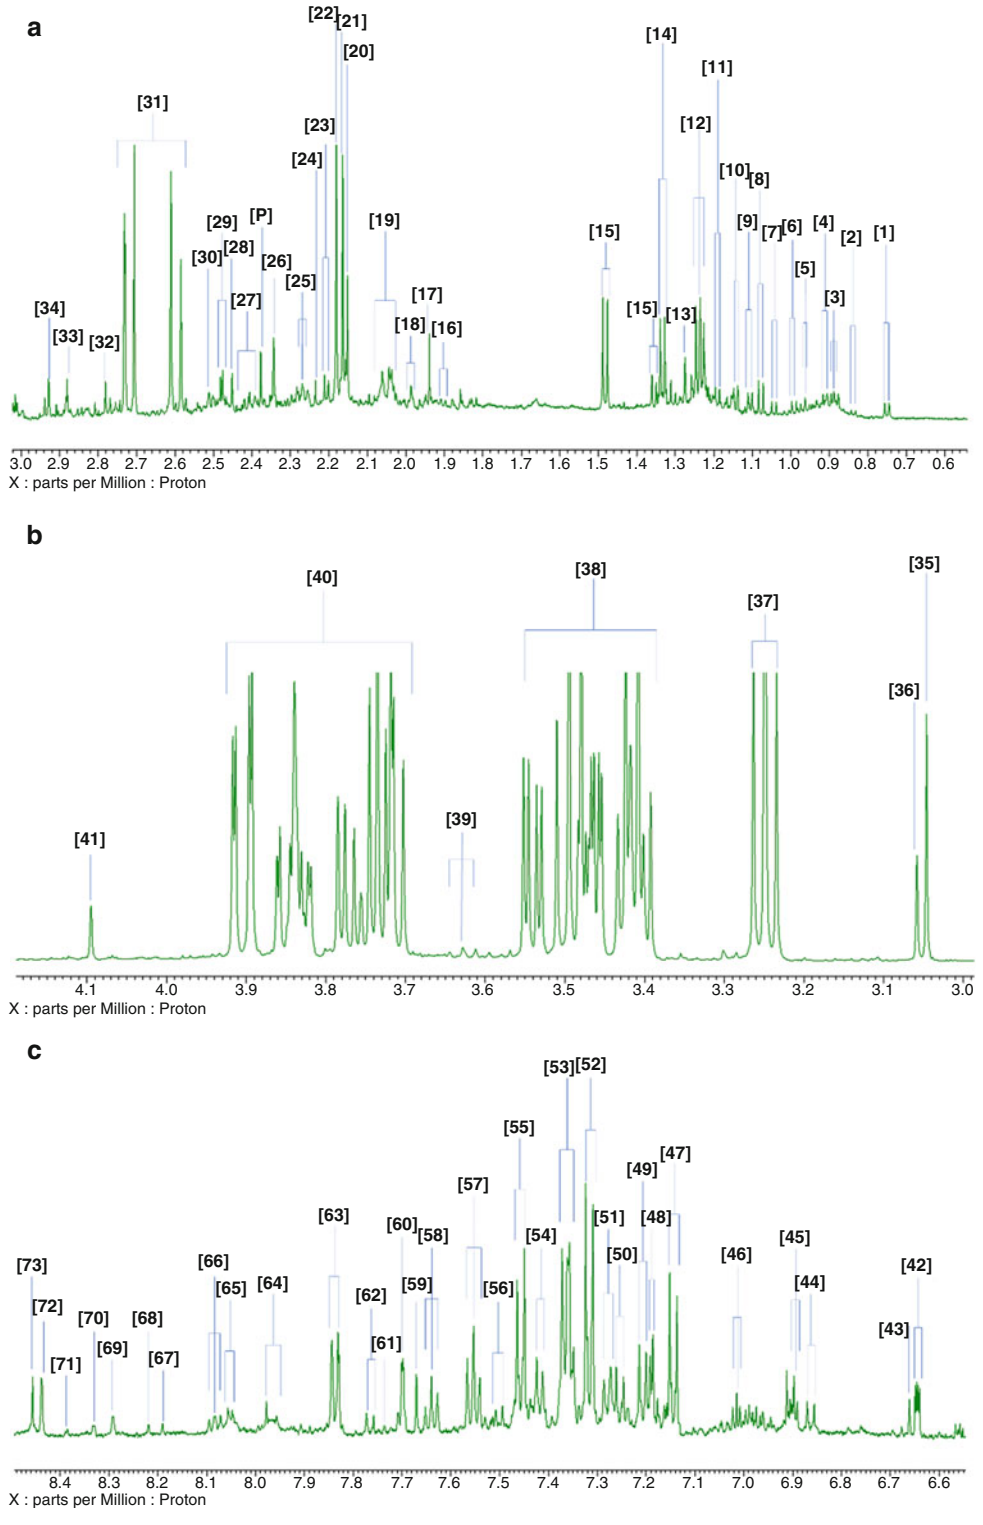

Fig. 20.1 (**a**), (**b**) and (**c**), Expanded 0.60–3.00, 3.00–4.15 and 6.50–8.50 ppm regions, respectively, of the 600 MHz ^{1}H NMR profile of a urine sample collected from a T2D patient receiving metformin treatment. Spectra acquired revealed that this patient was also taking paracetamol as an analgesic. Signals attributable to urea and water removed.

with those of other investigations. A full listing of significant ^{1}H NMR-detectable metabolites identified is also observed in the urinary profiles (Table 20.1).

Disturbed Metabolic Pathways Involved in T2D Pathogenicity

Energy metabolism, i.e. the tricarboxylic acid cycle or Krebs cycle (TCA), is unsurprisingly altered and this can be observed by metabolic changes in lactate, for example. Other disturbed pathways in saliva, urine and plasma include glycolysis, for example, pyruvate levels. However, these markers are not specific to T2D and are featured markers of many other diseases.

Lipid metabolism and amino acid metabolism are also observed to be modified in T2D chemopathogenesis. High levels of ketones are observed in T2D, which arise from the use of lipids as a source of body fuel rather than glucose, and also from the deamination of amino acids. Diabetic ketoacidosis arises from such elevated blood plasma ketone bodies. BCAAs, e.g. isoleucine and leucine, are also elevated in diabetes and are ascribable to a lack of uptake of energy sources, a further impairment of metabolic control (Suhre et al. 2010).

Personal Experience: Retrospective Network Pathway Analysis of Published Data

Using *MetExplore* in a qualitative context, we aimed to identify the possible metabolic sub-networks involved in the pathophysiology of T2D (Cottret et al. 2018). Based on this analysis, the predominant pathways involved in T2D are those involved in the biosynthesis and/or metabolism of amino acids, specifically BCAA metabolism; phenylalanine and tryptophan metabolism; tyrosine biosynthesis; alanine, aspartate and glutamate metabolism; glycine, serine and threonine metabolism; and arginine biosynthesis.

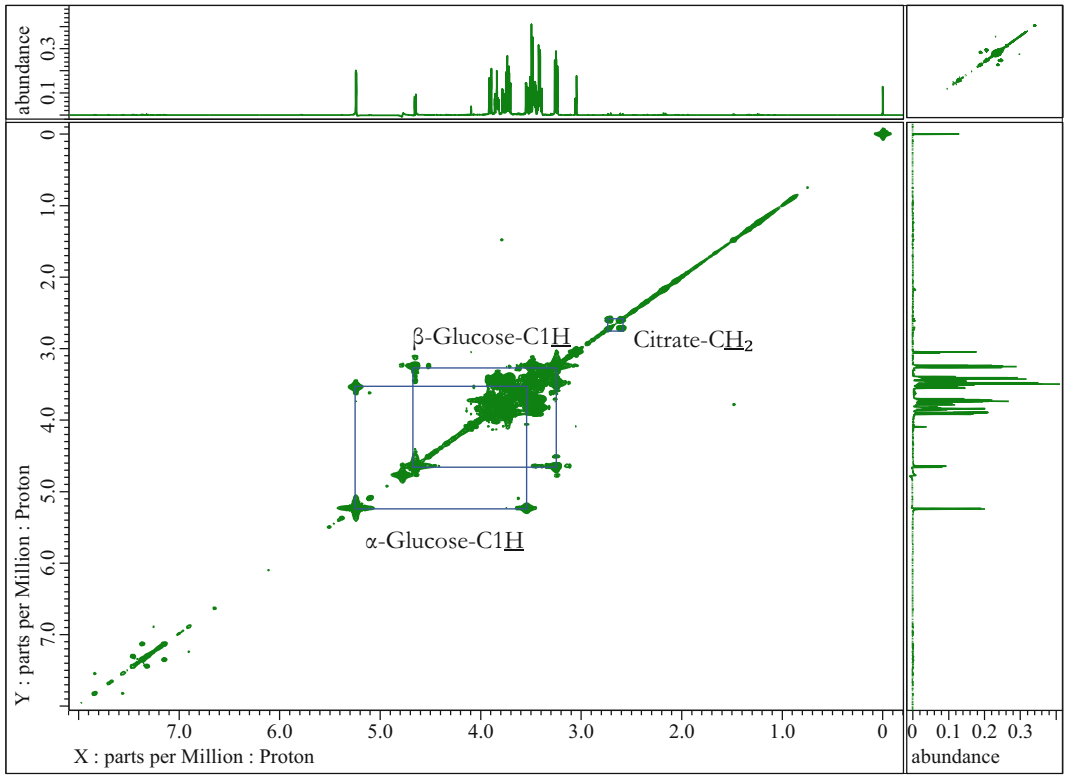

Fig. 20.2 2D ^{1}H-^{1}H NMR correlation spectroscopy (COSY) analysis of a T2D urine sample acquired using a 600 MHz facility (De Montfort University, Leicester, UK). Samples were prepared using 450 μL of urine, 50 μL of D_2O with TSP (0.5% (w/v)), 50 μL of sodium azide solution (0.04% (w/v)) and 50 μL of phosphate buffer solution (1.00 mol./L). Two clear connections are observed in the 2D NMR spectral profile ascribable to α- and β-Glucose-C1H resonances at $\delta = 5.21$ and 4.65 ppm, respectively. 1D projections are observable on the x- and y-axis

Further pathways featured are the biosynthesis of carbohydrates, glyoxylate and dicarboxylate metabolism and 2-oxocarboxylic acid metabolism. Figure 20.3 highlights the relationship between these pathways by displaying a sub-network using the lightest path algorithm, which forms the lightest paths between each pair of blood serum metabolites available in Table 20.1, and allows visualisation of metabolic paths between pairs of elements of interest.

The metabolic pathways highlighted in Fig. 20.3 are consistent with previous studies performed. For example, disturbances in BCAA metabolism have been demonstrated to arise from impaired insulin resistance (Zhao et al. 2016). Sun et al. (2019) also found alanine, aspartate and glutamate metabolism, glycine, serine and threonine metabolism and phenylalanine, tyrosine and tryptophan biosynthesis to be significant ($p<0.05$) pathways in their investigation, which assessed metabolomic signatures in T2D, using *MetaboAnalyst* pathway analysis. Interestingly, arginine biosynthesis and 2-oxocarboxylic acid metabolism pathways have also been demonstrated to be significantly enriched in downregulated T2D-associated genes (Wu et al. 2017).

Prognostic Fingerprints

There is considerable interest in the prognosis of T2D, which includes:

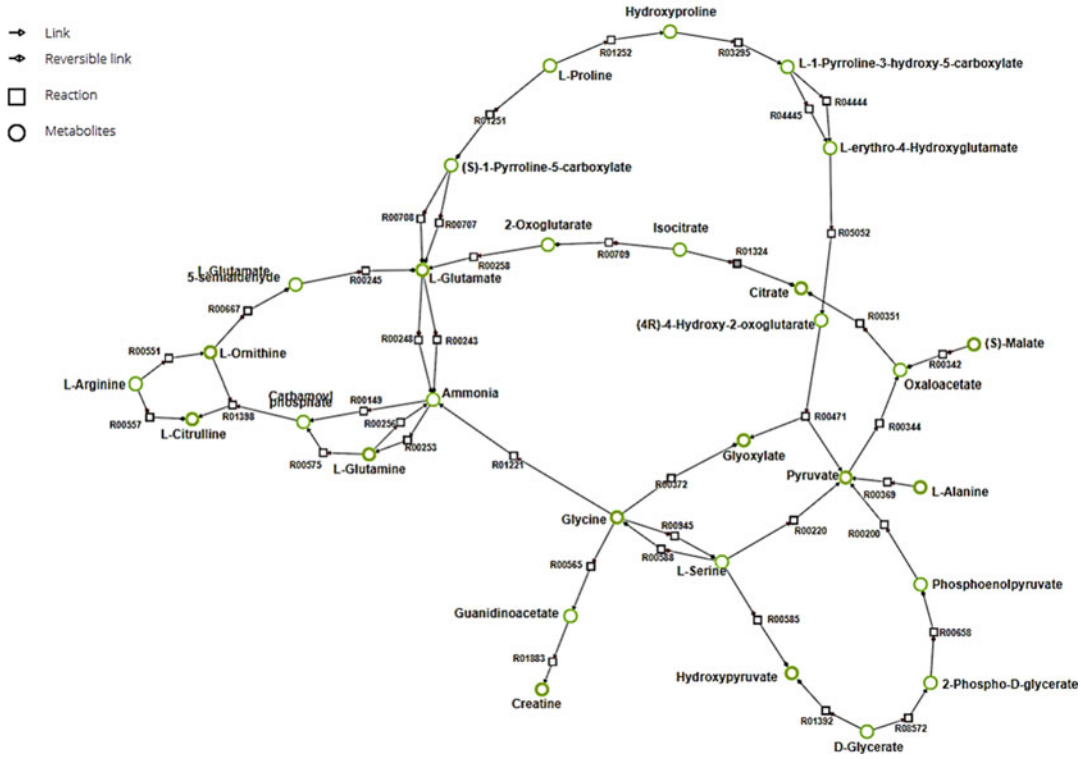

Fig. 20.3 Network pathway analysis of blood serum metabolome alterations in T2D patients, based on the biomarker listings in Table 20.1. Results shown are the sub-network, obtained by using the lightest path algorithm. This network highlights relationships between the TCA cycle, lipid metabolism and amino acid biosynthesis/metabolism in T2D. Enzyme abbreviations: R00149, Carbon-dioxide:ammonia ligase; R00200, ATP:pyruvate 2-O-phosphotransferase; R00220, L-serine ammonia-lyase; R00243, L-glutamate:NAD+ oxidoreductase (deamination); R00245, L-glutamate gamma-semialdehyde:NAD+ oxidoreductase; R00248, L-glutamate:NADP+ oxidoreductase (deaminating); R00253, L-Glutamate:ammonia ligase (ADP-forming); R00256, L-glutamine amidohydrolase; R00258, L-Alanine:2-oxoglutarate aminotransferase; R00342, (S)-malate:NAD+ oxidoreductase; R00351, acetyl-CoA: oxaloacetate C-acetyltransferase (thioester-hydrolysing); R00369, L-Alanine:glyoxylate aminotransferase; R00372, Glycine:2-oxoglutarate aminotransferase; R00551, L-Arginine amidinohydrolase; R00557, L-arginine,NADPH:oxygen oxidoreductase (nitric-oxide-forming); R00565, L-Arginine:glycine amidinotransferase; R00575, HCO3-:L-glutamine amido-ligase (ADP-forming, carbamate-phosphorylating); R00577, acyl-CoA:L-glutamine N-acyltransferase; R00585, L-Serine:pyruvate aminotransferase; R00658, 2-phospho-D-glycerate hydro-lyase (phosphoenolpyruvate-forming); R00667, L-Ornithine:2-oxo-acid aminotransferase; R00707, (S)-1-pyrroline-5-carboxylate:NAD + oxidoreductase; R00708, (S)-1-pyrroline-5-carboxylate:NADP+ oxidoreductase; R00709, isocitrate:NAD+ oxidoreductase (decarboxylating); R00945, 5,10-Methylenetetrahydrofolate:glycine hydroxymethyltransferase; R01221, glycine synthase; glycine cleavage system; R01251, L-Proline:NADP+ 5-oxidoreductase; R01252, L-Proline,2-oxoglutarate:oxygen oxidoreductase (4-hydroxylating); R01324, citrate hydroxymutase; R01392, D-Glycerate:NADP+ 2-oxidoreductase; R01398, Carbamoyl-phosphate:L-ornithine carbamoyltransferase; R01883, S-Adenosyl-L-methionine: guanidinoacetate N-methyltransferase; R03295, trans-4-hydroxy-L-proline:quinone oxidoreductase; R04444, L-1-pyrroline-3-hydroxy-5-carboxylate:NAD+ oxidoreductase; R04445, L-1-pyrroline-3-hydroxy-5-carboxylate:NADP+ oxidoreductase; R05052, L-erythro-4-hydroxyglutamate:2-oxoglutarate aminotransferase; R08572, ATP:(R)-glycerate 2-phosphotransferase

- Prediction and early assessment of pre-diabetes, acute T2D diabetes and chronic diabetes;
- Full assessment (deep phenotyping) of the diabetic condition itself, i.e. diabetes sufferers can present a range of other symptoms and disorders, including diabetic kidney damage, ocular problems, cardiovascular and other metabolic syndrome diseases, and, of course, diabetic ketosis/ketoacidosis.

Metabolomics can successfully be employed to evaluate the onset and diagnosis of T2D. As noted above, Yousri et al. (2015) performed an extensive study observing global changes in the T2D metabolome; however, more importantly, this investigation defined metabolites associated with acute, short- and long-term dysregulation of glycemic control (Yousri et al. 2015). For this investigation, 3-hydroxybutyrate (an intermediate in valine metabolism) and amino acid (e.g., leucine) levels in urine were the best indicators of acute glycemic dysregulation.

Short vs. Long-term Glycemic Homeostasis

Short-term glycemic dysregulation could be further determined by monitoring the salivary, plasma and urinary levels of a combination of metabolites, including those of urinary glycolate, plasma 3-hydroxyisobutyrate and salivary 1,5-Anhydroglucitol (1,5-AG) (Yousri et al. 2015). Blood serum 1,5-AG was also proposed as a short-term glycemic marker in an earlier investigation (Suhre et al. 2010). However, carbohydrate levels in plasma were the best indicators of long-term dysregulation (e.g. those of glucose anomers) (Yousri et al. 2015). Another longitudinal investigation using ultra-performance liquid chromatography-quadrupole time-of-flight mass spectrometry demonstrated plasma levels of iso-valeraldehyde, linoleate, lyso-phosphatidylcholine (18:1), 2-pyrroloylglycine and dityrosine as reliable indications for the development of T2D (Zeng et al. 2017).

Markers for insulin resistance have also been explored as part of metabolomics investigations, and BCAAs have shown promise as biomarkers for screening, enabling early intervention in the development of T2D by dietary or exercise interventions (Roberts, Koulman and Griffin 2014).

Kidney Dysfunction and Ketosis

Further validation is required in order to assess renal function in diabetic patients (Pena et al. 2015). Over 1 in 4 diabetic patients suffer from diabetic kidney disease (Pena et al. 2015), and hence the stratification of biomarkers for this purpose is currently an important consideration. Candidate biomarkers include urinary glutamine and tyrosine, and plasma butenoylcarnitine and histidine (Pena et al. 2014). However, the response of these biomarkers to approved treatments, a process required for their full validation, is yet to be explored.

Ketoacidosis is more prominent in type 1 diabetes; however, it can occur in T2D. Indeed, mild ketosis has been observed in metabolomics investigations with stable elderly T2D, which was indicated by increased 3-D-hydroxybutyrate blood plasma concentrations (Suhre et al. 2010).

Potential Bedside/'Point-of-Care' Metabolomics

Dipstick testing for glucose and ketone body levels, along with electronic meters, which can simultaneously detect and provide a reference range for plasma and urinary samples, is well established. This can be performed in a home or clinical setting. Ketones can be alternatively monitored in the blood using handheld devices; however, currently these are mostly used in veterinary medicine (Wang et al. 2015).

Needle-free flash glucose monitors can also be employed as a non-invasive option (Distiller, Cranston and Mazze 2016). To test for T2D, the usual recommendations encompass whole blood HbA1c and fasting plasma glucose levels, along with a 2 h plasma glucose after a 75g oral glucose load (oral glucose tolerance test/ OGTT) (American Diabetes Association 2018). In a paediatric setting, blood spots from the heel or finger pricks are often utilised.

Future Developments

The benefits of adopting metabolomics into personalised care (precision medicine) include pre-diagnosis, predictive outcomes and indicated treatment regimens.

Metabolic disturbances routinely monitored in diabetes are essentially limited to blood glucose, HbA1c, ketone body and lipid profiles. This neglects the TCA cycle, metabolites and those involving selected amino acids (Table 20.1). The unfortunate lack of translation of metabolomic technologies into clinical practice is largely ascribable to the size, required resources and expense of instruments used to obtain simultaneous metabolic fingerprinting information on biofluid samples. Additionally, dataset sizes acquired from metabolomics investigations are large, probing the status of often hundreds of metabolites, and hence it may be unfeasible for their large-scale applications within clinical practices (Blümuch 2019). Finally, the restraints on metabolomics investigations include ensuring that a strict experimental design is employed, which requires the selected participants adhering to particular criteria, i.e. fasting status, age range, sex, exercise regimen, dietary regimen, etc. (Ghini et al. 2019).

Bedside Devices

As technology advances, there is some promise for low-field (LF), near-portable benchtop NMR devices to become more commonplace, rather than the high-field facilities that are restricted to large industrial and research centres (Blümuch 2019). Moreover, smaller patterns of metabolites might be more feasible to monitor and interpret within a clinical setting. For the first time, Percival et al. (2019) presented the potential 'point-of-care' applications of urinary testing of T2D patients using a benchtop ^{1}H NMR-linked metabolomics strategy. There are clear benefits of this approach over the use of high-field facilities, including the lower operating, maintenance and initial costs of the facility, the ability to detect and quantify glucose and other metabolites simultaneously, and perform metabolomics investigations on biofluid samples, which would benefit clinical management. The disadvantages of this study are evident: the 60 MHz operating frequency of the benchtop NMR facility is not comparable to high-field facilities that have been utilised in previous studies, since the levels of metabolites detectable are significantly reduced (approximately 4–5 times).

The investigation would also benefit from a larger sample size in control and T2D cohorts. However, this shows the scope and potential applications, since technological advances are continually being accomplished in NMR, with higher operating frequencies now achievable with benchtop facilities (i.e. up to 100 or more MHz), and automation is made possible for these facilities with robotic autosamplers. Further developments in the miniaturisation of NMR spectrometers in order to increase sensitivity and translate into clinical settings have been explored (Wishart 2019; Blümuch 2019). This gives potential access to healthcare centres, GP surgeries, dental practices, community pharmacies and hospitals, and such NMR facilities are substantially more practical and cost-effective.

One solution to overcome the experimental design challenges of diurnal variation in metabolic profiles includes the collection of pooled urine or plasma samples, in order to provide an average profile for healthy or diseased individuals.

Sensible options for the translation of metabolomics strategies into clinical settings

comprise selection of the most significant metabolites for such clinical applications, and the development of reliable linear combinations of biomarkers or algorithms in order to provide a cheaper, efficient solution for early detection, diagnosis and prognosis.

Metabolomic Panels

The idea of a blood based-panel has shown some success by Varvel et al. (2014) who monitored 19 markers and demonstrated that this was an improved approach over the routine, established monitoring of HbA1c and fasting glucose levels for T2D patients. It would be ideal to use markers of pre-diabetes as demonstrated by Varvel et al. (2014), in order to control or avoid the onset of T2D, and therefore provide improved treatment outcomes and healthcare cost savings.

Portable Oral Prosthesis and Breath Volatolomic Analysis

Other devices that have potential use for the diagnosis and monitoring of T2D include salivary mouthguard biosensors with telemetry that are able to detect glucose concentrations from 5–1000 μmol/L (Arakawa et al. 2016). Other biosensors have been developed for the detection and determination of glucose in saliva include optical biosensors (Soni and Jha 2015). However, potential contaminations are possible from blood and food debris. This is a technology that could be further developed with wider metabolomics applications. Breath testing for ketones has also been demonstrated using gas-chromatography/mass-spectrometry, and the methodology has shown a high sensitivity and specificity (Qiao et al. 2014).

Another technology, which comes full circle from the history of the diagnosis of diabetes, is the development of an 'electronic nose' that is able to detect urinary levels of ammonia, ethyl methyl ketone and acetone. Indeed, the statistical testing provided a successful classification of diabetic and control patients using acetone alone (Seesard, Sriphrapradang, Kitiyakara and Kerdcaroen 2016).

Metabolomics has also been shown to support genotypic investigations (Kim et al. 2016), and could easily complement those involving the genetic profiling of T2D, in an integrative omics approach.

Artificial Pancreas and Wearable Technology

In the artificial pancreas context, continuous glucose monitoring has been conducted, and these systems release insulin if levels are above specified limits (Olczuk and Priefer 2017). Naturally, these devices are geared at advanced disease, primarily type 1 diabetes, and are not serving to inform a potentially preventable pre-condition, e.g. pre-diabetes. Moreover, they determine a single, albeit the most important metabolite, glucose, bypassing up- or downregulated markers in T2D as described here. Other further developments are likely to be observed in the smartphone, smartwatches and the smart application industries in general, with huge potential for monetary savings in future healthcare centres and systems (Wang and Kricker 2018).

Abstract

Type 2 diabetes (T2D) is a highly prevalent metabolic disorder associated with many other diseases like obesity, insulin resistance, atherosclerosis, hypertension, arthritis, and various types of cancers. Recent findings suggest that gut microbiome plays an important physiological role in many aspects like host defense, digestion, absorption and fermentation of complex sugars, short chain fatty acid (SCFA) production, metabolic signaling pathways, and reshaping the intestinal barrier. SCFA, a ligand to G protein couple receptors Gpr41 and Gpr43, can secrete peptide tyrosine (PYY), which increases gut motility and nutrient absorption. Gut microbiome could play a role in hepatic and muscle insulin sensitivity via the AMP kinase and other pathways.

Keywords

Microbiota · Short chain fatty acids · Intestinal barrier · Energy metabolism · Carbohydrate metabolism · PYY · Gut hormones · Insulin sensitivity

Introduction

Asia is reported to top the charts to have most rapidly emerging cases of type 2 diabetes (T2D) especially in countries like China and India (Kassi et al. 2011; Reaven 1988; Zheng et al. 2017). The major factors held responsible for the global T2D epidemic include obesity, sedentary lifestyle, and increased consumption of processed food, refined grains, and high sugar containing beverages. Among T2D cases, cardiovascular disease (CVD) is the major cause of mortality and morbidity, and additionally, kidney failure is also prevalent in such patients. Metabolic disorders are common in developing countries, attributed not just to increase in energy intake and decrease in physical activity in recent decades but also due to alterations in gut microbiota.

The gut harbors trillions of bacteria that are involved in regulating digestion, metabolism, extraction of nutrients from ingested food, synthesis of vitamins, prevention against pathogens, and immunomodulation (Brestoff and Artis 2013). In the past few years, different findings have confirmed the role of disbalanced gut microbiome in various metabolic disorders. It has also been observed that changes in gut microbiome could be a risk factor in diseases like T2D and CVD. Additionally, low grade inflammation, as well as modification in the secretion of incretin and butyrate formation, has been proposed to be a potential mechanism linking gut microbiota and T2D (Moreno-Indias et al. 2014).

The gut of healthy adults remains stable over time and is transiently altered under the effect of external influences such as diet, disease, and environment. Diet provides nutrients for both host and the residing microflora. Alterations in dietary intake account for 57% of total structural variation in gut microbiome as compared to genetics, which only contribute 12% (Zhang et al. 2010). Microbiota Accessible Carbohydrates (MACs) have been shown to play a role in shaping the microbial ecosystem and are significantly reduced with consumption of a 'western' diet (high in fat and carbohydrates and low in fiber) as compared to traditional diet (low in fat and carbohydrates and high in fiber).

Western diet/traditional diet also impacts the ratio of two important bacterial phyla, Firmicutes and Bacteroidetes , possibly resulting in impairment/establishment of various gut-associated physiological functions (Tidjani Alou et al. 2016; Turnbaugh et al. 2007).

European children have high levels of Bacteroidetes as well as of *Enterobacteriaceae* as compared to rural African children, which may be attributed to high fiber intake by Africans (Jacquemont et al. 2011). Studies have reported that a healthy individual has substantial concentrations of bacteria from Clostridiales order (*Roseburia* species and *Faecalibacterium prausnitzii*), which are efficient producers of the small chain fatty acid (SCFA) butyrate through the fermentation process (Parks et al. 2013; Karlsson et al. 2013). It is instrumental in fulfilling energy requirements of gut epithelium, in regulating inflammatory responses in the gut by serving as a ligand to GPCRs on immune cells, and in maintaining gut epithelial barrier (Parada Venegas et al. 2019).

The Disruptive Role of Antibiotics

Antibiotics exert selective pressure on important mediators of gut biology, leading to long term reduction in their diversity (Jernberg et al. 2010). Even veterinarian antibiotics such as avoparcin (a glycopeptide structurally similar to vancomycin) could play a role in weight increment in patients treated with vancomycin, due to colonization by *Lactobacillus spp*, which once exposed to that agent can become resistant to glycopeptides and are found in high concentrations in feces of obese individuals (Thuny et al. 2010; Brugman et al. 2006). One advance in the molecular investigation of metabolic disorders was the introduction of genome wide association studies (GWASs), which have helped identify candidate genes involved in increasing/decreasing insulin resistance in diabetes and variable metabolic phenotypes (Jacquemont et al. 2011).

A common feature that connects T2D and obesity is low grade inflammation in tissues involved in regulating metabolism. This inflammation is characterized by moderate rise in cytokines such as IL-6, IL-1, and TNF-alpha, which hampers insulin signaling and leads to insulin resistance in both conditions (Kahn et al. 2006; Hotamisligil 2006).

Lipopolysaccharide (LPS)-associated Endotoxemia

LPS is an endotoxin released by Gram negative bacteria. Changes in the proportion of Gram negative bacteria or disruption of gut epithelial barrier are blamed for release of LPS in systemic circulation (Musso et al. 2010). LPS-mediated endotoxemia can direct the release of pro-inflammatory cytokines by immune cells. LPS binds to CD14/TLR4 receptor present on macrophages to mount an inflammatory response and also promotes the expression of transcription factor NFKB and protein kinase MAPK in adipocytes. An opposite, protective mechanism attributed to gut microbes involves increase in production of incretins such as glucagon like peptide-1 (GLP-1). It is evident from several studies that rise in *Bifidobacterium spp* is accompanied by increase in levels of GLP-1 and PYY secreted by intestine (Cani et al. 2007a).

These two molecules have an important effect on decreasing insulin resistance and increasing functionality of beta cells. GLP-2, a nonincretin however produced by the same intestinal cells, plays a role in increasing expression of zona occludens-1 (ZO) protein, essential for maintaining the gut barrier and preventing LPS-associated endotoxemia (Cani et al. 2009). Another mechanism related to T2D pathophysiology, as alluded to, could be shifts in SCFA (butyrate) producing bacteria. Butyrate is an important source of energy for colonic cells and is produced with the help of *C. coccoides* and *Eubacterium rectale* groups, along with other butyrate fermenting bacteria in gut. Reduction of such bacteria has been reported to initiate increase in opportunistic pathogens deranging insulin signaling and predisposing to insulin resistance (Caricilli and Saad 2013).

Metformin and Gut Ecology

Metformin is popularly used to treat diabetes and is reported to increase the levels of butyrate and propionate producing bacteria. High fiber diet increases the abundance of *Prevotella*, while bariatric surgery has been shown to affect bacterial

composition in the gut, which may contribute to BMI independent amelioration of glucose metabolism (Brunkwall and Orho-Melander 2017).

Metabolic Syndrome and Obesity

The subclinical stages leading to metabolic syndrome are marked by alteration in gut microbiome, which was shown through an interesting finding demonstrating the relevance of increased abundance of *Akkermansia muciniphila* in maintaining adequate levels of free fatty acids (FFA) in humans, while subjects with subclinical metabolic alterations had decreased population of *A. muciniphila* and surprisingly increased levels of *Lactobacillus* , resulting in elevated factors such as FFA, pro-inflammatory cytokines, and serum IL-6 (Reaven et al. 1988; Randle et al. 1963; Rodriguez-Carrio et al. 2017).

Inflammation

Some probiotics have shown to be effective in modulating the immune system against altered gut microbiota associated with chronic low level inflammation, which can contribute to T2D (Zhang and Zhang 2013). One such probiotic, *Lactobacillus casei* (Matsuzaki et al. 1997), exhibited antidiabetic properties on oral administration to a noninsulin-dependent diabetes mellitus (NIDDM) model using KK-Ay mice. Other such examples include *Bifidobacterium longum* (Chen et al. 2011).

Composition of Gut Microbiota

The resident gut microflora is shaped by important factors during the course of our lifetime, which include early colonization depending on type of birth (vaginal vs c-section), age, lifestyle, host genetics, health/disease status, medications, and, most obviously, the dietary pattern. The main bacterial phyla residing in our gut are Firmicutes (Gram-positive), Bacteroidetes (Gram-negative), and Actinobacteria (Gram-positive). Firmicutes encompass more than 200 genera, the most predominant of which are *Bacillus and Clostridium*.

The infant microflora is modulated on consuming solid foods around the age of 2–3 years, progressively resembling stable adult microbiota with predominance of Firmicutes and Bacteroidetes (Odamaki et al. 2016) (Fig. 21.1).

Factors Involved in T2D Pathogenesis

Incretins

Incretins like glucagon like peptide-1 (GLP-1) and gastric inhibitory polypeptide (GIP) that are released by small bowel endocrine L cells and K cells, respectively, stimulate the pancreatic beta cells and increase insulin production and secretion. GLP-1 influences various functions like satiety, reduced dietary intake, and delayed gastric emptying, which are relevant therapeutic targets for patients suffering from both obesity and T2D (Nauck and Meier 2018). Often, patients suffering from T2D experience gut microbial dysbiosis, which leads to GLP-1 resistance by reduced expression of GLP-1R and neuronal nitric oxide synthase. There is a break in the gut brain axis for the control of insulin secretion and gastric emptying, controlled by a pattern recognition receptor (PRR)-dependent mechanism expressed by the enteric nervous system (Yamane and Inagaki 2018).

Short Chain Fatty Acids (SCFAs)

Major products derived from microbial fermentation are short chain fatty acids (SCFAs) such as acetate, propionate, and butyrate. These are taken up by host organs and have different metabolic fates. They similarly act as signaling molecules and are known ligands for at least two G protein coupled receptors, i.e., Gpr41 and Gpr43, (Greiner and Bäckhed 2016) which are dominantly expressed on colon, adipocytes, and distal small intestine. On binding GPCRs, they induce the secretion of peptide YY (PYY) (Karra et al. 2009) and leptin. PYY is a peptide hormone released by enteroendocrine cells of intestine and is

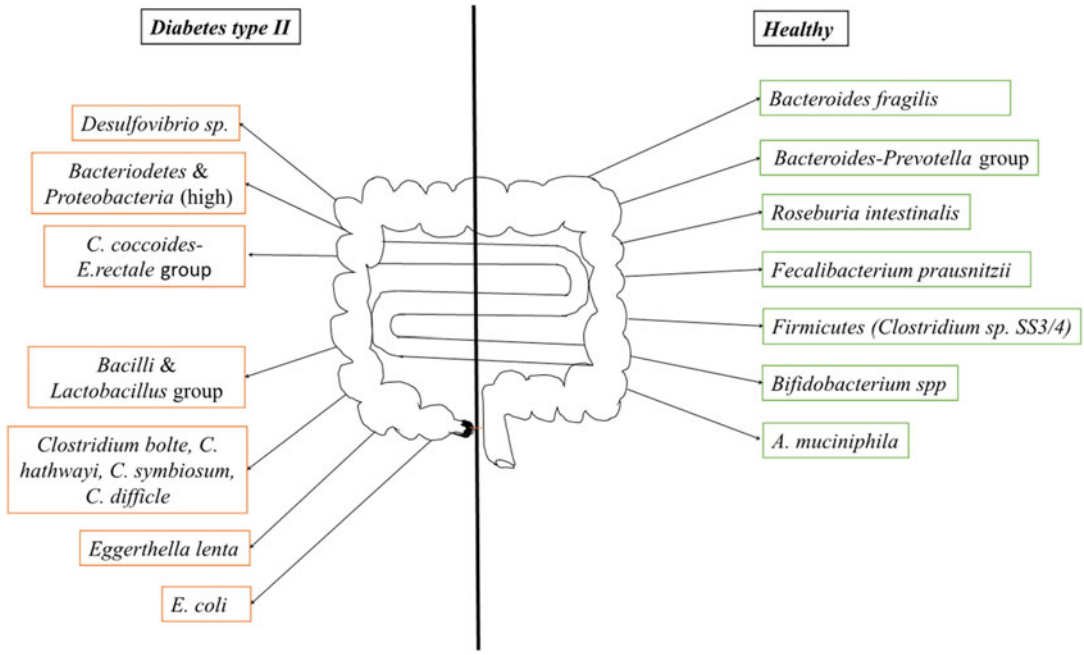

Fig. 21.1 Status of gut microbiome in type 2 diabetes (left side) and healthy individual (right side). *L. acidophilus, L. gasseri, L. salivarius* are increased inT2D

functionally important in gut motility and increased expression of liver fatty acid binding protein (L-FABP), a peptide responsible for intracellular free fatty acid (FFA) distribution, eventually promoting intestinal nutrient absorption. Various other roles of SCFAs are depicted in Fig. 21.2.

AMP-activated Protein Kinase (AMPK)

AMPK enzyme is expressed in liver and skeletal muscle and maintains the cellular energy homeostasis. Increased expression of AMPK increases beta oxidation in liver and muscles and favors weight loss. AMPK activation targets carnitine palmitoyltransferase-1 through Acyl-coA carboxylase activity, which disfavors anabolic pathways such as glycogen storage and improves insulin sensitivity (Angin et al. 2016). Gut dysbiosis affects the host health by inhibiting AMPK, which negatively affects the beta oxidation, promotes synthesis of cholesterol and triglycerides, and enhances the rate of lipogenesis. There are experimental evidences that suggest that these factors favor the host toward weight gain and obesity, which may be followed by T2D (Boulangé et al. 2016).

Metabolic Functions

Experimental evidences suggest that the gut microbes perform important metabolic functions by regulating the expression of host genes. For example, the gut commensal *Bacteroides thetaiotaomicron* found in the intestine of mice and humans maintains the expression of genes involved in several functions like nutrient absorption, mucosal barrier fortification, xenobiotic metabolism, angiogenesis (Stappenbeck et al. 2002), postnatal maturation of intestine, and increased capillaries in small intestine, which aid in absorption (Hooper et al. 2001). This might help indirectly in the digestion and absorption in an healthy individual as compared to a diabetic patient.

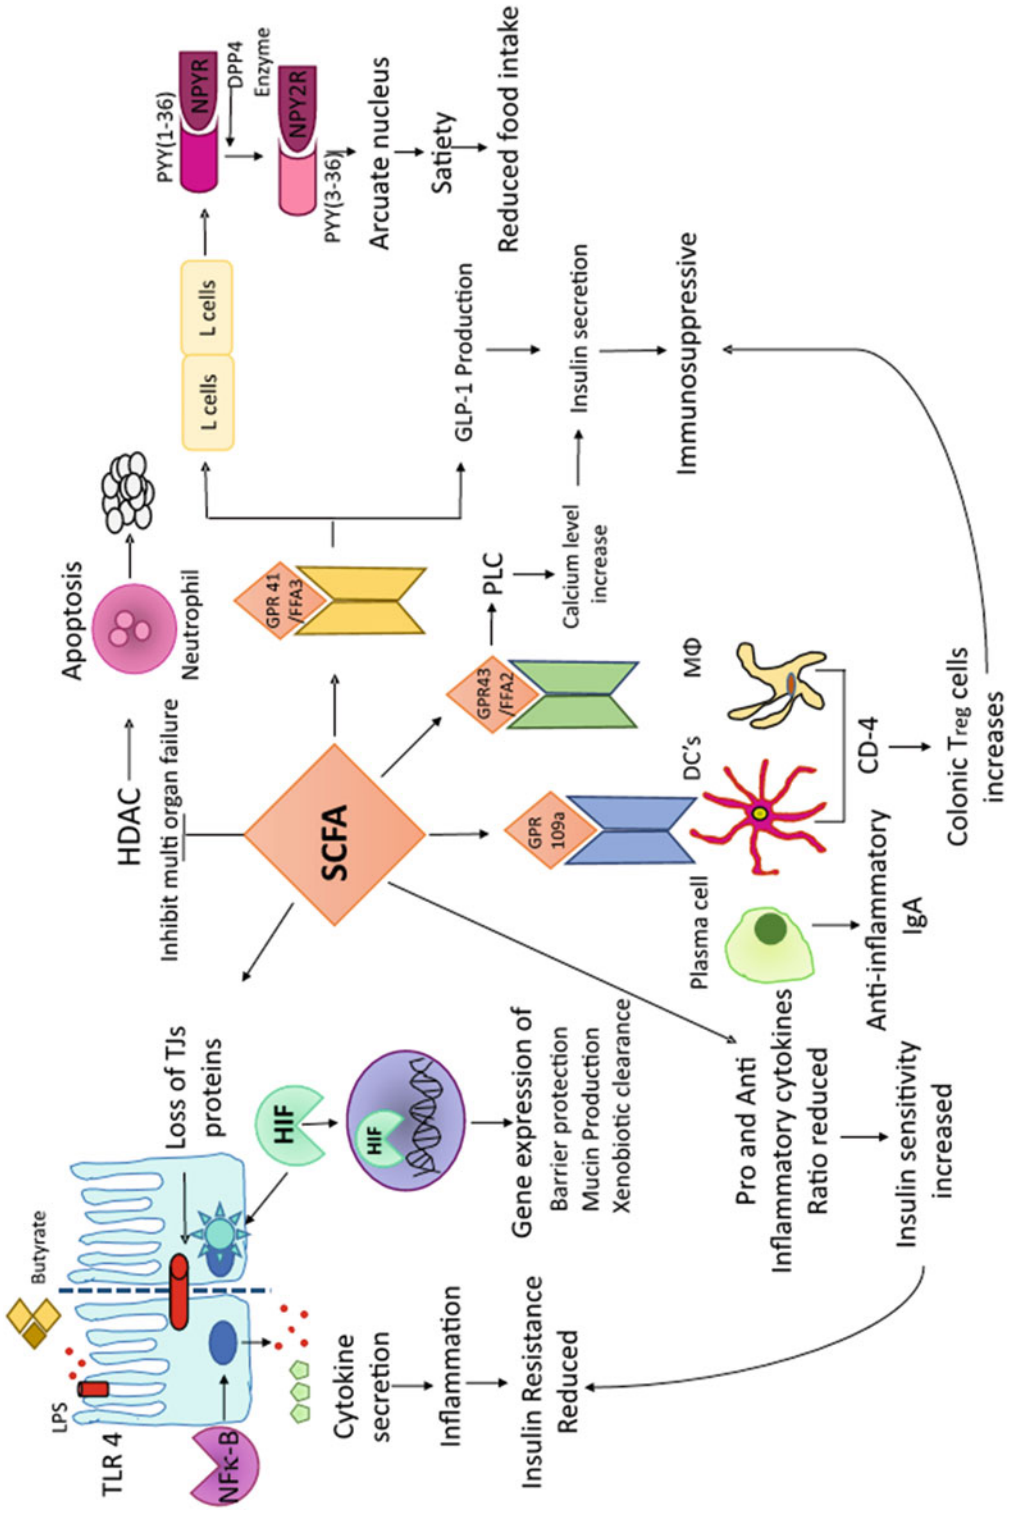

Fig. 21.2 Diverse roles of bacterially fermented short chain fatty acids (SCFAs) in various signaling pathways

Epithelial Barrier Impairment and Pro-Inflammatory Cytokines

Microbial dysbiosis, which is a main feature in correlating gut microbiome with T2D pathogenesis, is related to gut epithelial barrier impairment causing increased circulatory levels of tissue MAMPs such as LPS and PG (Salguero et al. 2019). This can cause low grade inflammation by releasing pro-inflammatory cytokines and can be a possible cause for obesity and T2D.

Bile Acid Transformation

Primary bile acids, cholic acid (CA) and chenodeoxycholic acid (CDSA), can function as ligand for nuclear transcription factor farnesoid X receptor (FXR), suppress hepatic gluconeogenesis and lipogenesis, increase fatty acid oxidation, and also play a role in improvement of extrahepatic insulin sensitivity. These are synthesized from cholesterol in liver and conjugated to taurine or glycine and on entering the GI tract is further metabolized by gut microbiota through cycle of oxidation, esterification, desulfation, and epimerization to form secondary bile acids deoxycholic acid (DCA) and lithocholic acid (LCA) in humans. Secondary bile acids are product of bacterial metabolism like which involves predominantly *Bacteroides fragilis, Bacteroides intestinalis*, and *E. coli.* (Ferrell and Chiang 2019). The bile acid metabolism is in loop with gut microbiota as bile acids control gut bacteria overgrowth and protect against inflammation, while the gut microbiota plays a role in biotransformation of bile acids (Ikegami and Honda 2018), bile acid composition, (Chiang and Ferrell 2018) and enterohepatic circulation of bile.

Gut Microbiome in Pathogenesis of T2D

T2D is accompanied by insulin resistance and beta cell dysfunction. Insulin resistance is defined as failure of uptake of glucose by peripheral tissues of the body, leading to imbalanced glucose homeostasis. During conditions of IR, insulin is produced in excessive amount to compensate for the loss of insulin sensitivity, termed as hyperinsulinemia. When this compensatory feedback loop is impaired or becomes nonfunctional, this can potentially result in T2D. The reason for this failure could be either change in beta cell function and mass or failure to respond adequately to secretory molecules (which stimulates beta cell to release insulin). Beta cell must be able to compensate for the decrease in insulin sensitivity for diabetes to occur.

The first evidence linking gut microbiota with glucose metabolism was shown in studies done on germ free mice in 2004 (Backhed et al. 2004). Subsequent studies done by several groups using metagenomics platform and 16S rRNA sequencing analysis have reported altered ratio of two important phyla: *Firmicutes* (Gram positive) and *Bacteroidetes* (Gram negative). Gut microflora interacts with host metabolism, leading to development of insulin resistance and T2D. One of the mechanisms linking insulin resistance and T2D is the low grade inflammation, which is a hallmark characteristic commonly observed in T2D and obesity, resulting due to prevalence of Gram-negative bacteria. Gram-negative bacteria have LPS on their outer membrane, which is a strong activator of Toll-like receptors that further activate increased production of inflammatory responses and pro-inflammatory cytokine in the bloodstream.

Several studies in the past have reported disrupted gut barrier function, leading to translocation of LPS into the circulation and resulting in microbiota-derived inflammation or endotoxemia contributing to pathogenesis of T2DM and obesity (Amar et al. 2011; Brun et al. 2007; Burcelin et al. 2012). Increased gut permeability is due to reduced expression of Zonula occludens-1 (ZO-1), claudin, and occludin, proteins that are required to restrict bacteria and substances from crossing intestinal lumen and enter the circulation. Reduction in SCFAs such as acetate, butyrate, and propionate also affects expression of tight junction proteins contributing to disturbed gut barrier function.

Breakdown of gut barrier leads to a release of LPS in blood, resulting in inflammation and its related metabolic disorders. LPS binds to TLR4 (TLR4 is a group of toll-like receptors expressed on most of the cells and macrophages and recognizes Pathogen-associated molecular patterns) to activate extensive downstream signaling, resulting in increased state of pro-inflammation as compared to TLR4 deficiency where these responses are attenuated (experiments performed on TLR4 and CD14 knockout mice). TLR4 inactivation in different tissues such as bone marrow derived cells and liver-specific TLR4 knockout mice showed improved glucose tolerance, and the absence of it in muscle prevents from diet-induced insulin resistance, which is an indication of protection against insulin resistance (Velloso et al. 2015).

One of the important roles of gut microflora is the production of nongaseous SCFAs in metabolizing dietary fiber. The significant commensal gut bacteria involved in SCFA generation are *Akkermansia muciniphila, Prevotella spp., Ruminococcus spp., Coprococcus spp., Faecalibacterium prausnitzii, Eubacterium rectale, and Roseburia spp* (Rinninella et al. 2019).It performs plethora of functions such as regulation of inflammatory response, production of intestinal hormone and lipogenesis, and most importantly maintenance of gut health. Butyrate is a source of energy for colonic epithelial cells and is also important for cell differentiation and growth (Ardawi and Newsholme 1985). On the other hand, acetate is a precursor of cholesterol and fatty acids and propionate may act as a precursor for gluconeogenesis (Sa'ad et al. 2010; Delzenne and Williams 2002).

Butyrate also increases the mucus production and impacts expression of tight junction proteins which leads to decrease in gut barrier permeability (Bordin et al. 2004; Peng et al. 2007). It has been observed that upon administration of acetate in mice fed with high fat diet, there is activation of AMPK resulting in increased fat oxidation and energy expenditure which in turn improve insulin resistance and glucose tolerance (Kahn et al. 2005). It has been shown that reduction of SCFA production can lead to increase in pro-inflammatory cytokine production, resulting in development of T2DM. SCFAs are ligand for G-protein-coupled receptors such as GPR41 and GPR43, affecting crucial functions like inflammation, expression of tight junction proteins, and enteroendocrine regulation (Kimura et al. 2014). Upon GPCR activation, there is induction of peptide YY (PYY) and leptin. Leptin is secreted by adipocyte with diverse effects on appetite and energy metabolism.

Current Therapeutics

Bariatric Surgery

Bariatric surgery has proven to achieve an effective weight loss, along with improvement of metabolic and inflammatory diseases . It has also helped to partially clarify the controversy about excess of Firmicutes in the obese population. Even though the Firmicutes/Bacteroidetes imbalance typical of obese animals is still debated regarding humans, a systematic review confirmed reduction of Firmicutes in parallel to marked weight loss during the first postoperative year. This is compatible with a role of this phylum in obesity pathogenesis. An increase in Proteobacteria as well as *Bacteroides* also occurred, with less obvious implications Luijten et al. (2019).

Prebiotics, Probiotics, and Synbiotics

Nondigestible polysaccharides including inulin, oligosaccharides, fructooligosaccharides, and galactooligosaccharides (prebiotics) promote enrichment of healthy bacteria such as *Bifidobacteria* and *Lactobacilli* over unhealthy bacteria and thereby increase the production of short-chain fatty acids (SCFAs). This results in reduction of inflammation, maintaining integrity of intestinal membrane and improvement in absorption of nutrients (Colantonio et al. 2019). Mice fed with high fat diet have reduced levels of *Bifidobacterium* as compared to control diet, which results in increased endotoxemia and

could be a potential reason for altered gut microbiota (Cani et al. 2007b). Enriching the feed of HF diet mice with prebiotic oligofructose restores the level of *Bifidobacterium* and is positively correlated with improved glucose tolerance, glucose-induced insulin secretion, and maintaining normalized inflammatory tone, which favor the prevention of high fat diet-induced metabolic disorders such as obesity and T2D. In another study, oligofructose has been shown to exert antidiabetic effect and increase the secretion of glucagon like peptide 1 (GLP-1) (Cani et al. 2006).

The presence of oligofructose improves glucose tolerance, fasting blood glucose, glucose-stimulated insulin secretion, and insulin sensitive hepatic glucose production, with reduced body weight gain (Cani et al. 2006). Treating type 2 diabetes (T2D) patients with transglucosidase (which generates prebiotic fibers, including oligosaccharides) was followed by reduction in levels of hyperglycemia and weight gain. This is believed to be the result of production of oligosaccharides and manipulation in gut microbiome (increased Bacteroidetes-to-Firmicutes ratio) (Cani et al. 2006).

Most of the probiotic products commercially available have *Bifidobacterium* and *Lactobacillus* as their chief constituents, eventually including other lactic acid bacteria. Synbiotics in turn convey mixtures of both probiotics (live microorganisms) and prebiotics (fermentable fibers that induce elevated proliferation of probiotics and other favorable species) (He and Shi 2017).

Supplementation Meta-analyses

Recent systematic reviews of randomized controlled trials have attempted to shed light on this highly discussed therapeutic area. Prebiotics and synbiotics for T2D triggered improvements for fasting blood glucose, HbA1c, and HDL cholesterol, whereas in a subgroup analysis, advantages were unearthed for additional lipid fractions (triglycerides and total cholesterol) (Mahboobi et al. 2018).

Probiotics prescribed to diabetics elicited similar results concerning fasting blood glucose, glycated hemoglobin, insulin, and homeostatic model of insulin resistance (Koutnikova et al. 2019; Tao et al. 2020). For overweight, however, not for obese participants, body weight and additional anthropometric measurements diminished (Koutnikova et al. 2019). Inflammatory and oxidative stress biomarkers are similarly listed among the targets of probiotics and synbiotics in the diabetic population, as high sensitivity C-reactive protein and malonyldialdehyde decreased, whereas total antioxidant capacity, nitric oxide, and glutathione were enhanced (Zheng et al. 2019).

With such encouraging responses notwithstanding, studies continue to be heterogeneous on account of different doses, bacterial strains, and treatment regimens. Outcomes are still associated with specific probiotic and synbiotic preparations and with certain countries (Koutnikova et al. 2019), an important reason why few societies include them in official guidelines.

Other Perspectives

Fecal Microbiota Transplant (FMT)

The procedure dates back to fourth century AD, when the Chinese doctor Ge Hong first documented fecal suspension ingestion in his handbook. It was used to treat patients with food poisoning or severe diarrhea. A Chinese doctor, Li Shizhen administered a cocktail of dry feces, fermented, fresh fecal suspension, and infant feces for treatment of severe diarrhea, fever, pain, vomiting, and constipation. In 1958 Ben Eisemen, an American surgeon, successfully treated with fecal enemas four patients who had developed severe pseudomembranous enterocolitis after antibiotic use.

The description of the multiple metabolic functions of the gut microbiota has raised the hypothesis of employing FMT for metabolic disorders. A few encouraging results were reported; however, further exploration is needed for testing its efficacy (Bakker and Nieuwdorp 2017).

Table 21.1 Impact of dietary patterns on gut microbiome

Diet	Impact on gut microbiome
Fat Diet	
High-saturated fat and low fiber diet (mice)	Decrease in Bacteroidetes Increase in Firmicutes and Proteobacteria
High fat diet (mice)	Increase in *Lactococcus* and *Allobaculum* and decrease in *Akkermansia*
High fat diet in healthy adults	Increase in *Alistipes and Bacteroides* and decrease in *Faecalibacterium*
Protein Diet	
Long term protein rich diet	*Bacteroides* enterotype
Short-term protein rich diet	Increase in bile tolerant bacterial species (*Alistipes* and *Bilophile)* Decrease in saccharolytic microbes (*Roseburia, Eubacteria rectale, and Ruminococcus bromii*)
Plant-based protein diet	Increase in lactobacilli and bifidobacteria (enhancing SCFA production)
Carbohydrate Diet	
Complex carbohydrate (long term)	Increase in *Prevotella*
Nondigestible carbohydrate (overweight individuals)	Increase in phylum Firmicutes (including *Ruminococcus* species)

Personalized Nutrient/Diet

Reshaping host microbiome by modulation of the dietary exposure opens a new horizon for "personalized diet". It is based on manipulation of host–microbiota interaction through dietary intervention in order to induce change in host physiology, including development and progression of diseases. Diet can bring changes in composition of gut microbiome and function in an individual specific manner. Big data platforms and machine learning tools are being applied to datasets combining microbiome and clinical features , in order to relate specific foods to physiology, including external influences from drugs and antibiotics and specific outcomes such as cardiovascular risk (Kolodziejczyk et al. 2019; Wan et al. 2019; Dudek-Wicher et al. 2018) (Table 21.1).

Plant Extract-based Therapy

Dietary polyphenols are one of the major plant fiber families, identified in tea, coffee, vegetables, and fruits. They are grouped into flavonoids and nonflavonoids. Similar to other potentially bioactive/phytotherapeutic agents, a small proportion of polyphenols are absorbed in the small intestine, while most of them collect in the large intestinal lumen, where they are acted upon by gut microbiota for further enzymatic processing.

Conversion of polyphenols and other fibers into bioactive compounds in gut can influence the population of gut microbiota and affect host health, including cardiovascular risk, obesity, and other metabolic diseases (Brochot et al. 2019). Most available microbiome investigations were conducted in mice; however, a few reviews and meta-analyses in humans, not necessarily addressing metabolic diseases, are starting to appear.

One of them focused on all types of fiber. Concentrations of *Bifidobacterium spp*. and *Lactobacillus spp*. were elevated , along with fecal butyrate. Fructans and galacto-oligosaccharides were endowed with the most robust effects of the microbiome (So et al. 2018). The favorable impact of prebiotic fibers concerning *Bifidobacterium* was confirmed in another meta-analysis (Wilson et al. 2019).

As regards metabolic syndrome, cardiovascular and neurodegenerative disorders, reviews with polyphenols and resveratrol suggest possible benefit, however, insisting that data are preliminary and sometimes inconsistent (Potì et al. 2019; Chaplin et al. 2018).

Abstract

Clinical availability of anti-obesity drugs is limited, and their inadequate effectiveness and safety concerns sometimes discourage widespread use. A therapeutic vaccine has the potential to be an attractive tool for preventing and treating obesity, because of the possibility of prolonged therapeutic effect and low frequency of administration. Experimental investigations have shown that vaccines targeting endogenous molecules that promote obesity could be a viable alternative. Recent novelties in drug-delivery systems and biotechnology will support further progress in vaccine development. This chapter provides an overview of recent advances in the area.

Keywords

Adenovirus 36 · Adipocyte · Glucose-dependent Insulinotropic Polypeptide · Ghrelin · Immunotherapy · Somatostatin · Vaccine

Introduction

The worldwide prevalence of obesity has markedly increased (nearly tripled in 40 years) (Flegal et al. 2013; Wilson et al. 2002; WHO 2020), and it is predicted that the condition will cost the U.S. healthcare system $48–$66 billion a year by 2030 (Wang et al. 2011). To combat the cardiometabolic comorbidities of obesity and their economic burden, global strategies for obesity prevention and treatment are required.

Lifestyle Interventions

Lifestyle initiatives targeting energy intake and physical activity are generally the first approach to weight reduction (Bray et al. 2016). They can trigger a 5–8% reduction in body weight (Heymsfield and Wadden 2017). However, obese persons often lack the motivation to continue with lifestyle management for weight reduction, because obesity is usually asymptomatic. Therefore, long-term weight management in obese persons remains a difficult task, and weight regain is a common problem following weight loss intervention (Heymsfield and Wadden 2017).

Pharmacological Management

The following prescription agents are approved by the U.S. Food and Drug Administration: phentermine (sympathomimetic amine), orlistat (lipase inhibitor), phentermine–topiramate (sympathomimetic amine and an antiepileptic drug), lorcaserin (5-HT2c receptor agonist), naltrexone–bupropion (opioid antagonist and aminoketone antidepressant), and liraglutide (glucagon-like peptide-1 [GLP1] receptor agonist). Yet relatively few patients receive sustained pharmacologic therapy for reasons that encompass insufficient weight loss, side effects, and prompt recurrence of obesity after treatment be interrupted (Heymsfield and Wadden 2017).

The Role of Vaccines

A therapeutic vaccine may be a potential candidate for improving treatment adherence. In general, a vaccine has prolonged therapeutic effects and low frequency of administration, when it succeeds in inducing neutralizing antibodies against a target molecule (Table 22.1).

Features of Therapeutic Vaccines

Therapeutic vaccines for the treatment of chronic diseases have the potential to increase treatment adherence, reduce healthcare costs, and offer enhanced specificity for target molecules. When administration of a therapeutic vaccine successfully induces antibodies that bind to the target self-molecule and inhibit its

Table 22.1 Potential vaccines targeting obesity

Target	Antigen	Species/References	Effect
Ghrelin	Ghr1 (1–10 a.a.)—KLH Ghr2 (13–28 a.a.)—KLH Ghr3 (1–28 a.a.) KLH	Male Wistar rat (Zorrilla et al. 2006)	No change in food intake 20% reduction in weight gain (Ghr1, Ghr3)
	Ghrelin (1–10 a.a.)—BSA	Male/female piglet (Vizcarra et al. 2007)	15% reduction in food intake 10% reduction in weight gain
	Ghrelin–NS1 (VLP-based)	DIO male C57BL6/J mouse (Andrade et al. 2013)	Decrease in food intake Increase in energy expenditure No change in weight gain
Adipocyte	Pig adipose tissue	Male/female human adult (Bourinbaiar and Jirathitikal 2010)	No change in body weight 7.6% reduction in waist size 25.9% increase in HDL-C
	Mouse adipocytes	Male/female Sprague Dawley rat (Lai et al. 2010)	About 50% reduction in weight gain
Somatostatin	Somatostatin-CAT	DIO male C57BL6/J Mouse (Haffer 2012)	12–13% reduction in body weight No change in food intake
Adenovirus 36	Inactivated Ad36	Ad36-infected C57BL6/J mouse (Na and Nam 2014)	No change in food intake 17% reduction in weight gain 20% reduction in epididymal fat

BSA, bovine serum albumin; DIO, diet-induced obesity; KLH, keyhole limpet hemocyanin; NS1, non-structural protein 1; VLP, virus-like particle

function, the vaccine should have a long-term therapeutic effect. In the case of hypertension vaccines, three doses of a peptide vaccine targeting angiotensin II type 1 receptor reduced blood pressures for 24 weeks after final immunization in hypertensive rats (Azegami et al. 2012), and a DNA vaccine targeting angiotensin II decreased blood pressure for at least 6 months in rats (Koriyama et al. 2015). The prolonged therapeutic effects of such vaccines will mean a low frequency of administration and may result in increased treatment adherence and savings in medication costs.

In addition to their prolonged effect, therapeutic vaccines have the potential to have greater specificity to target molecules compared with conventional low-molecular-weight drugs (Hansel et al. 2010). In general, high specificity to the target tends to result in few off-target effects and low rates of drug–drug interaction, and it may reduce the incidence of side effects (Hansel et al. 2010). Therapeutic vaccines also have some advantages over monoclonal antibody therapy, including lower production costs, no possibility of inducing anti-drug antibodies, and less frequent dosing (Hansel et al. 2010).

Ghrelin Vaccines

The especial feature of the ghrelin peptide is the *O*-acylation at the Ser^3 residue. It uniquely stimulates food ingestion with diminished energy expenditure (Kojima et al. 1999; Nakazato et al. 2001; Tschop et al. 2000; Wortley et al. 2004). Peripheral ghrelin, which is produced mainly in the gastric X/A-like cells, modulates the nucleus tractus solitarius via the vagus nerve. This results in an increase in noradrenaline in the arcuate nucleus of the hypothalamus and consequent appetite stimulation (Date et al. 2006). *O*-acylation at Ser^3 with octanoate, which is mediated by ghrelin *O*-acyltransferase (GOAT), provides the orexigenic action of ghrelin (Yang et al. 2008); unacylated ghrelin negatively impacts appetite and body weight (Asakawa et al. 2005).

Laboratory experiments demonstrate that antagonization of ghrelin ameliorates obesity. Genetic deletion of ghrelin increases energy

expenditure and locomotor activity in mice, which are less prone to diet-induced obesity (Wortley et al. 2005). Genetic deletion of ghrelin receptor (growth-hormone secretagogue receptor: GHSR), GHSR antagonists, and GOAT inhibitors attenuate diet-induced obesity in mice (Zigman et al. 2005; Maletinska et al. 2011; Barnett et al. 2010). However, as of 2019, no anti-obesity drug that targets ghrelin function—such as a ghrelin inhibitor, GHSR antagonist, or GOAT inhibitor—has been clinically available.

Vaccine Against Synthetic Ghrelin Peptides

Zorrilla et al. (2006) synthesized three ghrelin peptides (Ghr1, Ghr2, and Ghr3) for vaccine development in 2006. Keyhole limpet hemocyanin (KLH) and a couple of adjuvants were attached, and antigen-specific antibodies were elicited. Only Ghr1-KLH and Ghr3-KLH induced weight reduction (by 20%) (Zorrilla et al. 2006).

Also in a porcine model, vaccine comprising the N-terminal residues (1–10) of porcine ghrelin, combined with additional molecules, diminished appetite and weight accrual in piglets (Vizcarra et al. 2007).

Virus Like Particles (VLPs)

VLPs are viral proteins that reliably self-assemble and exhibit antigenic epitopes (Kushnir et al. 2012). Clinical trials in other areas have confirmed the concept (Maurer et al. 2005; Ambuhl et al. 2007). Also a ghrelin VLP vaccine was arranged and, in rodents, diminished appetite however not body weight (Andrade et al. 2013). More extensive studies are necessary in the area.

Nanogel-based vaccine

Advances in nanomaterial development have also been applied to the development of innovative anti-obesity vaccines. To avoid the risk of localized skin adverse events and psychological and physiological stress, when vaccines are administered by using injectable delivery methods, nanoparticle drug delivery to mucosal surfaces is an option (Lamichhane et al. 2014). Nanometer-sized polymer hydrogels (nanogels) can incorporate various proteins through hydrophobic interactions and subsequently allow their release in their native form (Azegami et al. 2018). The cationic type of cholesteryl-group-bearing pullulan (cCHP) nanogel is adequate for local application and interaction with nasal dendritic cells (Nochi et al. 2010). A recombinant fusion protein based on mouse ghrelin and PspA (pneumococcal surface protein A), paved the way for an intranasal vaccine using cCHP nanogel. In mice, serum IgG antibodies were elicited and weight gain was reduced (by 7%). Mitochondrial uncoupling protein 1 in brown adipose tissue was upregulated (Azegami et al. 2017).

Glucose-dependent Insulinotropic Polypeptide (GIP) Vaccines

GIP, as one of incretins, promotes pancreatic insulin secretion in a glucose-dependent manner (Sadry and Drucker 2013), and increases adipose tissue (Miyawaki et al. 2002). In animal experiments, a GIP receptor antagonist attenuated diet-induced obesity and subsequently improved glucose metabolism (McClean et al. 2007). GIP combined with bacteriophage Qβ VLPs allowed the development of a vaccine. In a mice model, weight gain was inhibited (by 35%), without hyperglycemia. The anti-obesity response was attributed to elevation of energy expenditure (Fulurija et al. 2008).

Adipocyte Vaccines

A small clinical trial with oral tablets of pig adipose tissue was conducted for 3 months (Bourinbaiar and Jirathitikal 2010). Waist circumference decreased (by 7.6%), however not

body weight. In turn, an intraperitoneally injected xenogeneic adipocyte vaccine in rats was followed by adipocyte apoptosis and 50% amelioration of weight increase (Lai et al. 2010).

Somatostatin Vaccine

Pharmacological supplementation with growth hormone (GH) decreases body fat in obese adults (Kim et al. 1999); however, the clinical applications of GH are limited by its very short half-life. Vaccine inhibition of somatostatin, which blocks GH secretion, was attempted by means of intraperitoneal immunization with somatostatin and carrier protein chloramphenicol acetyltransferase. Weight reduction (by 12–13%) and IgG production were achieved (Haffer 2012).

Adenovirus 36 (Ad36) Vaccine

In some large series, many obese persons tested positive for antibodies against Ad36 (Atkinson et al. 2005), and animals respond to Ad36 challenge with increased adiposity (Dhurandhar et al. 2002). An Ad36-based vaccine in mice was successful in preventing body fat elevation (Na and Nam 2014).

Future Possibilities

As therapeutic vaccines elicit the production of antigen-specific antibodies to neutralize biomolecules that promote weight gain, not only ghrelin, GIP, adipocytes, and somatostatin, but also other endogenous molecules can be targeted. The therapeutic vaccine approach is feasible for pathways with which no small-molecule drug has yet been able to interact. Brain and intracellular molecules that cannot be reached by neutralizing antibodies would not be suitable targets. In addition, enhancement of the immune reaction is a trade-off between preferable humoral immune responses and undesired autoimmune reactions.

Better selection of epitope sequences from self-antigens and adjuvants designed to elicit Th2 activity will help to induce Th2-dominant humoral immune responses. Enhanced drug-delivery systems and biotechnology will also help to develop effective and safe vaccines.

Contents

Abstract

Metabolic syndrome (Met S) has emerged as one of the major public health concerns of the modern times. Identification of this condition is based upon existence of certain features of clinical and metabolic disarray such as central obesity, hypertension, elevated plasma glucose, and dyslipidemias. Pathogenesis of Met S is an interplay of genomic and acquired factors that alter pathways of insulin action, along with inflammation, pro-oxidative, and

thrombotic cascades. Although genetic predisposition determines the susceptibility to various environmental modulators, lifestyle and dietary habits are usually central in the onset and progression of type 2 diabetes mellitus, hypertension, and dyslipidemias. Nutritional genetics might help in understanding the effects of different food constituents on gene regulation resulting in diet-related metabolic disorders. A healthy gut microbiome is also important in the prevention of type 2 diabetes mellitus, Met S, and cardiovascular diseases.

Introduction

Metabolic syndrome (Met S) refers to the aggregation of clinical and biochemical derangements that considerably increase the risk of coronary artery disease (CAD), diabetes mellitus (DM), and hepatic steatosis. These include high blood pressure, central obesity, dyslipidemias, and impaired blood glucose levels (Roberts et al. 2013). Met S was described for the first time by the Swedish physician Eskil Kylin in 1923 as an association of gout with impaired glycemic indices, obesity, and hypertension (Nilsson 2001). The hypothesis of insulin resistance (IR) as a core defect in Met S was forwarded by Gerald Reaven in 1988 when he delivered Banting lecture at the American Diabetes Association meeting and named this entity as Syndrome X. In the following years, Met S was described as "the deadly quartet" and "a secret killer" and besides the concept of IR, central or upper body obesity independent of whole body obesity was regarded to be a leading risk factor for Met S (Kaplan 1989; Foster 1989). Later on, various other studies also confirmed the association of visceral obesity with Met S and the related traits (Katzmarzyk et al. 2006).

Diagnosis: Conflicts and Regional Criteria

In 2005, the International Diabetes Federation (IDF) emphasized upon measurement of waist circumference as a simple screening method for assessment of IR and formulated its guidelines for the identification of Met S. These included abdominal obesity as a mandatory component, along with the presence of any two of the following features: impaired fasting glucose (IFG) or impaired glucose tolerance (IGT), hypertension, low HDL-c, and high triglycerides. It was observed that some ethnic groups showed features of Met S and IR at lower waist circumference levels (Roberts et al. 2013). In 2005, American Heart Association and National Heart Lung and Blood Institute (AHA/NHLBI) reconciled the different diagnostic criteria of Met S. Their recommendations showed difference from IDF guidelines regarding the consideration of waist circumference as a mandatory component of Met S but agreed upon the other four points of IDF definition. Finally, IDF and AHA/NHLBI conceded upon a common criterion. It required three out of the following five factors to be present: ethnic-specific criterion of waist circumference, IFG or IGT, hypertension, low HDL-c, and high triglycerides. These and other criteria for Met S are summarized in Table 23.1, and guidelines for waist circumference can be found in Table 23.2 (Alberti et al. 2009; Zafar et al. 2018; Aguilar-Salinas and Viveros-Ruiz 2019).

Worldwide Growth of Metabolic Syndrome

About 25% of the adult population in most of the countries is suffering from this metabolic derangement (Ranasinghe et al. 2017). Prevalence of obesity and T2DM is in parallel, although not synonymous with Met S (O'neill and O'driscoll 2015). In accordance with the revised guidelines of IDF, prevalence of Met S

Alberti et al. (2009)

in the United States ranges between 35 and 39%, whereas in Europe, it is reported to be 18–30% (Aguilar et al. 2015). In a meta-analysis in the Asian Pacific region, the lowest burden was found in the Philippines (11.9%) and highest was recorded from Aga Khan institutions (49.0%), Pakistan (Ranasinghe et al. 2017). Prevalence of Met S increases with advancing age in a sex-specific manner: below the age of 40 years about 20% of males and 16% of females, between 40 and 60 years 42% of males and 36% of females, and above 60 years 60% of males and 62% females. Aging is generally accompanied by decrease in lean muscle mass and deposition of abdominal fat; both of these increase IR. Moreover, with the aging process, specific defects in fatty acid oxidation in muscles also occur which further decrease insulin sensitivity (Ervin 2009).

Involved Organs and Pathways

Phenotypic expression of Met S is the result of acquired and genetic factors: (1) insulin resistance, (2) visceral obesity and adipose dysfunction, and (3) oxidative stress, proinflammatory, and prothrombotic state. One of the core defects in Met S is resistance to insulin actions (McCracken et al. 2018). It is associated with accelerated atherosclerotic cardiovascular disease, hyperuricemia/gout, chronic kidney disease, and obstructive sleep apnea.

Mechanism of Insulin Action

Insulin on reaching the target area rapidly interacts with its transmembrane tetrameric tyrosine kinase receptor, having two alpha and two beta domains. Alpha domains are extracellular and exhibit insulin-binding site. Beta domains are extracellular, transmembrane, and intracellular. Binding of insulin with the alpha domain results in auto-phosphorylation of tyrosine molecules in the beta domains at three sites: 1158, 1162, and 1163. This activated insulin receptor-kinase results in further phosphorylation of tyrosine molecules of the insulin receptor substrate (IRS) and acts as a docking site for IRS and other downstream effector proteins such as growth factor receptor-binding-protein 2 (Grb2), shc, and many others.

Insulin receptor phosphorylation and excitation leads to the activation of the following two downstream post-receptor signal transduction pathways: (1) Phosphoinositide kinase 3 (PI3-K)/protein-kinase-B (Akt)/molecular target for rapamycin (mTOR) and (2) ras-raf-mitogen-activated protein kinase (MAPK). PI3-k on phosphorylation by IRS-1 further activates phosphoinositide diphosphate (PIP2) to phosphoinositide triphosphate (PIP3), followed by the Akt activation and its recruitment to the cell membrane (Boucher et al. 2014).This activated Akt is responsible for various metabolic actions of insulin such as translocation of insulin-sensitive glucose transporter 4 (GLUT4) expressed by adipocytes and muscles, and inactivation of the enzyme glycogen synthase kinase (GSK), making it incapable of inhibiting the enzyme glycogen synthase, thus promoting conversion of glucose to glycogen. GSK is also a potent inhibitor of eukaryotic initiation factor (eIF) 2B required for the synthesis of cellular proteins. This process is reversed by the insulin-mediated activation of Akt, thereby increasing the production of proteins (Fig. 23.1). PI3-K/Akt pathway is responsible for various cellular

metabolic responses to insulin, while ras-raf-MAPK is responsible for gene expression and mitogenesis (Draznin 2010).

Insulin Resistance and Molecular Events

IR is described as impairment of insulin-mediated actions at its target areas such as skeletal muscle, liver, and adipocytes. In addition to these classical insulin responsive areas, IR also occurs in brain, gastrointestinal tract, pancreatic beta cells, and vascular endothelial cells (Nigi et al. 2018). There is decrease in tissue response to insulin-stimulated glucose uptake and its utilization, impaired glycogen synthesis, and inability to suppress lipid hydrolysis (Ormazabal et al. 2018). In T2DM and Met S, IR is mainly attributed to post-receptor signal transduction events. Instead of tyrosine, there is serine phosphorylation of insulin receptor substrate-1 (IRS-1) that leads to the decreased association of p-85KDA subunit of PI3-K with IRS-1, resulting in diminished activity of the enzyme PI3-K and impaired activation of the downstream signaling cascade.

This altered association of PI3-K with IRS-1 is highly correlated with decreased insulin-stimulated disposal of glucose by the skeletal muscles and also reduced activity of the glycogen synthase. There is also impaired PI3-K gene regulation in the skeletal muscles and similar derangement in adipose tissue of type2 diabetics. In 80–90% of type 2 diabetics, impaired phosphorylation of IRS-1 and PI3-K has been observed, despite of normal insulin receptor tyrosine phosphorylation (Wilcox 2005).

Insulin Resistance and Cardiovascular Disease

Insulin stimulates endothelial nitric oxide synthase (NOS) through PI3-K/Akt pathway, which in turn leads to the increased production

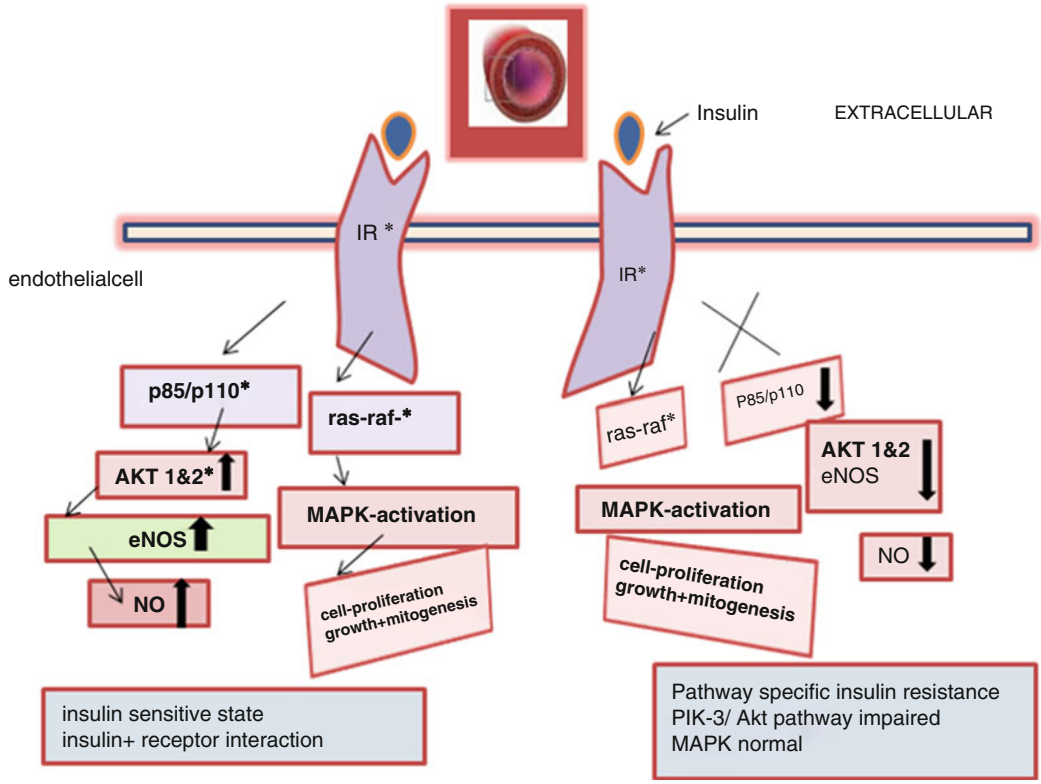

Fig. 23.2 Pathway dependent insulin resistance in endothelium. *eNOS* endothelial Nitric oxide synthase, *IR* insulin receptor, *MAPk* mitogen activated protein kinase, *NO* nitric oxide, *PIK3* Phosphoinositide kinase

of NO in the blood vessels. Insulin also activates MAPK pathway, thus promoting vascular smooth muscle proliferation. In states of IR, there is impairment of PI3-K activation while MAPK pathway remains intact (Fig. 23.2). This results in the attenuation of NO-mediated inflammation buffering actions, while increased MAPK-stimulated cellular proliferation sets the stage for endothelial dysfunction and vascular disease (Fulton 2009).

Skeletal Muscle IR

Skeletal tissue is the major area for the removal of excessive blood glucose. In IR and T2DM, insulin-stimulated uptake of glucose is reduced through GLUT4 as there is uncoupling of IRS-1 from insulin receptor, due to the phosphorylation of threonine/serine residues of IRS-1 (Fig. 23.3). Intracellular glucose utilization and synthesis of glycogen are also markedly compromised (DeFronzo and Tripathy 2009; Ruiz-Alcaraz et al. 2013). The exact cause of the skeletal tissue IR is not known.

Previous studies have linked this insulin-resistant state to the accumulation of intra-myocellular lipid metabolites such as diacylglycerol (DAG) and ceramides. Increased deposition of fat within the skeletal muscles could be a consequence of the excess supply of free fatty acids, or reduced rate of lipid oxidation within the muscles. Various studies have revealed intrinsic defects in mitochondrial capacity to oxidize fatty acids independent of the plasma free fatty acid levels, in T2DM and obesity. Insulin-resistant normo-glycemic offspring of type 2 diabetics are unable to increase the

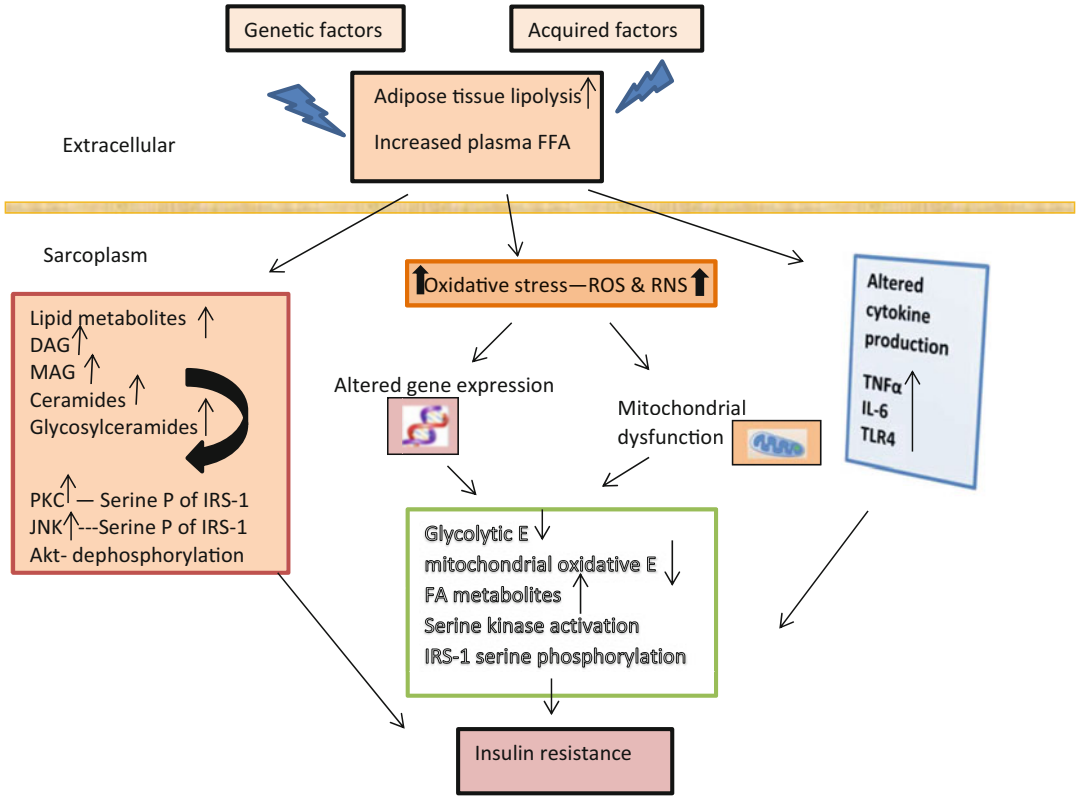

Fig. 23.3 Mechanisms linking lipotoxicity with skeletal insulin resistance. DAG (diacylglycerol); E (enzyme); FFA (free fatty acids); IL-6 (interleukin 6); IRS-1(insulin receptor substrate 1); JNK (janus kinase); MAG (monoacylglycerol); PKC (protein kinase C); RNS (reactive nitrogen species); ROS (reactive oxygen species); TLR4 (toll like receptor 4); TNFα (tumor necrosis factor alpha)

mitochondrial oxidative ability. Spectroscopic and biochemical studies provide evidence for the impaired activity of electron transport chain, decreased activity of mitochondrial enzymes and rate of synthesis of ATP (Abdul-Ghani and DeFronzo 2010).

Hepatic IR

Central obesity, adipose dysfunction, and muscle IR result in the diversion of metabolites toward the liver and accumulation of DAG in the hepatocytes. Lipolysis in the adipose organs is an important source of circulating free fatty acids that promote hepatic IR and steatosis. Non-alcoholic fatty liver disease (NAFLD) occurs when lipid transport to the liver exceeds its capacity to oxidize or export the lipids. Hepatic inflammation is the outcome; however, it can also be one of the causes of IR, especially in the presence of gut dysbiosis and lipopolysaccharide translocation. Due to accumulation of DAG in the hepatocytes, there is activation and translocation of protein kinase C to the cell membrane that results in altered phosphorylation of IRS-2, and diminished activation of PI3-K and Akt. Transcriptional activity of the enzymes involved in gluconeogenesis, i.e., glucose-6-phosphatase and PEPCK gene promoters is regulated by the forkhead box protein O (FOXO) 1 and 3 class of transcription factors (Fig. 23.4).

These factors are inactivated and phosphorylated by the insulin responsive Akt. In IR, due to impaired Akt activation, there is decreased FOXO-1 factor phosphorylation. As a

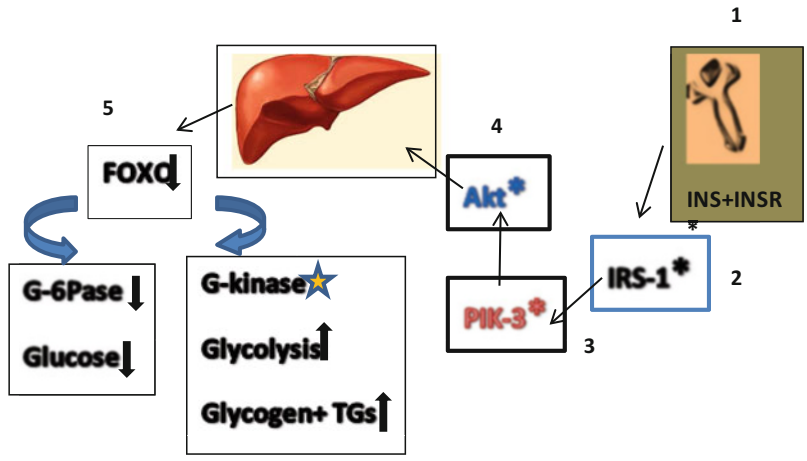

Fig. 23.4 Regulation of FOXO transcription factors by insulin. *AKT** protein kinase B activation, *FOXO* forkhead-box-protein-O inhibited, *G6Pase* glucose 6 phosphatase, *GKinase* Glucokinase activated, *INS+INSR** insulin + insulin receptor substrate activation, *PIK-3** phosphoinositide 3 kinase activation, *TGs* triglycerides

result, this transcription factor enters the nucleus and switches on the activity of the abovementioned rate determining enzymes, resulting in overt hyperglycemia. A paradox of selective IR is the inability of insulin to suppress hepatic glucose production, whereas its capability to activate lipogenesis and synthesis of triglycerides remains intact (Perry et al. 2014; Sparks et al. 2012). In IR and type 2 DM, there is hypersecretion of very low-density lipoproteins (VLDL) by the liver due to accelerated synthesis of Apo B, and increased hepatic influx of free fatty acids released from the adipose tissue. Persistent nuclear localization of FOXO-1 transcription factor also increases the expression of microsomal transfer protein (MTP) and apoC-111 by the hepatocytes (Samuel and Shulman 2016). There is increased hepatic production of inflammatory mediators such as plasminogen activator-inhibitor (PA-I) and C-reactive protein (CRP). These metabolic abnormalities contribute to the process of atherosclerosis (Rehman and Akash 2016).

Adipose Tissue IR

Adipose tissue influences lipid and glucose metabolism by the release of FFA, adipokines, and other inflammation provoking factors. Insulin acts on adipocytes by (1) stimulating uptake of glucose and synthesis of triglycerides, (2) suppressing breakdown of triglycerides and release of free fatty acids and glycerol into the blood. In adipose tissue IR, there is impaired suppression of triglyceride hydrolysis with increased release of FFA into the blood that results in altered skeletal muscle insulin signaling, glucose intolerance, uncontrolled hepatic gluconeogenesis and increased triglyceride synthesis (Gastaldelli et al. 2017). In states of central obesity or insulin resistance infiltration of white adipose tissue (WAT) with macrophages promotes lipolysis, resulting in increased release and delivery of FFA to the liver. This further enhances synthesis of triglycerides by the liver and aggravates hyperlipidemia. Moreover, increased delivery of FFA to the liver also accelerates hepatic gluconeogenesis that further worsens IR (Samuel and Shulman 2016).

Lipotoxicity and Glucotoxicity

In IR and obesity, insulin-mediated inhibition of lipolysis in the adipocytes is impaired which results in the increased release of free fatty acid in the blood. Persistent rise in plasma free fatty acids leads to their deposition in non-adipose

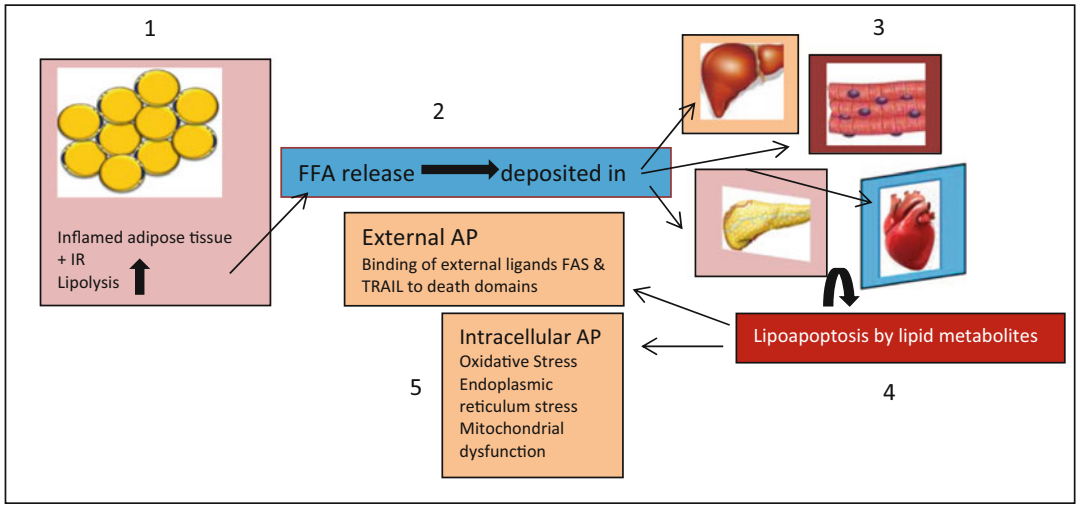

Fig. 23.5 Lipoapoptosis mediated by lipid metabolites. *AP* apoptotic pathway, *FFA* free fatty acids, *IR* insulin resistance

tissues (ectopic fat). The detrimental effect of lipid metabolites in skeletal muscles, liver, kidney, pancreas, and heart is one of the forms of "lipotoxicity" (Del Prato 2009) whereas "glucotoxicity" implies the injurious effects of glucose on the cells (Mota et al. 2016). In chronic hyperglycemia, due to increased glucose accumulation in the cells equilibrium between the defensive anti-oxidative mechanisms and synthesis of reactive oxygen species (ROS) is deranged. Lipotoxicity and glucotoxicity induce metabolic stress through diverse pathways such as ROS-mediated caspase activation followed by apoptosis, endoplasmic reticulum stress, insult of the mitochondrial oxidative pathways, alteration of insulin signaling by modification of protein kinase C, and dysregulation of renin-angiotensin cycle in the tissues. ROS-mediated alteration of cellular proteins (Fig. 23.5) results in various vascular complications of diabetes mellitus (Berdja et al. 2016).

Role of Inflammation in Met S

In obesity, excessive fat deposition in perivisceral and omental areas is closely associated with chronic inflammation and immune response; however obesity-related inflammation occurs in other organs as well, i.e., liver, skeletal muscles, pancreas and brain (Saltiel and Olefsky 2017). Adipose tissue hypoxia in hypertrophied adipose organs can initiate inflammation by the activation of hypoxia inducible factor-1 gene and upregulation of various other pro-inflammatory genes (Lee et al. 2014). Another proposed mechanism is that in obesity intestinal permeability is increased that results in higher blood levels of lipopolysaccharide (LPS) from intestinal bacteria. LPS can trigger inflammation by activation of toll-like receptor 4 (TLR) and other pattern recognition receptors located in the adipocytes and the liver (Amar et al. 2011). Moreover, increased circulating levels of various lipid-derived factors such as free fatty acids can initiate inflammation by binding with TLR 4 and 2, that trigger activation of nuclear factor kappa B and janus kinase 1.

These pathways on activation result in the increased production of chemokines such as MCP-1 (monocyte chemoattractant protein-1) by the adipocytes and the liver, which lead to the infiltration of these organs with the inflammatory macrophages.

In the lean adipose tissue, 10% of the total cell mass is constituted by macrophages while in obese fat the count is increased up to 40%.

These resident macrophages are categorized as M1 (classically activated) and M2 (alternatively activated) macrophages. M2 secrete insulin-sensitizing adipokines and anti-inflammatory factor as IL-10 and arginase (Saltiel and Olefsky 2017). On the other hand, there is increased production of pro-inflammatory cytokines such as tumor necrosis factor alpha (TNF-α), IL-6, and IL-12 by the M1 (Navarro-Gonzalez and Mora-Fernández 2008).

In the obese adipose tissue, the M1 to M2 ratio is considerably increased and M1 is intimately linked with inflammation and IR (Castoldi et al. 2016). In conclusion, inflammation follows obesity and it plays a significant role in the onset of IR, defective insulin secretion, and disruption of metabolic homeostasis (Saltiel and Olefsky 2017).

Adipose tissue a multifunctional metabolically active endocrine entity is involved in the production of a wide range of bioactive molecules such as cytokines, prostaglandins, hormones, and growth factors (Schmidt et al. 2015). In central obesity due to infiltration of visceral AT with M1 as compared to the M2 macrophages, secretion of proinflammatory cytokines such as TNF-α and IL-6 is increased whereas production of anti-inflammatory cytokines is suppressed.

Proinflammatory Cytokines

TNF-α was the first cytokine found to be positively associated with IR and obesity (Makki et al. 2013). TNF-α directly interferes with insulin signal transduction pathways by serine phosphorylation of IRS-1. It induces IR indirectly by alteration of adipocyte maturation and lipid homeostasis. TNF-α also aggravates the immune response by increasing the production of IL-6, a pro-inflammatory cytokine, and suppressing the expression of adiponectin, an adipose-derived insulin-sensitizing hormone (Makki et al. 2013).

IL-6 a multifarious peptide plays a central role in the regulation of immune mechanisms, inflammation, and host defense response. About one-third of the IL-6 circulating in the blood is derived from skeletal muscles, a small proportion is released from adipocytes, and the rest being originated from macrophages and other cells. Transient increase in IL-6 levels assists in maintaining normal glucose homeostasis whereas long-term increase in circulating IL-6 may lead to IR. IL-6 seems to play a dual role depending upon the metabolic demands and states of the tissues. During exercise IL-6 promotes glucose uptake by the skeletal muscles and increases AMP-mediated oxidation of fatty acids, leading to myogenesis and muscle hypertrophy. However, IL-6 exerts pro-inflammatory effects on adipocytes and liver by impairing insulin receptor and IRS-1 signaling, due to increased activation of SOCs3 (suppressor of cytokine signaling 3) (Senn et al. 2003). It worsens IR by inhibiting adipogenesis and differentiation of the stem cells to their mature state, dysregulating fatty acid metabolism, and downregulating the expression and production of adiponectin by the adipocytes (Pricola et al. 2009).

Leptin is an adipose-derived adipokine which under physiological states suppresses appetite, increases sympathetic activity and energy expenditure, and modulates neuroendocrine activity, by acting on the leptin receptor (ObRb) in the hypothalamus. Leptin exerts its insulin-sensitizing effects by promoting glucose uptake and fatty acid oxidation in the skeletal muscles (Mantzoros et al. 2011). However, elevated leptin levels are associated with abdominal obesity, increased risk of cardiovascular complications, and insulin resistance, being a biomarker for Met S (Li et al. 2011). In obese subjects, despite the high leptin levels, its effect as anorexic hormone is reduced due to leptin resistance that results from defects in molecular mechanisms associated with leptin receptor signaling, or decreased permeability of leptin through the blood-brain barrier (Gruzdeva et al. 2019).

Adiponectin, another adipose-derived hormone, acts as an intrinsic insulin sensitizer. It inhibits gluconeogenesis in the liver and promotes fatty acid oxidation and glucose uptake by the skeletal muscles. Adiponectin also reduces plasma concentration of low-density lipoprotein and apolipoprotein B, and low blood adiponectin

levels are found to be associated with hypertension. Adiponectin expression is suppressed by the pro-inflammatory cytokines, implying that inflammation is an important factor leading to hypo-adiponectinemia in obese and insulin-resistant states (Zhang et al. 2015). Most of the adipose-derived factors with the exception of adiponectin and adipsin show a positive association with total adipose mass and insulin resistance. The altered adipokine profile results in profound changes in insulin sensitivity, metabolic health, and energy homeostasis (Kumari et al. 2019).

Thrombotic Mediators and Prooxidants Associated with Metabolic Syndrome

Plasma thrombotic factors apo111 and CRP, uric acid, and ferritin levels also deserve attention (Thaman and Arora 2013). Plasminogen activator inhibitor 1 (PAI-1) is released from adipocytes, endothelial cells, and vascular smooth muscles. In insulin-resistant states, its secretion is increased due to various prooxidant and inflammatory factors. Increased circulating PAI-1 levels are intimately associated with deep venous thrombosis and myocardial infarction. Uric acid, an end-product of purine metabolism, is predominantly produced by the liver (McGillicuddy et al. 2009). In conditions of inflammation and IR, its levels in the blood represent oxidative tissue damage. Various studies have demonstrated that serum uric acid levels significantly correlate with Met S-related traits and associated future comorbidities, such as stroke and coronary artery disease (CAD). In the extracellular environment, such as blood vessels, uric acid acts as a powerful antioxidant by scavenging free oxygen species and chelating metals, whereas inside the cells, it exhibits prooxidant properties. It accelerates lipid peroxidation that decreases cholesterol transport, leading to inflammation. It induces vascular damage by increasing TNF-α secretion and decreasing NO-mediated vasodilation (McGillicuddy et al. 2009).

Is the Gut Microbiome Involved?

Various studies have reported the significant contribution of gut microbiome as an environmental factor toward the pathogenesis of IR and adiposity (Kho and Lal 2018). There is colonizing of the mucosal lining of human body by distinct microbial ecosystems (Arora and Bäckhed 2016). In addition to bacteria, these include viruses, phages, fungi, and yeasts. Dietary factors can modify the gene expression of gut microbes, that in turn influence host metabolism. Different macronutrients present in the food serve as substrates for the gut bacteria and results in the production of short-chain fatty acids (SCFAs) and bile acid metabolites. The SCFAs contributed by the gut microbial population include butyrate, propionate, acetate, and hexanoate. SCFAs increase the gut glucose absorption by enhancing the expression of sodium-glucose transporters in the enterocytes (Fig. 23.6).

These bacterial products also induce the release of incretins, leptin, and peptide YY by the enteroendocrine cells that affect satiety and modulate host energy homeostasis (Festi et al. 2014). SCFAs influence host lipid metabolism by promoting lipogenesis and inhibiting free fatty acid oxidation. Besides the synthesis of SCFAs, gut microbiota also synthesize micronutrients such as vitamin K1, K2, B5, and B12. Gut microbes also play an essential role in the interaction of bile acid metabolites with the host (Kho and Lal 2018).

Microbe and Host Cell Cross Talk

In the gastrointestinal tract, there is constant interaction between the lining epithelial cells and the gut microbiota. The host cells transmit key information from the gut bacteria to the immune cells located in the *lamina propria.* In normal conditions, the gut barrier (tight epithelial junctions, protective thick mucosal lining with various antimicrobial factors, inter-epithelial immune cells, and production of immunoglobulin

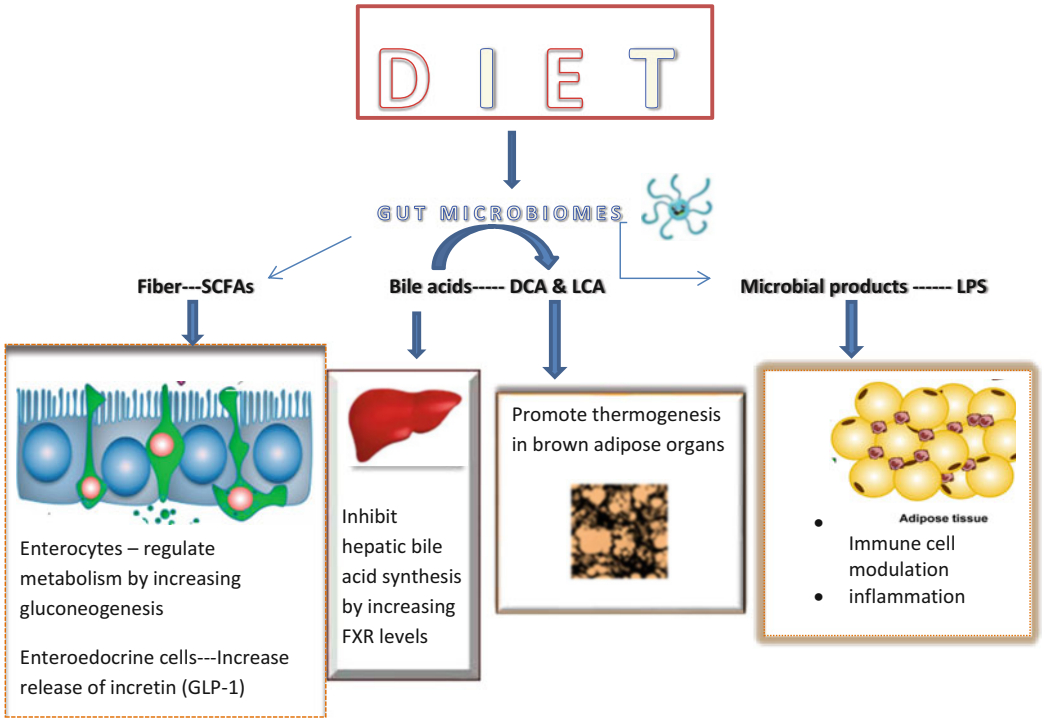

Fig. 23.6 Interaction between diet and gut microbes. *DCA* deoxycholic acid, *FXR* farnesoid × receptor, *GLP-1* glucagon like peptide-1, *LCA* lithocolic acid, *LPS* lipopolysaccharides, *SCFAs* short chain fatty acids

A) prevents translocation of microbes and deleterious metabolites. With bowel inflammation or unbalanced diet, certain bacterial components such as lipopolysaccharides (LPS) gain access through the protective mucosal barrier, and via interaction with the gut innate immune system can initiate low-grade inflammation and insulin resistance. The condition of increased gut microbe-derived lipopolysaccharides in the blood is termed as metabolic endotoxemia.

Immune Activation in Dysbiosis

The cells of innate immune system have various microbe monitoring sites such as toll-like (TOLs) receptors and nucleotide-binding oligomerization domain (NODs) receptors. TOLs are transmembrane proteins in the lysosomal compartment, whereas NODs are intracytosolic. These receptors can detect pathogen linked or danger linked molecular patterns from the microbes such as lipopolysaccharides, peptidoglycans, and lipoteichoic acid (Vidal 2019). In T2DM, there is reduction in butyrate-producing microbiome, whereas *Lactobacillus sp*. levels are increased (Arora and Bäckhed 2016). The microbe-derived product trimethylamine (TMA) plays a potential role in the development of atherosclerosis and cardiovascular diseases (CVD). TMA is readily converted to TMAO (trimethylamine-N-oxide) by the liver, and it is a biomarker for atherosclerotic lesions and CVD. Metagenomic studies have revealed that certain bacterial taxa observed in atherosclerotic plaques have also been found in the gut and oral cavity of the same subjects. This highlights the possibility that the gut microbiota may be the source of bacteria in the atherosclerotic vascular areas and in turn contribute to the pathogenesis of CVD.

Genetic Links Determine Susceptibility to IR and Met S

Met S and its heterogenous features have polymorphic genetic etiology (Ziki and Mani 2016).

The role of genetics has been estimated at between 44 and 65% for T2DM and dyslipidemias, and it is also very high for the other features of Met S, i.e., obesity and hypertension (Brunetti et al. 2014). Many of the genetic loci identified by candidate gene analysis and GWAS are linked with beta cell function, insulin secretion, insulin resistance, and lipid or energy homeostasis (Brown and Walker 2016). There is significant role of genetic pool and familial predisposition in the age of onset of Met S and its associated components, progression to the complications and response to the pharmacotherapy (Roomi et al. 2014).

Nutritional Genomics and Epigenetics in Met S

Nutritional genetics is a combination of nutrigenomics and nutrigenetics. Nutrigenomics deal with the effects of different food constituents on gene regulation and expression, while nutrigenetics is the study of individual variations regarding the effect of food constituents on gene expression. Nutritional genetics consider food as a major factor that determines the genetic response through various epigenetic mechanisms such as DNA methylation, histone remodeling, and micro RNA regulation. Stress, lack of exercise, and concomitant endocrine mechanisms also modify gene expression through molecular epigenetic pathways (Kuneš et al. 2015).

Possibilities of Prevention and Therapy

Dietary care in accordance with ATP111 (Alberti et al. 2009; Zafar et al. 2018) recommends to avoid or reduce the consumption of cholesterol, trans, and saturated fat, reduce the intake of refined carbohydrates, and increase the consumption of fruits, vegetables, and whole grains. There is an emergent concept of personalized nutrition which emphasizes that individuals vary in their response to macronutrients depending upon the genotype, microbiome, immune system, and phenotypic profile (Ludwig et al. 2018). Weight reduction (7–10% body weight over 6–12 months) is also widely adopted (Ley et al. 2006).

In order to maintain the desired weight, regular physical activity (30 min of moderate activity daily) cannot be overemphasized (Paley and Johnson 2018). Common suggestions include (1) introduction of shorts bouts of physical activity such as 10–15 min of brisk walking, jogging, cycling, or using treadmill and (2) reducing screen time and other sedentary leisure modalities (Naugle et al. 2014).

Use of statins in combination with fibrates especially fenofibrate is attractive to achieve the ATP111 target for LDL as well as HDL-cholesterol. Fenofibrate unlike gemfibrozil does not interfere with the statin metabolism in the liver so chance of myopathy is considerably less.

Another goal is to keep blood pressure (BP) $<$ 120/80. It is preferable to use angiotensin I blockers or angiotensin receptor blockers for the control of BP, as some clinical trials recommend that they have advantages over the other drugs in DM. However, the majority of the studies suggest that risk reduction is with lowering the BP alone irrespective of the drug advised (Abraham et al. 2015; January et al. 2019).

There is an emerging interest in the possibility that lowering IR with metformin also delays the onset of DM and associated comorbidities such as cardiovascular complications in insulin-resistant states. Other considerations include sodium-glucose co-transporter inhibitors and incretin receptor agonists. Good glycemic control by keeping the HbA1c $<$ 7% can delay the onset of cardiovascular complications. Choice of hypoglycemic agent if needed, beyond the lifestyle therapy depends upon the clinical assessment (Chaudhury et al. 2017).

Ongoing Studies and Future Perspectives

- Better recognition of metabolic and genetic factors contributing to the evolvement of IR and associated morbidities. Studies are going on to determine the potential therapeutic role of gene editing tool CRISPR/Cas9 in inflammatory and various immune-mediated diseases (Rodríguez-Rodríguez et al. 2019).
- Bariatric surgery and modern incisionless endoscopic alternatives are endowed with a conspicuously beneficial impact on Met S and its individual components. Despite relatively limited access in some countries, and eventual risks, they should be considered in patients refractory to lifestyle and pharmacologic interventions.

Abstract

Non-alcoholic fatty liver disease (NAFLD) is the most common liver disease, with a worldwide prevalence of 25%. NAFLD represents a spectrum of liver disease severity from simple hepatic steatosis to non-alcoholic steatohepatitis, which is a potentially progressive liver condition with ongoing liver injury. It is strongly associated with obesity, insulin resistance, metabolic syndrome, genetic factors, and lifestyle factors. However, the exact pathophysiology of NAFLD remains to be established. Moreover, the diagnosis of NASH also represents a major challenge. The reference standard in the diagnosis of NASH is considered liver biopsy. Due to its invasive nature, there is a major effort to optimize biochemical and imaging methods in terms of replacing liver biopsy. To date, a combination of noninvasive tests based on blood tests with imaging methods is recommended. Although there is no consensus about the pharmacological therapy of NASH, the international guidelines recommend achieving significant weight loss and lifestyle modification. In conclusion, the combination of high prevalence and its high burden warrant further research in that area.

Keywords

Non-alcoholic fatty liver disease · Non-alcoholic steatohepatitis · Fibrosis · Liver failure · Liver transplantation

Worldwide Growth of Non-alcoholic Fatty Liver Disease

Non-alcoholic fatty liver disease (NAFLD) represents an umbrella term of clinical and pathologic entities, which encompasses simple hepatic steatosis, non-alcoholic fatty liver (NAFL), to non-alcoholic steatohepatitis (NASH), which according to compelling evidence is associated with fibrosis, cirrhosis, and, in some cases, hepatocellular carcinoma (HCC), in the absence of significant alcohol ingestion or other secondary causes of hepatic fat accumulation (Chalasani et al. 2018; European Association for the Study of the Liver (EASL); European Association for the Study of Diabetes (EASD); European Association for the Study of Obesity (EASO) 2016; Kaya and Yılmaz 2019a; Yilmaz 2012a).

There are different NAFLD prevalence reported around the world, mainly due to different study populations, but also due to the heterogeneity of the methods used to diagnose NAFLD. There are numerous noninvasive methods such as conventional ultrasonography, computerized tomography, magnetic resonance imaging (MRI), controlled attenuation parameter (CAP) by transient elastography (TE), and MRI-derived proton density fat fraction (PDFF-MRI). Depending on the accuracy, they can lead to over- or under-diagnosis (Kaya and Yılmaz 2019b). In a comprehensive meta-analysis, NAFLD is recognized as the most common chronic liver disease, with a prevalence of 25% worldwide. The highest prevalence was reported from the Middle East and South America, reaching 32% and 30%, respectively, whereas the lowest corresponds to Africa with 13% (Younossi et al. 2016).

From those 25% of the adult world population, approximately 20% (one-fifth) were classified as NASH corresponding to 16.5 million people (Estes et al. 2018a). Considering the future progress, by 2030 NAFLD prevalence was projected at 33.5%. As a reflection of the ageing population and disease progression, NASH was expected to increase by 27%. In this scenario, NASH is predicted to increase the number of liver-related deaths until 2030 by 178%. Therefore, NAFLD represents a significant public health issue worldwide (Sayiner et al. 2019).

NASH, the more progressive subtype of NAFLD, has an increased risk of proceeding to decompensated liver cirrhosis, hepatocellular carcinoma (HCC), and finally liver failure. Moreover, NAFLD has been recognized as a major contributor to the global burden of HCC. In the coming future, considering the trends of increase in NAFLD prevalence, NAFLD is expected to become the leading cause of HCC (Younossi

et al. 2019a). In addition to this, NASH is the most rapidly growing aetiology for liver transplantation (Estes et al. 2018b).

Correlations with Obesity, Diabetes, and Metabolic Syndrome

The prevalence of NAFLD has increased in many countries both in the paediatric and adult populations as a result of the spread of sedentary lifestyle and westernized diet (Golabi et al. 2018). NAFLD is mostly associated with increased visceral obesity and metabolic abnormalities such as insulin resistance, diabetes mellitus, and dyslipidaemia. It became increasingly clear that NASH is the hepatic manifestation of the metabolic syndrome. Additionally, the prevalence of NASH is higher among diabetic and obese individuals. The risk of developing NASH was also reported to be in line with an increased number of components of metabolic syndrome (Chalasani et al. 2018; Younossi et al. 2019a). Moreover, being female, age over 50 years, obesity, metabolic syndrome, hypertension, dyslipidaemia, and hypertriglyceridaemia were reported as risk factors for developing NASH (Povsic et al. 2019).

According to a recent meta-analysis, more than 80% of NASH patients were overweight or obese (Chalasani et al. 2018). Obesity is known to increase the risk of developing NAFLD (Younossi et al. 2018; Singh et al. 2015). In fact, the prevalence of NAFLD is directly proportional to the increase in body mass index (BMI) (Younossi et al. 2019b). Given that NAFLD is associated with visceral obesity, the mutual evaluation of BMI and waist circumference can be more accurate in the classification of obesity in terms of NAFLD (Mongraw-Chaffin et al. 2015). NAFLD appears to increase at the same rate as obesity (World Health Organization (WHO) 2020; Fan et al. 2017). Although the prevalence of NAFLD was estimated to be around 25%, it could reach 90% in morbidly obese individuals, making possible even further prevalence elevations of NAFLD and related comorbidities (Younossi et al. 2019b).

Obese and Nonobese NAFLD

The majority of the patients undergoing bariatric surgery due to severe obesity have NAFLD, with a prevalence of approximately 95% (Sasaki et al. 2015; Subichin et al. 2015). On the other hand, a subgroup of patients, so-called lean NAFLD, were also reported to have NAFLD, although the BMI is normal (Akyuz et al. 2015; Yılmaz et al. 2019). As known, overweight is defined as >23 kg/m^2 for Asian and >25 kg/m^2 for Caucasian ethnicities (Consultation WHOE; WHO Expert Consultation 2004). Epidemiological data show a prevalence of 5–26% in Asian and 7–20% in Western populations (Consultation WHOE; WHO Expert Consultation 2004). Recent studies showed that NAFLD without the presence of obesity implies added severity, with increased rates of diabetes mellitus, metabolic syndrome and cardiovascular disorders (Sung et al. 2009).

NAFLD and Diabetes

Type 2 diabetes mellitus appears to be a major driver in the development of NAFLD. Moreover, type 2 diabetes mellitus accelerates the progression of liver disease (Stefan et al. 2019). According to a recent meta-analysis, the global prevalence of NAFLD among patients with type 2 diabetes mellitus was estimated to be over 55%, which corresponds to 4.7% of the global population. The prevalence of NASH among the diabetic population is estimated to be around 37%. In the same study, among the biopsied diabetic patients with NAFLD, the prevalence of advanced fibrosis was reported as 17% (Younossi et al. 2019c). Therefore, noninvasive screening of diabetic patients for both NASH and liver fibrosis is recommended, with the use of available noninvasive tools (Arrese et al. 2019).

Additionally, those patients had higher rates of other metabolic comorbidities. The vast majority of diabetic patients with NAFLD met the criteria of metabolic syndrome. More than half of them had hyperlipidaemia and hypertension; approximately one-fourth had cardiovascular disease

(Kalra et al. 2013; Targher and Byrne 2015; Firneisz 2014). In fact, NAFLD itself is significantly associated with an increased risk of cardiovascular events and cardiovascular-related deaths (Targher et al. 2016).

NAFLD is considered the hepatic manifestation of metabolic syndrome due to its frequent coexistence with metabolic syndrome. However, the presence of metabolic syndrome is not sufficient to explain the coexistence of NAFLD. Because neither all the patients with NAFLD fulfil the criteria of metabolic syndrome nor all metabolic syndrome patients have NAFLD (Yilmaz 2012b). In fact, 20–80% of the patients with NAFLD have sufficient criteria for metabolic syndrome (Green 2003). In a recent community-based study, NAFLD alone was not associated with mortality, but those NAFLD patients with metabolically abnormal profiles had an increased risk of mortality (Niriella et al. 2019).

The Natural Course of NAFLD

NAFLD is associated with increased all-cause mortality. However, isolated hepatic steatosis without hepatic inflammation behaves differently than NASH, exhibiting no increase in liver-related mortality and minimal risk for disease progression. Approximately 80% of the NAFLD patients remain as non-alcoholic fatty liver for life. The remaining 20% develop NASH, and from those, approximately 7% progress to HCC over 6.5 years (Torres DM1, Williams CD, Harrison SA. 2012). The annual development of HCC among NAFLD-associated cirrhosis patients was approximately 3% (Ascha et al. 2010). In another 8 years, 30% of those cirrhotic subjects are estimated to progress to hepatic decompensation (Torres DM1, Williams CD, Harrison SA. 2012). Patients with NASH showed progression to significant fibrosis at a rate of 13% in 17 years, to cirrhosis 2% in 20 years and without NASH to significant fibrosis at a rate of 10% in 19 years, to cirrhosis 3.1% in 7.6 years (Hagström et al. 2017a; Calzadilla Bertot and Adams 2016). The probability of developing cirrhosis is estimated to be annually 6% for F2 fibrosis and 8% for F3 fibrosis (Singh et al. 2015; Argo et al. 2009; Singh et al. 2015). The natural course of NAFLD is schematized in Fig. 24.1.

Based on a meta-analysis with 11 cohort studies including 411 biopsy-proven NAFLD patients, and over 2145.5 person-years of follow-up evaluation, 33.6% of the subjects showed progression in fibrosis, 43.1% remained stable, and 22.3% had improvement regarding fibrosis stage. Progression of fibrosis at stage 1 was determined as 14.3 years for patients with NAFL and 7.1 years with NASH. Among NASH patients, 20% had rapid progression rates in the fibrosis stage (Singh et al. 2015). In a meta-analysis of Dulai et al., fibrosis stage was found to be directly associated with all-cause mortality and liver-related mortality. This increase is more

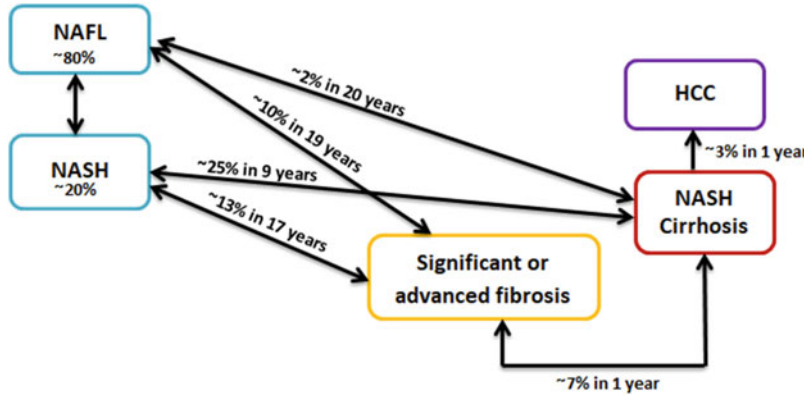

Fig. 24.1 Natural course of NAFLD

pronounced in patients with fibrosis stages of 3–4 (Dulai et al. 2017).

Liver-related mortality is not the leading cause of death among patients with NASH. In decreasing order, the most common aetiologies for mortality are cardiovascular disease, malignancies and then liver-related causes (Francque et al. 2011; Dam-Larsen et al. 2009; Söderberg et al. 2010). Diabetes mellitus, severe insulin resistance, increased BMI, significant weight gain (Adams et al. 2005), and cigarette smoking (Enc et al. 2019) are associated with disease severity. On the other hand, the effect of increased serum transaminases at disease severity remains controversial. Studies have shown that although increased serum aminotransferases indicate the probability of NAFLD, the absence of increased aminotransferases does not exclude NAFLD (Mofrad et al. 2003). NAFLD patients with normal liver enzymes are characterized by a severe metabolic profile, however, similar rates of advanced fibrosis compared to subjects with elevated aminotransferases (Ulasoglu et al. 2019).

Coffee and Alcohol

Coffee consumption is considered a protective factor for NAFLD (Yesil and Yilmaz 2013). A meta-analysis showed a significantly decreased risk of NAFLD among coffee drinkers, including less risk of liver fibrosis among patients with NAFLD, who consumed coffee regularly, which can make coffee a preventive factor for NAFLD and NAFLD-related complications (Wijarnpreecha et al. 2017). There are also studies showing the benefits of low amounts of alcohol consumption. Up to 13 units per week were shown to be associated with a lower stage of fibrosis (Hagström et al. 2017b).

One unit (10 ml ethanol) roughly corresponds to 25 ml of distilled drinks, 80 ml of wine, and 170 ml of beer. However, there is insufficient evidence about the benefits of alcohol consumption. Heavy episodic drinking may accelerate fibrosis progression and increase the risk of hepatocellular carcinoma. Therefore, considering the overlap between the pathophysiological mechanisms of NAFLD and alcoholic fatty liver disease, alcohol consumption is discouraged (Ajmera et al. 2017). In parallel, recent data showed there is no safe level or beneficial level of alcohol consumption. The safe level must be no consumption at all (Burton and Sheron 2018).

Noninvasive Diagnostic Methods vs. Liver Biopsy

Liver biopsy is considered the gold standard in approach for identifying the presence of NASH and a histological classification of the disease in terms of fibrosis. However, due to major limitations such as high cost, sampling errors, patients' discomfort, and the presence of procedure-related morbidity and even mortality, its use in the clinical practice remains questionable. Therefore, there has been significant interest in developing noninvasive methodologies to predict the severity of the disease (Musso et al. 2011). Risk factors for NAFLD are summarized in Table 24.1.

The fibrosis stage is specifically associated with the prognosis of the disease. Stages 3–4

Table 24.1 Risk factors for non-alcoholic fatty liver disease

Risk factors for NAFLD
Female gender
>50 years of age
Obesity
Metabolic syndrome
Diabetes mellitus type 2
Dyslipidaemia
Genetic predisposition
Dysbiosis

increased the risk of liver-related mortality by 50–80%. In this context, noninvasive detection of the fibrosis stage has been a major focus. The most common noninvasive scores are NAFLD Fibrosis Score (NFS), the Fibrosis-4 Score (FIB-4), the AST to Platelet Ratio Index (APRI), and the BARD Score, which includes several clinical and biochemical parameters obtained by routine clinical examinations (Drescher et al. 2019). The NAFLD guideline of the American Association for the Study of Liver Diseases (AASLD) recommends FIB-4 and NFS as clinically useful tools for the prediction of advanced fibrosis (F≥3) (Chalasani et al. 2018), Kaya et al. 2020. However, those scores have a high negative predictive value rather than positive predictive value, which means they can be confidently used for exclusion of advanced fibrosis rather than detection of it as also recommended in the guideline of European Association for the Study of the Liver (EASL) (European Association for the Study of the Liver (EASL); European Association for the Study of Diabetes (EASD); European Association for the Study of Obesity (EASO) 2016; Kaya et al. 2019).

Single vs. Multiple Criteria

Moreover, those scores include a grey zone, in which NAFLD patients are classified as having an indeterminate risk for advanced fibrosis. Another clinically important question concerns the management of those patients. Therefore, noninvasive scores are useful in the first-line stratification of the disease. Owing to the high-negative predictive values of those tests, patients classified as low risk for advanced fibrosis are recommended to be managed in primary care, whereas those at high risk should be directly referred to secondary care. For the patients in the indeterminate zone, Fibroscan examination is recommended for detecting the future management strategy. A noninvasive fibrosis marker or score, a diagnostic test, or an algorithm incorporating a panel of biomarkers is not capable of making a comprehensive statement of the disease outcome. Therefore, the combined use of noninvasive scores with imaging methods has been advised to increase diagnostic accuracy (Jafarov et al. 2019; Zhou et al. 2019).

Imaging Tools

Conventional ultrasonography is recommended for the diagnosis of moderate-to-severe steatosis, with a sensitivity of 85% and a specificity of 94% (Hernaez et al. 2011). However, it is incapable of detecting steatosis lower than 20% or in morbidly obese patients (Chalasani et al. 2018). Computerized tomography is more effective for evaluating hepatic steatosis; however, it remains also limited by insufficient accuracy for mild-to-moderate hepatic steatosis, and it involves radiation exposure (Schwenzer et al. 2009). Alternatively, controlled attenuation parameter (CAP) by Fibroscan, which measures the hepatic fat quantity by attenuation of the shear waves, and magnetic resonance-derived proton density fat fraction (MRI-PDFF), are more accurate and up-to-date methods for detection of hepatic steatosis. MRI-PDFF is a robust noninvasive method to monitor the treatment effect by means of hepatic fat quantification (Caussy et al. 2018). It is considered more accurate, reproducible, and reliable than liver histology. However, its use remains limited due to high costs, need for expertise, and long examination duration (Dulai et al. 2016). In terms of quick accessibility and cost-effectiveness, CAP (Fibroscan) is preferred over MRI-PDFF in clinical routine (Leung et al. 2013).

First-line Liver Fibrosis Assessment

Vibration-controlled transient elastography (VCTE) is the first Food and Drug Administration-approved modality by FibroScan employing ultrasound-based technology, which measures the velocity of a shear wave that is emitted by a probe in the intercostal space into the liver (Leung et al. 2013). Magnetic Resonance Elastography (MRE) is an excellent method as well for assessment of fibrosis stage in NAFLD. According to recent information, MRE performs

better than VCTE for the identification of significant fibrosis; on the other hand, it performed equally well for the quantification of advanced fibrosis (Loomba et al. 2014).

Pathophysiology

The development of NAFLD classically relies on the "multiple hit and organ theory," in agreement with a large spectrum of metabolic dysfunctions caused by the interaction of genetic and environmental factors (Buzzetti et al. 2016). Liver fat accumulation, caused by obesity and insulin resistance, seems to represent the "first hit" (Fang et al. 2018). Hepatic fat accumulation in the liver is mainly comprised of triacylglycerol (TAG) derived from the esterification of glycerol and free fatty acids (FFA) (Buzzetti et al. 2016). TAG in hepatic fat is hydrolysed and secreted into the blood circulation as very-low-density lipoprotein particles. Disruption of those pathways can result in hepatic steatosis (Musso et al. 2013). Peroxisome proliferator-activated receptor-α (PPAR-α) plays a significant role in the regulation of β-oxidation in hepatocytes. The downregulation of PPAR-α was significantly associated with NAFLD and NASH (Tanaka et al. 2017). De novo lipogenesis in hepatocytes is mainly regulated by activation of transcriptional factor sterol regulatory element-binding protein 1c (SREBP-1c), which is enhanced by hyperglycaemia, and explains the close association between NAFLD and insulin resistance (Tanaka et al. 2019).

Subsequent Steps

Hepatic fat accumulation does not represent alone strong toxicity for the liver. There is no association between the degree of steatosis and NAFLD severity. However, TAG-derived molecules and its precursors such as palmitate, diacylglycerol (DAG), and ceramide are likely to be a detriment to hepatocytes. Palmitate increases oxidative stress leading to lipoapoptosis. DAG activates protein kinase C disrupting the insulin signalling pathway, and ceramide promotes the production of palmitate (Akazawa and Nakao 2018; Jiang et al. 2015; Gan et al. 2014). Furthermore, overloaded TAG storage creates metabolic distress and following this lipotoxicity, which increases together oxidative stress.

Normally, oxidation of FFAs ensues through α-, β-, and ω-oxidation. Mitochondrial β-oxidation and peroxisomal α-, β-oxidation are normal metabolic processes. However, if these metabolic pathways are impaired, ω-oxidation occurs in endoplasmic reticulum leading to reactive oxygen species production. It was observed that ω-oxidation and oxidation via NADPH oxidase in Kupffer cells are increased in NAFLD patients, causing inhibition of mitochondrial β-oxidation. All these metabolic processes lead to DNA damage in cell nucleus and mitochondria, and release of cytokines which promotes hepatocellular injury (Yao et al. 2019).

The Liver Damage Cascade

Hepatocellular injury causes the release of several pro-inflammatory mediators recruiting immune cells and activating Kupffer cells, which result in the release of bioactive molecules further damaging hepatocytes (Zhang et al. 2015). Chronic hepatocyte death or impaired hepatocyte regeneration leads to alternative replacement by fibres and extracellular matrix, resulting in significant scar tissue formation and remodelling of the normal structure of hepatic lobules. Fibrogenesis mainly in the perisinusoidal space is relatively specific to steatohepatitis (Lee et al. 2015).

The Microbiota and the Gut Barrier Function

There is increasing research interest on gut-liver axis dysfunction including intestinal dysbiosis, bacterial overgrowth, and alteration of gastrointestinal mucosa permeability. In the development of NAFLD, gastrointestinal microbiota play a significant role in maintaining barrier integrity and intestinal permeability. There are several

mechanisms associated with alteration in gastrointestinal microbiota and development of NAFLD: Deterioration in microbiota can damage the intestinal epithelium and tight junction proteins in the gut, which allow harmful substances such as bacteria, ethanol, and endotoxins entering into the portal circulation. Furthermore, microbiota digest and ferment the excessive dietary energy into short-chain fatty acids and produces ethanol, affecting the liver similarly to chronic alcoholism (Doulberis et al. 2017).

According to the study of Zhu et al., there is a significantly increased population of alcohol-producing bacteria in patients with NASH compared to obese and healthy subjects. Furthermore, a significantly increased serum ethanol concentration was observed in NASH patients, although there was no difference between obese and healthy subjects (Zhu et al. 2013). In a more recent study, high alcohol-producing Klebsiella pneumonia was found to be associated with up to 60% of individuals of the study cohort. Moreover, clinical isolates of high alcohol-producing Klebsiella pneumonia transferred via oral gavage or faecal transplant also induced NAFLD in mice, supporting the strong association with NAFLD development (Yuan et al. 2019).

Disease-specific Variants

NAFLD is also associated with a genetic predisposition. Although only a minority of the genetic modifiers of NAFLD has been validated, there are several genetic associations to mention. The initial genome was identified as PNPLA3, which was validated in different ethnic groups as a modifier of NAFLD severity. In obese children and adolescents, the PNPLA3 rs738409 variant was also suspected to affect the histological severity in NAFLD (Valenti et al. 2010). Additionally, PNPLA3 has been accepted globally as a major determinant of not only steatosis but also the severity of NASH, fibrosis stage, and probability of HCC development (Anstee and Day 2013). Recently, the TM6SF2 gene has been reported as another disease modifier, which might be clinically useful in the future for estimating the disease progression severity (Dongiovanni et al. 2015).

TM6SF2 rs58542926 T-allele mediates hepatic accumulation of triglycerides and cholesterol creating a predisposition to NAFLD-related fibrosis, whereas C-allele carriage protects liver excreting VLDL from the liver, at a price of increased atherosclerosis and cardiovascular disease (Kahali et al. 2015). More recently, HSD17B13 was found to play role in the progression of liver disease from steatosis to later stages of non-alcoholic steatohepatitis, fibrosis, and cirrhosis, since the reduced activity of HSD17B13 was associated with a lower risk of progression from steatosis to steatohepatitis (Abul-Husn et al. 2018). MBOAT gene was also associated with disease severity in both NAFLD and alcoholic fatty liver disease (Caussy et al. 2019).

Lifestyle and Pharmacological Interventions

NAFLD has been associated with a diet of high caloric amount, which contains excessive saturated fats, refined carbohydrates, and high fructose (Barrera and George 2014), along with sedentary behaviour (Gerber et al. 2012). Therefore, lifestyle modification is the cornerstone treatment of NAFLD and has an important impact on the natural course of the disease (Kugelmas et al. 2003). Weight loss between 5 and 7% can diminish fat accumulation, whereas a 7–10% weight loss is significantly associated with improvement in NASH and fibrosis, with a chance of 64% and 50%, respectively. Weight loss of >10% was associated with up to 90% chance of NASH resolution and up to 81% of regression in fibrosis (Vilar-Gomez et al. 2015).

According to the recent studies and expert opinions, following a Mediterranean diet can reduce liver fat even without weight loss, which is characterized by reduced carbohydrate and increased monounsaturated and ω-3 fatty acid intake (Romero-Gomez et al. 2017). Therefore, it has been also recommended as the preferred diet type in the major guidelines (Chalasani

et al. 2018; European Association for the Study of the Liver (EASL); European Association for the Study of Diabetes (EASD); European Association for the Study of Obesity (EASO) 2016). In addition to diet modifications, exercise should also be recommended. Aerobic exercise training of 150 min per week contributed to weight reduction and had an impact on intrahepatic fat (Hashida et al. 2017).

Zelber-Sagi et al. demonstrated that weight gain was a predictor of NAFLD development even among nonobese individuals. Loss of 5% of the initial body weight resulted in remission of NAFLD in 75% of those individuals (Zelber-Sagi et al. 2012). Both lean and obese individuals seem to similarly benefit from weight loss in terms of NAFLD remission (Varol Hamurcu et al. 2020).

Bariatric Interventions

In line with weight reduction, bariatric surgery is an excellent method to recommend for morbidly obese patients. After a one-year follow-up, in more than 85% of the patients, resolution of NASH has been observed. Moreover, in those patients, pathological features were also ameliorated (Laursen et al. 2019). In a meta-analysis, steatosis, inflammation, and ballooning mostly improved or completely resolved. An extensive review emphasizes that in most patients, liver fibrosis diminishes, whereas refractory cases exist in which both fibrosis and inflammation persist or progress (Laursen et al. 2019).

Drug Therapy

There is no specifically licensed pharmacological treatment for NAFLD. Yet, given the close association between NAFLD and type 2 diabetes mellitus, pioglitazone has been utilized in NASH targeting both adipose tissue metabolism and inflammation through PPAR-γ. Thus, it reduces hepatic steatosis, inflammation, and ballooning increasing uptake of fatty acid by adipocytes. However, because of its side effects such as weight gain and the conflict of its effect on the improvement of hepatic fibrosis, its use recommended only in selected diabetic patients (Cusi et al. 2016).

Although there is no convincing evidence about vitamin E and improvement of liver fibrosis, given the antioxidative and anti-inflammatory effect of vitamin E, it has been investigated as a therapeutic option in NASH. However, due to lack of further data, vitamin E is not recommended in NASH patients with diabetes, NAFLD without liver biopsy, NASH cirrhosis, or cryptogenic cirrhosis. The risks and benefits must be discussed for each patient individually (Chalasani et al. 2018).

There are several pharmaceutical agents with completed or ongoing phase III controlled trials. Obeticholic acid improves hepatic insulin sensitivity and decreases lipogenesis, inflammation, and fibrosis. The interim analysis of the phase 3 REGENERATE Study showed that obeticholic acid use resulted in fibrosis improvement without worsening of NASH (Younossi et al. 2019d). However, due to its side effects such as LDL increase and pruritus, its use in clinical routine remains limited considering that 13% discontinued therapy and 17% exhibited increased LDL levels (Younossi et al. 2019d). Another agent selonsertib inhibits apoptosis signal-regulating kinase 1, which reduces hepatocyte apoptosis and fibrosis. Still selonsertib failed to meet endpoint in STELLAR-3 and STELLAR-4 phase III clinical trials (Trial Site 2019; Clinical Trials 2019). Also Emricasan, an oral pan-caspase inhibitor, suppresses apoptosis failed to meet endpoint, also worsening liver histology (Shiffman et al. 2019). The ongoing phase III trials are with elafibranor, a PPARα and PPARδ agonist, which also improves insulin sensitivity and hepatic inflammation (Yuan et al. 2019), and cenicriviroc, a dual C-C chemokine receptor type 2 and 5 (CCR2/5) inhibitor (Yuan et al. 2019). The results of these trials are expected to be released through the midyear of 2020. In conclusion, diet and exercise remain still the cornerstone of NAFLD therapy.

Abstract

NAFPD is a novel disease entity that is gaining popularity similar to NAFLD. It has an association with features of the metabolic syndrome, especially obesity. Given increased awareness, it is being diagnosed more commonly and at times is discovered as an incidental finding on imaging. Research thus far has shown that it carries clinical significance and can lead to pancreatitis as well as surgical risk, and even potentially pancreatic cancer. Though treatment strategies are not well established, given the links to metabolic syndrome one of the common approaches is weight loss. Medications such as oral hypoglycemic agents have been studied in animals but there have yet to be studied in humans. As NAFPD still remains a mystery in many ways, it requires further research into the pathophysiology as well as the long-term consequences and management.

Keywords

Non alcoholic pancreatic steatosis · Alcoholic pancreatic steatosis · Metabolic syndrome · Chronic pancreatitis · Pancreatic cancer · Ectopic fat

Abbreviations

AT1R	Angiotensin type-1 receptor

CT	Computed Tomography
EUS	Endoscopic ultrasound
MRI	magnetic resonance imaging
MRS	magnetic resonance spectroscopy
NAFLD	nonalcoholic fatty liver disease
NAFPD	Nonalcoholic Fatty Pancreatic Disease
PFF	pancreatic fat fraction
WHO	World health organization

Introduction

There has been a tenfold increase in obesity among children and adolescents in the last 4 decades, and the trend is expected to continue by 2022 (WHO 2020). Comorbidities associated with obesity such as coronary artery disease, cerebrovascular accidents, type 2 diabetes mellitus, and cancers are primary etiologies for many preventable deaths (Pi-Sunyer 2009). There is a medical spending difference in obesity, and it can be as high as $1429 per patient/year. In the United States, the estimated medical spending in the obesity population was close to $147 billion dollars in 2008 (Finkelstein et al. 2009). Adult females hold higher prevalence in obesity in Asians, Hispanics, and African American populations (CDC 2020).

The Spectrum of Metabolic Syndrome

Metabolic syndrome comprises five risk factors according to the National Institutes of Health namely obesity, hypertriglyceridemia, low HDL, hypertension, and fasting hyperglycemia or diabetes mellitus (Younossi 2019). The link between metabolic syndrome and nonalcoholic fatty liver disease (NAFLD) is very well-established, as it can lead to nonalcoholic steatohepatitis and eventually cirrhosis, obviously without any significant alcohol intake (Fazel et al. 2016). Unlike nonalcoholic fatty liver disease and metabolic syndrome, pancreatic steatosis or fat deposition in the pancreas has just earned attention in the last few years.

Historical Notes

John Schaefer in 1926 was probably the first to identify the normal weight of the pancreas in the adult population (Schaefer 1926). He was followed by Ogilvie in 1933, who noticed in a case-control study of 19 cadavers of obese and

Table 25.1 Nomenclature for pancreatic steatosis

Nomenclature	Definition
Pancreatic lipomatosis Pancreatic steatosis Fatty pancreas	Nonspecific terminologies
Lipomatous pseudo-hypertrophy	Extreme pancreatic fat accumulation
Fatty replacement	Adipocytes associated with acinar extinction
Fatty infiltration	Obesity-induced adipocyte accumulation
Nonalcoholic fatty pancreas disease	Metabolic syndrome-associated fat accumulation
Nonalcoholic fatty steatopancreatitis	Pancreatitis due to fat deposition

Adapted from Smits and Van Greenen (2011)

lean patients, and increase in the mean pancreatic fat deposition (17.1%, range 0–48.5%), compared to the lean group (9.3%, range 2.5–23.6%) (Ogilvie 1933). Olson in 1978, analyzing 394 autopsies, identified strong correlation between older age/overweight status and the degree of lipomatosis of the pancreas (Olsen 1978). Association was found between other elements of metabolic syndrome, including diabetes mellitus and dyslipidemia, with pancreatic fatty deposition.

Nomenclature

Smits and van Greenen suggested to standardize nomenclature for better definition of pancreatic steatosis as listed below (Smits and Geenen 2011) (Table 25.1).

Epidemiology

Wang et al reported in 2014 prevalence of pancreatic steatosis in 16% of a cohort which included 8097 patients; it was significantly associated with diabetes (12.6% versus 5.2%) (Wang et al. 2014). Pham et al performed a retrospective chart review of 232 pediatric patients (age 2–18) in Texas who obtained computed tomography imaging in an emergency room visit. The calculated pancreatic steatosis prevalence was 10% (Pham et al. 2016).

Singh et al in 2017 reported the pooled prevalence of NAFPD from 11 studies (12,675 patients), reaching 33%. There was association between NAFPD and metabolic syndrome, diabetes mellitus, and hypertension (Singh et al. 2017). Hispanics seem to exhibit higher pancreatic fat fraction (PFF) than African Americans, and increasingly so with age. Also males have higher PFF than females. PFF was related to visceral adipose tissue, circulating free fatty acids, and hepatic fat fraction (Le et al. 2011). In another study, pancreatic triglyceride levels in the Hispanic and Caucasian population were higher when compared to African Americans (Szczepaniak et al. 2012).

Pathogenesis of NAFPD—Obesity

Obesity leads to develop nonalcoholic fatty pancreatic disease (Sepe et al. 2011). Visceral and ectopic fat have been recognized, as adipokines which promote oxidative stress initiate local inflammatory cascades and eventually organ damage (Tilg and Hotamisligil 2006), analogously to nonalcoholic fatty liver disease and steatohepatitis (Schaefer 1926; Mathur et al. 2007a).

One of the main accepted mechanisms that can lead to pancreatic steatosis is acinar cell death, which is subsequently replaced by adipocytes and fat deposition (intracellular triglycerides), mainly in type 2 diabetes mellitus and obesity (Yu and Wang 2017). The pancreas is thought to have higher sensitivity to fatty infiltration than the liver (Yu and Wang 2017). Pancreatic steatosis majorly happens via adipocyte infiltration to the pancreatic parenchyma, yet intracellular triglyceride accumulation has been noticed in both acinar

and islet cells (Smits and Geenen 2011). The high-fat diet responsible for high insulin levels, oxidative stress, and cellular influx of free fatty acids with decreased beta-oxidation, could result in triglyceride deposition (Fraulob et al. 2010). In a prospective study, it was shown that the risk for pancreatic steatosis will increase by 5% for every 1 kg/m² increment in BMI (Sepe et al. 2011).

Age

Increasing fatty infiltration of the pancreas with aging is well established (Rössle 1921; Ogiu et al. 1997). The ratio between fat to acinar cells increases with age, and pancreatic atrophy could simultaneously happen (Saisho et al. 2007). Sonographic studies confirm increased pancreatic steatosis with aging (Glaser and Stienecker 2000). Moreover, fat-pancreatic ratio increases steadily in both genders (Saisho et al. 2007). Olson et al had reported that 15% of the elderly between age of 60 and 69 years had severe pancreatic fatty infiltration; meanwhile, no cases of severe pancreatic fatty infiltration were observed below age of 40 (Olsen 1978). Age independently from body weight is considered as a significant element for pancreatic steatosis development (Schmitz-Moormann et al. 1981).

Metabolic Syndrome

Metabolic syndrome is strongly linked to increasing risk of cardiovascular disease, diabetes mellitus, cerebrovascular accidents, and mortality by coronary disease (Huang 2009; Tenenbaum and Fisman 2011). NAFLD is a relevant hepatic manifestation for metabolic syndrome, as visceral fat is more pathologically and inflammatorily significant than subcutaneous fat. Nonalcoholic steatohepatitis, hepatocellular carcinoma, and cirrhosis are accepted complications in NAFLD patients (Perumpail et al. 2015). Wu et al found in a fatty pancreatic group higher hemoglobin A1c, fasting blood glucose, total cholesterol, triglyceride, and LDL-C ($p<0.03$). Higher systolic blood pressure rather than diastolic blood pressure was registered as well (Wu and Wang 2013). In an EUS-based evaluation of 284 subjects, 110 were found to have pancreatic steatosis. Associations included age older than 60 years, BMI more than 25 kg/m2, diabetes mellitus, hypertension, dyslipidemia, and fatty liver. Visceral adipose tissue was correlated with pancreatic steatosis independently from BMI ($p<0.01$) (Choi 2010).

β-Cell Function

It is debated whether pancreatic fatty infiltration contributes to pathogenesis of type 2 diabetes mellitus (Zhao et al. 2015). Animal studies suggested that pancreatic steatosis could impact β-cell function and accelerate their apoptosis. Zhao et al reported that a high-fat, high-sucrose diet in Bama minipigs leads to enlarged islet cells and β-cell injury, through increased lipid peroxidation and decreased pancreatic antioxidant enzyme function (Zhao et al. 2015).

In eleven nondiabetic children with heterozygous carboxyl-esterase lipase mutation (CLE), i.e., a rare mutation involved with diabetes, pancreatic exocrine dysfunction, and adult pancreatic steatosis, pancreatic steatosis was found before the occurrence of diabetes. Decreased first-phase insulin secretion also occurred (Raeder et al. 2007).

Pancreatic fatty content is higher among adult men with type 2 diabetes, as measured by MRS. Pancreatic lipomatosis was negatively linked with β cell function in nondiabetic men, however not in those with type 2 diabetes (Tushuizen et al. 2007). Heni et al reported an inverse relationship between pancreatic fatty content and β cell function among patients with impaired oral glucose tolerance/impaired fasting glucose. Pancreatic fat was associated with lower levels of insulin secretion (Heni et al. 2010). In Hong Kong, 110/685 healthy subjects exhibited NAFPD. Those subjects displayed higher insulin resistance and when combined with NAFLD, the correlation with insulin resistance was even higher, independently from BMI (Wong et al. 2014).

Other Possible Etiologies

Alcohol is an important factor. Consumption that exceeds 14 grams a week can lead to pancreatic steatosis (Tariq et al. 2016). By causing pancreatitis, alcohol can upregulate transcription factors responsible for cholesterol and triglyceride expression (Al-Haddad et al. 2009). Rosiglitazone, corticosteroids, gemcitabine, and octreotide are linked as well to pancreatic steatosis /fatty pancreas development (Ye and Liu 2017).

Iron overload is also a potential mechanism. One of the most common causes of iron overload is hemochromatosis, a hereditary condition in which iron accumulates in the reticuloendothelial system, liver, heart, skin, pancreas, and exocrine glands. In the pancreas, iron toxicity through oxidative stress leads to acinar and islet cell apoptosis with ultimate replacement with adipocytes. This was also well-recognized in patients with Cooley's anemia and myelodysplastic syndrome since they receive frequent blood transfusions (Midiri et al. 1999; Lin et al. 2007). Viruses like HIV, hepatitis B, and reovirus have also been linked to pancreatic steatosis. Malnutrition could predispose to pancreatic steatosis especially in conditions like alcoholism, AIDS, and kwashiorkor, by altering pancreatic structure followed by replacement with fat (Chehter et al. 2000). Congenital disorders like cystic fibrosis, heterozygous carboxyl-ester-lipase mutations, Johnson blizzard syndrome, and Shwachman-Diamond syndrome are associated with pancreatic steatosis (Raeder et al. 2007; Daentl et al. 1979). In cystic fibrosis, mucous plugs inside pancreatic ductules injure pancreatic cells, which will eventually be replaced by fat (Walters 1966).

Diagnosis

Imaging findings of a fatty pancreas alone are not sufficient to make the diagnosis. NAFPD entails a fatty infiltration of the pancreas along with the presence of components of the metabolic syndrome (as per the International Diabetes Federation or the National Cholesterol Education Program Adult Treatment Panel III). Independent diseases that lead to fatty replacement of the pancreas should be excluded (Pinte et al. 2019; Grundy 2019). Though histological examination can provide information on the degree of fatty infiltration of the pancreas, it is too invasive for routine use. A histological classification system known as the pancreatic lipomatosis score, established by Olsen in 1978, could confirm the severity of pancreatic steatosis, in selected cases (Olsen 1978). Hence, the primary modalities used for diagnosis are imaging studies.

Confounding Variables

Due to the variable morphology of the pancreas, the margins may not be clearly delineated and fat infiltration may not be homogenous, interfering with assessment (Matsumoto et al. 1995). Moreover, there is normal fatty replacement of the pancreas as an age-related physiological process (Kühn et al. 2015; Chantarojanasiri et al. 2014). Body habitus can be a challenge, as transabdominal ultrasound may not provide good visualization if there is substantial abdominal fat. Study-related factors like cost and accessibility also need to be considered.

Transabdominal Ultrasound

Transabdominal ultrasound is a readily available, cost-effective, fast, and noninvasive. An increased echogenicity is seen in the pancreatic tissue when there is fat infiltration, and the kidney or the liver is used for comparison (Yu and Wang 2017; Al-Haddad et al. 2009; Romana et al. 2018). It does have inherent limitations such as impaired visualization of the pancreatic tissue if the patient is obese, or if there are overlying shadows due to bowel gas. It is also an operator-dependent technique, which can impact the accuracy of the test and the quality of the images. Fibrosis of the pancreatic tissue is also seen as increased echogenicity, and this could be difficult

to differentiate from steatosis (Ustundag 2011). Some attempt at using quantitative techniques to evaluate the echogenicity pancreas like the pancreato-perihepatic fat index (linked to metabolic syndrome) (Jeong et al. 2014).

Endoscopic Ultrasound (EUS)

As the probe is of a higher frequency and is able to get in closer approximation to the pancreatic tissue, it allows for an enhanced quality of the images obtained (Pinte et al. 2019). Another benefit is that it allows for a more complete visualization of the pancreas, and for simultaneous comparison of the echogenicity to adjacent organs (Al-Haddad et al. 2009). However, it is an invasive test with an inherent risk of complications (Polkowski et al. 2017). It is similarly operator dependent, with some difficulty in differentiation from fibrosis[50.] Real-time elastography during EUS has been tried as a measure of pancreatic steatosis; however, it did not show an association between elasticity and steatosis like it did for fibrosis (Kuwahara et al. 2017; Barreto et al. 2018). NAFPD can be divided into four grades of severity on EUS when comparison is made of the echogenicity of the pancreas and the main pancreatic duct, against that of the spleen. Normal pancreatic tissue is associated with grades I and II and fatty infiltration seen with grades II and IV (Sepe et al. 2011).

CT Scan

CT scan employs Hounsfield units, and areas of fatty infiltration will be hypodense in comparison to the spleen or the liver (Pinte et al. 2019). When CT with contrast is performed, the normal pancreatic tissue will appear enhanced as compared to the regions of fatty infiltration (Kim et al. 2014a). CT scan is endowed with correlation to histology as well (Pinte et al. 2019). Measurements such as the pancreas-to-spleen attenuation ratio and fat/ parenchyma ratio can be derived from the CT scan and used for quantification of pancreatic fat (Saisho et al. 2007; Kim et al. 2014a). Among the downsides, radiation exposure and potential contrast exposure require attention.

MRI and MRS

Magnetic resonance imaging (MRI) and magnetic resonance spectroscopy (MRS) are among the preferred imaging modalities. Advantages include lack of radiation exposure and of invasiveness (Pinte et al. 2019). There is a good correlation with the amount of fatty infiltration detected on MRS and the amount of triglycerides present in the islet cells, and hence, MRS can be used as a surrogate for quantitative assessment of fat deposition within the islet cells (Lee et al. 2009; Lingvay et al. 2009). Single-voxel MR spectroscopy has been shown to be most comparable to histology, being considered the most accurate imaging modality (Kim et al. 2014a; Lee et al. 2009; Lingvay et al. 2009; Catanzaro et al. 2016; Ma et al. 2014). A novel MRI modality known as three-dimensional iterative decomposition with echo asymmetry and least-squares estimation (IDEAL) is stated to be superior to MRS for detection of pancreatic lipomatosis (Hu et al. 2009). Though it has several advantages including greater accuracy, there are drawbacks such as being more expensive as compared to the other techniques and more time consuming to perform, with limited availability.

Histology

In nonalcoholic fatty liver disease, there is deposition of triglyceride within the cells however in NAFPD the main mechanism of steatosis is the infiltration by adipocytes into the pancreatic tissue (Catanzaro et al. 2016). Intracellular accumulation of triglycerides in the islet and acinar cells can still occur (Catanzaro et al. 2016). Both forms of fat accumulation can be damaging to the pancreatic tissue. The adipocytes can exert a paracrine effect on the acinar and islet cells and induce injury, whereas the intracellular accumulation can lead to direct damage (Catanzaro et al. 2016). Scoring systems such as the pancreatic lipomatosis score formulated in 1978 by Olsen

can be used to grade the severity of steatosis (Olsen 1978). A modification of this score by van Geenen et al has also been developed (Pinte et al. 2019).

Possible Complications—Metabolic Syndrome

Shared disease entities encompass fatty liver disease, diabetes as well as the potential for cardiovascular disease (Pinte et al. 2019; Bi et al. 2019). Increased fatty accumulation has been seen in the pancreas of those with impaired glucose tolerance, and this could eventually progress to the development of overt type II diabetes (Li et al. 2017; Ou et al. 2013). Cardiovascular risk is also seen to be increased in patients with pancreatic steatosis, in the form of atherosclerosis. NAFPD has been associated with increased epicardial adipose tissue and increased intima-media thickness of the aorta, and NAFPD could be a surrogate for the presence of subclinical atherosclerosis (Kul et al. 2019). In non-obese type II diabetic patients, there was increased prevalence of carotid artery plaque and vascular stiffness (Kim et al. 2014b). Patients with NAFLD also tend to have NAFPD but the reverse association is not as clear (Lesmana et al. 2015; Li et al. 2017).

Acute and Chronic Pancreatitis

Obesity and other aspects of the metabolic syndrome are considered to be predisposing factors to acute pancreatitis (Pinte et al. 2019). The degree of pancreatic steatosis has been associated with the severity of the inflammation in acute pancreatitis (Smits and Geenen 2011). By promoting the release of cytokines such as IL-1β and TNF-α, pancreatic steatosis exacerbates the inflammatory response in acute pancreatitis and hence the severity of the injury (Papachristou et al. 2006). Acinar cells respond to cytotoxicity by the release on enzymes including lipases, with causes lipolysis yielding free fatty acids (Catanzaro et al. 2016; Acharya et al. 2014). Unsaturated fatty acids further exert direct damage to the acinar cells resulting in necrosis, and areas surrounding necrotizing fat endure more severe injury, known as peri-fat acinar necrosis (Acharya et al. 2013; Navina et al. 2011).

The association between pancreatic steatosis and chronic pancreatitis is not as clear, and there may be a negative association between the two (Mathur et al. 2007b). In cases of chronic pancreatitis with recurrent acute episodes and features of metabolic syndrome, the mechanism is not due to fatty infiltration but instead to fibrosis. Decrease in normal pancreatic parenchyma and fatty replacement could be just a consequence (Pinte et al. 2019).

Pancreatic Insufficiency

Fatty infiltration of the pancreas potentially causes exocrine pancreatic insufficiency by inducing lipotoxicity to the acinar cells, when there is intracellular accumulation of fat (Catanzaro et al. 2016). The adipocytes can also exert an adverse paracrine influence, and the death of acinar cells can occur (Catanzaro et al. 2016). However, there is limited evidence, and this is only hypothetical.

Pancreatic Fibrosis

Long-standing inflammation in NASH eventually progresses to liver fibrosis, and it is speculated that a similar progression would occur in nonalcoholic steatopancreatitis (NASP) (Catanzaro et al. 2016). Diabetic rats given a high-fat diet suffered intracellular fat deposition in the acinar cells and eventually fibrosis (Matsuda et al. 2014). Another study conducted on swine did not show a link between pancreatic fat accumulation and fibrotic changes (Fullenkamp et al. 2011). In over 900 human autopsies, there was no correlation between pancreatic steatosis and fibrosis (van Geenen et al. 2011). A study performed by Mathur et al revealed that there was a negative association between pancreatic steatosis and fibrosis (Mathur et al. 2007b).

Pancreatic Cancer

Obesity is a known predisposing factor for pancreatic cancer, and NAFPD has been shown to be an independent risk factor for its development as well (Catanzaro et al. 2016). An association between pancreatic steatosis (intra- and extralobular deposition) and pancreatic intraepithelial neoplasia has been seen (Rebours et al. 2015). A proposed mechanism for carcinogenesis in NAFPD may be similar to that in the liver, in that the increase in adipocytes can cause inflammation and NASP, which can predispose to malignant changes over time (Smits and Geenen 2011). Pancreatic cancers that develop as a consequence of NAFPD may have a worse prognosis compared to those without a fatty pancreas (Catanzaro et al. 2016). NAFPD can promote the spread of the tumor and increase the associated mortality, by causing changes in the microenvironment of the tumor giving it more aggressive properties (Mathur et al. 2009).

Surgical Risk

With pancreatic steatosis, there is a higher likelihood of blood loss during surgery and formation of a pancreatic fistula postoperatively (Catanzaro et al. 2016; Mathur et al. 2007b). With regard to pancreatic transplant, obesity and older age (elderly patients that are obese likely have steatosis) of the transplant donor and recipient are associated with pancreatic fistula, graft pancreatitis, and thrombosis as well as infections (Catanzaro et al. 2016). Interestingly, however, obesity does not impact allograft failure or rejection (Hanish et al. 2005). Hence, preoperative investigations aimed to detect any pancreatic steatosis are helpful for decreasing perioperative risks and salvaging organs for ideal candidates (Pinte et al. 2019; Catanzaro et al. 2016).

Treatment

As it is linked to metabolic syndrome and type II diabetes mellitus, similar approaches to treatment with weight loss and dietary modifications have been anticipated (Pinte et al. 2019). Oral hypoglycemic agents used in type II diabetes patients such as metformin, DPP-4 inhibitors, and thiazolidinediones have been preliminarily assessed and show some promise (Pinte et al. 2019).

Weight Loss

Weight loss is associated with a reduction in the amount of pancreatic fat and increased insulin sensitivity (Honka et al. 2015; Lim et al. 2011). Postbariatric surgery, there is a significant reduction in pancreatic fat and fatty acid uptake in pancreatic tissue with preservation of pancreatic blood flow, and no alteration of the pancreatic fat-free volume(Honka et al. 2015). In another bariatric protocol, eight weeks after the surgery, there was an improvement in the first-phase insulin response and pancreatic fat content only in those with diabetes, however not in the other group. Hence, the decrease in the pancreatic fat was linked to the underlying presence of diabetes and not simply a consequence of reduction in total body fat (Steven et al. 2015).

Oral Hypoglycemic Agents

Metformin reduces the oxidative stress on islet cells and may even impact insulin secretion favorably (Piro et al. 2012). It may decrease visceral fat and insulin resistance (Tajima et al. 2017). Incretin-based therapies like DPP-4 inhibitors such as Sitagliptin can be used alone or in addition to metformin for decreasing pancreatic fat (Reimer et al. 2014).

Abstract

There is a large proportion of individuals affected with type 2 diabetes and metabolic disorders in the south Asian population. However, as per the recent global burden of disease study, there are very few individuals with obesity located in this region. This paradox has reinforced the concept of normal-weight obesity, actually originated in 1981 as metabolically obese normal-weight individual (MONW). It is defined as presence of normal weight despite presence of an increased body fat percentage. The several deterrents in the diagnosis and management of normal-weight obesity, as well as of metabolically normal obese subjects, are addressed in this chapter.

Keywords

Metabolically healthy obesity · Normal-weight obesity · Body mass index cutoff points · Obesity/South Asians · Diabetes/ South Asians

Introduction

Due to a unique phenotype of higher body fat and the occurrence of type 2 diabetes, dyslipidemia, and other cardiovascular morbidities at a lower range of body mass index (BMI) (Conus et al. 2007; Ashwell et al. 2014) and waist circumference (WC) in South Asians, lower cutoff values have been defined :BMI: 23–24.9 kg/m^2 for overweight and $\geq$ 25 kg/m^2 for obesity (Gray et al. 2011). A consensus guideline for these revised measures has been developed for Asian Indians (Misra et al. 2009).

In Ethiopian adults, the optimal cutoff for obesity using body mass index was 22.2 kg/m^2 for males and 24.5 kg/m^2 for females with waist circumference values of 83.7 cm and 78.0 cm, respectively. For females, BMI cutoffs for metabolic syndrome markers ranged from 24.8 kg/m^2 to 26.8 kg/m^2, and for WC, 82.1–96.0 cm. As regards, waist/ height ratio (WHt-R) 0.47–0.56 was proposed for the healthy population, and for markers of metabolic syndrome, 0.78–0.89. For males, the optimal BMI cutoffs for metabolic syndrome markers ranged from 21.0 kg/m^2 to 23.5 kg/m^2 (Sinaga et al. 2018). More recent evidence from the Indian subcontinent shows that upto one-third of the south Indian population could have normal weight obesity (Kapoor et al. 2020a).

BMI does not account for age and gender and does not discriminate between individuals with higher lean body mass and low body fat (Pasco et al. 2014). WC, waist-to-hip ratio (WHR), Wht-R, and abdominal and supra-iliac skinfold thickness could be helpful. However, in individuals with metabolic obesity, anthropometric parameters such as WC, WHR, and Wht-R would not be accurate (Madeira et al. 2013).

Healthy Versus Unhealthy Lean and Obese Subjects

As alluded to, normal-weight individuals with metabolic derangements were first postulated in 1981 (Ruderman et al. 1981). In contrast, certain obese individuals remain insulin sensitive and metabolically healthy (Goossens 2017). Metabolically obese, normal-weight individuals with BMI less than 25 kg/m^2 present with hyperinsulinemia or insulin resistance, along with

Fig. 26.1 Deterrents of normal-weight obesity in the society

hypertriglyceridemia and hypertension which predispose such individuals to a higher risk of cardiovascular diseases. On the other hand, obese individuals with either extreme insulin sensitivity or insulin resistance are a usual paradox. The term "metabolically healthy obesity"(MHO) describes the absence of any metabolic disorder including type two diabetes, dyslipidemia, and hypertension in an obese individual (Conus et al. 2007; Phillips 2017). However, there are no clear cutoffs demarcating insulin-sensitive and insulin-resistant groups in metabolically healthy obese persons. The several deterrents in the diagnosis and management of normal-weight obesity are summarized in Fig. 26.1.

The major difference between obese, metabolically unhealthy, and healthy subjects is high insulin sensitivity, high HDL levels, low ectopic fat, low triglyceride levels, and low degree of subclinical inflammation. Further, lower visceral, liver, and muscle fat contents are present in MHOB subjects than insulin-resistant obese individuals.

Prevalence of Normal-weight Obesity

The prevalence ranges between 5% and 45%, due to differences in phenotype, sample size effects, social and demographic factors, and lack of consensus on diagnostic criteria (Ding et al. 2016). The first study to define metabolic obesity targeted high body fat percentage (>30%) with no metabolic derangement (De Lorenzo et al. 2006). Meta-analysis studies have shown about 30% worldwide prevalence of metabolic obesity in normal-weight subjects (Wang et al. 2015), or 10–37% (Badoud et al. 2015). In American Hispanics, 43.1% were classified as metabolically obese (Benziger et al. 2015), and in Chinese, 9.5% for men and 6.1% for women were observed at the BMI range < 24.0 kg/m^2 (Jia et al. 2018).

In Koreans with BMI < 23 kg/m^2, Kim et al. detected 36% in men, with body fat % $> 20.6\%$ and 29% in women, with body fat % $> 33.4\%$ (Kim et al. 2014), while only 9.1% was reported in young Latin Americans (20–55 years of age) (Madeira et al. 2013). Just 2.2% was noticed in Spain by Goday et al. (Ding et al. 2016). In South India, the prevalence was 15.1% and 14.8% in obese subjects (Geetha et al. 2011). Among 6854 multi-ethnic women, the prevalence was 5.4%, especially in Indian women (Moy and Loh 2015)

Diagnostic Criteria for Normal weight obesity

Classically, a major criterion used is insulin sensitivity using the upper quartile of an insulin sensitivity index and Homeostasis model of assessment of insulin resistance (HOMA-IR). A lower level of insulin sensitivity was noted in overweight and obese groups; however, the metabolically normal, obese group with normal insulin sensitivity was similar to the normal-weight group for HOMA-IR value. Further, the metabolically normal, obese group had significantly lower mean total cholesterol and fasting glucose levels suggestive of an important role of hepatic fat, rather than visceral fat in insulin resistance (Zhao et al. 2016; Stefan et al. 2008). A hyperinsulinemic-euglycemic clamp (HEC) study in nonobese (BMI < 25 kg/m^2) Japanese subjects to evaluate muscle and hepatic insulin sensitivity has suggested impaired insulin sensitivity in peripheral tissue and low hepatic glucose production. This is probably due to decreased endogenous insulin sensitivity, in the

metabolically obese group, which had significantly higher subcutaneous fat area and total fat than the metabolically nonobese group. Furthermore, oral glucose tolerance test (OGTT) studies showed lower values of Matsuda index but high values of fasting insulin and HOMA-IR in the metabolically obese group (Kaga et al. 2017). MHO subjects feature low amounts of visceral adipose tissue with higher levels of high-density lipoprotein (HDL) cholesterol and lower levels of fasting triglycerides, fasting glucose, fasting insulin, as well as reduced glucose and insulin area under the curve during an oral glucose tolerance test (Karelis et al. 2005)**.**

The HOMA-IR has been combined with other metabolic criteria in order to identify MHO subjects. This implies the presence of fewer than two of the cardiometabolic abnormalities namely systolic/diastolic blood pressure above 130/80 mm Hg, triglycerides above 1.7 mmol/L, fasting glucose levels above or equal to 5.6 mmol/L, C reactive protein (CRP) above 0.1 mg/L, HDL levels less than 1.3 mmol/L (Wildman et al. 2008). In contrast, fulfilling four out of the five metabolic parameters namely HOMA index less than or equal to 2.7 mmol/L, triglycerides less than or equal to 1.7 mmol/L, and low-density lipoprotein cholesterol (LDL) less than or equal to 2.6 mmol/L, and CRP levels less than or equal to 3.0 mg/L were deemed sufficient to identify normal-weight metabolic obesity (MONW) with risk for cardiovascular diseases (Karelis and Rabasa-Lhoret 2008).

Possible Contribution of Free Fatty Acids (FFAs)

FFAs released by lipolysis from the adipocytes are elevated in subjects with metabolic obesity, as in obese subjects. FFAs combine with glycerol to form triglycerides (TG) and are then consolidated by the liver in water-soluble form as very low-density lipoprotein (VLDL) particles. These particles are large and mainly contain TG, along with some cholesterol. Triglyceride, being an energy substrate, is hydrolysed in various tissues. Particles become smaller and dense gradually, forming intermediate-density lipoprotein (IDL) and low-density lipoprotein (LDL) cholesterol particles (Sniderman et al. 2001). High levels of FFAs are strongly associated with hepatic and peripheral insulin resistance, T2DM and cardiovascular diseases (Rachek 2014), due to generation of deleterious lipid metabolites (Boden et al. 2001), and pro-inflammatory cytokines (Boden et al. 2005), which induce oxidative stress in the endoplasmic reticulum (Manna and Jain 2015) and endothelial dysfunction (Ghosh et al. 2017). Thus, it is deemed ideal to include estimation of fasting FFAs as criterion to define metabolic obesity in subjects with normal weight or low BMI.

Pathogenesis and Cardiometabolic Risk of Normal-weight Obesity

Intra-abdominal adipose tissue (IAAT), or visceral adipose tissue (VAT), is a determinant of insulin resistance and cardiovascular disease risk, differently from gluteo-femoral adiposity (Kn 2001; Ibrahim 2010). The IAAT is located primarily in the mesentery and omentum and drains directly through the portal circulation to the liver. The IAAT is more cellular, vascular, innervated, and contains a larger number of inflammatory and immune cells, lesser pre-adipocyte differentiating capacity and a greater percentage of large adipocytes, glucocorticoid, and androgen receptors, when compared to subcutaneous adipose tissue (SCAT). The adipocytes in IAAT are metabolically active, more sensitive to lipolysis, and more insulin resistant than SCAT adipocytes (Fig. 26.2). IAAT has a greater capacity to generate free fatty acids and to uptake glucose than SCAT and is more sensitive to adrenergic stimulation (Goossens 2008), while SCAT is more avid in absorption of circulating free fatty acids and triglycerides.

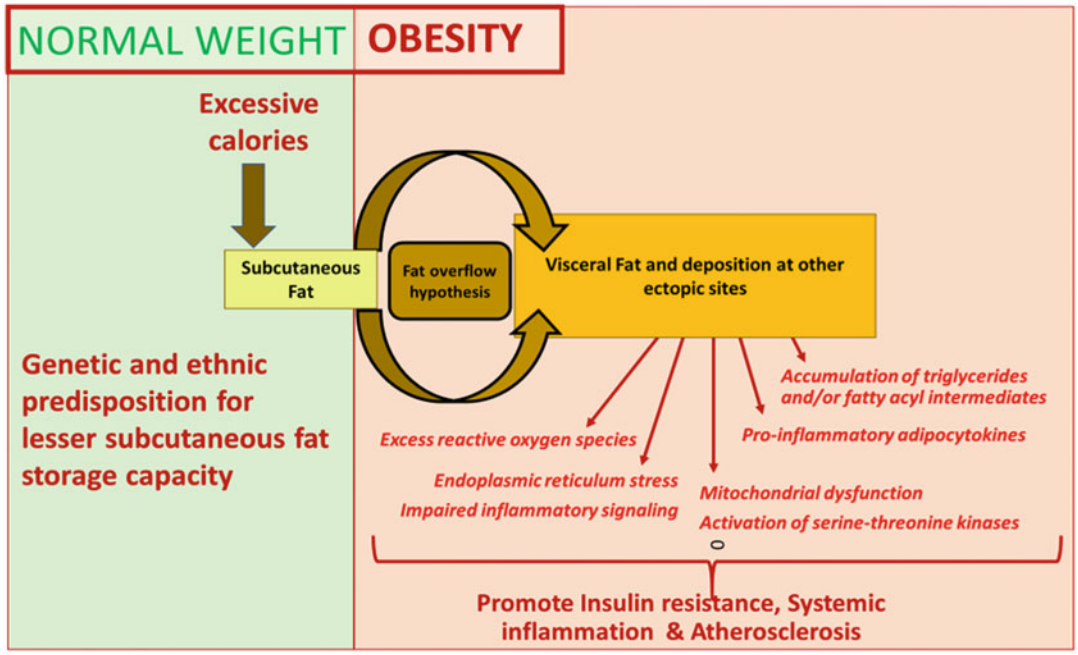

Fig. 26.2 Pathogenesis of normal-weight obesity

Metabolic Consequences of Normal-weight Obesity

Insulin resistance due to deranged lipid parameters, deficient adipose tissue FFA turnover, increased CRP levels, and oxidative stress along with possible influence of age, dietary, and physical activity patterns lead to increased risk for type 2 diabetes (Jean et al. 2014) and cardiovascular diseases (Romero-Corral et al. 2010a). In normal-weight subjects, ectopic fat in liver, skeletal muscles, and the pancreas are additional risk factors (Shulman 2014).

Liver Fat Accumulation

Non-alcoholic fatty liver disease (NAFLD) affects nearly 25% of the global population (Zhu et al. 2015), with insulin resistance being a signature mark, irrespective of body weight. Specifically, peripheral insulin resistance is a robust correlate of liver cirrhosis in NAFLD, more than visceral adiposity (Rosso et al. 2016). In patients with NAFLD, glucagon secretion, and signaling is dysregulated resulting in fasting and postprandial hyperglucagonemia (Foghsgaard et al. 2017), due to impaired paracrine functions of pancreatic beta cells (Unger and Cherrington 2012) and increased hepatic glucose production (Girard 2017). This metabolic state undergoes a vicious feedback cycle leading to homeostatic stress and impaired glycemic status, which has significant implications for renal and cardiovascular diseases (Petta et al. 2019). In addition, circulating FFAs (the major energy substrate for all tissues except brain) are markedly high during fasting state, due to adipose tissue lipolysis and lipoprotein spillover coupled with reduced plasma clearance. FFAs are re-esterified to triglycerides and accumulate in the muscles (intra-myocellular) and liver (intra-hepatocellular) and result in insulin resistance. Increased FFA levels result in elevated production of pro-atherogenic proteins through activation of the IKK/I B–/NF B and JNK pathways.

Fatty Pancreas

An important and heterogeneous entity in metabolic obesity is NAFPD or "fatty pancreas." NAFPD is a clinical phenomenon, wherein increased intracellular lipids and adipocytes infiltrate the pancreatic tissue, along with insulin resistance and beta-cell secretory defect (Tariq et al. 2016). Of note, the pancreas seems to be more susceptible to fat deposition when compared to the liver (Della Corte et al. 2015). Recent studies have shown that NAFLD patients with NAFPD have higher insulin resistance as evidenced by OGTT, HOMA-IR, and HOMA-b, in comparison with patients without NAFPD. This can be attributed to infiltration of triglycerides in the pancreas over time, which also results in exocrine dysfunctions (van Raalte et al. 2010), and cell apoptosis irrespective of body weight (Romana et al. 2018).A recent meta-analysis of 13 studies has shown that non-alcoholic fatty pancreas disease (NAFPD) was associated with a significant increased risk of metabolic syndrome (RR = 2.25; 95% CI, 2.00–2.53; $P < 0.0001$), hypertension, diabetes mellitus, and central obesity (RR = 1.91; 95% CI, 1.67–2.19; $P < 0.0001$) (Bi et al. 2019).

Normal-weight Central Obesity (NWCO) - A Similar Entity as Normal Weight Obesity

NWCO corresponds to a BMI of 18.5–23.9 kg/m^2 and a waist circumference (WC) >85 cm in males or >80 cm in females, a waist-to-height ratio (WHt-R) of ≥0.5, and a waist-to-hip ratio (WHR) of ≥0.9 in males or ≥0.85 in females. Among Chinese adults, it became much more prevalent from 1993 to 2011. Cardiometabolic risks encompass hypertension, diabetes, insulin resistance, decreased insulin sensitivity, and elevated low high-density lipoprotein and triglyceride levels (Song et al. 2019). In a large meta-analysis, an increased risk for cardiovascular events (RR, 1.24; 95% CI, 1.02 to 1.55) was perceived with ≥10 years of follow-up. All metabolically unhealthy groups were considered: normal weight (RR, 3.14; CI, 2.36 to 3.93), overweight (RR, 2.70; CI, 2.08 to 3.30), and obese (RR, 2.65; CI, 2.18 to 3.12). Cardiovascular events seem to cluster in overweight and obese persons even without overt metabolic abnormalities (Kramer et al. 2013).

In a European cohort, obesity without metabolic abnormalities was not associated with myocardial infarction, in contrast to heart failure, particularly long-lasting or severe obesity (Mørkedal et al. 2014). Also risk for diabetes, coronary heart disease (CHD), stroke, and mortality was demonstrated in people with unhealthy obesity (Guo and Garvey 2016).

Metabolically obese, normal-weight subjects exhibited increased arterial stiffness and carotid atherosclerosis (Choi et al. 2013). Risk for subclinical atherosclerosis was comparable to metabolically unhealthy obese adults (Rhee et al. 2014). In the Women´s Health Initiative, following 161,808 postmenopausal women for over a decade, a cumulative effect of excessive body weight and aberrant metabolic profile occurred. Diabetes risk approximately doubled among those with metabolically unhealthy normal weight, as well as the metabolically healthy obese, whereas diabetes affected nearly four times more those both obese and metabolically unhealthy (Cordola Hsu et al. 2020).

Abdominal Obesity

Abdominal obesity leads to cardiomyocyte hypertrophy, myocardial fibrosis and activation of inflammatory pathways relating to macrophage infiltration and cytokine gene expression (Murase et al. 2012). Specifically, low muscle mass and abdominal obesity in normal-weight individuals pose an adverse cardiometabolic risk profile, when compared to those without abdominal obesity. Metabolically, such individuals had higher values for glucose, insulin, HOMA-IR, branched-chain amino acids, and a higher prevalence of metabolic syndrome (Beijers et al. 2017). Hypertriglyceridemia, low and dysfunctional HDL, and increased small

LDL levels, and characteristics of atherogenic dyslipidemia are also relatively common (Chapman et al. 2011). Much of the cholesterol might be embedded in VLDL, IDL, and other remnant lipoproteins, including chylomicron remnants in the non-fasting state. These particles are equally potent as LDL in predicting cardiovascular events and all-cause mortality (Varbo et al. 2015).

Epicardial Adipose Tissue (EAT)

The EAT is located between the myocardium and visceral pericardium, mainly on the right ventricle surface and the anterior wall of the left ventricle of the heart. EAT volume and thickness are considered as surrogate markers of insulin resistance. EAT thickness of 9.5 mm or more in males and 7.5 mm or more in females has a high sensitivity and specificity for prediction of metabolic syndrome (Iacobellis et al. 2008).

A meta-analysis of 38 studies has shown significant correlations of EAT with components of metabolic syndrome specifically fasting blood glucose (FBG), systolic blood pressure (SBP), TGs and HDL-C, independent of obesity. A strong correlation of EAT with VAT was noted (Rabkin 2014). Magnetic resonance imaging in nondiabetic individuals with normal ventricular function has shown positive association of peripheral insulin resistance and glucose tolerance status with cardiac fat accumulation (Sironi et al. 2004). Similarly, EAT thickness measured by ultrasound was increased inversely to glucose disposal, as observed in euglycemic-hyperinsulinemic clamp study in obese subjects (Iacobellis and Leonetti 2005).

Involved Pathways

The EAT serves as a local reservoir of excess of FFAs to maintain myocardial energy supply and prevent toxic effects. During metabolic stress, EAT releases FFAs at high rate and regulates homeostasis of FFAs through the coronary circulation, including expression of transporters fatty acid-binding protein-4 [FABP-4] (Furuhashi et al. 2016). It also controls the vascular tension and the effect of insulin on microcirculatory networks (Meijer et al. 2015).

The EAT decreases vascular tension through the release of adipocytokines such as adiponectin, adrenomedullin, omentin, and other adipocyte-derived relaxing factors to retard vascular remodeling (Gruzdeva et al. 2017). Cytokines released from dysfunctional myocardial endothelium impair insulin signaling (Salgado-Somoza et al. 2012). Shifts in glucose uptake and lipogenesis along with more abundant FFA occur in both CAD and heart failure (HF), even in nondiabetic subjects (Burgeiro et al. 2016). Hyperglycemia and hyperinsulinemia favor accumulation of myocardial lipids, potentially leading to cardiac steatosis (Winhofer et al. 2012).

Diagnostic Tools: Body Composition Analysis

Fat mass, fat-free mass, lean mass, and body mineral density are precisely estimated on dual-energy X-ray absorptiometry (DEXA), while on bioimpedance, it is approximated on the basis of resistance of body to a small electrical impulse to estimate body water content and composition (Peppa et al. 2017; Teixeira et al. 2015) . Many years ago, the WHO has defined the cutoff values for body fat % in male and female obesity as $\geq$25% and $\geq$35%, respectively (WHO 1995), although the topic is controversial and different values can be found in the literature. Moreover, technological discrepancies exist regarding body fat percentage, among bioimpedance analysis and more direct methods such as DEXA or magnetic resonance imaging (MRI).

Phenotypically, Asians have a smaller body frame, based on the wrist circumference or elbow width, and are shorter in height when compared with Caucasians (Zhang et al. 2005). Importantly, South Asians feature higher body fat, lesser lean mass, higher ectopic fat with higher odds of metabolic obesity when compared to Caucasians, Hispanics, and other ethnic groups (Patel et al. 2016). In this purview, cutoff values

for fat mass and lean mass have been defined by Misra et al., (Joseph et al. 2011) for Asian Indians, using the DEXA technique, exclusively for males and females. Accordingly, the appropriate cutoff values for total body fat (%), fat mass (kg), total lean mass (%), lean mass (kg), and fat-free mass (kg) were 25.5, 15.1, 73.7, 46.3, and 48.8 for males and 38.0, 20.3, 59.0, 32.6, and 34.8 for females. Corresponding values for fat arm (%), fat mass arm (kg), fat leg (%), fat mass leg (kg), fat trunk (%), and fat mass trunk (kg) were 19.8, 1.4, 21.9, 4.1, 30.1, and 8.8 for males and 43.3, 3.1, 38.9, 6.9, 38.5, and 9.5 for females (Joseph et al. 2011).

Based on MRI, appropriate cutoff values for abdominal adipose tissue compartments have also been defined for Asian Indians. Accordingly, the gender-specific cutoff limits for total abdominal adipose tissue, intra-abdominal adipose tissue, and subcutaneous abdominal adipose tissue were 245.6 cm^2 for males and 203.46 cm^2 in females, 135.3 cm^2 (male) and 75.73 cm^2 (female), and 110.74 cm^2 (male) and 134.02 cm^2 (female), respectively. For detection of CV risk factors, distinct gender differences were seen in ORs for SCAT [3.54 (95% confidence interval [CI], 1.10–11.46) and 6.6 (95% CI, 1.75–24.85) in males and females, respectively] but not for intra-abdominal adipose tissue, a result that conflicts with other experiences (Misra et al. 2010).

Other Asian Populations

A DEXA-based study on 2798 Japanese individuals aged between 20 and 79 years determined cutoff values for fat mass %, truncal fat mass, and truncal fat mass-leg fat mass ratio. Accordingly, the cutoff points were 24% for fat mass %, 8 kg for truncal fat mass and 1.6 for truncal fat mass-leg-fat mass ratio in males, and 35% (fat mass %) 9 kg (truncal fat mass) and 1.4 (truncal-fat mass ratio) females. WHR and truncal fat mass/leg fat mass ratio most accurately detected cardiovascular risk factors (Ito et al. 2003). A bioimpedance-based study on 1687 Sri Lankan individuals aged above 20.6 years, determined total body fat % and fat mass index thresholds of 25.6% and 7.0 kg/m² in men, and 39.0% and 11.9 kg/m² in women, as cutoff values to detect risk of metabolic syndrome (Ramírez-Vélez et al. 2017). Subsequently, another study on Sri Lankans aged between 18.5 and 25.1 kg/m^2 validated the International Diabetes Federation cutoff values for muscle-to-fat ratio to screen for metabolic syndrome. The cutoff value of fat-to-muscle ratio for metabolic syndrome was 0.225 kg and 0.495 kg for men and women, respectively (Ramírez-Vélez et al. 2018).

A cross-sectional study on 383 Chinese subjects aged between 18 and 24 years and BMI between 18.5 and 23.9 kg/m^2, defined metabolic obesity as a body fat percentage of $> 20\%$ or $> 30\%$ in male and female students, respectively. Individuals with higher body fat had low physical fitness due to low muscle mass (Zhang et al. 2018). Overall, it is evident that there is potential health risk for individuals with metabolic obesity. While there are significant differential effects due to inter-ethnic differences in comparative studies, due to methodological variations, confounding effects of age, gender, and sample sizes, there is a thrusting need for prospective studies to refine the diagnostic criteria for different populations (Franco et al. 2016).

Metabolomic Research in Normal-weight Obesity

Linoleic acid, β-alanine, histidine, carnitine, and aspartate/asparagine metabolism pathways are upregulated in normal-weight obese and overweight/obesity adults. Metabolites of lysine, glycine, serine, and the urea cycle were elevated only in case of overweight/obesity (Bellissimo et al. 2019). A higher profile of branched-chain amino acids, tyrosine, glutamic acid, and diacylphosphatidylcholines C32:1 and C38:3 was characteristic of normal-weight metabolically obese subjects, whereas a reduced pattern of acylcarnitine C18:2 and acyllysophosphatidylcholine C18:1 occurred in the metabolically healthy obese subjects (Bagheri et al. 2018).

Genomic Sequencing

Genome Wide Association Studies (GWAS) raise the possibility that *FTO* gene and other loci regulate body fat (Huang et al. 2018). Associations have also been detected for the *IRS1*, *FTO*, and *SPRY2* loci, along with nine novel loci (Morris et al. 2012). One allele at the *IRS1* locus was involved with lower HDL-C, higher TG levels, and elevated insulin resistance. The effect size for each allele was −0.20% and −0.06% of body fat for men and women, respectively. A higher VAT/SAT ratio resulted in men only. In addition, adiponectin diminished in men, without changes of leptin in either gender (Miki et al. 2001). Four other loci (in or near *COBLL1/GRB14, IGF2BP1, PLA2G6, CRTC1*) have been linked to body fat %. Lower expression of *GRB14* in subcutaneous and omental fat corresponded to one of the fat-reducing loci. The loci near *IRS1* and *PLA2G6* had more impact on men, contrasting with those close to *TMEM18* and CRTC1 which were more relevant for women (Lu et al. 2016).

Therapeutics and Prevention of Normal-weight Obesity

A longitudinal follow-up of normal-weight obese school children revealed increased cardiometabolic risk in early adulthood, seven years after diagnosis. In previously published results from our center, in relatively older individuals, a significant reduction in some but not all cardiovascular risk factors occurred (Wiklund et al. 2017). In another Swedish cohort of 3010 adults, it was found that normal-weight obesity was associated with higher levels of serum triglycerides, low-density lipoprotein cholesterol, C-reactive protein, apolipoprotein B, and blood pressure, along with lower high-density lipoprotein cholesterol. In our data, at least two of these parameters, namely HDL cholesterol and systolic blood pressure, significantly improved with lifestyle intervention (Berg et al. 2015). These findings are pertinent as normal-weight obesity increases the risk of developing atherosclerosis and macrovascular disease (Kim et al. 2015). At this point, it is unclear if individuals with normal-weight obesity would respond after a longer duration of lifestyle change, or they are inherently resistant. The potential impact of drugs like metformin and pioglitazone (insulin sensitizers) on improving the cardiometabolic profile of this unique phenotype also deserves attention.

NWO women are to metabolic syndrome (Marques-Vidal et al. 2010). Higher blood pressure, cholesterol, and fasting blood glucose were unveiled, when compared to low body fat counterparts. In the same study elevated leptin, interleukin-1a, interleukin-1b, and interleukin-8- levels occurred. In the NHANES III database, women with normal-weight obesity showed an independent association with cardiovascular mortality (Romero-Corral et al. 2010b). The association was maintained after adjustment for risk factors such as hypertension, dyslipidemia, and waist circumference. A more recent study revealed that with a peer-led lifestyle intervention only a minimal favourable change in systolic blood pressure and LDL was noted after 2 years (Kapoor et al. 2020b).

Conclusion

Normal-weight obesity is an obscure yet a common disorder prevalent not only in the south Asian population, but also in other parts of the world. Little is known about its therapeutic and prevention aspects. Moreover, the genetic predisposition of this phenotype needs to be more extensively explored. Improving the awareness of this clinical entity among physicians would promote earlier diagnosis and prevention of its associated complications.

Abstract

Childhood obesity is a growing concern, which may result in major comorbidities, previously felt to be adult-specific diseases. Genetics, environment, and behavior count among the pillars of this condition. Lifestyle modification is paramount, whereas indications for metabolic and bariatric surgery are becoming popular as well for severely affected adolescents. The scarcity of approved drugs progressively leads to off-label adjunct prescriptions in those refractories to diet and exercise. Comorbidities can persist into later life- impacting morbidity and mortality. Besides prevention and treatment of ongoing problems, long-term sequelae should be avoided to allow for a long and healthy adult life.

Keywords

Childhood/adolescent obesity · Lifestyle modification · Pharmacotherapy · Bariatric surgery · Obesity-related comorbidities

Pediatric Obesity: A Worldwide Concern

Obesity is one of the leading chronic diseases affecting children across the globe and contributes to increased morbidity across the lifespan. This complex disease, characterized primarily by excess body weight for height, requires thorough assessment for etiologies both common and rare. There are many risk factors for excess weight gain including genetic profile, prenatal environments, and postnatal exposures. Though most treatment options for pediatric obesity have focused on behavioral modifications to combat our increasingly obesogenic environments, treatment options for severe obesity have increased over the last decade, including pharmacological and surgical options. It is important that obesity and associated comorbidities are treated and addressed in the clinical setting to decrease the persistence into adulthood; however, it is likely that public health and policy measures will be most effective in meaningful decreases in pediatric obesity prevalence at the national scale.

Table 27.1 Weight classification by BMI percentile for children aged 2–20

Weight Status		CDC BMI Percentile
Underweight		<5th Percentile
Normal Weight		5th percentile < 85th percentile
Overweight		85th percentile—< 95th percentile
Obesity	Class I Obesity	95th percentile—< 120% of the 95th percentile
Severe Obesity	Class II Obesity	120% of the 95th percentile—< 140% of the 95th percentile, or a BMI of 35 (whichever is lower)
	Class III Obesity	140% of the 95th percentile and above, or a BMI of 40 (whichever is lower)

Definitions of Obesity

For children greater than 2 years of age, Body Mass Index (BMI) percentiles are used to define pediatric weight status. The raw BMI is an indirect measure of body fat and is calculated as [weight (kg)/height $(m)^2$]. The CDC percentiles can be used as outlined in Table 27.1 to determine weight classification for children 2 years and older (Flegal et al. 2009).

Pediatric obesity has been redefined, as rates of severe obesity have increased, where "severe obesity" is typically defined as either Class II or Class III obesity. It is helpful to use newly designed CDC growth charts for children and adolescents with obesity, to track BMI trajectories over time (Gulati et al. 2012). Obesity classifications allow for more precise characterization of a patient's degree of excess weight and also easily convert to adult classifications of obesity (Racette et al. 2017) (Table 27.2).

Table 27.2 Adult weight classification by BMI

Adult weight classification	BMI
Overweight	25.0–29.9
Class I Obesity	30.0–34.9
Class II Obesity	35.0–39.9
Class III Obesity	>40

BMI: kg/ m^2

Epidemiologic Trends

From 1975 to 2016, age-standardized prevalence of obesity increased in girls from 0.7% to 5.6% and in boys from 0.9% to 7.8%. Obesity prevalence has increased in every region of the world and has disproportionately affected low-income regions. Though mean childhood BMIs have seemed to plateau in high-income countries, it is apparent that BMIs are continuing to increase across most of Asia and other lower-income regions (NCD Risk Factor Collaboration (NCD-RisC) 2017).

In the United States, overweight and obesity affect over one in three children aged 2–17 years, with current obesity prevalence of 17.4%. Rates of severe obesity have also increased, with 10% of adolescents having Class II or III obesity using the NHANES 2013–2014 data (Skinner et al. 2018).

Disparities also exist, such that in highly developed countries, low income is generally associated with higher rates of obesity (NCD Risk Factor Collaboration (NCD-RisC) 2017; Shrewsbury and Wardle 2008). There are also racial disparities; African American and Hispanic youth have higher rates of obesity than white and Asian Americans (Weaver et al. 2019).

Risk Factors

During the prenatal period, both maternal obesity and excessive gestational weight gain increase risk of large for gestational age and neonatal adiposity (Starling et al. 2015; Goldstein et al. 2017). Maternal smoking during pregnancy can also increase risk of obesity in childhood (Suzuki et al. 2009; Dubois and Girard 2006).

In the postnatal period, excessive weight gain early in life as well as early adiposity rebound has been shown to increase risk of adolescent obesity, persistence of obesity into adulthood, and worse cardiometabolic outcomes (Geserick et al. 2018; Aris et al. 2019). Breastfeeding has been shown to decrease risk of obesity, with suggestion that

there is a dose-response relationship in protection (Horta et al. 2015; Gibson et al. 2017).

There are also many risk factors which include broadly: dietary intake high in energy-dense foods, fast food consumption, physical inactivity, excessive screen time, poor sleep, and parenting styles (Mihrshahi and Baur 2018; Melis Yavuz and Selcuk 2018; Vos and Welsh 2010).

Primary vs. Secondary Causes of Obesity

Primary obesity accounts for most pediatric cases and generally occurs when multifactorial influences result in excess weight gain. It is often related to dietary quality, physical inactivity, psychological factors, and environmental factors in a manner that affects the ratio of energy intake to energy expenditure.

Secondary causes of obesity include a wide variety of underlying disorders that impact a person's pathophysiology, leading to excessive weight gain. Specific medical causes of obesity are generally related to endocrinopathies, specific genetic mutations, or syndromic causes, with the most commonly considered etiologies listed in Table 27.3. These should be suspected and further investigated when related findings and clinical history are present, when weight gain appears to be severe, or when the presentation does not support primary obesity.

Note that for many of the genetic and endocrine causes of obesity, presence of short stature and/or developmental delay can be useful distinguishing features (Table 27.4) (Stipančić 2018). It is notable that neither Melanocortin 4 receptor (MC4R) deficiency nor POMC deficiency is related to decreased height or developmental delay. Defects in MC4R may account for up to 6% of severe pediatric obesity and are

Table 27.3 Endocrine, monogenic, and syndromic causes of obesity

Endocrine	Monogenic	Syndromic
• Hypothyroidism • Cushing disease • Polycystic ovarian syndrome • Growth hormone deficiency • Hypothalamic obesity • Hypogonadism • Pseudohypoparathyroidism • Insulinoma	• POMC deficiency • Melanocortin 4 receptor deficiency • Leptin or Leptin receptor deficiency	• Prader-Willi syndrome • Bardet-Biedl syndrome • Beckwith-Wiedemann syndrome • Alstrom-Hallgren syndrome • Carpenter syndrome • Cohen syndrome

Table 27.4 Key Findings in Select Secondary Causes of Obesity

	Developmental Delay?	Short stature?	Key Findings
Prader-Willi Syndrome	X	X	Hypotonia, hypogonadism, small hands, and feet
Bardet-Biedl Syndrome	X	X	Polydactyly, syndactyly, retinitis pigmentosa, hypogonadism, kidney disorders
Carpenter Syndrome	X	X	Polydactyly, syndactyly, hypogonadism in boys
Cohen Syndrome	X	X	Microcephaly, marked central incisors, long thin fingers
Hypothyroidism		X	Fatigue, constipation, dry skin, and hair
Growth Hormone deficiency		X	Centripetal obesity, young appearance
Cushing's Syndrome		X	Round face, acne, striae, hirsutism, hypertension
Hypothalamic Obesity		X	Signs of increased intracranial pressure, hypopituitarism, history of neuropathology
Alstrom Syndrome		X	Blindness, deafness, type 2 diabetes, acanthosis nigricans

commonly found with accelerated linear growth and hyperinsulinemia (Farooqi et al. 2003). POMC deficiency is notable for presence of adrenal insufficiency and hypopigmentation (Stipančić 2018).

Drug-induced Secondary Obesity

Many anti-diabetic medications such as insulin or sulfonylureas are known to cause weight gain. Centrally acting antipsychotics, antidepressants, and antiepileptic medications are also commonly used in pediatric populations and may especially lead to weight gain when used near the time of puberty. Children receiving high-dose steroids are also prone to excessive weight gain. It is important for the clinician to be aware of these interactions and to consider weight-neutral options when appropriate (Leslie et al. 2007).

Genetic Risk Scores and Epigenetics

Though specific monogenic and syndromic forms of obesity are detailed in Table 27.3, a person with primary obesity may still have an increased risk of obesity due to polygenic factors. Genome-wide studies have shown that specific genetic variations are associated with higher BMI, such that those with the highest risk scores were 25 times as likely to have severe obesity as compared to those with the lowest risk scores. Though BMI differences based on risk score appear even by age 3, research is still growing in this and it is not commonly used in clinical practice (Khera et al. 2019).

There is also increasing evidence that epigenetics, such as DNA methylation, modifications to microRNA, and histone tails, are important in the development of obesity. This is especially convincing as more evidence suggests that perinatal factors, exposure to environmental pollutants or obesogens, and specific gut microbiota affect both epigenetic factors and obesity risk (Lopomo et al. 2016).

Table 27.5 Clinical evaluation of an obese child and adolescent

History	Physical Exam
• Dietary history • Physical activity assessment • Review of medications • Developmental history • Sleep history • Review of systems • Family history of obesity and related comorbidities • Psychosocial screening	• Measurement of height and weight for BMI, BMI percentile, and BMI z-score calculations • Blood pressure measurement with appropriate sized cuff • Assessment for dysmorphic and for Cushingoid features suggestive of a primary cause
Laboratory screening	
Overweight (BMI 85th–95th %) All: • Fasting lipid profile If ≥10 years AND ≥1 risk factor(s)[a]: • Fasting blood glucose or hemoglobin A1c • Aminotransferases (AST, ALT) • Repeat fasting lipid profile every 2 years	Obese (BMI ≥95th %) All: • Fasting lipid profile If ≥10 years regardless of risk factors: • Fasting blood glucose or hemoglobin A1c • Aminotransferases (AST, ALT) • Repeat fasting lipid profile every 2 years

[a]Risk factors: elevated blood pressure, elevated lipid levels, current tobacco use, or family history of obesity-related diseases

Clinical Evaluation

The clinical evaluation of an obese child includes a complete history and physical exam directed at identifying the cause and related comorbidities (Table 27.5) (Kumar and Kelly 2017; Armstrong et al. 2016). The 2017 U.S. Preventive Services Task Force recommends BMI measurement to screen for obesity in children ≥6 years; however, the American Academy of Pediatrics (AAP) recommends annual plotting of BMI on a growth chart for all patients 2 years and older (Quattrin and Wilfley 2017). While no consensus exits about laboratory screening tests and when to screen in children with obesity, general recommendations are summarized in Table 27.5 (Kumar and Kelly 2017; Krebs et al. 2007). Universal screening with a fasting lipid panel has been recommended by the US National Heart, Lung, and Blood Institute 2011 expert panel

Table 27.6 Stepwise approach to weight management in children and adolescents

Stage 1 Prevention Plus: Lifestyle intervention provided by a primary care provider
Stage 2 Structured Weight Management: Monthly visits with a primary care physician and support from a registered dietician
Stage 3 Comprehensive Multidisciplinary[a] *Intervention:* Intensive weight loss program composed of weekly visits for a minimum of 8–12 weeks at a pediatric weight management center
Stage 4 Tertiary Care Intervention: Use of medical diets, medications, and surgery in addition to Stage 3 interventions

Adapted from Table 8 in Barlow, 2007 (see ref. (Barlow 2007))

[a]Multidisciplinary team approach includes a medical provider, registered dietician, exercise specialist, mental health professional, nurse, and social worker.

between 9 and 11 years of age and again between 17 and 21 years of age, although these guidelines remain controversial (Gillman and Daniels 2012). Children with clinical evaluation suggestive of a genetic or endocrine cause or comorbidity may need additional specific testing.

Lifestyle Interventions

Behavioral changes (engaging the family), dietary regimen, and a higher activity level are the official guidelines (Table 27.6) (Kumar and Kelly 2017; Barlow 2007; Spear et al. 2007). Results with low glycemic index and low-carbohydrate diets are similar to those achieved with portion controlling, yet dropout rate is high (Ebbeling et al. 2003; Sondike et al. 2003). The Mediterranean-style diet (MSD) is highly regarded for grown-ups, inhibiting the advent and progression of metabolic syndrome (MetSyn) (Grosso et al. 2014; Babio et al. 2009), and could be an option for the pediatric age bracket (Velázquez-López et al. 2014). The low-fructose diet could attenuate elevated LDL-C and nonalcoholic fatty liver disease (NAFLD); however, weight loss did not materialize (Mager et al. 2015). Family involvement in the utilization of less high calorie density snacks and drinks, and more nutrient-dense components, could be a winning strategy (Epstein et al. 1990; Epstein et al. 1994).

According to the American Academy of Pediatrics (AAP), daily pediatric needs include at least 60 minutes of substantial activities, with no screen exposure under age 2, and at most 2 hours for older children (Hassink et al. 2015).

For cases with advanced adiposity lifestyle, corrections are often insufficient (Ryder et al. 2018; Greenway 2015; MacLean et al. 2011); nevertheless, they alleviate comorbidities (Savoye et al. 2014; Ryder et al. 2013). The government, society, and other stakeholders should join in a common effort to combat the obesogenic environment and its consequences.

Pharmacotherapy

Pharmacotherapy, in conjunction with lifestyle modification, may be the next logical step in the treatment of pediatric obesity refractory to lifestyle modification alone (Ryder et al. 2018; Kelly and Fox 2017; Srivastava et al. 2019). Suggested BMI criteria for pharmacotherapy initiation in adolescents include BMI $\geq$95th% (or BMI $\geq$30 kg/m^2, whichever is lower) plus at least one obesity-related comorbidity; or BMI $\geq$120% of the 95th% (or BMI $\geq$35 kg/m^2, whichever is lower) irrespective of comorbidity. There is no upper BMI threshold for initiation of pharmacotherapy. Obesity pharmacotherapy can also be considered in patients meeting criteria for bariatric surgery; wherein surgery may not be appropriate or possible at that time, or when medications are recommended as adjunctive therapy (Srivastava et al. 2019). While there has been a surge in FDA-approved medications for adult obesity treatment, pharmacologic options for obese youth remain limited. Table 27.7 provides a summary of FDA-approved adult obesity medications and off-label drug use of medications in the pediatric obesity population (Srivastava et al. 2019; Shettar et al. 2017).

Table 27.7 Summary of FDA-approved adult obesity medications and off-label drug use of medications in the pediatric obesity population

Drug name	MOA	FDA indication	Off-label drug use	Side effects	Contraindications & Warnings
FDA approved					
Orlistat	Pancreatic and gastric lipase inhibitor	Obesity ≥12yo	Not indicated	Flatulence, oily stools, diarrhea, vitamin/mineral deficiency	Chronic malabsorption syndrome, cholestasis
Phentermine	Sympatho-mimetic amine	Obesity >16yo "short term"; combination phentermine/ topiramate ER approved for long-term treatment of obesity in adults	<16yo or long-term; beneficial in obesity with low energy states, sleep apnea, hunger, decreased satiety	Increases HR, BP, dry mouth, insomnia, constipation, anxiety, irritability	Cardiovascular disease, hyperthyroidism, active drug use, glaucoma, agitated states
Non-FDA approved					
Metformin	Activation of protein kinase pathway	≥10yo for T2DM	PCOS, insulin resistance, prediabetes, MetSyn, antipsychotic-medication-induced weight gain, stress eating/ emotional eating	Bloating, diarrhea, flatulence	Hold 48hrs prior to contrast, lactic acidosis
Topiramate	Modulation of various NTs	Treatment of epilepsy >2yo and migraines >12yo; combination phentermine/ Topiramate ER approved for long-term treatment of obesity in adults	Weight loss in adult and pediatric patients; useful adjunct in binge eating disorders and weight regain postbariatric surgery	Cognitive dysfunction, kidney stones, metabolic acidosis, teratogenic—adolescents pregnancy counseling (decreased efficacy of OCPs)	Inborn errors of metabolism with hyperammonemia and encephalopathy, acute myopia and secondary angle-closure glaucoma, rapid withdrawal can precipitate seizures, neuropsychiatric dysfunction, metabolic acidosis
Exenatide	GLP-1 agonist	T2DM in adults	<18yo for polygenic obesity (presence of diabetes, hypothalamic, syndromic)	Bloating, nausea & vomiting, abdominal pain, elevation pancreatic amylase & lipase	Post-marketing reports: pancreatitis, renal impairment, severe GI disease
Liraglutide	GLP-1 agonist	Saxenda (3mg dose) approved for obesity in adults, Victoza approved for T2DM in adults	<18yo	Abdominal pain, nausea & vomiting, diarrhea, potential hypoglycemia	Post-marketing reports: pancreatitis, renal impairment, severe GI disease

(continued)

Table 27.7 (continued)

Drug name	MOA	FDA indication	Off-label drug use	Side effects	Contraindications & Warnings
Lisdexamfetamine	Central nervous system stimulant	≥6yo for ADHD, short-term use of binge eating disorder in adults	Beneficial for younger children with ADHD and obesity or binge eating disorder	Anorexia, decreased appetite, decreased weight, diarrhea, dizziness, dry mouth, irritability, anxiety, insomnia, nausea & vomiting, abdominal pain	Serious cardiovascular reactions such as sudden death, BP and HR increases, psychiatric adverse reactions, suppression of growth, peripheral vasculopathy (Raynaud's), serotonin syndrome with serotonergic agents
No pediatric data					
Lorcaserin	5-hydroxy-triptamine-Receptor (R) 2C agonist	Long-term treatment of obesity in adults	<18yo with obesity	Headache, dizziness, fatigue, dry mouth, constipation, headache, back pain, cough in diabetes patients	Serotonin syndrome or neuroleptic malignant-like syndrome when co-administered with other serotonergic or anti-dopaminergic agents, discontinue with signs of valvular heart disease
Naltrexone/ bupropion SR	Blockade of opioid-R-mediated POMC auto-inhibition/ selective inhibition of reuptake of dopamine and nor-adrenaline	Long-term treatment of obesity in adults	Children and adolescents: warning for increased suicidal ideation	Nausea, constipation, headache, dizziness, insomnia, dry mouth, diarrhea	Uncontrolled HTN, seizures, anorexia nervosa, bulimia, active alcohol or chronic opioid use, angle-closure glaucoma, increase suicidal thought, and ideation
Pending new FDA approval					
Setmelanotide	Melano-cortin-4 receptor agonist	Phase 3 trials for monogenic obesity, FDA approval pending for monogenic obesity in adults and children	None; will be approved for pediatric patients as well	Dry mild induration at injection site, darkening of skin nevi	Caution use in structural heart disease and arrhythmias because of potential to increase HR and BP

Adapted from Table 3 in Srivastava et al., 2019 (see ref. (Srivastava et al. 2019))
MOA: mechanism of action; HR: heart rate; BP blood pressure; T2DM: type 2 diabetes mellitus; NTs: neurotransmitters; GLP: glucagon-like 1 receptor; POMC: proopiomelanocortin; OCPs: Oral contraceptives;

Table 27.8 Comorbidity indications for metabolic bariatric surgery and surgical outcomes

Comorbidities	% Remission at 5 years
Type 2 diabetes, prediabetes, insulin resistance	86 (Inge et al. 2019)
Hypertension Low HDL High triglyceride	68 (Inge et al. 2019) 78 (Inge et al. 2019) 81 (Inge et al. 2019)
Obstructive Sleep Apnea with apnea/hypopnea index (AHI) ≥ 5	60 (Amin et al. 2017)
Idiopathic intracranial hypertension (pseudotumor cerebri)	
Nonalcoholic fatty liver disease and nonalcoholic steatohepatitis	85 (Manco et al. 2017)
Gastroesophageal reflux disease	
Slipped capital femoral epiphysis (SCFE) or Blount's disease	
Impaired quality of life	

Pratt et al. (2018), Inge et al. (2019), Amin et al. (2017), Manco et al. (2017)
Remission informed whenever available; Blount's disease: tibia bowing, bowed legs

Metabolic and Bariatric Surgery

Metabolic and bariatric surgery (MBS) is currently the most effective sustainable method for weight loss and comorbidity management in children/adolescents with severe obesity. According to the most recent guidelines by the American Society for Metabolic and Bariatric Surgery (ASMBS) published in 2018, and the AAP guidelines published in 2019, bariatric surgery should be considered for adolescents ages 10–18 years (ASMBS) and $\geq$ 13 years (AAP) Class III obesity (BMI 140% $>$ 95th percentile) without any comorbidities, or Class II obesity (BMI 120% $>$ 95th percentile) with severe comorbidities (Table 27.8) (Pratt et al. 2018; Armstrong et al. 2019; Inge et al. 2019; Amin et al. 2017; Manco et al. 2017). The current procedures utilized in adolescents include the Roux-en-Y gastric bypass (RYGB) and the vertical sleeve gastrectomy (VSG).

Initially, the mechanical and digestive effects of the surgeries (restriction and malabsorption) were the primary considerations, but it is now known that hormonal regulation and metabolism are altered as well (Akkary 2012; Peterli et al. 2012). MBS disrupts hormonal signals between the gastrointestinal tract, the brain stem, and the hypothalamus (Akkary 2012; Peterli et al. 2012). Additionally, MBS impacts the physiological regulation of weight through the alteration of food intake, food absorption, appetite and satiety, energy balance, and behavioral response to food (Table 27.9) (Akkary 2012; Shikora et al. 2007).

RYGB was first performed as an open procedure in 1967 and until 2014, was the most common MBS operation in adults and adolescents (Abraham et al. 2016). The mechanism of the RYGB for weight loss includes restriction, malabsorption, and hormonal changes. A small pouch (20–30 mL) is created (restriction) bypassing >90% of the stomach, and the proximal intestine including the duodenum and the common bile duct. A Roux limb of intestine is created connecting the pouch to the jejunum

Table 27.9 Influence of metabolic bariatric surgery on gut hormones that influence appetite and satiety

Hormones	Pathway location	Hormone effect on appetite	RYGB effect on hormones	VSG effect on hormones	AGB effect on hormones
Ghrelin	V, BS, HT	↑	↓	↓	↑↑
GLP-1	V, BS, HT	↓	↑	↑	No Δ
PYY	V, BS, HT	↓	↑	↑	No Δ
PPP	V, BS	↓	↑	↑	No Δ
CCK	V, BS, HT	↓	No Δ	↑	No Δ

Adapted from Table 2 in Akkary, 2012 (see ref. (Akkary 2012))
RYGB: Roux-en-y gastric bypass; VSG: vertical sleeve gastrectomy; AGB: adjustable gastric band; GLP-1: glucagon-like peptide 1; PYY: peptide YY, PPP: pancreatic polypeptide; CCK: cholecystokinin; V: vagus nerve; BS: brain stem; HT: hypothalamus;

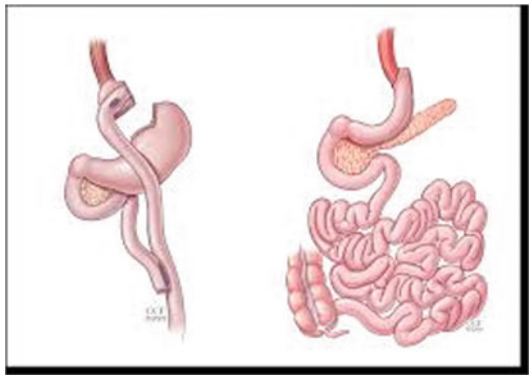

Fig. 27.1 Roux-en-Y gastric bypass (left) and vertical sleeve gastrectomy (right)

(Fig. 27.1) (Göthberg et al. 2014). Bypassing the majority of the stomach and proximal intestine causes malabsorption, including carbohydrates and fat. Additionally, multiple hormones are affected to increase satiety (Table 27.9) (Akkary 2012). RYGB results in approximately 30% total weight loss or 70% excess weight loss. Excess weight loss is the pre-surgery weight—the weight loss divided by the ideal body weight (or BMI=25), depending on the source.

A relatively common side effect of RYGB is dumping syndrome, sometimes precipitated by high carbohydrate and fat consumption, and featuring diarrhea, hypotension, presyncope, and nausea (Göthberg et al. 2014). These symptoms decrease over time, but diarrhea to some degree can persist. Other risks include small bowel obstruction, hernia, overstretching the pouch, and occasionally the need for revisional surgery, especially if weight regain refractory to prescription drugs is detected after some time.

VSG removes 75–80% of the stomach and is currently the most common procedure (80% in

Table 27.10. Nutritional deficiencies, as a complication of metabolic bariatric surgery

Procedure Type	RYGB, VSG	RYGB	RYGB	
Site of nutrient absorption in GI Tract	Stomach	Duodenum	Jejunum	Ileum

Adapted from Table 2 and Figure 4 in Shikora et al., 2007 (see ref. (Shikora et al. 2007))
Vitamin and mineral supplementation for life is advised after all bariatric and metabolic procedures. Dosage should be higher for malabsorptive than restrictive modalities.
VSG: vertical sleeve gastrectomy—vitamin B12 deficiency due to the lack of the production of intrinsic factor and fluoride deficiency. Additional vitamin supplementation is recommended due to limited intake of food and possible rapid transit of food during digestion.
[a]Requires hydrogen chloride (HCL) for absorption
[b]Affected secondary due to decreased intrinsic factor production

some countries) performed in adults and adolescents. VSG results in approximately 30% weight loss (Fig. 27.1) (Parrott et al. 2017). VSG restricts the amount of food that can be consumed, decreases ghrelin secretion significantly, and results in alterations of other hormonal pathways (Table 27.9) (Akkary 2012; Peterli et al. 2012). VSG is associated with fewer nutritional complications compared with the RYGB, but still requires monitoring for vitamin deficiencies long-term (Table 27.10) (Shikora et al. 2007). Specific side effects include leak and stricture. Side effects for all bariatric procedures include deep vein thrombosis and pulmonary emboli. Weight loss and improvements in obesity-related comorbidities are similar with both mentioned interventions (Table 27.8) (Pratt et al. 2018; Armstrong et al. 2019; Inge et al. 2019; Amin et al. 2017; Manco et al. 2017). Weight regain can happen in 25% of patients for either procedure, which generally responds to weight loss medication. MBS should be considered in adolescents with severe obesity.

Comorbidities and Long-term Follow-up

A child who is overweight or obese is at increased risk for several comorbidities in the short and long term. The severity of these comorbidities, particularly cardiometabolic, directly correlates with obesity severity (Kumar and Kelly 2017; Skinner et al. 2015). Key cardiometabolic and non-cardiometabolic risks of childhood obesity are described. These patients require long-term follow-up to screen for and, in some cases, to ultimately manage these comorbid conditions.

Cardiovascular Risk

More humans die from cardiovascular disease (CVD) than from any other cause (Mozaffarian et al. 2015), and premonitory endothelial lesions are documented in early childhood. Excessive adiposity and disturbed lipid profile precipitate precocious CVD. Recognized risks occur in most adolescents with excessive body weight, and one in ten accumulates three or more factors (Daniels 2009; Freedman et al. 1999; Steinberger et al. 2009).

Natural History of Atherosclerosis

Fatty streaks in the intima of the aorta can be identified even in infants and although many disappear, progression to fibrous plaques and clinical complications cannot be ruled out (Magnussen et al. 2009), as revealed by the classic Bogalusa Heart Study (Berenson et al. 1998) and Muscatine Study, both including long-term follow-up (Mahoney et al. 2001). Carotid intima-media abnormalities and deranged endothelial response have similarly been demonstrated in later years (Freedman et al. 2004; Urbina et al. 2009; Urbina et al. 2010).

Higher cardiac output and blood volume can follow as well, along with sleep apnea and hypoventilation, which do not bode well for heart and lung physiology (Speiser et al. 2005). Left ventricular mass also increases in obese youth, irrespective of systemic hypertension (Urbina et al. 2009; Yoshinaga et al. 1995; Daniels et al. 1998), potentially aggravating CVD morbidity and mortality (Flynn and Alderman 2005).

Dyslipidemia

Excessive body weight in adolescence mostly continues in later life (Freedman et al. 2007; Juonala et al. 2008), and a deranged lipid profile is common (Kit et al. 2015), usually defined by combined dyslipidemia of obesity (CDO). CDO aberrations include hypertriglyceridemia with less prominent deviation of LDL cholesterol than seen in older ages, yet with small, dense particles. One-third of sixth graders with excessive adiposity exhibited TG/HDL-C ratio > 3.0, and 11.2% had a non-HDL-C >145 mg/dL (Mietus-Snyder et al. 2013).

Future propensity toward myocardial infarction and/or death from CVD has been predicted

on the basis of a CDO (Robins et al. 2011) or similar pattern (Morrison et al. 2012).

Management of Dyslipidemia

Diet and physical exercise are mainstays of lipid profile correction, especially when counseling for the whole family is provided by a dietitian (National Heart L and BI 2012). When excessive body weight is simultaneously diminished, all age brackets are benefited (Nemet et al. 2005; Kirk et al. 2012; Ebbeling et al. 2007; Ebbeling et al. 2012; Meyer et al. 2006). Simple sugars and easily hydrolyzed starches are closely linked to triglyceride concentration (Sondike et al. 2003; Ebbeling et al. 2007; Pieke et al. 2000; Pereira et al. 2004), and reduction could also lead to better weight control (Dornas et al. 2015). Fiber and low-mercury fish should be encouraged instead (2X week). Pharmacological agents should basically be considered for refractory cases (De Ferranti et al. 2019).

Hypertension

Blood pressure < 90th percentile for age, sex, and height should always be sought (National Heart L and BI 2012). Values up to the 95th percentile for systolic or diastolic measurements (> 120/80 for adolescents) point toward prehypertension, whereas higher readings confirm the clinical condition. As with adults, three similar findings are required to establish diagnosis.

Excessive body weight predisposes to the condition, and weight loss ameliorates it (Haynes 1986; Rocchini et al. 1988). Sodium, caffeine, and fat foods are deemed deleterious, contrasting with potassium, calcium, and magnesium (He and MacGregor 2006; Dwyer et al. 1998; Sinaiko et al. 1993; Knuiman et al. 1988; Falkner et al. 2000; Simons-Morton et al. 1997).

Salty Foods

Commercial and industrial food carry the largest share of sodium intake, not domestic seasoning, and not more than 1.2 g/day (ages 4–8) or 1.5 g/day (> 8 years old) is allowed (Appel et al. 2006).

The Dietary Approaches to Stop Hypertension (DASH) diet, notably with sodium restriction, is a highly regarded option for grown-ups (Sacks et al. 2001). Young children with reduced consumption of fruits, vegetables, and low-fat dairy foods are prone to hypertension (Moore et al. 2005). Among teenagers, the DASH protocol has also conducted to less deranged systolic blood pressure (Couch et al. 2008).

Semi-vegetarian Diets

More recently, the adoption of a plant-based, no meat, and no added fat diet was shown to significantly decrease systolic blood pressure (along with other cardiovascular risk factors), in a small cohort of children compared to baseline (Macknin et al. 2015). Indeed, dietary changes can significantly impact cardiovascular risk factors in youth.

Insulin Resistance/Type 2 Diabetes

Glucose homeostasis is determined by beta-cell insulin secretion and the response to insulin in peripheral tissues, including the liver, skeletal muscle, and adipose tissue (Vidal and Kahn 2001). Insulin resistance (IR) refers to the state of reduced tissue response to insulin-mediated glucose metabolism (Levy-Marchal et al. 2010). In the setting of reduced tissue sensitivity, insulin secretion must increase to preserve euglycemia (Bergman et al. 1985). Abnormalities of glucose homeostasis may occur when insulin secretion is not adequate to compensate for the degree of IR (Arslanian et al. 2018a). IR is one of the key components for the development of type

2 diabetes (T2D), and it is strongly associated with obesity (Abrams et al. 2013).

Measurement of insulin sensitivity in children can be done by several methods. The hyperinsulinemic-euglycemic clamp is considered the gold standard (DeFronzo et al. 1979). It consists of a predetermined insulin infusion delivered simultaneously with a glucose infusion, with the goal of maintaining the glucose concentration at a "clamped" fasting level (Ighbariya and Weiss 2017; Brar et al. 2013). Clamps are expensive, time-consuming, and invasive, and are used mainly for research purposes (Levy-Marchal et al. 2010; Ighbariya and Weiss 2017; Brar et al. 2013). The frequently sampled intravenous glucose tolerance test (FSIGT) is an alternative method validated in children, that is based on serial insulin and glucose levels after an intravenous glucose administration (Brar et al. 2013). Simpler surrogate measures have been developed using oral glucose tolerance tests (Matsuda Index), and fasting samples such as the Homeostatic model for assessment of IR (HOMA-IR) (Ighbariya and Weiss 2017). HOMA-IR has been validated in obese children and adolescents with prediabetes and T2D (Brar et al. 2013; George et al. 2011).

Adolescents experience a characteristic phase of reduced insulin sensitivity during Tanner stage II-IV, followed by recovery by Tanner stage V (Moran et al. 1999). The mechanism of this phenomenon is not completely understood and may involve changes in body composition and variations in growth hormone secretion (Amiel et al. 1986; Goran and Gower 2001; Moran et al. 2002). The reduced insulin sensitivity seen in adolescents worsens in the presence of excess adipose tissue (Abrams et al. 2013). A dramatic increase in the prevalence of pediatric obesity has contributed to the escalating incidence of T2D in this population (Collaboration et al. 2017; Arslanian et al. 2018b; Mayer-Davis et al. 2017). Mayer-Davis et al (2017) reported a 7.1% annual increase in the incidence of T2D among youths 10–19 years of age during 2011–2012, compared to 2002–2003 (Mayer-Davis et al. 2017).

Table 27.11 Diagnostic criteria for prediabetes and diabetes (Arslanian et al. 2018a)

Prediabetes
• HbA1C 5.7% to 6.5% (39 to 48 mmol/mol)[a] • Fasting glucose ≥100 but <126 mg/dL (≥5.6 but <7.0 mmol/L). • OGTT[b]: 2-hour plasma glucose ≥140 but <200 mg/dL (≥7.8 but <11.1 mmol/L)
Diabetes
• HbA1C >6.5% (>48 mmol/mol)[a] OR • Fasting plasma glucose ≥126 mg/dL (7.0 mmol/L) OR • OGTT[b]: 2-hour plasma glucose ≥200 mg/dL (11.1 mmol/L) OR • Symptoms of hyperglycemia (polyuria, polydipsia, polyphagia) plus a random plasma glucose ≥200 mg/dL (11.1 mmol/L)

[a]The test should be performed in a laboratory using a method that is NGSP certified and standardized to the DCCT assay

[b]The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 1.75 mg/kg (maximum 75 g) anhydrous glucose dissolved in water

Fasting is defined as no caloric intake for at least 8 hours

HbA1C: hemoglobin A1C; OGTT: oral glucose tolerance test; NGSP: national glycohemoglobin standardization program; DCCT: diabetes control and complications trials;

Severity of Adolescent T2D

There is evidence that youth-onset T2D has a more rapid progression and increased prevalence of complications in comparison with adult-onset T2D (Arslanian et al. 2018b; Hannon and Arslanian 2015; Levitt Katz et al. 2011; McKay et al. 2012). For those reasons, screening for glucose abnormalities is important to identify children at risk and subsequently to implement early interventions that can modify progression. The American Diabetes Association (ADA) recommends to screen for prediabetes and/or T2D in asymptomatic children and adolescents (after onset of puberty or after age 10), who are overweight or obese (BMI ≥85th % for age and sex) and have 1 or more additional risk factors including: (1) first- or second-degree relative with T2D, (2) minority race or ethnicity, (3) signs of IR (acanthosis nigricans) or comorbidities such as

hypertension, dyslipidemia, polycystic ovarian syndrome, or (4) mother with history of diabetes or gestational diabetes during child's pregnancy (ADA 2019).

Pediatric Prediabetes

Prediabetes refers to a condition of blood glucose above normal, however not at the level considered diagnostic for diabetes (Table 27.11) (Arslanian et al. 2018a; Khokhar et al. 2017). Whereas in adults, the progression from prediabetes to overt T2D occurs gradually in about 5–10 years; in obese youth, this transition may only take 2.5 years (Weiss et al. 2005). Lifestyle and drug-based interventions can restore glucose to normal levels and decrease the risk for diabetes in adults; however, large-scale data in youth are limited (Khokhar et al. 2017; Knowler et al. 2002). The Diabetes Prevention Program (DPP) was a large randomized clinical trial conducted on adults with prediabetes that demonstrated a significant reduction in the risk for T2D with intensive lifestyle changes and treatment with Metformin (Knowler et al. 2002). The HEALTHY study trial of nutrition, physical education, and behavior change in middle school children showed significant reduction in obesity and mean insulin level (Foster et al. 2010).

Metabolic Syndrome

The concept of a group of metabolic disorders associated with increased risk for cardiovascular disease was postulated since the 1920s (Eckel et al. 2005). Gerald Raeven in 1988 introduced the term "syndrome X" and recognized IR as the common feature (Reaven 1988). Central obesity was not included as part of the syndrome until the late 1940s, and the term "metabolic syndrome" was preferred as the unifying definition (Eckel et al. 2005). The International Diabetes Federation defines metabolic syndrome (MetSyn) in adults as central obesity (ethnicity specific and measured by waist circumference unless BMI >30 mg/m2) plus any two of the following: 1)

Table 27.12 Diagnostic criteria for metabolic syndrome in children and adolescents

Authors	3 or more criteria
Cook et al. (2003)	• Waist circumference ≥90th percentile • Systolic or diastolic blood pressure ≥90th percentile • Triglycerides ≥1.24 mmol/L or HDL-C ≤1.03 mmol/L • Fasting glucose ≥6.11 mmol/L
Cruz and Goran (2004)	• Waist circumference ≥90th percentile • Blood pressure ≥90th percentile • Triglycerides ≥90th percentile or HDL ≤ 10th percentile • Glucose intolerance (ADA criteria)
Weiss et al. (2004)	• BMI z-score ≥2.0 • Blood pressure >95th percentile • HDL <5th percentile • Triglycerides >95th percentile • Glucose intolerance (ADA criteria)
De Ferranti et al. (2004)	• Waist circumference >75th percentile • Blood pressure >90th percentile • Triglycerides ≥1.1 mmol/L or HDL <1.2 mmol/L (girls), <1.3 mmol/L (boys • Fasting glucose ≥6.1 mmol/L
Viner et al. (2005)	• BMI ≥95th percentile • Systolic blood pressure ≥95th percentile • Triglycerides ≥11.69 mmol/L or HDL ≤0.91 mmol/L or total cholesterol ≥95th percentile • Insulin ≥104.2 pmol/L or fasting glucose ≥5.55 mmol/L
Zimmet et al. (2007)	• Waist circumference ≥90th percentile • Systolic blood pressure ≥130 mm Hg or diastolic blood pressure ≥85 mm Hg • Triglycerides ≥1.7 mmol/L or HDL ≤1.03 mmol/L • Fasting glucose ≥5.6 mmol/L
Ahrens et al. (2014)	Monitoring level (action level) • Waist circumference ≥90th (95th) percentile • Systolic/Diastolic blood pressure ≥90th (95th) percentile • Triglycerides >90th (95th) percentile or HDL ≤10th (5th) percentile • HOMA-IR[a] ≥90th (95th) percentile or fasting glucose ≥90th (95th) percentile

[a]Homeostatic model assessment of insulin resistance

Raised Triglycerides ≥150 mg/dL (1.7 mmol/L), 2) Reduced HDL cholesterol < 40 mg/dL (1.03 mmol/L) in males < 50 mg/dL (1.29 mmol/L) in females, 3) Raised blood pressure systolic BP ≥130 or diastolic BP ≥85 mm Hg, and 4) Raised fasting plasma glucose (FPG) ≥ 100 mg/dL (5.6 mmol/L) (Alberti et al. 2006).

Several expert groups have established diagnostic criteria for MetSyn in adults; however, there is lack of consensus regarding a definition in children and adolescents. The scientific interest to adapt a definition for children grew with the recognition of the remarkable increase in pediatric obesity worldwide (Collaboration et al. 2017). Despite conflicting definitions (Table 27.12), most authors agree that the key components are abnormalities in glucose metabolism, central obesity, hypertension, and dyslipidemia (Cook et al. 2003; Cruz and Goran 2004; Weiss et al. 2004; De Ferranti et al. 2004; Viner et al. 2005; Zimmet et al. 2007; Ahrens et al. 2014).

Visceral and ectopic fat deposition are hallmarks in the pathogenesis of the MetSyn. Lipid accumulation in the liver stimulates secretion of adipocytokines and consequently activation of inflammatory pathways (Magge et al. 2017; Bussler et al. 2017). It has been postulated that this low-grade inflammatory state may explain the IR and endothelial dysfunction seen in the MetSyn (Yudkin 2007).

Recently, the focus on MetSyn has shifted toward differentiating it as a distinct pathophysiology or a cluster of cardiometabolic risk factors (Kahn et al. 2006; Bayturan et al. 2010). Some studies showed that the CVD progression and mortality in patients with MetSyn are driven by its individual components rather than by the presence of the syndrome itself (Bayturan et al. 2010; Wang et al. 2007).

This new approach may be particularly important in the pediatric population for which there is less evidence on the definition and utility of the syndrome. In pediatrics, intensive interventions should target children with multiple component risks who are in great need of risk reduction (Magge et al. 2017).

Table 27.13 Diagnostic Criteria for PCOS in Adult Women and Adolescents

Adult women
National Institutes of Health (NIH) criteria (1990) Requires both criteria: • Oligo-ovulation/anovulation • Clinical and/or biochemical signs of hyperandrogenism
Rotterdam Criteria (2003)[a] Requires 2 criteria: • Oligo-ovulation/anovulation • Clinical and/or biochemical signs of hyperandrogenism • Polycystic ovaries (by ultrasound)
Androgen Excess Society (2006) Requires both criteria: • Clinical and/or biochemical signs of hyperandrogenism • Oligo-ovulation/anovulation and/or polycystic ovaries
Adolescents
Amsterdam Criteria (2012) Requires all three criteria: • Oligo-ovulation/anovulation • Clinical and/or biochemical signs of hyperandrogenism • Polycystic ovaries (by ultrasound)
Endocrine Society Criteria (2013) Requires both criteria: • Oligomenorrhea • Clinical and/or biochemical signs of hyperandrogenism
Pediatric Endocrine Society Criteria (2015) • Abnormal uterine bleeding pattern – Abnormal for age or gynecological age – Persistent for 1–2 years • Evidence of hyperandrogenism – Persistent elevated testosterone levels – Moderate-severe hirsutism – Moderate-severe inflammatory acne vulgaris

Polycystic Ovarian Syndrome

Polycystic Ovarian Syndrome (PCOS) is a heterogenous endocrine disorder that affects a significant proportion of reproductive-aged women, including adolescents. It is defined by a combination of clinical features of androgen excess (hirsutism, moderate-severe acne), ovarian dysfunction (oligo-ovulation), and/or polycystic ovarian morphology that are not otherwise explained (Escobar-Morreale 2018). Additionally, PCOS is associated with metabolic disorders

including T2D, obesity, dyslipidemia, hypertension, and MetSyn (Tehrani and Amiri 2019).

PCOS is caused by a complex interaction between genetic and environmental factors (Rosenfield 2015; Witchel et al. 2019). IR plays an important role in the pathogenesis of PCOS and is seen in both lean and obese women (Tehrani and Amiri 2019; Witchel et al. 2019).

There is consensus for diagnostic criteria of PCOS in adult women (Table 27.13). Diagnosis in adolescents becomes problematic as some of the features (menstrual irregularities, acne, mild hyperandrogenism, or multifollicular ovarian morphology) can be seen in normal pubertal development (Witchel et al. 2019). In addition, symptoms of PCOS are often evolving and may not be clearly evident in adolescents (Table 27.13). A comprehensive assessment of the history, physical exam, and laboratory data is important to identify the adolescents at risk for PCOS, and if indicated, to initiate treatment that can significantly impact their quality of life.

Nonalcoholic Fatty Liver Disease (NAFLD)

Within a few decades, this has become the number one chronic liver condition for all age brackets (Wong et al. 2015), although the impact on children with excessive adiposity is still not well established (1.7–85%). One pediatric case in four displays nonalcoholic steatohepatitis (NASH), a more inflammatory modality which can advance to cirrhosis (7–10%) and even require transplantation (Molleston et al. 2002; Rubinstein et al. 2008). Alanine aminotransferase increase (boys: ALT $\geq$50 mg/dL, girls: ALT $\geq$44 mg/dL) at age $\geq$10 years has been employed as a screening tool in populations with increased adiposity, only severe cases requiring biopsy (Vos et al. 2017). There is more experience with imaging tools such as Fibroscan in adults than in children (Xanthakos et al. 2017).

NAFLD Management

Healthier food intake and weight loss are advised (Nobili et al. 2006; Nobili et al. 2008), even though no particular diet has been adopted (Ramon-Krauel et al. 2013). Elimination of high sugar drinks looks promising (Ebbeling et al. 2012; De Ruyter et al. 2012), along with aerobic and resistance exercise (Lee et al. 2012). Prescription of obeticholic acid for adults was beneficial (Younossi et al. 2019), and an FDA new drug application for alleviation of fibrosis in adults (NASH) has been accepted. Within the 8–17 age bracket, Metformin was disappointing whereas Vitamin E was beneficial for histology, however not for liver enzymes (Lavine et al. 2011). Other pharmacologic protocols are going on (Konerman et al. 2018), and metabolic/bariatric surgery could also be an alternative for adolescents with excessive adiposity and NASH.

Non-cardiometabolic Comorbidities

Obstructive Sleep Apnea (OSA)

Childhood obesity is associated with a much higher prevalence of OSA (Spilsbury et al. 2015). Anderson et al. recently showed OSA prevalence of 44.6% in overweight/obese children compared with 9.1% in those normal weight (Andersen et al. 2019). The rate of weight gain is an important predictor of severe OSA. A retrospective cohort study showed that yearly change in weight among obese adolescents with severe OSA was significantly higher than those without severe OSA (Johnson et al. 2019). While adenotonsillectomy is effective at reversing failure to thrive in OSA, it is not as effective at treating obesity-associated OSA, for which new and different treatment options need to be considered (Keefe et al. 2018).

Musculoskeletal (MSK) issues

Obese children tend to reduce their level of physical activity and have an increased risk of MSK injuries and pain. Contributing factors include

gait/postural impairments, increased load/impact to the lower extremities and back, lower extremity malalignment, and reduced bone mineral density (Chan and Chen 2009; Steinberg et al. 2018). This is illustrated by a study showing obese children walk with increased patellofemoral loads, enhancing risk of developing chronic knee pain (Kim et al. 2019). Obese children should be screened for these biomechanical factors prior to any exercise program to reduce risk for future MSK issues (Steinberg et al. 2018).

Vitamin D (VitD) deficiency

VitD deficiency has been reported in 34% and 49% of obese and severely obese children, respectively. Low 25-hydroxy-Vitamin D (25-OHD) in obese may be explained by inadequate dietary consumption, decreased sun exposure, and trapping of 25-OHD in adipose tissue (Nowicki et al. 2019; Corica et al. 2019). The bone/calcemic effects of VitD are well known, and more recently, the non-bone/non-calcemic effects have been better elucidated. VitD plays an essential role in the regulation of glucose homeostasis, insulin secretion mechanisms, and inflammation associated with obesity (Zakharova et al. 2019). Low 25-OHD has been shown to negatively influence beta-cell function and insulin sensitivity in obese nondiabetic children (Corica et al. 2019). Higher cholecalciferol doses are likely needed to achieve serum 25-OHD targets in obese children (Zakharova et al. 2019).

Psychological Impact and Considerations

Youth with obesity are more likely than their average-weight peers to experience weight-related stigma, bullying, depression, anxiety, low self-esteem, and difficulty with self-regulation including attention deficit hyperactivity disorder (ADHD) (Zeller et al. 2004). Family and parental characteristics play an important role in overweight and obesity in children. Poor family communication and high family conflict are linked to overeating and obesity in children. Maternal depression, overly permissive or overly restrictive parenting practices, and high parental distress about their child's weight are associated with obesity in children. On the other hand, authoritative parenting styles, characterized by high expectations, warmth, and responsiveness are associated with healthier eating habits and average weight in children (Halliday et al. 2014). Parental modeling of healthy lifestyle behaviors is an important indicator of child and adolescent health behaviors.

Mental health diagnoses, such as autism spectrum disorder, ADHD, depression, and anxiety, are more common in obese children. Such concordant diagnoses can significantly interfere with patient/family adherence to weight management interventions. Appropriate behavioral health referrals for mental health diagnoses are imperative to the success of any weight management intervention (Small and Aplasca 2016). Even if a child does not meet criteria for a specific mental health diagnosis, it is important to take the child and family psychosocial functioning into account, as the most effective interventions for weight management center around behavior modification. Common barriers to lifestyle modification adherence include child disruptive behavior, emotional eating, conflict around food, and food sneaking behaviors. Therefore, the most effective multidisciplinary weight management programs are those who have the support of behavioral health professionals, who focus on the child's self-esteem and quality of life without negatively impacting family functioning (Ward et al. 2012).

Ongoing Studies and Future Perspective

As rates of pediatric obesity remain high globally, we are beginning to see consequences affect the health of whole populations. Obesity that persists into adulthood is associated with decreased quality of life, higher morbidity, and shorter life expectancy (Grover et al. 2015). For this reason, public health interventions that focus on obesity prevention should be prioritized, including policy measures that improve food and beverage advertising practices to children, sugar-sweetened beverage taxation, and strengthening school food and physical activity policies, all of which have shown promise in various settings (Kelly et al.

2010; Yoshida and Simoes 2018; Wharton et al. 2008).

Addressing pediatric obesity in the clinical setting continues to evolve with increased use of medication and surgical treatment as outlined above for severe cases, and a growing body of research supporting optimal use. There is also significant ongoing research on the use of health technologies in treatment, including mobile-health tools, activity, and nutrition tracking applications (Turner et al. 2015; Quelly et al. 2016).

There is also much interest in time-restricted feeding and intermittent fasting in treatment of adult obesity and comorbidity management; however, research in adolescents is limited (Stockman et al. 2018). It is also recommended that all obesity interventions directed at children and adolescents be conducted with the utmost sensitivity, awareness of weight bias and stigma, and in a way that supports psychological well-being, so as to avoid potential unintended negative consequences of weight management in children (Pont et al. 2017).

Abstract

Obesity is related to metabolic defects that may promote not only cancer initiation, but also its progression. The molecular basis for the association between obesity and cancer is not fully understood; however, many pathways are being investigated including hyperinsulinemia/insulin resistance (IR) and abnormalities of the insulin-like growth factor-1 (IGF-1) signaling, sex hormones biosynthesis and pathway, alterations in adipokines pathophysiology, and subclinical chronic low-grade inflammation. In this chapter, we analyze the current knowledge on the proposed biological mechanisms, especially focusing on the role of adiponectin (APN).

Keywords

Obesity · Cancer · Insulin-like growth factor-1 signaling · Sex hormones · adipokines · adiponectin · Low-grade inflammation

Introduction

White adipose tissue (WAT) was formerly studied in connection with caloric reserves, mechanic and thermal insulation, and sexual attraction. However, it is unquestionably a complex endocrine organ (Coelho et al. 2013). Adipocytes constitute 90% of the cells, whereas the stromal-vascular components include endothelial cells (10–20% of cells), pericytes (3–5%), fibroblasts, and others (15–30%). Stem and progenitor cells (0.1%) should not be neglected, along with T- and B-lymphocytes, macrophages, dendritic cells, and others (Cozzo et al. 2017). Sex steroid hormones, insulin resistance, growth factors, cytokines, and adipokines are all influenced by this cellular environment (Osborn and Olefsky 2012). Many cancer types are impacted by the same molecules and pathways (Sung et al. 2019).

Excessive body weight promotes elevated free fatty acids (FFA), triglycerides, glucose, insulin resistance, and insulin production, some of which could also stimulate cancer progression (Osborn and Olefsky 2012).

Comorbidities

Obesity predisposes to metabolic, cardiovascular diseases, as well as of several malignancies (Sung et al. 2019; Global BMI Mortality Collaboration et al. 2016; Goodwin and Stambolic 2015; GBD 2015 Obesity Collaborators et al. 2017), a phenomenon called as "adiponcosis" (Bifulco and Ciaglia 2017).

Cancers of digestive organs, like colon cancer, and tissues with endocrine links, such as breast, ovarian, endometrial, and prostate cancers, receive most attention (Sung et al. 2019; Kyrgiou et al. 2017; Tumminia et al. 2019). Cancer is the number two most fatal human condition, after cardiovascular disease, whereas obesity and related aberrations could be aggravating oncological mechanisms (Sung et al. 2019; Goodwin and Stambolic 2015).

Biological Mechanisms Linking Obesity to Cancer

Possible biological mechanisms comprise hyperinsulinemia/insulin resistance (IR) and abnormalities of the insulin-like growth factor-1 (IGF-1) signaling, sex hormones biosynthesis and

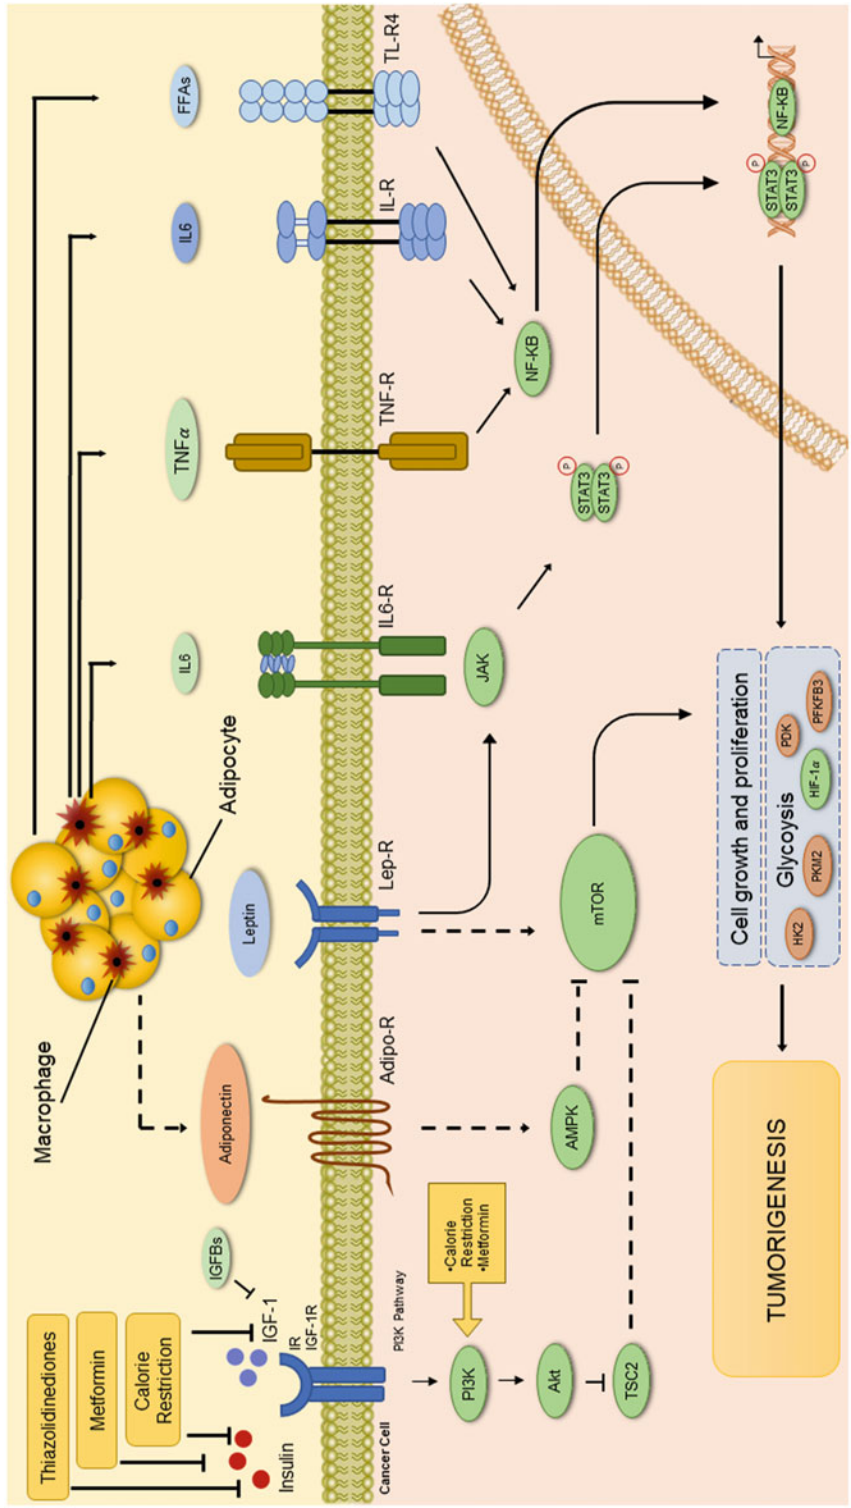

Fig. 28.1 Molecular pathways linking obesity and cancer. Insulin and insulin-like growth factor 1 (IGF-1) trigger off the phosphatidylinositol 3-kinase (PI3K) pathway, which in turn upregulates glycolysis and other metabolic pathways to generate energy needs for proliferation. Adipose tissue in the obese condition is a site of profound inflammatory activity using immune cells that secrete an abundance of cytokines that can influence on neighboring cancer cells to promote tumorigenesis through different metabolic levels.

pathway, alterations in adipokines pathophysiology, and subclinical chronic low-grade inflammation (Fig. 28.1).

Hyperinsulinemia/Insulin Resistance

Insulin resistance is a common feature of obese patients resulting in a compensatory increase in systemic insulin and IGF-1 levels (Ackerman et al. 2017). The excess of body weight is not the only parameter determining hyperinsulinemia: the distribution of the extra weight and of visceral adipose tissue is also a key variable. Hyperinsulinemia induces the production of IGF-1 by hepatocytes and downregulates the secretion of IGF-1 binding proteins (IGFBPs), resulting in an increase in bioavailable IGF-1. Several cancer cell types respond to insulin and IGF-1 receptor binding, by activating PI3K and MAPK pathways or other downstream networks, promoting cell survival, growth, and motility (Di Zazzo et al. 2014; Ackerman et al. 2017).

Insulin resistance, hyperinsulinemia, and high IGF-1 levels increase the risk of endometrial, breast, colorectal, and prostate cancer (Goodwin and Stambolic 2015). When colorectal cancer-susceptible mice were treated with an IGF-1-receptor inhibitor disrupting downstream signaling, tumor burden was significantly reduced (Ackerman et al. 2017).

In adipose tissue, insulin controls lipid storage and inhibition of lipolysis. Once glucose and insulin levels are elevated for prolonged periods as a consequence of overeating or lack of exercise, insulin can induce lipid storage in non-adipose tissue such as skeletal muscle. This inappropriate accumulation of intramuscular fatty acids contributes to altered insulin signaling.

Sex Hormones

Peripheral adipose tissue performs steroids aromatization: androgens and androgenic precursors are converted to estradiol by aromatase. In obesity, the excess of adipose tissue and the increased aromatase activity lead to a higher conversion rate, resulting in higher levels of circulating estrogens (Gérard and Brown 2018). In men and in postmenopausal women, the conversion of androgens to estrogens is dependent upon adipose tissue mass. Estrogen signaling has several consequences in tumor growth promotion. Indeed, estradiol is able to stimulate cell proliferation of breast epithelial and endometrial cells, to inhibit apoptosis, and to induce angiogenesis (Andò et al. 2019). Additionally, obesity is associated with lower plasma levels of sex hormone-binding globulin (SSBG), thus increasing bioavailable concentrations of estradiol and testosterone, resulting in a greater cancer risk (Di Zazzo et al. 2018).

Adipokines and Cancer

Adipokines are bioactive molecules released by WAT that acts locally in an autocrine and paracrine manner, but they also have a systemic, endocrine effect through blood circulation (Diedrich et al. 2015). Adipokines include adiponectin (APN), leptin, resistin, omentin, and chemerin; under physiological conditions, they regulate several processes such as energy balance, lipid metabolism, insulin sensitivity, inflammation, innate and adaptive immunity, angiogenesis, hematopoiesis, and cell proliferation (Schrover et al. 2016).

Abnormal accumulation of adipose tissue induces adipocyte dysfunctions, resulting into the alteration of its endocrine functions and consequently affecting the secretion of different adipokines, usually leading to increased leptin and decreased APN blood concentration. Abnormal adipokine secretion often represents a factor leading to cancer (Fig. 28.1) (Di Zazzo et al. 2019). Upon analysis of a panel of 14 obesity-related hormones, cytokines, coagulation factors, and other biomarkers, C-peptide, IL-6, and TNF-α pointed toward clear-cell renal carcinoma risk (Wang et al. 2019).

Adiponectin and Cancer

APN behaves as insulin-sensitizing, anti-apoptotic, and immune regulatory (Ackerman et al. 2017). Various homo-oligomers are recognized, and as adiposity accumulates, APN diminishes in the same proportion (Di Zazzo et al. 2019). APN usual receptors, AdipoR1 and AdipoR2, are physiologically highly relevant. Hexameric and multimeric APN binds to a different receptor, from the cadherin superfamily (Di Zazzo et al. 2019).

Signaling pathways for cellular responses include AMPK, mTOR, PI3K/AKT, MAPK, STAT3, and NF-kB, (Di Zazzo et al. 2019). AdipoR1 and AdipoR2 also impact energy balance, including insulin sensitization (Di Zazzo et al. 2019). Ceramidase stimulatory activity, which depletes intracellular ceramide, inhibits apoptosis (Holland et al. 2011).

Hypoadiponectinemia

Poor response to APN during excessive adiposity could be explained by low receptor values (Yamauchi et al. 2014). The same tends to occur during inflammation linked to diabetes and atherosclerosis (Di Zazzo et al. 2019). APN is usually classified as an anti-cancer molecule, with anti-inflammatory, anti-proliferative, and pro-apoptotic impact (Porcile et al. 2014; Di Zazzo et al. 2019).

Breast Cancer

Breast Cancer (BC) risk is heightened during advanced adiposity: (i) aromatization of androgens to estrogens stimulates growth of mammary cells; (ii) interference with APN physiology prevents its protective response (Avgerinos et al. 2019). Low APN levels are certainly deleterious in this context (Ye et al. 2014), including cancer growth and virulence. In the ERα-negative human BC cell line MDA-MB-231, Genes involved in cell cycle progression and apoptosis are one of the possible mechanisms (Mauro et al. 2014).

In an ERα-positive cell culture, APN leads to expression of ERα and cell growth (Mauro et al. 2014). Cross talk between APN/AdipoR1, IGF-IR, and ERα seems relevant (Mauro et al. 2015). Insulin and estrogen elevation, which favor cancer progression, contrast with depressed APN, including postmenopausal and ER-positive breast tumors (Di Zazzo et al. 2014; Mauro et al. 2014). APN modulates cell migration and invasion (Jia et al. 2014), AdipoR2 signals lymphatic and vascular penetration, and all of them are markers of metastatic disease (Jeong et al. 2011).

Gastrointestinal Malignancies

Strong correlation between obesity and the development of gastrointestinal (GI) cancers is reported (Murphy et al. 2018). The largest adipose intra-abdominal depot is the omentum, the so-called fatty apron connecting the stomach to the colon, enriched with immune cells and responsible for local inflammation. Obesity disrupts the homeostatic profiles of innate and adaptive immune cell populations within the omentum (O'Sullivan et al. 2018). APN plasma levels were found decreased in patients with GI cancers (Nagaraju et al. 2015). APN is suggested to be involved in esophageal mucosa remodeling, and it might have a protective role against cancer transformation, contributing to the link between obesity and lower esophageal carcinoma (EC) (Almers et al. 2015). Patients with metabolic syndrome, associated with increased leptin and decreased APN serum levels, are prone to Barrett's esophagus, a metaplastic change occurring in response to gastroesophageal reflux disease that can potentially lead to the EC. Moreover, high levels of LMW-APN are associated with a decreased risk of Barrett's esophagus (Tilg and Moschen 2014).

Beales and colleagues demonstrated that in OE33, an esophageal carcinoma cell line, leptin was able to induce proliferation, invasion, and migration and inhibit apoptosis in a STAT3-dependent manner and, by contrast, APN

inhibited leptin-stimulated proliferation *via* AdipoR1 (Beales et al. 2014). In gastric cancer, APN inhibited proliferation in *vitro* with most prominent effects in AZ521 and HGC27 gastric cell lines expressing high levels of AdipoR1/R2 mRNA. Moreover, higher concentrations of APN significantly reduce tumor volume and peritoneal metastases in *vivo* (Ishikawa et al. 2007), consistent with previous findings suggesting an anti-angiogenic and tumor suppressive role for this adipokine (Bråkenhielm et al. 2004). In the same models, APN elicits its biological effects through AdipoR1/R2 activation, whose expression was significantly associated with histological type and overall survival (Ishikawa et al. 2007). Negative AdipoR1 immunostaining was found in patients with lymphatic metastasis and peritoneal dissemination, while positive AdipoR1 expression corresponded to a longer survival rate (Tsukada et al. 2011).

Circulating APN levels have been also associated with increased risk of pancreatic cancer (Pothuraju et al. 2018). APN exerted its inhibitory effect through modulation of the β-catenin signaling pathway. In BxPC-3 and CFPAC-1, pancreatic cell lines both expressing the AdipoRs, APN reduced serum-induced phosphorylation of GSK-3β, decreased the nuclear accumulation of β-catenin, and downregulated the expression of cyclin D1. Knockdown of AdipoRs abolished the growth-inhibiting effect induced by APN in *vitro* and in xenograft models (Jiang et al. 2019).

Colorectal Cancer

Low APN is a marker of colorectal cancer (CRC) (Di Zazzo et al. 2019). Both AdipoR1 and AdipoR2 in turn could signal lymphatic metastasis (Ayyildiz et al. 2014), as well as (for AdipoR1) the ability to survive the illness (Choe et al. 2018). APN negatively controls CRC growth, by inhibiting the mechanistic target of rapamycin (mTOR) *via* AMPK phosphorylation, and decreasing PI3K and Akt phosphorylation (Parida et al. 2019).

In CRC models, APN knockdown resulted in increased multiplicity of aggressive colorectal polyps. In an APN-deficient mice model, APN treatment inhibited cancer progression and angiogenesis (Moon et al. 2013). APN deficiency also aggravated azoxymethane-induced colon cancer in C57BL/6J mice (Mutoh et al. 2011).

APN conferred protection against inflammation-induced colon cancers by preventing apoptosis in the goblet cells and promoting conversion of epithelial to goblet cells (Saxena et al. 2012). In HCT116, HT29, and LoVo CRC cell lines, APN induced G1/S cell cycle arrest with concomitant overexpression of p21 and p27 *via* AMPK phosphorylation; inhibition of AdipoRs released cells from APN-induced growth blockade (Kim et al. 2010). APN anticancer effect is glucose-dependent, possibly explaining why CRC survival is enhanced in a low glucose medium; however, the opposite occurs with APN in high glucose conditions (Habeeb et al. 2011).

Ovarian Cancer

Ovarian cancer patients have a lower blood concentration of APN than healthy women (Jin et al. 2016); low APN concentration was associated with longer progression-free survival times and a better tumor responsiveness to chemotherapy (Diaz et al. 2013; Slomian et al. 2019). In addition, AdipoR1 expression level in ovarian cancer tissues could represent a marker of prognosis, being positively associated with overall patient's survival (Li et al. 2017). Low APN plasma levels may favor ovarian cancer growth, induced by persistent activation of PI3K/Akt/mTOR signaling. Moreover, APN is able to repress human ovarian cancer cell growth and reverse the stimulatory effects of 17β-estradiol and IGF-1 on cell proliferation through the downregulation of their receptors (Hoffmann et al. 2018).

Endometrial Cancer

Low APN blood levels were associated with an increased risk and a worse prognosis of endometrial cancer (EMC). Low expression of AdipoR1

in endometrial cancer cells is associated with advanced tumor stage (Tumminia et al. 2019). Several hypotheses have been formulated the role of APN implying: (i) activation of AMPK (resulting in cell growth suppression and apoptosis); (ii) extracellular signal-regulated protein kinase (ERK) and Akt pathway inhibition; (iii) reduction of Cyclin D1 expression (Moon et al. 2011). Association seems more evident for type II EMC, and APN modulators are being explored for potential therapeutic avenues (Garikapati et al. 2019).

Prostate Cancer

Conflicting reports about APN exist (Hu et al. 2016). APN concentration in prostate cancer patients was low and connected to disease advent (Goktas et al. 2005). A lower AdipoR1 and AdipoR2 expression was observed in prostate neoplastic tissues compared with healthy prostate tissue (Michalakis et al. 2007). Growing evidence indicates that APN exerts an anti-proliferative action in prostate cancer cells, inhibiting dihydrotestosterone-activated cell proliferation (Bub et al. 2006). The ectopic overexpression of APN in prostate cancer cell lines inhibited mTOR-mediated neoplastic cell proliferation (Gao et al. 2015).

No links are also advocated (Baillargeon et al. 2006), or a significant positive correlation between APN concentrations and incidence of low- or intermediate-risk prostate cancer (Ikeda et al. 2015). Higher APN plasma levels were detected in subjects with cancer stage T3 (advanced) than in subjects with T2 (confined within the prostate). AdipoR2 findings could be a signal of cancer progression and metastasis (Rider et al. 2015).

Low Chronic Inflammation

Large adipocytes become distant from the blood supply, which can trigger chronic hypoxia and inflammation (Boutari and Mantzoros 2018).

Neutrophils and mast cells enhance inflammation whereas the opposite is expected from eosinophils and myeloid-derived suppressor cells. B- and T-lymphocytes and natural-killer cells are also engaged in the process, as well as M1 pro-inflammatory macrophages (ATMs) (Ouchi et al. 2011).

Macrophages constituting crown like structures elicit nuclear factor-kappa B (NF-κB) aggravating chronic inflammation (Ouchi et al. 2011). The cross talk between adipocytes and cancer engages IL-1, IL-6, and TNF-α, ROS generation, adipokines, and other molecules (Fig. 28.1) (Avgerinos et al. 2019). Cancer cells can also induce phenotype alteration of adjacent adipocytes, encompassing reduction of their lipid content and release of adipokine and matrix metalloproteinases (Dirat et al. 2011).

Inflammasome is an innate immune pathway activating proinflammatory cytokines, including IL-1 and IL-18 (Lamkanfi and Dixit 2014). Inflammasome-related genes are encountered in adipocytes (Yin et al. 2014), potentially stimulating cancer growth (Guo et al. 2016). Obesity treatment tends to ameliorate this negative profile (Hagman et al. 2017).

The Obesity Paradox in Cancer

Obesity negatively influences cancer recurrence, prognosis, and survival (Lennon et al. 2016). However, opposite evidence in certain circumstances suggests that obesity reduces cancer incidence and improves survival. Obesity has been ruled out as a risk for cancer mortality (Kuk et al. 2018). Body fatness reduced the nerve sheath tumor risk (Wiedmann et al. 2017); overweight or obesity attenuated mortality of bladder (Pavone et al. 2018); and lung cancer (Zhang et al. 2017) after surgery or chemotherapy. A meta-analysis also showed that obese patients with esophageal cancer had better long-term survival (Kayani et al. 2012).

The use of BMI as a measure of adiposity could partly explain the discrepancies, as it does not fully characterize the intricate biology and physiology of excess body fat. BMI cannot differentiate between lean mass and adipose tissue and depends upon gender, age, ethnicity, and race. Additionally, BMI does not estimate the

visceral adipose tissue (VAT), which seems to be metabolically more relevant. Computed tomography and MRI are better alternatives for quantification of VAT; however, they are not always feasible (Allott and Hursting 2015). Anthropometric measures, such as waist circumference (WC) and waist-to-hip ratio (WHR), are viable techniques (Sung et al. 2019), however, not perfect ones, as both VAT and subcutaneous abdominal tissue (SAT) are lumped together in the results (Avgerinos et al. 2019).

Obesity and Therapy

Obesity and comorbidities like dysglycemia, hypertension, and dyslipidemia could reduce the response to chemotherapy. Elevated BMI was associated with poor prognosis in patients affected by colon cancer who received surgical resection of primary tumor and adjuvant chemotherapy with capecitabine and oxaliplatin (Lashinger et al. 2014). In bevacizumab-treated metastatic CRC patients, high visceral fat and BMI were significantly associated with absence of a response and increased progression. BMI was negatively associated with response to standard first-line chemotherapy with platinum and taxanes in ovarian cancer patients (Califano et al. 2014). These results could be related to the expression by adipose tissue of angiogenic factors (in particular VEGF) (Ottaiano et al. 2018). Hyperinsulinemia, a known growth factor, could trigger chemoresistance to 5-fluorouracil, anthracyclines, taxanes, and other drugs upregulating P-glycoprotein (Wei et al. 2015).

Drug Dosage

Pharmacokinetic studies rarely address the obese. The most common strategy is dose-capping or dose-fixed regimens. The consequence of this "depotentiation" attitude may be the use of subtherapeutic strategies, conducting to disease recurrence and mortality. According to the American Society of Clinical Oncology, full weight should be adopted for dosage calculation.

Specific Cancer Therapies for Obese and Diabetic Patients?

A balanced and healthy diet may control factors that sustain obesity-related disease (i.e., IGF-1, insulin, leptin) (Avgerinos et al. 2019). In addition, vigorous aerobic exercise leads to a peak of circulating APN levels (Saunders et al. 2012). Moreover, there is an increasing interest in testing diabetes and cholesterol-lowering drugs for cancer therapy.

Metformin

Metformin could decrease incidence and mortality of cancer by inducing hepatic gluconeogenesis and reducing IR of peripheral tissues, resulting in lower insulin and IGF-1 levels (Gallagher and LeRoith 2015). Metformin blocks tumor growth and induces apoptosis through insulin-independent mechanisms (Safe et al. 2018). Furthermore, metformin decreases cancer recurrence by directly inducing cancer stem cell death (Gallagher and LeRoith 2015).

Glycemic control with metformin can restore adipokine concentrations, increasing APN, and decreasing pro-inflammatory adipokine levels in both humans and mice (Avgerinos et al. 2019). For prostate and breast malignancies, large meta-analyses failed to demonstrate benefits for metformin regarding cancer risk and mortality (Feng et al. 2019; Au Yeung and Schooling 2019; Wang et al. 2020). Yet in other contexts, such as rectal cancer treated by neoadjuvant chemoradiotherapy, better cancer response and lower risk of recurrence were elicited (Kim et al. 2020). Clinical trials are going on. Twelve of them address the following cancers: breast (five), along with head and neck, thyroid, endometrial, multiple myeloma, lymphocytic leukemia, and various gynecologic/ solid tumors (one of each) (www.cancer.gov, 2020).

Thiazolidinediones (TZDs) and Other Agents

Activation of PPAR-γ by TZDs could restrict cell proliferation by decreasing insulin concentration and also influencing key pathways of the Insulin/IGF-1 axis, such as MAPK, PI3K/mTOR, and Glycogen synthase kinase (GSK)3-β/Wnt/β-catenin cascades, which modulate cancer cell survival and differentiation. Additionally, the PPARγ agonists TZDs, rosiglitazone, and pioglitazone augment the circulating level of APN directly, enhancing its gene and protein expression in a dose-dependent manner (Parida et al. 2019). Yet, meta-analysis results are conflicting.

For bladder cancer, an increased risk with pioglitazone was announced, possibly dose and time dependent (Tang et al. 2018). As regards colorectal cancer, no advantages were detected with pioglitazone, whereas other PZDs seemed moderately protective (Liu et al. 2018). A lack of association with breast cancer risk is reported (Du et al. 2018). This last outcome is consistent with a meta-analysis addressing digestive cancers, in which the risk did not differ for incretin mimetics, insulin, metformin, sodium-glucose co-transporter 2, sulfonylureas, TZDs, alpha-glucosidase inhibitors, or placebo (Chai et al. 2019).

Therapies Targeting APN

Increasing plasma APN levels or mimicking some of its cancer-protective properties could mitigate the deleterious effects of metabolic dysfunctions on tumor development and progression (Vansaun 2013; Tumminia et al. 2019). Therefore, pharmacological increase in serum APN levels, up-regulation of AdipoRs expression, or synthesis of AdipoRs agonists could represent promising therapeutic strategies.

Using a high-throughput assay, several natural compounds showing AdipoRs agonist activity were identified. These compounds, acting preferably on AdipoR1 (e.g., matairesinol, arctiin, arctigenin, gramine) or AdipoR2 (e.g., syringin, parthenolide, taxifolion, deoxyschizandrin), shared important anti-cancer properties, including anti-proliferative and anti-inflammatory effects (Sun et al. 2013). ADP355, a peptide-based APN receptor agonist, prevented the proliferation of AdipoRs-positive cancer cell lines. ADP 355 showed high affinity with AdipoR1, and through the regulation of the canonical APN-regulated pathways (i.e., AMPK, Akt, STAT3, and ERK1/2), reduced breast tumor growth both *in vitro* and *in vivo* (Otvos Jr et al. 2015). Additionally, three peptides BHD1028, BHD43, and BHD44 have been designed to mimic APN actions. BHD1028 showed the highest affinity with AdipoR1 and the main activation of AMPK already at low concentration, more than ADP 355 (Kim et al. 2018).

Oral Adiponectin Receptor Agonist

AdipoRon (AdipoR) is the first oral AdipoRs agonist able to bind and activate AdipoR1 and AdipoR2 that successfully re-established APN functions, mainly activating AMPK and PPARγ pathways in obesity-related type 2 diabetes (Okada-Iwabu et al. 2013). Initial reports have also investigated the possible anti-cancer role of AdipoR in preclinical models, especially in pancreatic and ovarian cancer (Akimoto et al. 2018; Ramzan et al. 2019). However, modifying AdipoRs interactions could also result in infertility, cardiac damage, and reduced bone density (Holland and Scherer 2013).

Statins and Assorted Drugs

Statins have been reported to be effective in increasing circulating APN levels. Statins function by releasing cellular oxidative stress, resulting in increased APN multimerization and

secretion. Angiotensin converting enzyme inhibitors as well as angiotensin receptor antagonists Ramipril, Quinapril, Losartan, Telmisartan, Irbesartan, and Candesartan have similarly shown promising results in clinical trials. They function by enhancing APN secretion *via* PPARγ, though some of them are also known to induce transcription. Other potential drugs include non-statin anti-hyperlipidemic drugs like Fenofibrate and Zetia, non-TZD anti-diabetic drugs, such as Acarbose and the sulfonylurea Glimepiride and Sulfonylureas (Parida et al. 2019).

Cognitive Impairment in Obesity and Diabetes

29

Cristina Carvalho and Paula I. Moreira

Contents

Abstract

Alzheimer's disease (AD), the most common form of dementia, affects 55 million people worldwide, and this number is expected to increase to 88 million by 2050. Understanding the molecular mechanisms underpinning pathological cognitive deficits and AD onset and progression is urgently needed, to identify biomarkers and therapeutic targets. Besides

ageing, type 2 diabetes (T2D) and obesity are considered major risk factors for cognitive decline and AD. Here, we discuss the mechanistic relationship between AD and metabolic disorders, particularly T2D and obesity. The repurposing of anti-diabetes and anti-obesity approaches in the treatment of AD will be also debated.

Keywords

Type 2 diabetes · Obesity · Cognitive impairment · Alzheimer's disease · Anti-diabetes and anti-obesity approaches

Introduction

By the age of 60, about 12–18% of the population suffers from mild cognitive impairment (MCI) (Petersen 2016), and 14% of cases present a clinical panel of dementia (Morley et al. 2015).

The increase in the number of individuals with cognitive defects represents an enormous economic burden and a significant challenge for patients, families, caregivers and clinicians (Morley et al. 2015). Over the last decades, type 2 diabetes (T2D) and obesity emerged as major risk factors for cognitive decline and dementia (Pugazhenthi et al. 2017). Indeed, a convergence in risk, comorbidities and pathophysiology seems to occur between obesity, T2D and cognitive impairment, this convergence being exacerbated in diabesity (co-occurrence of diabetes and obesity) (Newcombe et al. 2018; Cardoso and Moreira 2019) (Fig. 29.1).

T2D has a 1.2- to 1.7-fold increased risk for development of neurodegenerative conditions, particularly Alzheimer´s disease (AD), the most common form of dementia in the elderly. Obesity can be responsible not only for a significant decline in cognition later in life, but can also lead to a decrease in memory performance in the short-term, particularly during middle adulthood (Dye et al. 2017).

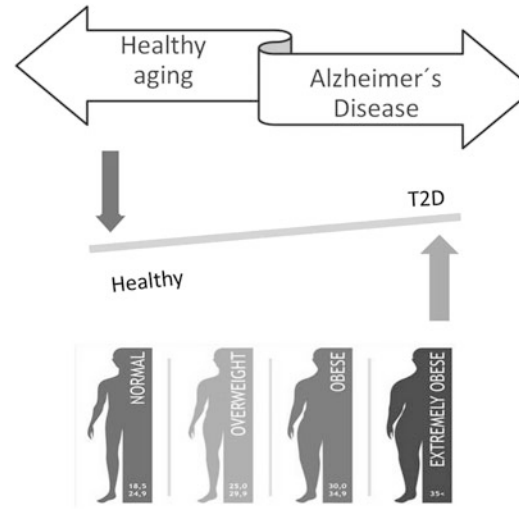

Fig. 29.1 Correlation between obesity and/or T2D and the risk for AD development. Over the last decades, type 2 diabetes (T2D) and obesity emerged as two major risk factors for cognitive decline and dementia, including Alzheimer's disease (AD), the risk being exacerbated when both metabolic diseases co-occurrence

Obesity, Cognitive Decline and Dementia

An estimated number of 41 million of children under the age of 5 are overweight or obese, according to the World Health Organization (WHO 2020), numbers that are expected to rise to approximately 541 million by 2030 (Kelly et al. 2008). Obesity "kills" more people than undernutrition (Fruhbeck et al. 2013). The increased risk for dementia in obese individuals was further confirmed by several studies (Pedditzi et al. 2016; Kivimaki et al. 2018). It has been reported that obesity can be responsible for impaired episodic and working memory, verbal learning and stimulus reward learning (Cournot et al. 2006; Cheke et al. 2017; Coppin et al. 2014).

Nonetheless, a careful analysis should be performed when describing obesity as a risk factor for dementia, since there seems to exist an "obesity paradox" (Pegueroles et al. 2018). During middle life, the risk for dementia is elevated;

while in advanced ages, obesity can have opposite effects, conferring some protection against cognitive decline (Anjum et al. 2018). Evidence for the risk is robust < 65 years however inconclusive between the ages of 65 and 74 (Albanese et al. 2017; Gustafson et al. 2003; Tolppanen et al. 2014; Bowman et al. 2019). Obese adults between 30 and 39 years seem to have a 3.5-fold increase in the relative risk for dementia, and after this age range, the risk seems to decrease in a stepwise fashion till 70 years, becoming significantly reduced from 80 years onward (Dye et al. 2017). An abrupt weight loss precedes dementia diagnosis by approximately 6–10 years (LeBlanc et al. 2017).

One of the major limitations of the studies aimed at exploring the interrelation between obesity and dementia is the gap in gender-inherent differences. It has been postulated that gender-associated susceptibility to cognitive decline and dementia does exist (Candeias et al. 2017; Fisher et al. 2018; Pontifex et al. 2018; Nyarko et al. 2018) and future studies should fill this gap.

Type 2 Diabetes, Cognitive Decline and Dementia

T2D is a complex metabolic disorder characterized by hyperglycaemia, hyperinsulinaemia, dyslipidaemia, as well as lipotoxicity, culminating in a progressive decline of insulin secretion and insulin action (Yazici and Sezer 2017).

Alterations in brain cortical thickness and white matter integrity alongside with decreased psychomotor speed performance are more pronounced in overweight/obese T2D individuals than in those with normal weight (Cardoso and Moreira 2019; Yoon et al. 2017). Moreover, T2D has been associated with reduced performance in verbal memory, processing speed, attention, spatial working memory, verbal fluency, executive function and alterations that are correlated with global brain atrophy (Wisse et al. 2014), sustaining the hypothesis of T2D as an accelerator of cognitive ageing (Dye et al. 2017; Karvani et al. 2019).

T2D can exist independently of obesity driven by genetics, fatty liver disease, inflammation, autoimmunity or stress (Benedict and Zhang 2017; de Candia et al. 2019). In Goto-Kakizaki rats, a non-obese T2D animal model, it was shown that spatial memory impairment, evaluated by the Y-maze test, and hippocampal synaptic dysfunction, evaluated by long-term potentiation (LTP) assays, was correlated with a reduction in synaptosomal nerve-associated protein 25 (SNAP25) and synaptophysin levels, suggesting synaptic dysregulation in this T2D animal model (Duarte et al. 2018; Spinelli et al. 2019).

Insulin Alterations, Inflammation and Oxidative Stress in Obesity/T2D

Insulin has a pivotal role in the central nervous system (CNS). It can also be produced by neuronal and glial cells (Blazquez et al. 2014; Gray et al. 2014). There is clear evidence that insulin resistance (IR) contributes to neurodegenerative events impacting brain function such as memory and learning (Holscher 2019; Folch et al. 2019). In the CNS, insulin modulates the phosphatidylinositol-3-kinase (PI3K)/protein kinase B (Akt) pathway and mitogen-activated protein kinases/Ras (MAPK/Ras) pathway. These pathways are highly involved in the regulation of neuronal survival, neuroplasticity and glucose uptake (Grillo et al. 2009). Furthermore, a role for insulin in the modulation of N-methyl-D-aspartate (NMDA) expression in the cell membrane, induction of long term potentiation (LTP) (Lee et al. 2011) and modulation of acetylcholine and norepinephrine levels (Arnold et al. 2018; Blazquez et al. 2014; Gray et al. 2014; Maciejczyk et al. 2019) has also been reported.

Male Wistar rats exposed to a 50% fat diet gained body weight, which contributed to peripheral IR and cerebral insulin deficiency, resulting in cognitive decline (Nameni et al. 2017). The decrease in cognitive performance may result from the deficient binding of insulin to its receptors that seem to be mainly situated in synapses of brain areas intimately related with memory formation (Spinelli et al. 2019). Brain

cortical IR in obese patients may contribute to decreased performance in episodic memory tasks (Cheke et al. 2017). High-fat diet combined to sugar intake induced obesity in male C57BL/6NHsd mice, which contributed to a significant decrease in tyrosine phosphorylation of the insulin receptor and an increase in serine phosphorylation of the insulin receptor substrate (IRS) 1, resulting in neuronal IR (Kothari et al. 2017). Insulin alterations were deeply associated with alterations in inflammatory [Nuclear factor-κB (NFκB), c-Jun N-terminal kinase (JNK)] and stress (p38 MAPK and C/EBP Homologous Protein) responses. Obesity is able to activate inflammatory-related negative regulators of IRS proteins, with emphasis on the suppressor of the 23 cytokine signalling (Socs) protein, which has the capacity to bind phosphorylated insulin receptors blocking the activation of IRS proteins (Johnson and Olefsky 2013).

Using magnetoencephalography, Tschritter and co-workers (2006) evaluated spontaneous and insulin-stimulated cerebrocortical activity in lean and obese humans during a two-step hyperinsulinaemic-euglycaemic clamp. Obese individuals did not respond to insulin infusion (Tschritter et al. 2006). Nevertheless, weight loss and improved IR fail to change grey matter volume or cortical thickness (Drummen et al. 2019).

Obesity can lead to an overproduction of ceramides by the liver, which can cross the blood-brain barrier (BBB) and interfere with insulin receptors causing brain IR (Arboleda et al. 2007). Kabadi (2017) reported that alterations in insulin secretory capacity are more pronounced in lean T2D subjects than IR, although these alterations also affect glucose tolerance. Both obesity and T2D-related IR can affect at least two different mechanisms: (1) peripheral insulin transport across the BBB (described as a receptor-mediated saturable process) and (2) intraneuronal defects in the insulin signalling cascade of either a primary (i.e., genetic) or secondary (i.e., due to an obesity-related factor) nature (Ono 2019).

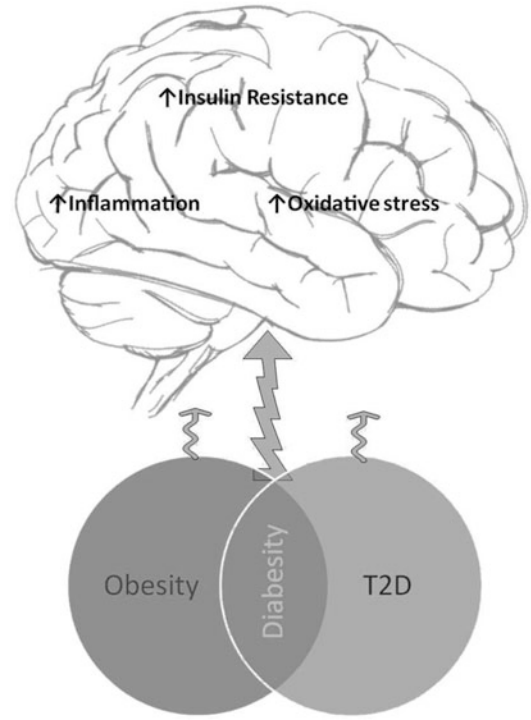

Fig. 29.2 The impact of obesity and/or T2D in the brain. Obesity and type 2 diabetes (T2D) increase brain insulin resistance, inflammation and oxidative stress, these alterations being potentiated when both pathologies co-occur, the so called "diabesity." Together, these alterations increase the risk of cognitive decline and dementia

Additional Pathways

Brain IR induced by obesity or T2D (Fig. 29.2) also causes the loss of the inhibitory function mediated by FoxO transcription factors, which normally modulate cellular metabolism and autophagy, increase amyloid-beta (Aβ) formation and deposition and phosphorylation of tau protein and neurofibrillary tangle formation and decrease synaptic plasticity, predisposing to cognitive impairment (Kothari et al. 2017), among other alterations, which affect mood and memory (Kullmann et al. 2016). The impairment of memory performance caused by IR in humans has been associated with a clear reduction in grey

matter volume (Willette et al. 2013) suggesting that insulin signalling disturbances in the brain can underlie cognitive impairment (Talbot et al. 2012). It has been reported that brain IR can be overcome by the intranasal insulin administration, a strategy that has been reported to no interfere with peripheral glucose homoeostasis (Cheke et al. 2017). Furthermore, structural alterations (e.g., hippocampal atrophy) have also been shown in individuals with impaired glucose tolerance and IR (Ursache et al. 2012).

Obesity induces an increase in circulating free fatty acids along with systemic inflammation due to the secretion of pro-inflammatory adipokines by the adipose tissue, and a decrease in adiponectin levels, known for its anti-inflammatory role (Dye et al. 2017; Nigro et al. 2014). In obese and T2D individuals, peripheral macrophages can reach the brain, mainly due to the increased permeability of BBB (Van Dyken and Lacoste 2018), causing low-grade inflammation (Buckman et al. 2014). Kumar and co-workers (2014) reported an increase in mRNA and protein levels of key chemokines in the brains of diabetic db/db mice, compared to wild-type counterparts. Once in the brain, macrophages activate microglia causing hormonal dysregulation (leptin and insulin resistance), increased immune sensitivity and cognitive impairment (Van Dyken and Lacoste 2018).

Mitochondrial dysfunction and oxidative stress are also important players in T2D and obesity, being closely associated with IR and inflammation (Fig. 29.2). Inherited defects leading to decreased mitochondrial capacity to oxidize fatty acids cause the overproduction of mitochondrial reactive oxygen species (ROS) and oxidative stress that, in turn, predispose to inflammation and IR (Dayre et al. 2016). Associated with increased oxidative stress is the decrease in glutathione metabolism, the principal brain antioxidant and regenerator of other free radical scavengers (e.g., vitamins C and E) (Maciejczyk et al. 2019). Increase in ROS production and oxidative stress leads to increased cell membrane permeability, ATP depletion and accumulation of protein aggregates. Importantly, increased ROS production seems to activate pro-inflammatory enzymes contributing to brain inflammation (Pugazhenthi et al. 2017; Sripetchwandee et al. 2018).

The Intestinal Microbiota and the Gut-brain Axis

Hippocrates, the father of medicine said that "all diseases begin in the gut." In fact, evidence suggests that obesity and/or T2D are influenced by dysfunction in the gut-brain axis (Fig. 29.3). The axis consists of a bidirectional communication (Heiss and Olofsson 2018) that integrates neural, hormonal and immunological signalling between the gut and the brain (Collins et al. 2012). The brain communicates with the gut microbiota directly via neurotransmitters (e.g., catecholamines, 5-hydroxytryptamine (5-HT), and γ-aminobutyric acid (GABA)) that can be sensed by the microbes, or indirectly via vagus nerves that modulate intestinal secretion and motricity, and thus its internal milieu (Collins et al. 2012). Gut microbiota can also send signals to the brain via blood-borne substances or afferent spinal and vagal nerves, regulating the release and activity of hormones involved in energy balance such as peptide YY (PYY) and glucagon-like peptide-1 (GLP-1) (Covasa et al. 2019).

Gut microbiota has emerged as an environmental factor that modulates the energy balance of the host (Heiss and Olofsson 2018), eventually causing low-grade inflammation, excess lipid accumulation and loss of insulin sensitivity, which potentiate the risk of developing metabolic diseases and comorbidities (Boulange et al. 2016).

Metabolic Endotoxemia

As previously mentioned, both T2D and obesity are characterized by a low-grade inflammatory state. This inflammatory response can be mediated by the altered gut microbiota (called dysbiosis), through an increase in lipopolysaccharide (LPS) production and its release to

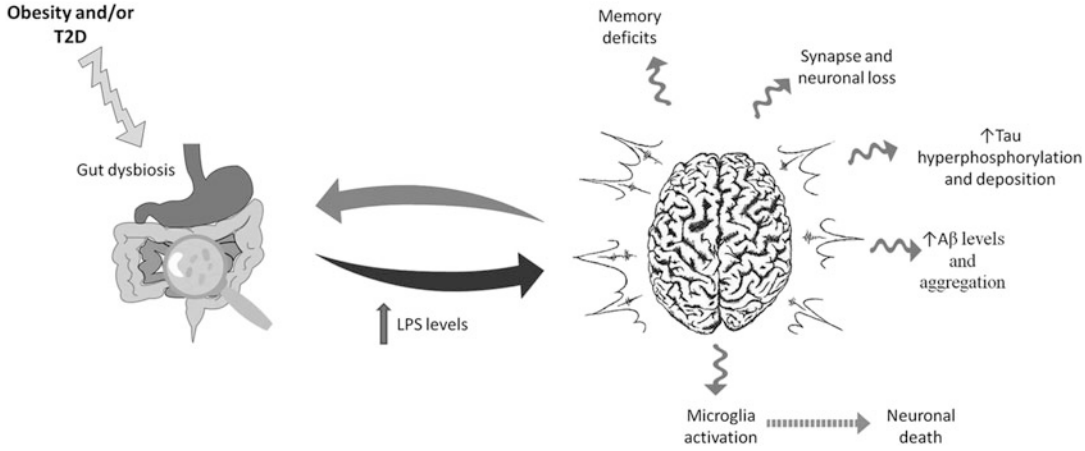

Fig. 29.3 Obesity and/or T2D affects gut-brain axis and predispose to dementia. Throughout life, changes in the intestinal ecosystem can occur leading to development of several pathologies. Also, gut microbiota changes (called dysbiosis) resulting from the consumption of high calories diets cause an increase in lipopolysaccharide (LPS) production and its release to circulating plasma. LPS can easily access the brain activating microglia that can cause neuronal death through increased nitrosative/oxidative stress, inflammation, formation and aggregation of amyloid β (Aβ) and tau proteins and phagocytosis of synapses and neurons. All these alterations may contribute to cognitive decline and dementia

plasma due to an increased permeability of the intestinal barrier (Cani et al. 2008). LPS can then access the brain due to an altered BBB permeability (Cardoso et al. 2012) leading to the activation of microglia (Fig. 29.3). Upon activation, microglia can cause neuronal death through oxidant and cytokine production or by phagocytosis of synapses and neurons (Brown 2019). Moreover, it has already been shown that LPS can trigger Aβ and tau proteins aggregation (Asti and Gioglio 2014; Gardner et al. 2016), causing the loss of brain synapses and neurons and memory deficits (Fig. 29.3), and predisposing to neurodegenerative events (Brown 2019).

Neurotransmitters

Studies involving germ-free animals support a pivotal role for gut microbiota in brain development and function including its influence in exploratory and learning processes (Neufeld et al. 2011; Diaz Heijtz et al. 2011). Germ-free animals are holders of significant alterations in anxiety-related neurotransmitters such as noradrenaline, dopamine and 5-HT (Clarke et al. 2013; Neufeld et al. 2011), as well as altered levels of proteins involved in normal development and function of neuronal synapses, as, for example, the levels of synaptophysin and post-synaptic density protein 95 (PSD95) (Diaz Heijtz et al. 2011). After transfection of gut microbiota from a patient with Alzheimer´s disease to germ-free C57BL/6N mice, Object Location Test and Object Recognition Test were significantly reduced, along with faecal excretion of metabolites related to the nervous system, including γ-aminobutyrate, taurine and valine (Fujii et al. 2019).

Vascular Alterations in Obesity and/or T2D: More than an Oxygen Issue

The quote “the way you breathe affects your memory” suggests the importance of oxygen to brain health. In this line, any alterations compromising the proper delivery of oxygen to the brain impacts its homoeostasis. Body weight is related to alterations in brain structure, white

matter and BBB, compromising the homoeostatic regulation of central energy metabolism (Anjum et al. 2018). Increased body fat content compromises vascular integrity, not only through the disruption of BBB integrity, but also via an accentuated decrease in oxygen and glucose delivery to brain cells (Jain et al. 2010). Obesity is involved with endothelial dysfunction, which impacts vascular tone, microvascular insulin resistance, secretion of nitric oxide and endothelin, influencing vascular structure and perivascular inflammation. Microvascular dysfunction in obesity could predispose to chronic diseases, including microvascular dementia (Sorop et al. 2017). Also in diabetic patients undergoing cardiac surgery, a widening of the physiological saturation gap between regional cerebral oxygen saturation ($rScO_2$) and central venous oxygen saturation ($ScvO_2$) was observed during general anaesthesia. $rScO_2$ was lower before induction, and this difference was maintained throughout the operation (Sudy et al. 2019). Decreased cerebral perfusion can lead to vascular damages, flow alteration, abnormal expression of amyloid β and tau proteins, as well as behavioural and cognitive deficits (Dong et al. 2018).

Obesity is responsible for a decrease in endothelial nitric oxide (NO) synthesis and action causing an increased nitrosative/oxidative stress that affects endothelial function (Toda et al. 2014). *In vitro* and animal studies from our group showed that T2D compromises BBB integrity and aorta function through mitochondrial dysfunction and increased oxidative/nitrosative stress potentiating the development of AD-like brain changes (Carvalho et al. 2013, 2014; Sena et al. 2015). Other studies show that metabolic syndrome and hypercholesterolemia also cause alterations in vascular function (Kivipelto et al. 2002; Campos-Pena et al. 2017), which may also contribute to brain alterations.

The two-hit vascular hypothesis postulates that cerebrovascular damage is sufficient to cause neuronal injury and AD-like neurodegeneration (Nelson et al. 2016). Thus, events that compromise vascular health could initiate a cascade of deleterious events that culminate in AD development. It must be emphasized that other neurodegenerative diseases (e.g., Parkinson and Huntington diseases) are also characterized by vascular alterations (Al-Bachari et al. 2017; Lee and Pienaar 2014; Lin et al. 2013; St-Amour et al. 2015).

Obesity and/or T2D are Associated with AD

AD is the fifth cause of death among those with 65 years or older (Alzheimer's Association 2020). The co-occurrence of obesity and T2D increases the risk of AD by 65 % (relative risk in T2D is 1.46) (Caruana et al. 2015). Several cross-sectional studies also show that T2D patients have lower scores in cognitive tests, especially those regarding verbal memory and complex information processing (Zilliox et al. 2016). In fact, AD is also considered a metabolic disorder characterized by deregulated glucose control, described in 80% of the cases, together with impairments in brain insulin responsiveness, glucose utilization and energy metabolism, which lead to increased oxidative stress, and inflammation that worsens IR, and is even designated as type 3 diabetes (Dye et al. 2017).

The existence of common mechanisms between T2D and AD has been supported by clinical studies showing that T2D patients exhibit regional brain atrophy, evaluated by fluorodeoxyglucose-positron emission tomography (FDG-PET), and cognitive impairment, even if they are not diagnosed as having AD (McNay and Recknagel 2011). Interestingly, Boersma and co-workers (2018) reported significantly higher brain glucose uptake rate in T2D and prediabetes subjects, confirming FDG-PET imaging in T2D rats (Ryu et al. 2019; Barriere et al. 2018).

Obesity/T2D-associated insulin signalling impairment and AD have been emphasized (Arnold et al. 2018). mRNA/protein expression of insulin receptors, insulin-like growth factors (IGF1 and IGF2), IRS1 and PI3K/Akt decrease in an inverse proportion to AD neuropathological markers, suggesting a key role for IR in the

progression of AD (Maciejczyk et al. 2019). Obesity is associated with thinner brain cortex, along with reduced total cerebral volume (Caunca et al. 2019). A similar picture of diminished cortical thickness is true for diabetes, with an indirect pathway linking T2D and cognitive decline (Moran et al. 2019). Formation of amyloid plaques (APs) and neurofibrillary tangles (NFTs) is related to the insulin signalling pathway in the brain, including GSK3β, JNK, CamKII, CDK5, CK1, MARK4, PLK2, Syk, DYRK1A, PPP, and P70S6K pathways. NFTs and APs lead to the impairment of synaptogenesis, neurotrophy and apoptosis, which are regulated by insulin, cholesterol and glucose metabolism (Rad et al. 2018). Studies from our laboratory show that T2D mice and the triple transgenic mouse model of AD (3xTg-AD) present similar behavioural and cognitive alterations (Carvalho et al. 2013), associated with alterations in the levels of pre- and post-synaptic protein markers as well as increased levels of Aβ and phosphorylated tau proteins (Carvalho et al. 2012, 2015).

There is also evidence that obesity per se or associated with T2D also impact the brain. Besides IR and inflammation, it was recently shown that excessive body fat affects the fornix white matter compromising its role in connecting the hippocampus to other brain regions, which contribute to AD development (Metzler-Baddeley et al. 2019).

Leptin, a hormone produced by adipocytes, has been shown to be involved in obesity/AD relationship in the absence of diabetes. Obese subjects also present increased levels of circulating leptin, usually related to leptin resistance. Leptin influences the functioning of the hippocampus, a region that degenerates in AD. Leptin has cognitive enhancing properties that could facilitate the cellular events that underlie hippocampal-dependent learning and memory. Reductions in leptin ability to regulate hippocampal synaptic function occur with age and also entail increased risk of AD. Leptin administration was associated with beneficial effects in animal models of AD (McGregor and Harvey 2018).

Nevertheless, further studies are required to establish the connections between obesity and/or T2D and neurodegenerative diseases, particularly AD, as inconsistencies and controversial results are recognized (Arnold et al. 2018; McGregor and Harvey 2018).

Can Anti-obesity and Anti-T2D Therapy be Repurposed for AD?

Non Pharmacological Approaches

Some longitudinal studies show that weight loss in midlife seems to reduce the incidence of AD, yet the knowledge about this topic is scarce (Sun et al. 2018). In fact, even small reductions in body weight associated with alterations in diet, bariatric surgery and/or exercise can restore or prevent cognitive dysfunction (Dye et al. 2017). Caloric restriction (CR) or changes in diet composition have been shown to restore blood glucose levels, increase life expectancy and decrease diabetes-related complications (Fontana and Partridge 2015). Several studies also show that the Mediterranean diet (enriched in fresh fruits, vegetables, nuts, fish and olive oil) ameliorates cognition and reduces the risk of developing dementia and AD (Wengreen et al. 2013; Tsivgoulis et al. 2013; Singh et al. 2014; Psaltopoulou et al. 2013). However, other studies show no association between Mediterranean diet and protection against cognitive decline (Dye et al. 2017).

Physical exercise plays also a major role in preventing or reducing obesity and/or T2D and associated complications (Teixeira-Lemos et al. 2011; Yang et al. 2019; Bernardo et al. 2016). Interestingly, CR and physical exercise reduce Aβ deposition associated with selective promotion of anti-amylogenic α-secretase activity and activation of astrocytes in AD animal models (Mouton et al. 2009; Wang et al. 2005). Moreover, both CR and physical exercise seem to reduce the deleterious effects of oxidative stress and IR, promoting an improvement of glucose metabolism as well as neurotrophic functions, thus facilitating neurogenesis and synaptogenesis and improving memory and cognitive functions in animal models of AD (Chen et al. 2016; Paillard et al. 2015). Likewise, also in humans CR and

exercise seem to improve neurocognitive functions of healthy or overweight patients (Smith et al. 2010; Il'yasova et al. 2018). Indeed, verbal memory scores increase about 20% after CR and seem to be correlated with decreases in fasting plasma levels of insulin and C-reactive protein, improved insulin sensitivity and reduced inflammatory activity, which contribute to enhanced synaptic plasticity and stimulation of neurofacilitatory pathways in the brain (Witte et al. 2009). Additionally, aerobic exercise and dietary modifications in individuals with high blood pressure who were sedentary and overweight or obese lead to improvements in executive function, memory, learning and psychomotor speed (Smith et al. 2010).

Bariatric surgery can improve white and grey matter integrity as well as memory and executive function, a benefit that persists for several years (Spitznagel et al. 2015; Nota et al. 2020). The positive outcome could be the result of adiposity reduction and increased GLP-1 and peptide YY levels, improved inflammatory status and insulin sensitivity or increased diversity in gut microbiota composition which results in altered composition of short-chain fatty acids that influence host metabolism, including gut hormone secretion and insulin sensitivity (Nota et al. 2020). Much less is known about the response of older adults, as well as those with genetical risk for AD. A longitudinal protocol addressing brain function and structure after bariatric surgery is now going on (Vreeken et al. 2019). It is worth mentioning that all the above non-pharmacological approaches may originate distinct outcomes depending on age, sex and disease stage. Therefore, their prescription should involve personalized health recommendations to achieve desirable results without detrimental side effects (Flannery and Trushina 2019).

Pharmacological Approaches

Intranasal administration of insulin was shown to boost mental activity, improve attention, cognitive functioning and verbal memory in patients with early AD (Claxton et al. 2015), improvements that remained after 4 months of intranasal insulin in MCI and AD patients (Craft et al. 2017). Also in obese and/or T2D patients, the administration of intranasal insulin caused significant improvements in memory and cognitive function (Novak et al. 2014; Claxton et al. 2015). In older T2D adults, intranasal insulin also rescued the network communication between the hippocampus and multiple default mode network regions (a large-scale brain network of interacting brain regions known to have activity highly correlated with each other and distinct from other networks) (Zhang et al. 2015). In fact, intranasal insulin administration may modify the functional connectivity among brain regions regulating memory and complex cognitive behaviours (Zhang et al. 2015; Schilling et al. 2014). Nevertheless, the "Study of Nasal Insulin in the Fight Against Forgetfulness" clinical trial, communicated in the "Clinical Trials on Alzheimer's Disease Conference" held in 2018, shows no effect of intranasal insulin on cognition, although the leader investigator claims that the lack of positive results may result from a change in the delivery device during the trial (Trials of Diabetes-Related Therapies: Mainly a Bust 2018).

Other metabolic hormone-based therapies have been explored in the context of T2D-related neurodegenerative disorders, particularly AD. Pramlintide, a synthetic analogue of the pancreatic hormone amylin, was recently shown to recover Aβ-related decreases in LTP in hippocampal slices from AD mice (Grizzanti et al. 2018).

Pioglitazone has been shown to significantly reduce the incidence of dementia in people with diabetes (Heneka et al. 2015). Likewise, pioglitazone showed significant benefits in early stages of AD and mild-to-moderate AD, causing a significant reduction in Aβ and tau pathology (Cheng et al. 2016). The poor blood-brain barrier (BBB) permeability and important side effects limited its success. Intranasal nano lipid carriers of pioglitazone are being developed to circumvent such shortcomings (Jojo et al. 2019).

Metformin has been shown to modulate the ageing process by reducing oxidative stress and

improving memory performance (Campbell et al. 2018). A meta-analysis performed by Zhang and co-workers (2020) showed that metformin therapy significantly improves cognitive function in patients with T2D. However, at least one study reported that long-term use of metformin can actually increase the risk of developing AD (Imfeld et al. 2012). It has been suggested that the effect of metformin may depend on the different profiles of comorbidities of the patient receiving the drug (Wang et al. 2017).

GLP-1 analogues confer protection against mitochondrial deficits, including improvements in ATP synthesis, and oxidative stress leading to the up-regulation of hippocampal expression of neurotrophic tyrosine kinase receptor type 2 (NTRK2) and mammalian target of rapamycin (mTOR) genes, involved in the modulation of synaptic plasticity and long-term potentiation in T2D and/or AD (Bomba et al. 2013; Lennox et al. 2014). A recent study from our laboratory also shows that exendin-4, a GLP-1 analogue, is able to protect the brains of T2D GK rats through the regulation of autophagy (Candeias et al. 2018). Bomba and co-workers (2013) reported that exenatide restored cognitive function of presenilin-1 knock-in mice, a mice model of AD. GLP-1 analogue liraglutide reduces Aβ accumulation by partially reverting inflammation and oxidative stress (Duarte et al. 2020). Also, liraglutide administration promoted antiapoptotic effects and ameliorated insulin synthesis in db/db T2D mice (Shao et al. 2014). Liraglutide was able to attenuate T2D-related loss of brain plasticity, disrupted energy homoeostasis, including reductions in mitochondrial transcription factor A (TFAM), sirtuin 1 and 5' AMP-activated protein kinase (AMPK) phosphorylation (Agrawal et al. 2014).

Abstract

The prevalence of both obesity and neuropsychiatric disorders is growing worldwide. While sociocultural changes have been implicated in this phenomenon, biological factors might also play a role. This chapter will address the intricate relationship between obesity and neuropsychiatric disorders, focusing on mood disorders, schizophrenia and major neurocognitive disorder or dementia. Obese people have a higher risk of developing depression than non-obese subjects. Conversely, depression contributes to unhealthy lifestyle (e.g. sedentarism) and unhealthy eating habits, which favour weight gain. The prevalence of obesity and overweight is elevated among patients with schizophrenia. Unhealthy behaviours and, notably, the use of antipsychotics can contribute to weight gain in this population. High BMI and central obesity in midlife may increase the risk of dementia later in life. After midlife, however, lower BMI has been associated with faster progression of dementia. Therefore, specific mechanisms can be involved in the relationship between obesity and each neuropsychiatric disorder, including inflammation, alterations in neurotransmitter biosynthesis, endocrine pathways (e.g. insulin, leptin and cortisol production and/or sensitization) and changes in gut microbiota. The treatment of obesity must consider the potential comorbidity with neuropsychiatric disorders.

Keywords

Obesity · Depression · Schizophrenia · Dementia · Inflammation · Gut microbiota

Abbreviations

BDNF	brain-derived neurotrophic factor
BH2	dihydrobiopterin
BH4	tetrahydrobiopterin
BMI	body mass index
DM2	diabetes mellitus type 2
GLP-1	glucagon-like peptide-1
GTP	guanosine-triphosphate
GTP-CH1	GTP-cyclohylase 1
HPA	hypothalamic-pituitary-adrenal
IDO	indoleamine 2,3-dioxygenase
IGF-I and IGF-II	growth factor type I and II
IRS	insulin receptor substrate
IFN	interferon
LPS	lipopolysaccharide
PAMPs	Pathogen-associated molecular patterns
PI-3K	phosphatidylinositol-3 kinase
TNF	Tumour necrosis factor alpha

Introduction

At least 30% of the population experiences a mental disorder, such as major depression and generalized anxiety disorder, at some point of their life, which can affect the quality of life and cause disability (Vigo et al. 2016; Steel et al. 2014). Five different psychiatric disorders or mental illnesses appear in the top 20 causes of the Global Burden of Disease study, 2013: major depression (2nd), anxiety disorders (7th), schizophrenia (11th), dysthymia (16th) and bipolar disorder (17th) (Vigo et al. 2016).

Technological development and increase in life expectancy have been hypothesized as contributing factors to growing prevalence of neuropsychiatric disorders in the last decades. Ageing is a major factor underlying the increased prevalence of Alzheimer's disease and other forms of dementia (Haines 2018).

According to Twenge et al. (2017), social media and electronic devices have a major impact on adolescent mental health. The relationship between time spent on electronics and mental health problems seems to be straightforward: the more time a teenager spends on electronic devices, the greater the propensity for mental health problems. On the other hand, adolescents who have high social interaction through sports

and/or religious services are less likely to develop psychiatric disorders (Twenge et al. 2017). Interestingly, screen media exposure has also been associated with increased risk of developing obesity (Robinson et al. 2017). Previous studies have shown the strong relationship between time spent in front of television and prevalence of obesity (Gortmaker et al. 1996). Obesity prevalence has strongly increased in the last decades in all age groups, causing a huge health and economic burden worldwide (Engin 2017).

Neuropsychiatric Disease and Obesity

Obese people have 60% more chance to develop depression than non-obese subjects (Strine et al. 2008). Adiposity also seems to have an effect on cognition (Boeka and Lokken 2008; Fergenbaum et al. 2009; Gunstad et al. 2006). When comparing obese and non-obese adolescents, the former group had worse cognitive performance in tests evaluating attention and mental flexibility (Yau et al. 2012). Moreover, longitudinal studies have suggested an association between obesity and dementia later in life (Pedditzi et al. 2016). On the other hand, weight loss promoted by bariatric surgery or diet restriction has been associated with cognitive improvement in adults (Siervo et al. 2011).

Neuropsychiatric Disease and Obesity

Mood Disorders and Obesity

Mood disorders involve changes in emotions and motivation (Rakofsky and Rapaport 2018). Major depressive disorder and bipolar disorder are the most relevant. Major depressive disorder includes recurrent and/or persistent depressive symptoms, whereas with bipolar disorder mania (pathological euphoria and/or irritability) (bipolar I) or hypomania (bipolar II) can alternate with depressive episodes (Martins et al. 2019).

Obese people are prone to depression (Macedo et al. 2015). It further contributes to sedentarism and unhealthy eating habits, eventually leading to additional obesity (Strine et al. 2008; Luppino et al. 2010). Carbohydrate-craving or consumption of more palatable and caloric foods is not uncommon, two further detrimental habits for excessive adiposity (Ventura et al. 2014; Corsica and Spring 2008).

Depressive symptoms correlate with unhealthy food consumption, such as sweets, cookies, snacks and fast food (El Ansari et al. 2014). Conversely, in a recent cross-sectional study involving more than 13,000 participants, Jackson et al. (2019) observed that the consumption of dark chocolate decreases depressive symptoms (Jackson et al. 2019). Chocolate components, such as analogues of anandamide (cannabinoid agonist), phenylethylamine (a neuromodulator) and flavonoids (anti-inflammatory effect), may contribute to the improvement of depressive symptoms. The pleasurable experience of eating tasty food could activate hedonistic neural pathways by the release of dopamine, serotonin and endorphins (Jackson et al. 2019). Also carbohydrates, via the tryptophan/serotonin pathway, could favour a hedonic response (Ventura et al. 2014; Corsica and Spring 2008). Also the motivational system through endogenous opioids could participate (Ventura et al. 2014; Corsica and Spring 2008). As both obesity and mood interfere with each other, therapy should consider both possibilities.

Schizophrenia and Obesity

Psychotic symptoms (hallucinations and delusions), negative symptoms (avolition, flat affect, social withdrawal) and cognitive dysfunction are the hallmarks of schizophrenia (Kahn et al. 2015). Obesity and overweight are common, possibly related to sedentary lifestyle, unhealthy eating behaviours and, notably, the use of antipsychotics (Citrome and Vreeland 2008).

Antipsychotic treatment often triggers weight gain (Tarricone et al. 2010), notably second-generation drugs, like olanzapine and clozapine (Manu et al. 2015). Appetite increases and eating preferences shift, conducting to excessive caloric intake. Olanzapine may reduce glucagon-like peptide-1 (GLP-1) levels (Smith et al. 2011), which is involved in satiation signalling (Smith et al. 2011; Shin et al. 2008; Shah and Vella

2014). Orexigenic protein expression (neuropeptide Y) can increase, along with reduction in the anorexigenic protein expression (POMC) in the arcuate nucleus and upregulation of ghrelin signalling, all favouring hyperphagia (Manu et al. 2015; Weston-Green et al. 2012; Hsu et al. 2015; Dipasquale et al. 2013) (Fig. 30.1)

Excess of saturated fat and diminished fruit and dietary fibre are frequent in schizophrenia, paving the way for metabolic syndrome, diabetes mellitus type 2 (DM2), and reduced life expectancy (Dipasquale et al. 2013). Brain insulin resistance may be involved in memory impairment, suggesting both psychiatric and metabolic approaches (Wijtenburg et al. 2019).

Dementia and Obesity

Alzheimer's disease is the main cause of dementia, followed by vascular dementia and other neurodegenerative conditions. Increase in β-amyloid plaques and neurofibrillary tangles in cortical regions are typically featured (Kivipelto et al. 2018).

Prevalence reaches 35% at age 85. By 2050, 131.5 million people could be affected (ADI 2015). This is also the sixth principal cause of death (Haines 2018).

In midlife, elevated BMI is associated with dementia later on, as observed in a large cohort of women (Gustafson et al. 2003), with about 1.4-fold risk increase (Pedditzi et al. 2016). Mechanisms could include inflammatory mediators and adipokines; vascular dysfunction and the consequences on cerebral perfusion; gut microbiota and inflammation, disturbing the brain-gut axis and insulin resistance (Anjum et al. 2018; Solas et al. 2017).

After midlife, dementia is more frequent in those with lower BMI (Kiliaan et al. 2014), consistent with a reversed trend (Gustafson 2012; Whitmer et al. 2008; Whitmer et al. 2007; Gustafson et al. 2009). In a series of 1,349,857 adults, higher BMI 20 years earlier favoured dementia, whereas 10 years earlier the risk diminished (Kivimaki et al. 2018). Frailty could be involved as an independent predictor of dementia (Rogers et al. 2017). The frail elderly suffer more falls, hospitalizations, disability, institutionalization and death (Rogers et al. 2017).

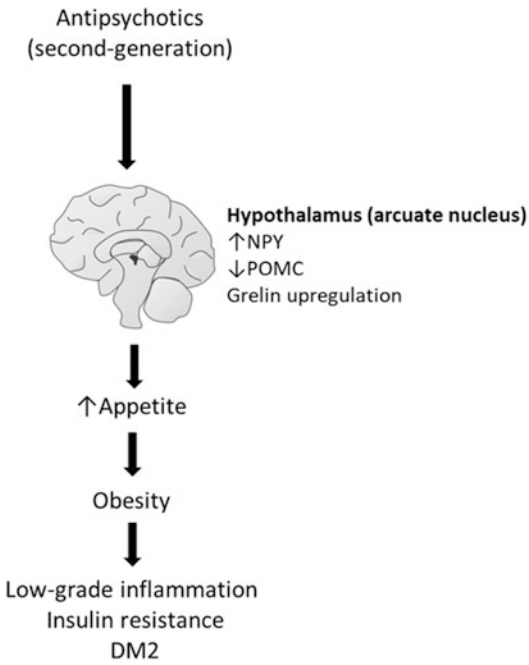

Fig. 30.1 Central effects of antipsychotics in the appetite and metabolic consequences. Second-generation antipsychotics may increase orexigenic protein (NPY, neuropeptide Y) and decrease the anorexigenic protein (POMC) expression in the arcuate nucleus. Second-generation antipsychotics also upregulate ghrelin signalling, leading to hyperphagia which contribute to obesity and metabolic complications development

Biological Mechanisms

Inflammation

Adipocyte hypertrophy, recruitment of immune cells and derangements of cytokines and adipocytokines released by adipose tissue can lead to low-grade inflammation during obesity (Kusminski et al. 2016). Circulating cytokines can reach the central nervous system, triggering neuroinflammation, especially in the hypothalamus and hippocampus, related to appetite and memory/learning (Castanon et al. 2015; Dinel et al. 2011). Upregulation of genes responsible for microglia activation and hippocampal

inflammation is impar for cognitive function in experimental models (Valcarcel-Ares et al. 2018).

Impairment of learning, memory and executive functioning is associated with obesity (Miller and Spencer 2014). High saturated fat diet has been linked to hypothalamic inflammation (Maric et al. 2014), potentially precipitating apoptosis of anorexigenic neurons in the arcuate nucleus, involved with satiety (Velloso 2009). Glial activation and inflammatory markers in hypothalamus have been noticed in experimental models (Maric et al. 2014). A diet with elevated inflammatory score could trigger depressive symptoms, anxiety and lower likelihood of well-being (Phillips et al. 2018).

Inflammation can alter neurotransmitter signalling involved in emotion and cognitive function, as cytokines are able to interfere with indoleamine 2,3-dioxygenase (IDO) and Guanosine-triphosphate-cyclohydrolase-1 (GTP-CH1), related to serotonin and dopamine production (Castanon et al. 2015). The enzyme IDO catabolizes tryptophan into kynurenine reducing serotonin production. Cancer chemotherapy with interferon-alpha (IFN-α) has been linked to depressive symptoms via the kynurenine pathway (Raison et al. 2010). IDO activity becomes elevated in adipose tissue in the course of obesity, along with decreased plasma tryptophan, in parallel with immune activation (Brandacher et al. 2007; Favennec et al. 2015; Wolowczuk et al. 2012). Besides reducing serotonin levels, the increase of IDO activity could induce depressive symptoms (Qin et al. 2018)

Immune activation enhances GTP-CH1 activity, catalysing the conversion of guanosine-triphosphate (GTP) into dihydrobiopterin (BH2). BH2 is then converted into neopterin due to tetrahydrobiopterin (BH4) production, which is part of dopamine and serotonin synthesis pathways (Fig. 30.2). In major depression, besides diminished serotonin, increase in neopterin correlates with the number of depressive episodes (Celik et al. 2010). Systemic inflammation and neurologic inflammation have been linked to mood disorders, schizophrenia and dementia (Colpo et al. 2018; Noto et al. 2015; Modabbernia et al. 2013; Kohler et al. 2017; Bauer and Teixeira 2018; Keller et al. 2017; Lara et al. 2013).

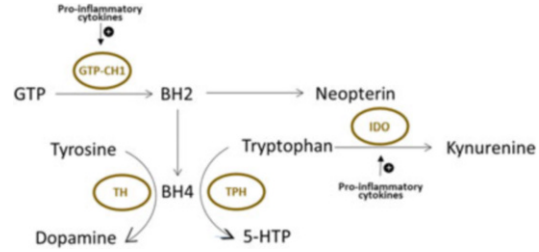

Fig. 30.2 Inflammatory mediators such as pro-inflammatory cytokines increase the enzyme GTP-cyclohydrolase-1 activity which catalyses the conversion of guanosine-triphosphate (GTP) into dihydrobiopterin (BH2) which is then converted into neopterin at the expense of tetrahydrobiopterin (BH4) (a cofactor of the tryptophan hydroxylase (TPH) and tyrosine hydroxylase (TH)). Inflammatory cytokines also activate the enzyme indoleamine 2,3-dioxygenase (IDO) with catabolizes tryptophan into kynurenine, diverting it away from 5-HTP (serotonin) production

Obesity-associated Insulin Resistance

Poor insulin signalling could be a result of an increase in pro-inflammatory cytokines release, such as tumour necrosis factor alpha (TNFα), which leads to serine kinases activation and insulin receptor substrate (IRS) 1 phosphorylation, diminishing insulin-induced activation of phosphatidylinositol-3 kinase (PI-3K) pathways, involved in the glucose uptake (Guo 2014). Deranged glucose homeostasis and specifically diabetes mellitus type 2 (DM2) are associated with major depression and Alzheimer's disease (Lyra e Silva et al. 2019). Insulin acts in hypothalamus and hippocampus, along with other areas (Lyra e Silva et al. 2019).

Depression and Type 2 Diabetes

DM2 can favour depression (20% increased risk) while depression also precedes (60% additional risk) the onset of DM2 (Nouwen et al. 2009; Mezuk et al. 2008; Moulton et al. 2015). The immune-inflammatory response, HPA axis

(Keller et al. 2017), neuroendocrine regulation and insulin resistance (Moulton et al. 2015; Grillo et al. 2019) could underlie such intertwining. Activation of innate immunity and inflammatory response is mentioned in DM2 pathophysiology, possibly contributing to bridge the gap between cognition and mood, and glucose homeostasis (Moulton et al. 2015).

Alzheimer's Disease, Insulin Resistance and Type 2 Diabetes

Previous studies that examined post-mortem brain tissue of Alzheimer's disease patients observed abnormalities in insulin and insulin-like growth factor type I and II (IGF-I and IGF-II) signalling mechanisms (Steen et al. 2005; Rivera et al. 2005). These findings led some authors to propose that Alzheimer's disease might be considered a "type 3 diabetes" (Steen et al. 2005; Rivera et al. 2005). These data also suggest that insulin resistance and DM2 observed in obese patients may contribute to the development of neurodegenerative diseases.

Hypercortisolaemia

Increase in inflammatory cytokine release can also activate the hypophysis pituitary adrenal (HPA) axis (Moulton et al. 2015). HPA axis is similarly activated in both obesity and neuropsychiatric disorders. BMI and waist-to-hip ratio have been correlated with the concentration of hair cortisol, the main stress hormone produced by the adrenal glands (Stalder et al. 2017). Hypercortisolaemia is also observed in early stage of Alzheimer's disease, suggesting activation of the HPA axis (Notarianni 2017). Cortisol plays an important role in glycaemic control. Cortisol suppresses glucose uptake by muscle cells and adipocytes through the inhibition of glucose transporter 4 (GLUT 4) translocation to the cell surface, causing insulin resistance (Kamba et al. 2016). Hypercortisolaemia is implicated in impaired glycose tolerance and pre-diabetes. Therefore, it has been suggested that hypercortisolaemia in Alzheimer's disease has a diabetogenic effect (Notarianni 2017).

Leptin / Leptin Receptor

Leptin is an adipocytokine (cytokine produced by adipocytes) whose primary role is to provide information on energy stores (adipose tissue) to the central nervous system, reducing appetite and controlling energy expenditure (Enriori et al. 2006). Leptin production occurs proportionally to the adipose tissue size; therefore, obese people usually have high levels of serum leptin. But obese people are "leptin resistant" since leptin enters in the brain through a saturable transport mechanism. In other words, hyperleptinaemia in obese people does not promote the expected central effects of reducing appetite (Farr et al. 2015). Actually, previous studies have shown that cerebrospinal fluid level of leptin is low in obese people, despite the high serum levels (Farr et al. 2015; Caro et al. 1996; Schwartz et al. 1996).

Leptin receptor is expressed in various regions of the brain, including cortex, hypothalamus, olfactory bulb, the dorsal raphe nucleus, hippocampus and the nucleus of the solitary tract (Farr et al. 2015; Zou et al. 2019). Leptin plays a role in brain development, organization and maturation of the nervous system (Farr et al. 2015). Leptin replacement therapy given to three genetically leptin-deficient adults resulted in increase of grey matter volume in cerebellum, inferior parietal and anterior cingulate cortices (Matochik et al. 2005).

Leptin also influences the release of brain-derived neurotrophic factor (BDNF), a factor that acts in mood regulation and memory/learning (Martins et al. 2017). BDNF acts in synaptic plasticity and neuronal survival in the hippocampus and other brain regions (Farr et al. 2015). Changes in the cerebral expression of BNDF, i.e. decreased levels and mutations in the gene, have been associated with obesity in human and animal models (Sandrini et al. 2018). Experimental studies have shown that nutritional strategies that prevent weight gain have been associated

with "normalizing" BDNF levels in hippocampus and improving cognitive changes (Moy and McNay 2013).

Alterations in serum levels of leptin in neuropsychiatric disorders, such as mood disorders and schizophrenia, have been observed (Atmaca et al. 2002; Jow et al. 2006; Kraus et al. 2001). In an experimental model, leptin receptor ablation in hippocampus caused depressive behaviour (Guo et al. 2013). In humans, an inverse correlation between leptin and depressive symptoms has been reported regardless of body fat and BMI (Jow et al. 2006; Miller et al. 2003; Lawson et al. 2012). Recently, Xu et al. (2018) observed that patients with schizophrenia have higher plasma leptin levels than healthy controls, and there was a negative correlation between leptin levels and depressive symptoms (Xu et al. 2018).

In this specific context, it is important to acknowledge that antipsychotics used to treat schizophrenia increase leptin levels and contribute to weight gain (Ragguett et al. 2017). In a longitudinal study, Venkatasubramanian et al. (2010) observed that antipsychotic-naïve schizophrenia patients had significantly lower leptin levels than controls. After treatment, leptin levels and BMI increased significantly (Venkatasubramanian et al. 2010). Opposite findings have been reported in female antipsychotic-naïve schizophrenic patients (Wang et al. 2007). Therefore, the role of leptin in schizophrenia remains to be clearly defined.

Leptin and Dementia

Besides playing an important role in the normal development of the hypothalamus, leptin participates in learning and memory processes through its action on hippocampal neurons (Anjum et al. 2018; Kiliaan et al. 2014; Carro 2009). Experimental studies have shown reduction in β-amyloid burden after peripheral leptin administration (Kiliaan et al. 2014; Carro 2009). In humans, a negative correlation was observed between the risk for Alzheimer's disease and blood leptin levels in older adults (Fewlass et al. 2004; Lieb et al. 2009). These latter results suggest the participation of leptin in prevention of dementia.

Intestinal Microbiota

Inflammatory mechanisms and HPA axis seem to link gut microbiota and brain function (Jiang et al. 2015). Intestinal microbiota responds to diet, medications, diseases and other environmental influences (Baothman et al. 2016). Dysbiosis, characterized by an imbalance in abundance and composition of microbial populations, may activate immune cells in the intestinal mucosa with repercussions on the gut-brain axis, comprising brain, gut, enteric nervous system and vagus nerve (Jiang et al. 2015; Daulatzai 2014; Round and Mazmanian 2009; Ley et al. 2005; Ley et al. 2006; Rodrigues-Amorim et al. 2018; Jiang et al. 2017).

Microbiota Fingerprints in Metabolic and Psychiatric Disorders

Aberrant gut permeability to macromolecules is an often addressed phenomenon (Fasano 2017). Abnormalities of gut handling of microbial-associated molecular patterns (MAMPs), such as lipopolysaccharide (LPS), a peptidoglycan of gramnegative bacteria cells, can cause activation of immune cells and release of inflammatory markers (Zhang et al. 2009; Rieder et al. 2017). Obese people have higher LPS plasma levels than non-obese people, and after bariatric surgery, LPS levels significantly reduce (Trøseid et al. 2013).

Besides the fact that obesity *per se* contributes to development of proinflammatory state, alterations in gut microbiota in obese individuals may increase LPS and immune cells activation, exacerbating the release of inflammatory mediators. As previously discussed, these mediators can lead to neuroinflammation and consequently to changes in neurotransmitter production and HPA axis functioning (Daulatzai 2014; Rea et al. 2016). The role of microbiota in behaviour has been investigated in germ-free (GF) animals, which have shown enhanced depressive-like behaviours. Interestingly enough, when GF mice were colonized with

microbiota from depressive patients, depressive-like behaviours increased (Zheng et al. 2016), along with excessive adiposity (Walker and Parkhill 2013).

Probiotics in Psychiatric Diseases

In a clinical trial conducted with healthy subjects, there was reduction in depressive symptoms following the use of *Lactobacillus helveticus* R0052 and *Bifidobacterium longum* R0175 (3×10^9 colony-forming units/stick) for 30 days compared to placebo (Messaoudi et al. 2011). Findings from other clinical trials support the benefits of probiotic use on the improvement of depressive symptoms (Kuo and Chung 2019) (Huang et al. 2016). In addition to depression, several studies have linked the use of probiotics with cognitive improvement in Alzheimer's disease (Akbari et al. 2016) and schizophrenia (Nemani et al. 2015; Tomasik et al. 2015; Dickerson et al. 2014). Figure 30.3 summarizes the putative mechanisms involved in the

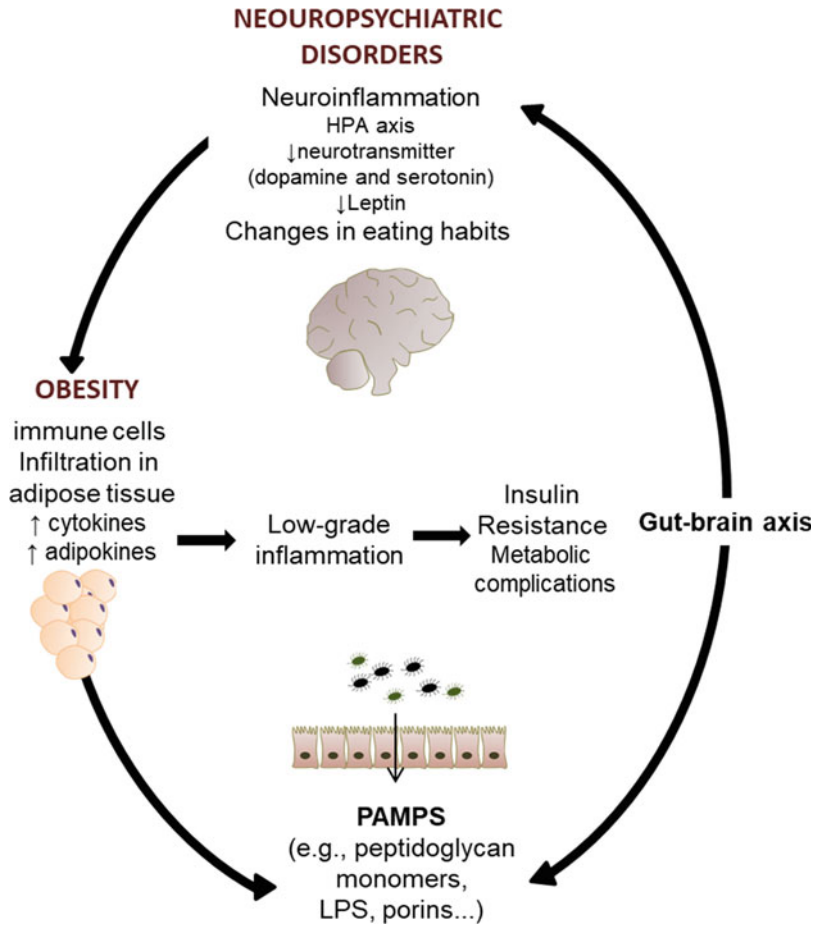

Fig. 30.3 Putative mechanisms involved in the relationship between obesity and neuropsychiatric disorders. Adipose tissue hypertrophy is associated with immune cells infiltration and chronic low-grade inflammation characterized by increased cytokines and adipokines secretion. Inflammatory cytokines impair insulin sensitivity while the excessive production of leptin (an adipokine involving in satiety signalling) causes a central leptin resistance. Obesity is also associated with changes in gut microbiota composition, increased intestinal permeability and activation of immune response through microbial- or pathogen-associated molecular patterns (PAMPs), such as lipopolysaccharide (LPS). The inflammatory molecules can reach the circulation and the central nervous system, where it may cause neuroinflammation and alterations in hypothalamus-pituitary-adrenal (HPA) axis and neurotransmitter production, including serotonin and dopamine, which influences cognition and behaviour

relationship between obesity and neuropsychiatric disorders.

Heart Failure and the Obesity Paradox 31

Marijana Tadic and Cesare Cuspidi

Contents

Abstract

Heart failure (HF) represents a complex cardiovascular disease with a wide range of risk factors, different pathophysiology, and various manifestations. Obesity is one of the most important comorbidities and one of the risk factors in HF patients. It seems that obesity has a more important role in development of HF patients with preserved left ventricular ejection fraction (HFpEF) than in HF patients with reduced ejection fraction (HFrEF). The role of obesity on HF with mid-range ejection fraction (HFmrEF) is a matter of debate. The impact of obesity on outcome in HF patients is still unclear. The relationship varies from the linear to the U-shaped. The "obesity paradox," which suggests the reduced risk in mildly overweight subjects in comparison with normal- and underweight individuals, drew significant attention. The mechanisms that relate obesity and HF vary from obesity-induced hemodynamic changes to biohumoral systems

such as adipocytokines, renin-angiotensin-aldosterone and sympathetic nervous systems, natriuretic peptide, and oxidative stress. In the absence of a satisfactory pharmacological approach, which would improve the outcome of this large group of patients, alternative methods such as weight loss and physical activity seem to provide encouraging results.

Current Status of Chronic Heart Failure

Heart failure (HF) represents a complex cardiovascular disease. HF definitions and diagnostic criteria have largely changed over the years, and therefore its incidence and prevalence significantly varied in the last few decades. For a long time, HF was defined primarily as the reduction of left ventricular (LV) systolic function defined by ejection fraction (HFrEF), and typical HF symptoms (lung congestion, fluid retention, dizziness, weakness, fatigue) (Tanai and Frantz 2015). Considering the fact that these symptoms are unspecific, a new biochemical marker was recently introduced—brain natriuretic peptide (BNP) and its precursor pro-BNP. This biomarker is currently used in emergency rooms for differential diagnosis of patients with shortness of breath (Senthong et al. 2017).

About two decades ago, a new entity called HF with preserved LV ejection fraction (LVEF), or HFpEF was introduced, with conserved LV pump function and symptoms comparable to HFrEF (Tanai and Frantz 2015). HF with midrange LV ejection fraction (HFmrEF) was subsequently included, with LVEF of 40–50% with symptoms and increased pro-BNP (Ponikowski et al. 2016). The authors are still in doubt if HFmrEF represents a new entity or only an overlap group between HFpEF and HFrEF; however, follow-up studies indicate differences in prevalence and survival.

The American Heart Association found among 110,621 HF patients, 50% with HFrEF, 14% with HFmEF, and 36% with HFpEF (Benjamin et al. 2018). Others observed 25.6% with HFpEF, 21% with HFmrEF and 53.5% with HFrEF (Webb et al. 2018). The OPTIMIZE-HF trial involved 54% with HFrEF, 20% with HFmrEF, and 27% with HFpEF (Fonarow et al. 2007). In contrast, the GWTG-HF protocol announced 47% displaying HFpEF, 39% HFrEF, and 14% HFmrEF (Cheng et al. 2014).

Heart Failure and Obesity

Overweight (1.9 billion) and obesity (600 million) are growing in the world (World Health Organization 2013). Obesity represents one the most important and modifiable causes of cardiovascular mortality (World Health Organization 2013; Kenchaiah et al. 2002; Baena-Díez et al. 2010). Obesity is related with decreased cardiorespiratory fitness, which is an important characteristic of HF. Nevertheless, the prognosis of HF is less ominous in this population, a phenomenon is known as an obesity paradox (Carbone et al. 2017).

Obesity underpins an increment of fat mass; however, obese patients can also have increased amount of lean mass. The latter could potentially explain the obesity paradox, as it is related with improved cardiorespiratory fitness, an important prognostic parameter. However, fat mass could provoke high systemic inflammation that could negate the protective effects.

Prognosis in Decompensated Patients

Mortality rates seem to be higher in HFrEF patients, however, similar among HFmrEF and HFpEF patients (Fonarow et al. 2007; Cheng et al. 2014; Sweitzer et al. 2008; Bhatia et al. 2006). The OPTIMIZE-HF study reported 3.9% mortality in HFrEF, 3.0% in HFmrEF, and 2.9% in HFpEF (Fonarow et al. 2007). In the ADHERE trial, rates were 4.7% with LVEF <25%, 3.4% with LVEF 25–40%, 3.2% when LVEF was

41–54%, and 3.0% with LVEF >55% (Sweitzer et al. 2008). During the GWTG-HF investigation, 30-day and 1-year mortality rates in HFrEF of 9.5% and 37.5% were encountered. In cases with HFmrEF they were 8.2% and 35.1% and in HFpEF, 8.5% and 35.6%, respectively (Cheng et al. 2014). In the Canadian experience, mortality at the same intervals in HFrEF was 7.1% and 25.5%, whereas in HFmrEF and in HFpEF they were 5.1% and 21.3%, and 5.3% and 22.2%, respectively (Bhatia et al. 2006). In both previous studies, there was no difference between HFmrEF and HFpEF (Cheng et al. 2014; Bhatia et al. 2006).

According to a large meta-analysis, adjusted mortality risks deteriorate with every 5–10% reduction in LVEF below 40%, however not with LVEF >40% (Meta-analysis Global Group in Chronic Heart Failure (MAGGIC) 2012). The CHARM trial confirms an adjusted hazard ratio of 1.31 for all-cause mortality per 10% reduction in LVEF <45% (Solomon et al. 2005), however, not when LVEF <40% or >40% (Pocock et al. 2013).

In the GWTGHF series, unadjusted in-hospital mortality for HFpEF diminished between 2005 and 2010, however, not for HFmrEF or HFrEF (Steinberg et al. 2012). In those admitted for acute decompensated HF, almost 49% had HFpEF (EF $\geq$ 50%), 37% had HFrEF (EF $\leq$ 40%), and 14% had HFmrEF (EF 41–49%) (Coles et al. 2014). Survival rates were better at 1, 2, and 5 years for HFpEF (Coles et al. 2014). Prognosis at 1 year improved for all HF groups; however, later on mortality for HFrEF and HFpEF remained elevated (Coles et al. 2014).

Outcomes in Obese Patients

Abdominal obesity has a stronger link to HFpEF than HFrEF. However, the impact of obesity on outcome in HFpEF, HFrEF, and HFmrEF is still a matter of debate. In the series of Savji et al. with a 12-year follow up**,** BMI correlated more with risk of HFpEF than of HFrEF, notably for women (Savji et al. 2018). Insulin resistance was related only to HFpEF development, not to HFrEF. There is some consensus that the BMI curve for all-cause mortality (including HF) is U-shaped, however not about the nadir, which can change from 32–33 kg/m^2 (Zhang et al. 2019) to 26.5–30.9 kg/m^2 (Haass et al. 2011). Values <23.5 kg/m^2 and >35 kg/m^2 are reported as risky (Haass et al. 2011). Again abdominal obesity is highlighted when all-cause, cardiovascular and noncardiovascular mortality are considered in the HF context (Tsujimoto and Kajio 2017). Yet BMI is not entirely overlooked, as findings >25 kg/m^2 signal risk, which seems higher for HFpEF than HFrEF (Pandey et al. 2017).

Among postmenopausal women, excessive adiposity was related with HFpEF only, not HFrEF, particularly for African American women. Hypertension (40.9%) and obesity (25.8%), were the paramount prognostic markers (Eaton et al. 2016).

In contrast, higher BMI indicated lower risk of symptomatic HF in another series, different from waist-to-height ratio (WHR), which was a positive prognostic marker for the composite outcome (Chandramouli et al. 2019). Low BMI paired with high WHR had a more ominous course than elevated BMI and normal WHR (Chandramouli et al. 2019).

Possible Involved Pathways and Biomolecules

Obesity is strongly related with systemic arterial hypertension, diabetes, insulin resistance, metabolic syndrome, and obstructive sleep apnea, all of which contribute to the development of HF. On the other hand, reduced cardiorespiratory fitness in HF patients could be the cause of obesity and therefore the "circulus vitiosus" is difficult to interrupt. Obesity induces hemodynamic, structural, neurohormonal changes, and systemic inflammation that induce functional and structural cardiac remodeling (Fig. 31.1), including HFpEF, and its impact on outcome in HFrEF patients is significant. However, the influence of obesity on HFmrEF is less clear.

The hemodynamic changes in obesity consider elevated central blood volume, reduced systemic

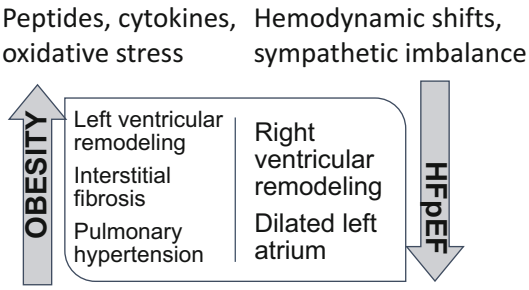

Fig. 31.1 Local and systemic changes associated with obesity

vascular resistance and stroke volume, and ultimately elevated cardiac output proportional to the degree of obesity but not to body surface area (Carbone et al. 2017; Tadic and Cuspidi 2019) (Fig. 31.1). Lean (fat-free) mass in obese patients is one of the most important parameters responsible for the development of a hyperdynamic state. Heart rate is only slightly increased; thus, cardiac output follows elevations of left ventricular (LV) stroke volume.

Cardiac effort, and particularly LV effort, in obese patients exceeds predicted values due to elevated LV stroke work. LV end-diastolic pressure and pulmonary capillary wedge pressure are commonly elevated in moderate-to-severe body adiposity.

The persistent increase in cardiac output due to elevated preload induces an initial LV dilatation, according to the Frank-Starling law, followed by a compensatory hypertrophic response confirmed at the cellular and organ level. LV hypertrophy represents a compensatory mechanism to decrease wall stress and oxygen demand according to LaPlace's law.

Pulmonary artery pressure is often increased due to LV failure, and retrograde transmission of increased LV filling pressure over pulmonary veins to pulmonary circulation, resulting in the increase of pulmonary vascular resistance particularly in those with sleep apnea or pulmonary hypoventilation (Alpert et al. 2018). RV filling pressure is frequently increased, which further induces elevated venous returns to the pulmonary circulation. Dyspnea becomes common in such context.

At the beginning, increased LV filling pressures and impairment in LV diastolic function were considered as the result of LV hypertrophy. However, studies found that obese patients may have LV diastolic dysfunction without LV hypertrophy (Dote et al. 2012; Russo et al. 2011), which indicates that some other mechanisms of LV remodeling besides LV hypertrophy may be involved (Fig. 31.1). LV hypertrophy could be even a protective response in face of increased preload by reduction of wall stress. Obese patients with HFpEF had increased relative wall thickness and smaller cardiac volumes even in the absence of increased LV mass, which demonstrates LV concentric remodeling (Yagmur et al. 2017; Zile et al. 2011).

Anthropometric Measurements

The visceral adipose tissue points toward decreased cardiac output and increased systemic vascular resistance, with opposite correlations for lower body fat. Abdominal subcutaneous fat seems to play a secondary role regarding LV concentric remodeling, only visceral adipose tissue being relevant (Shah et al. 2014). LV hypertrophy and LV mass have strong links with excessive body weight, eccentric hypertrophy being more common than the concentric phenotype (Neeland et al. 2013).

Other Heart Chambers

Right ventricular (RV) remodeling assessment by echocardiography is challenging in obese patients due to the position of the RV in the chest and increased thickness of chest wall, yet reduced function without overt heart disease has been perceived (Cuspidi et al. 2014), including larger volume and mass (Wong et al. 2006). Left atrial

(LA) dilatation, connected with HFpEF, has also been linked to elevated adiposity (Chahal et al. 2012). LA volume seems to follow visceral, yet not subcutaneous abdominal fat (Chahal et al. 2012). LA function and mechanics can deteriorate as well in HFpEF (Oliver et al. 2017).

Biohumoral and Neurohormonal Changes

Activation of the renin-angiotensin-aldosterone and the sympathetic nervous system, natriuretic peptide, systemic inflammation, and oxidative stress are reported. Cytokines such as interleukin (IL) 1 beta, tumor necrosis factor alpha, and IL-1 alpha, experimentally induce diastolic dysfunction (Van Tassell et al. 2013; O'Brien et al. 2014), and anti-inflammatory could ameliorate HFpEF and HFrEF. An IL-1 receptor antagonist improved cardiorespiratory fitness in patients with HFrEF and HFpEF, with increase of peak oxygen consumption (Van Tassell et al. 2012, 2014).

All these mechanisms might induce cardiac interstitial fibrosis that further decreases cardiac elasticity and compliance, and subsequently increases energy consumption during LV diastole—an extremely energy-demanding process. Moreover, these biohumoral and neurohormonal mechanisms promote enhanced atherosclerosis, which also may induce HF.

Obesity Paradox

In addition to an excess of fat mass, obese patients usually also have more lean mass. Patients with heart failure with increased amount of lean mass showed better cardiopulmonary fitness, a major determinant of clinical outcomes in the general population, and therefore lower mortality risk, which could be related to the "obesity paradox" phenomenon. Elevated lean mass represents a stronger predictor in heart failure in comparison with fat mass, whereas elevated fat mass in patients with coronary heart disease could have protective effects when fat mass is not related with increased systemic inflammation (Carbone et al. 2019). Obese patients with decreased amount of lean mass, despite increased BMI and fat mass, namely, sarcopenic obesity, suffer increased mortality. This suggests that lean mass plays a key role, and therefore exercise training and dietary interventions could represent important strategies.

Cardiovascular Mortality

The "obesity paradox" does not reduce risk in morbidly obese patients, only in mildly overweight cases. Nevertheless, there is still no agreement regarding the U-shape relationship between BMI and mortality or risk for HF development (Table 31.1). Mildly overweight patients had the lowest rates of death or cardiovascular hospitalization (Haass et al. 2011), and absence of obesity was an independent predictor of mortality in both HFpEF and HFrEF (Ather et al. 2012). On the other hand, Mohammed et al. reported that obesity was related with better outcome after adjustment for age, sex, and other comorbidities, and this association did not show U-shape (Mohammed et al. 2012).

BMI < 30 kg/m^2 pointed toward less 30-day mortality for HFpEF in one experience (Powell-Wiley et al. 2018). A modest association was found in HFrEF subjects, with no risk increase when BMI > 30 kg/m^2. The "obesity paradox"was not present in HFpEF (Table 31.1).

In another series, lack of obesity was related with mortality in HFpEF and HFrEF (Iorio et al. 2018). Further confirmation that mortality risk had a U-shaped form in both HFpEF and HFrEF is available, however, with the nadir at 30.0–34.9 kg/m^2 (Padwal et al. 2014).

One potential mechanism that could explain the "obesity paradox" is adiponectin, an adipocyte-specific cytokine, inversely related

Table 31.1 The association between obesity paradox and HFpEF

Refs.	Sample size	HFpEF/ HFrEF	Study type	Main findings
I-PRESERVE (2011)	4109 patients	HFpEF	Follow-up (4 years)	Overweight was related with lower mortality Or cardiovascular hospitalization. Underweight And severely overweight patients had higher Mortality rates than overweight
Ather et al. (2012)	942 patients	HFpEF/ HFrEF	2-year follow-up	Nonobese patients had higher mortality in HFpEF and HFrEF patients
Powell-Wiley et al. (2018)	39,647 patients	HFpEF/ HFrEF	30-day and 1-year follow-up	The obesity paradox for 30-day mortality Existed at all BMI levels only in HFrEF patients
Iorio et al. (2018)	2314 patients	HFpEF/ HFrEF	31-month follow-up	Nonobese patients had higher overall mortality In HFpEF and HfrEF patients and mortality rate Between these groups was similar
Padwal et al. (2014)	23,967 subjects	HFpEF/ HFrEF	Meta-analysis (3-year follow-up)	U-shaped form of relationship between mortality And BMI was found in HFpEF and HFrEF patients With highly positioned nadir at 30.0–34.9 kg/m^2

BMI body mass index, *HFpEF* heart failure with preserved ejection fraction, *HFrEF* heart failure with reduced ejection fraction

with BMI in HF patients. Lower adiponectin levels are associated with increased mortality, which means that patients with increased BMI have higher adiponectin and lower mortality. The other mechanisms of "obesity paradox" involve anti-inflammatory effects of elevated lipoproteins, and decreased response of the renin-angiotensin-aldosterone system.

Risks of Bias in the Interpretation of the Paradox

HF is characterized by decreased and/or inadequate cardiac output and elevated systemic vascular resistance, which is why the obese patients with preserved skeletal muscle mass have a better prognosis than HF patients with reduced lean mass, independent of stroke volume and cardiac output (Yancy et al. 2013). Furthermore, obese patients usually have lower systemic vascular resistance, particularly if they do not exhibit arterial hypertension (Alpert et al. 2014; Lavie et al. 2009). Afterload reduction results in improved forward flow and better cardiac output.

Recommended Lines for Further Investigation

Large randomized studies that evaluate intentional weight loss are still missing. Investigation of the impact of fat mass and lean mass on HF occurrence and outcome should be encouraged. It might be reasonable to hypothesize that increase of lean mass would be associated with greater muscular strength and better cardiorespiratory fitness, which altogether improve outcome in HF patients.

Abstract

Up to half of all patients with diabetes will develop diabetic kidney disease (DKD), the leading cause of end-stage kidney disease worldwide. The excess morbidity and mortality experienced by individuals with diabetes are primarily driven by the development of this microvascular complication. Recent research findings implicate inflammation as a major mechanism underlying kidney damage, including the pathological changes associated

J. Faintuch and S. Faintuch (eds.), *Obesity and Diabetes*, https://doi.org/10.1007/978-3-030-53370-0_32

with DKD. Historically, there has been a paucity of therapies that are effective in arresting the development and progression of DKD. Recently, however, glucose-lowering agents in the glucagon-like peptide-1 receptor agonist (GLP-1 RA) class of medications have been shown to preserve declining kidney function and reduce albuminuria in patients with diabetes. In addition to controlling modifiable risk factors such as hyperglycemia, blood pressure, and weight, it appears that GLP-1 signaling imparts direct anti-inflammatory, antifibrotic, and antioxidant effects. Thus, a number of clinical trials are underway to examine the impact of GLP-1 RAs on DKD development and progression.

Diabetic kidney disease · Inflammation · GLP-1 receptor agonists · Kidney outcome trials

Introduction

The end of the twentieth century and the first two decades of the twenty-first century are marked by a global epidemic of diabetes, with over 500 million individuals projected to have diabetes worldwide by the year 2030 (Whiting et al. 2011). This pandemic is largely driven by the staggering burden of obesity. Globally, the number of people with obesity increased from 104 million in 1975 to 641 million in 2014 (Collaboration NCDRF 2016), with the adjusted prevalence of obesity in the United States (U.S.) climbing to 35% and 40% among men and women, respectively (Flegal et al. 2016).

A microvascular complication of diabetes, diabetic kidney disease (DKD), occurs in up to half of patients with diabetes and is now the leading cause of end-stage kidney disease (ESKD) (Reutens 2013; Alicic et al. 2017). Clinically, DKD is identified by persistently elevated urinary albumin excretion (urinary albumin-to-creatinine ratio [UACR] >30 mg/g), or a reduction of kidney function (estimated glomerular filtration rate [eGFR] <60 mL/min/1.73 m^2) (National Kidney Foundation 2012). A diagnosis of obesity often precedes the diagnosis of diabetes and DKD, with obesity acting as a continuous risk factor (Macisaac et al. 2014).

The development of DKD amplifies the already-increased cardiovascular risk of individuals with diabetes, and also puts these individuals at greater risk for infections and cancer (Cheung et al. 2017; Rao Kondapally Seshasai et al. 2011). In fact, most of the excess risk for both all-cause and cardiovascular-related mortality in patients with diabetes is related to the presence of DKD (Afkarian et al. 2013). Even early stages of DKD are associated with a threefold increase in all-cause mortality, and a 16-year loss in life expectancy (Wen et al. 2017). Indeed, only a minority of DKD patients live long enough to reach ESKD and require kidney replacement therapy. Unfortunately for those who do survive long enough to require kidney replacement therapy, dialysis and kidney transplant are cost prohibitive in many parts of the world, thus equating a diagnosis of ESKD to a death sentence (Couser et al. 2011).

The number of deaths attributed to DKD almost doubled between 1990 and 2012 (Lozano et al. 2012). These data underscore the compelling need for both an improved understanding of the pathomechanisms behind the genesis and perpetuation of the disease, and the development of more effective therapies to prevent and treat DKD.

The Inflammatory Pathogenesis of Diabetic Kidney Disease

Activation of the innate immune response and associated inflammatory pathways is increasingly recognized as the origin of the functional and structural changes observed in DKD (Alicic et al. 2017, 2018). Inflammatory mediators are detectable in the urine of patients diagnosed with diabetes long before and after development of DKD, thus indicating a role of inflammation in both instigation and progression of the disease (Alicic et al. 2018; Van et al. 2017; Goldberg 2009). While the specific mechanisms responsible for obesity-induced kidney damage remain to be fully elucidated, it appears that endothelial

Inflammatory Mechanisms as New Biomarkers and Therapeutic Targets for Diabetic Kidney Disease, pages 181–191, Copyright by the National Kidney Foundation, Inc. (2017))

injury and activation of inflammatory pathways are important contributors (Alicic et al. 2017, 2018; Van et al. 2017; Goldberg 2009; D'Agati et al. 2016).

The phenotype of diabetes—hyperglycemia, oxidative stress, and elevated production of advanced glycation end-products—collectively activates the interstitial population of macrophages and dendritic cells (the *mononuclear phagocyte system*) in the kidney (Fig. 32.1) (Pichler et al. 2017; Navarro-Gonzalez et al. 2011). Once activated, these innate immune cells are engaged in the kidney and recruit additional cells, resulting in excessive immune cell invasion of the kidney and the destruction of important structures. This self-perpetuating cycle of activation and recruitment is mediated by the release of proinflammatory cytokines from activated immune cells, which recruits other circulating populations of immune cells, including monocytes, macrophages, and mast cells (Fig. 32.2) (Alicic et al. 2018).

Recruitment of mast cells in particular perpetuates this cycle through release of inflammatory cytokines, as well as release of chymase, which converts angiotensin I to II, thus directly perturbing glomerular hemodynamics (Maeda et al. 2010; Reilly et al. 1982). The degree of

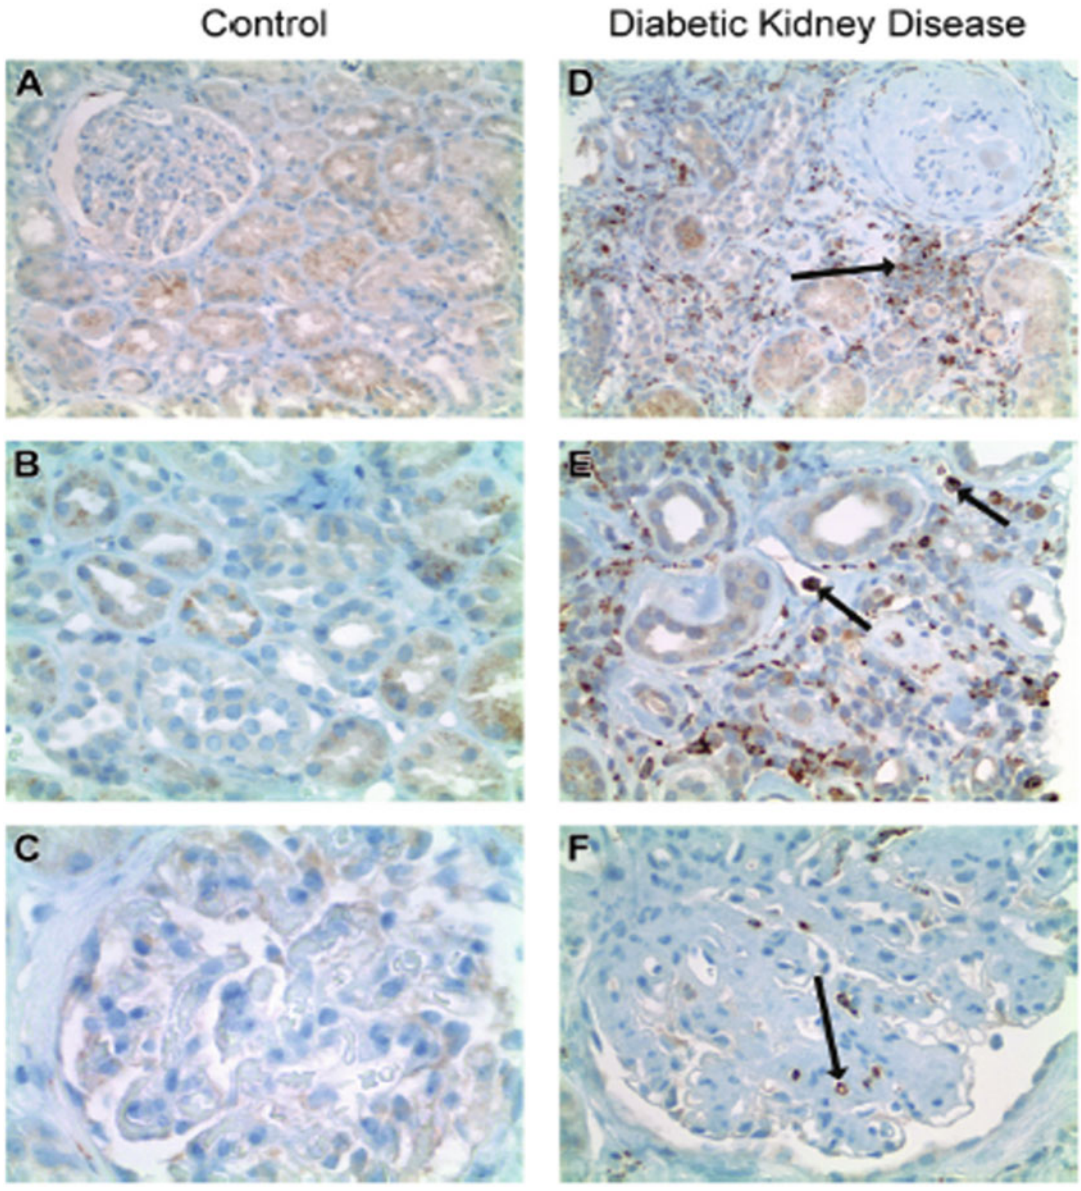

Fig. 32.2 Anti-CD68 (KP-1) immunohistochemistry of kidney biopsies from diabetic patients without and with histological features of diabetic kidney disease. (**e**) Macrophage lineage cells in peritubular capillaries (magnification: 400×). (**f**) Macrophage lineage cells in glomerular capillary (magnification: 600×). (Reprinted with permission from (Alicic et al. 2018). This figure was published in *Advances in Chronic Kidney Disease,* volume 25, Alicic RZ, Johnson EJ, Tuttle KR. Inflammatory Mechanisms as New Biomarkers and Therapeutic Targets for Diabetic Kidney Disease, pages 181–191, Copyright by the National Kidney Foundation, Inc. (2017))

tubulointerstitial inflammation, glomerulosclerosis, and rate of loss of eGFR are closely related with the degree of macrophage infiltration and mast cell degranulation (Hiromura et al. 1998; Okon and Stachura 2007; Ninichuk et al. 2007; Furuta et al. 1993).

The proinflammatory cytokines are a group of polypeptide signaling molecules that promote autocrine, paracrine, and juxtacrine signaling to coordinate the innate immune response. Their release by activated immune cells is associated with numerous abnormalities observed in DKD. Interleukin (IL)-1 contributes to perturbed hemodynamics via increased production of prostaglandin E (Pfeilschifter and Muhl 1990), and increased endothelial permeability in the kidney vasculature (Royall et al. 1989). IL-6 contributes to basement membrane thickening and albuminuria (Nosadini et al. 2000; Dalla Vestra et al. 2005; Nagayama et al. 2014) and worsens interstitial invasion by neutrophils (Kaplanski et al. 2003; Jones 2005). Through mechanisms that are not fully understood, IL-18 contributes to microvascular damage in the diabetic kidney, and its levels correlate with early signs of kidney impairment and macroalbuminuria (UACR >300 mg/g) (Fujita et al. 2012; Araki et al. 2007).

The inflammatory cytokine tumor necrosis factor α (TNFα) is released by activated immune cells, and is elevated in the urine and serum of patients with DKD compared to that of patients without diabetes or with uncomplicated diabetes. TNF-α is cytotoxic to kidney cells, alters glomerular hemodynamics, and increases oxidative stress (Navarro et al. 2005; Navarro and Mora-Fernandez 2006).

Monocyte-chemotactic protein-1 (MCP-1)/chemokine C-C motif-ligand 2 (CCL2), C-X3-C motif chemokine (CX3CL1), and C-C motif chemokine 5 constitute a subgroup of cytokines known as *chemoattractant* molecules, which recruit inflammatory cells to the kidney, furthering tissue damage (Navarro-Gonzalez et al. 2011; Furuta et al. 1993). Janus kinase/signal transducer and activator of transcription (JAK/STAT), an intracellular cytokine-associated signaling pathway, is upregulated in the glomerular cells of patients with DKD and correlates inversely with eGFR (Table 32.1) (Berthier et al. 2009; Brosius et al. 2016).

In sum, inflammatory markers have a clear association with the development, progression, and severity of DKD. The histological damage and functional impairment associated with DKD are primarily driven by the excessive and misdirected immune cell invasion of the kidney, which damages important kidney structures, and results in a self-exacerbating cycle of inflammation (Fig. 32.3).

Conventional Therapeutic Interventions for the Treatment of Diabetic Kidney Disease

Optimized blood glucose and blood pressure control has historically been the cornerstone of therapy, as poor glycemic control is clearly associated with the development and progression of DKD. Early in the course of diabetes, intensive glycemic control in patients with type 1 diabetes (HbA1c 6–6.9) reduces the risk of developing DKD (Nathan and Group DER 2014; Group DER et al. 2011; UK Prospective Diabetes Study (UKPDS) 1991). For instance, an absolute difference in HbA1c of 0.9% is associated with a 20% relative risk reduction in the development of macroalbuminuria (UACR >300 mg/g), ESKD, kidney-related death, or eGFR <30 mL/min/1.73 m^2 (Zoungas et al. 2017; Retnakaran et al. 2006).

It is hypothesized that the prolonged beneficial effects of early intensive glycemic control, often referred to as the "legacy effect" or "metabolic memory," can be explained by prevention of metabolism-driven epigenetic modifications (Tonna et al. 2010; Thomas 2014). Unfortunately, once diabetes complications develop, intensive glycemic control (targeting HbA1c levels <7%) places patients at risk for hypoglycemic episodes, and does not appear to decrease risk of cardiovascular complications (Group AC et al. 2008; Duckworth et al. 2009; Gerstein et al. 2008). Lower HbA1c may be even more detrimental to people with DKD, who showed 30% and 40% higher risk for all-cause mortality and

Table 32.1 Recognized actions of inflammatory molecules and pathways in diabetic kidney disease (DKD)

Innate immune cells	
Cell type	*Actions/biological effect*
Kidney Mononuclear Phagocytic System (coexpressing markers of macrophages and dendritic cells)	• Release cytokines and paracrine signaling molecules (Pichler et al. 2017; Navarro-Gonzalez et al. 2011) • Recruit circulating monocytes and macrophages (Nelson et al. 2012; Chow et al. 2005) • Magnitude of infiltration correlates with glomerulosclerosis, loss of eGFR, and tubulointerstitial inflammation (Ninichuk et al. 2007; Furuta et al. 1993; Nguyen et al. 2006; Lin et al. 2012)
Mast cells	• Conversion of angiotensin I to angiotensin II (Reilly et al. 1982) • Release many inflammatory mediators and proteolytic enzyme (Maeda et al. 2010)
Interleukin and tumor necrosis family	
Adhesion molecules	*Actions/biological effect*
Interleukin -1 (IL-1)	• Augment the expression of chemokines and adhesion molecules (Elsherbiny and Al-Gayyar 2016) • Stimulate prostaglandin E2 formation leading to alteration in glomerular hemodynamics (Pfeilschifter and Muhl 1990) • Increase vascular endothelial cells permeability and mesangial cell proliferation (Vesey et al. 2002) • Upsurge glomerular cellularity by elevating hyaluronan production (Jones et al. 2001)
Interleukin -6 (IL-6)	• Instigate podocyte hypertrophy, thickening of GBM (Dalla Vestra et al. 2005; Nagayama et al. 2014) • Cause alterations in plasma flow rate (Roscioni et al. 2014)
Interleukin -18 (IL-18)	• Promote production of cytokines by mesangial cells (Schrijvers et al. 2004) • Induce tubulointerstitial lesions (Turner et al. 2014) • Associated with albuminuria in early stages of DKD (Kim et al. 2012)
Tumor necrosis factor alpha (TNF-α)	• Regulate immune cells and cytokine release (Navarro and Mora-Fernandez 2006) • Alter glomerular hemodynamics (Baud et al. 1998) • Directly induce production of ROS (Koike et al. 2007) • Related to kidney hypertrophy and sodium retention (DiPetrillo et al. 2003) • Induce cell necrosis and apoptosis (O'Brien et al. 1998)
Chemokines	
Adhesion molecules	*Actions/biological effect*
C-C motif chemokine 2 (CCL2) or monocyte chemoattractant protein 1 (MCP-1)	• Involved in release of monocytes from bone marrow (Moser and Loetscher 2001) • Increased levels correlate with kidney macrophage accumulation (Wang et al. 2000) • Angiotensin II probably induces MCP/CCL2 expression (Mizuno et al. 2006; Amann et al. 2003) • In vitro, induce podocyte proliferation, migration, and affects podocyte motility (Burt et al. 2007) • Urine levels correlate with albuminuria (Lee et al. 2009)
CX3-C motif chemokine 1 (CX3CL1)	• Chemoattractant for monocytes, T-cells, and natural killer cells (Umehara et al. 2004) • Induce cell adhesion (Umehara et al. 2004)

(continued)

Table 32.1 (continued)

C-C motif chemokine 5 (CCL5) RANTES	• Chemoattractant for immune cells (Appay and Rowland-Jones 2001) • Expressed by fibroblasts mesangial and tubular epithelial cells (Appay and Rowland-Jones 2001) • Expression in tubular cells directly correlated with the degree of albuminuria (Herder et al. 2006)
Adhesion molecules	
Adhesion Molecules	*Actions/biological effect*
Intercellular adhesion molecule 1 (ICAM-1)	• Involved in leukocyte endothelial transmigration (Gu et al. 2012) • Associated with cardiovascular and all-cause mortality (Astrup et al. 2008) • Levels correlated with severity of albuminuria (Rubio-Guerra et al. 2009)
Vascular cell adhesion protein 1 (VCAM-1)	• Promote adhesion of immune cells (Ina et al. 1999) • Expressed by endothelial and smooth muscle cells (Ina et al. 1999) • In patients with HTN and DM 2 circulating levels correlate with albuminuria (Rubio-Guerra et al. 2009) • High plasma concentration correlates with increased risk of death, independent of other risk factors (Stehouwer et al. 2002)
Endothelial cell-selective adhesion molecule (ESAM)	• Selectively expressed by glomerular endothelial cells (Nasdala et al. 2002) • Regulate vascular permeability and adhesion (Nasdala et al. 2002) • Suggested that its downregulation may promote albuminuria (Nasdala et al. 2002)
E-selectin (CD62E)	• Selectively expressed on endothelial cells following exposure to cytokines (Navarro-Gonzalez et al. 2011) • Soluble levels correlate with the albuminuria and presence of cardiovascular disease in DM 1 patients (Soedamah-Muthu et al. 2006) • Strongly correlated with presence of DKD (Lopes-Virella et al. 2008)
A-Actinin 4	• Exclusively expressed in podocytes C (Kimura et al. 2008) • Expression inversely correlated with the extent of mesangial expansion (Kimura et al. 2008)

cardiovascular-related mortality, respectively, with intensive glycemic control compared with standard therapy (Papademetriou et al. 2015). Control of hyperglycemia is therefore recommended to be stratified based on clinical and demographic factors, and patients with diabetes and kidney disease should generally not be treated to an HbA1c target of <7.0% (National Kidney Foundation 2012; ADA 2020).

Arterial Hypertension

Hemodynamic insults to the kidney accelerate the progression of DKD. For instance, after 15 years of follow up, individuals newly diagnosed with type 2 diabetes and treated to blood pressure <150/85 mmHg had significant reduction in overall risk of microvascular complications (37%, $p = 0.009$) compared to those treated to a target blood pressure <180/105 mmHg (Adler et al. 2000). Each 10-mmHg increase in mean

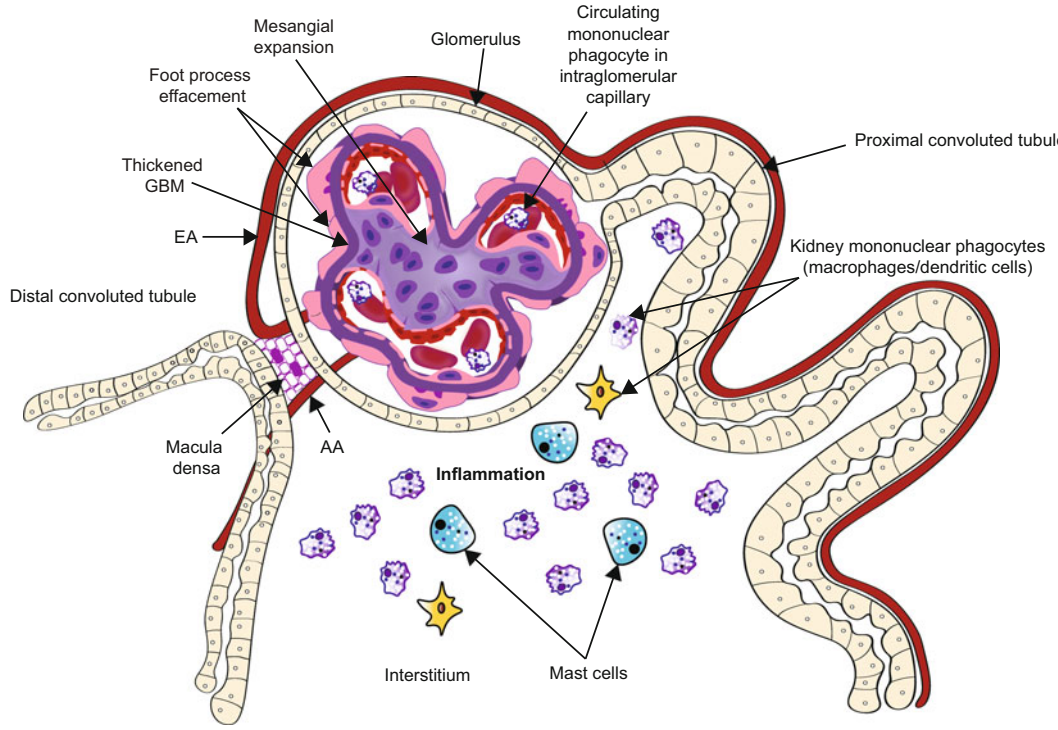

Fig. 32.3 Conceptual model of immunity and inflammation in diabetic kidney disease. Metabolic and hemodynamic abnormalities induced by diabetes instigate cytokine production and activate resident macrophages, dendritic cells, and mast cells. This leads to recruitment of the additional immune cells and further cytokine release. Biological effects of the inflammatory process include podocyte foot process effacement, thickening of the glomerular basement membrane, mesangial expansion, extracellular matrix remodeling, and phenotypic transformation of a variety of kidney cells to myofibroblasts. (Reprinted with permission from (Alicic et al. 2018). This figure was published in *Advances in Chronic Kidney Disease,* volume 25, Alicic RZ, Johnson EJ, Tuttle KR. Inflammatory Mechanisms as New Biomarkers and Therapeutic Targets for Diabetic Kidney Disease, pages 181–191, Copyright by the National Kidney Foundation, Inc. (2017))

systolic blood pressure was associated with a 13% ($p < 0.0001$) increase in hazard ratio for development of both micro- (UACR $\geq$30 to $\leq$300 mg/g) and macroalbuminuria and impaired kidney function, defined as eGFR <60 mL/min/1.73 m^2, or doubling of the blood creatinine level (Adler et al. 2000).

There is a clear evidence that blood pressure control with renin-angiotensin system (RAS) blockade, with either an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB), reduces the progression of established DKD in patients with macroalbuminuria (Adler et al. 2000; Bakris et al. 2003; Pohl et al. 2005; Brenner et al. 2001). Current treatment guidelines recommend that the majority of patients with diabetes should be treated to a systolic blood pressure (SBP) goal of <140 mmHg and a diastolic blood pressure (DBP) <90 mmHg. Lower SBP and DBP goals, such as <130/80 mmHg, may be appropriate for individuals at high risk of cardiovascular disease, with use of a maximally tolerated dose of either an ACE inhibitor or ARB in patients with diabetes and UACR $\geq$30 mg/g creatinine, and particularly in those with UACR $\geq$300 mg/g creatinine. ACE inhibitors and ARBs can essentially be considered interchangeable, but should not be given together due to higher risks of hyperkalemia and acute kidney injury, without additional benefits for DKD (National Kidney Foundation 2012; ADA 2020; de Boer et al. 2017; Fried et al. 2013).

Healthy Lifestyle

The Verona Diabetes Study reported that obese participants with type 2 diabetes and preserved kidney function (baseline eGFR ≥60 mL/min/1.73 m^2) exhibited significantly faster age-adjusted annual eGFR decline during 10 years of follow-up (−1.2 ± 0.1 mL/min/1.73 m^2/year) compared with normal weight individuals (Zoppini et al. 2012). Lifestyle modifications such as regular physical activity, reduction of dietary fat consumption, and smoking cessation are also known to reduce incidence of DKD, and attenuate loss of kidney function (Pongrac Barlovic et al. 2019; Gaede et al. 2003, 2008).

New Therapeutic Approaches: Glucagon-Like Peptide-1 Receptor Agonists

GLP-1 RAs are analogs of the pleiotropic hormone, GLP-1. GLP-1 is produced by enteroendocrine (EEC) intestinal L- cells and is released post-prandially. In vivo, the hormone is quickly degraded by DPP-4, a proteolytic enzyme. Intestinal L-cells are regulated by nutrients, cytokines, bacterial metabolites, and endotoxins (Drucker 2016). Endogenous GLP-1 stimulates glucose-dependent insulin secretion from pancreatic β-cells, suppresses inappropriately elevated glucagon secretion from pancreatic α-cells, delays gastric emptying, and induces satiety via a direct action in the central nervous system (Neumiller 2012). The GLP-1 receptor is most abundantly expressed in the pancreas and duodenum, followed by the stomach and kidney, with very low expression in the heart, lung, and distal intestine, and undetectable expression in the liver and thyroid (Mima et al. 2012; Park et al. 2007; Fan et al. 2019). Currently available GLP-1 RAs are resistant to the DPP-4 enzyme, and can be divided into two main structural categories: shorter-acting exendin-4-based (exenatide and lixisenatide), and longer-acting human GLP-1-based analogs (liraglutide, dulaglutide, and semaglutide) (Table 32.2) (Neumiller 2012; Ahren 2011; Trujillo and Nuffer 2014).

Stemming from the 2008 FDA Guidance for Industry (FDA 2008), all newly marketed glucose-lowering therapies must undergo assessment for cardiovascular safety in a designated cardiovascular outcome trial (CVOT). Implementation of this guidance has provided the medical community reassurance that newly marketed glucose-lowering therapies are safe from a cardiovascular perspective. In CVOTs for the GLP-1 receptor agonists, a multitude of unexpected beneficial biological and clinical effects beyond

Table 32.2 Summary of Currently Available GLP-1 RAs

Entity	Route of administration	Administration frequency	Half-life	Recommended renal dose adjustment
Exenatide	SC Injection	Twice daily	~2.4 h	• Not recommended with CrCl <30 mL/min • Caution recommended with initiating or escalating the dose with CrCl 30–50 mL/min
Lixisenatide	SC Injection	Once daily	~3 h	• Not recommended with CrCl <15 mL/min
Liraglutide	SC Injection	Once daily	~13 h	• No dosage adjustments recommended
Exenatide XR	SC Injection	Once weekly	~1 w	• Not recommended with eGFR <45 mL/min/1.73 m^2 or ESKD
Dulaglutide	SC Injection	Once weekly	~5 d	• No dosage adjustments recommended
Semaglutide	SC Injection	Once weekly	~1 w	• No dosage adjustments recommended
	Oral	Once daily

glycemic control were observed, including reduction of macroalbuminuria and attenuation of kidney function loss in patients with type 2 diabetes, with or without chronic kidney disease (Greco et al. 2019; Pfeffer et al. 2015; Mann et al. 2017; Marso et al. 2016a, b; Tuttle et al. 2018a).

Glucagon-Like Peptide-1 Receptor Agonist Trials

Dulaglutide

The AWARD-7 trial enrolled 577 individuals with moderate-to-severe DKD (mean eGFR: 38 mL/min/1.73 m^2) who were randomized to receive (1:1:1) dulaglutide 1.5 mg once weekly, dulaglutide 0.75 mg once weekly, or insulin glargine. All participants received insulin lispro for prandial glucose control. Following 52 weeks of treatment, both dulaglutide treatment groups experienced less eGFR decline when compared to those participants in the insulin glargine group: average eGFR decline was −3.3 mL/min/1.73 m^2 in the insulin-treated group and −0.7 mL/min/1.73 m^2 in both higher (1.5 mg weekly) and lower (0.75 mg weekly) dose dulaglutide-treated groups (Tuttle et al. 2018a). Among AWARD-7 patients with macroalbuminuria at high risk for progression, attenuation of mean eGFR decline was maintained (−5.5 mL/min/1.73 m^2 in insulin glargine group compared with −0.7 mL/min/1.73 m^2 and 0.5 mL/min/1.73 m^2 in dulaglutide 0.75 mg and 1.5 mg groups, respectively) (Tuttle et al. 2018a).

Notably, fewer patients in the higher dose dulaglutide group reached the composite endpoint of end-stage kidney disease or >40% eGFR decline, compared to the insulin glargine group (5.2% versus 10.8%, $p = 0.038$) (Fig. 32.4) (Tuttle et al. 2018b). The lesser decline was not influenced by body weight loss (Tuttle et al. 2019a). An additional post hoc analysis found that a composite endpoint of ≥40% eGFR decline or ESKD was lower by approximately half in participants receiving dulaglutide 1.5 mg once-weekly versus those receiving insulin glargine (Tuttle et al. 2019b).

More recently, the Researching Cardiovascular Events with a Weekly Incretin in Diabetes (REWIND) trial findings were reported (Gerstein et al. 2019). Approximately 20% and 35% of the participants had eGFR <60 mL/min/1.73 m^2 and microalbuminuria, respectively. REWIND included a predefined secondary kidney composite outcome inclusive of new-onset macroalbuminuria, a sustained decline in eGFR of ≥30% from baseline, or chronic kidney replacement therapy. Significantly less participants receiving dulaglutide experienced a kidney-related event when compared with placebo (17% vs. 20%, respectively), thus supporting the kidney protective effects observed in AWARD-7 (Fig. 32.4) (Gerstein et al. 2019).

Liraglutide

The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial enrolled participants with type 2 diabetes and high cardiovascular risk (Marso et al. 2016a). Approximately 23% of participants had moderate-to-severe DKD. Prespecified secondary kidney outcome was a composite of new-onset persistent macroalbuminuria, persistent doubling of the serum creatinine level, end-stage kidney disease, or death due to disease (Mann et al. 2017). Liraglutide treatment was associated with a lower rate of kidney events compared to those receiving placebo (161 vs. 215 patients; hazard ratio (HR): 0.74; 95% CI: 0.60 to 0.91; $p = 0.004$). The progressive decline in eGFR at 36 months was 7.44 and 7.82 mL/min/1.73 m^2 in the liraglutide and placebo groups, respectively, corresponding to a 2% less decrease observed with liraglutide (Fig. 32.4) (Mann et al. 2017). This finding is supported by several other studies in patients with type 2 diabetes reporting a reduction in albuminuria with liraglutide (Zavattaro et al. 2015; von Scholten et al. 2015). However, results from the Liraglutide Versus Placebo as Add-on to Glucose-Lowering Therapy in Patients With Type 2 Diabetes and Moderate Renal Impairment (LIRA-RENAL) trial did not report a beneficial effect of liraglutide treatment

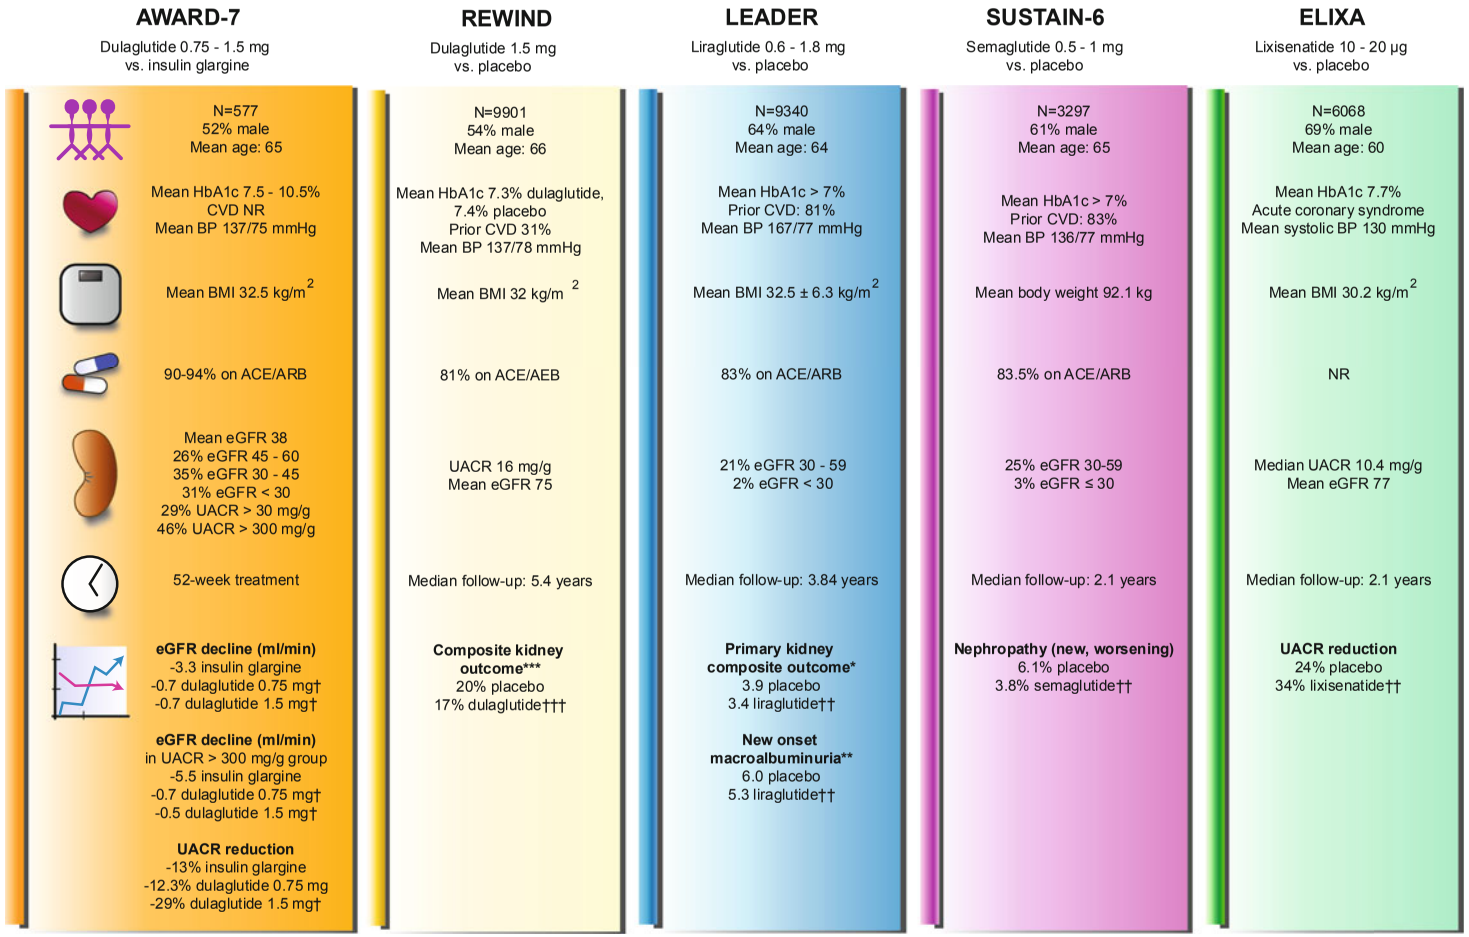

Fig. 32.4 Kidney outcomes in major clinical trials for glucagon-like peptide-1 receptor agonists. Outcomes from clinical trials evaluating members of the glucagon-like peptide-1 receptor agonist class of medications in patients with type 2 diabetes, as well as cardiovascular and renal disease. *Primary composite outcome, new-onset persistent macroalbuminuria, persistent doubling of serum/creatinine and eGFR $\leq$45 mL/min/1.73 m^2, requirement for renal replacement therapy, or renal death in number of patients (rate per 1000 patient-years of observation). **Rate per 1000 patient-years of observation. ***Composite of new-onset macroalbuminuria sustained eGFR decline $\geq$30 mL/min/1.73 m^2, or chronic kidney replacement therapy. †Significant from insulin glargine ($p < 0.05$). †† Significant from placebo ($p < 0.05$). ††† Significant from placebo ($p = 0.0004$). Abbreviations: *ACE/ARB* angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, *BMI* body mass index, *BP* blood pressure, *CVD* cardiovascular disease, *DKD* diabetic kidney disease, *eGFR* estimated glomerular filtration rate in units of mL/min/1.73 m^2, *GLP-1* glucagon-like peptide-1, *NR* not reported, *UACR* urine albumin-to-creatinine ratio. on eGFR decline over a shorter period of time of 26 weeks (Davies et al. 2016).

Semaglutide

The Trial to Evaluate Cardiovascular and Other Long-term Outcomes with Semaglutide in Subjects with Type 2 Diabetes (SUSTAIN-6) was designed to assess the cardiovascular safety of injectable semaglutide (Marso et al. 2016b). SUSTAIN-6 included a secondary outcome of new or worsening nephropathy, which was lower in the group receiving semaglutide (HR: 0.64; 95% CI: 0.46–0.88; $p = 0.005$) (Marso et al. 2016b). This finding was largely driven by an observed reduction in new-onset macroalbuminuria in the semaglutide (2.5%) versus placebo (4.9%) groups (Fig. 32.4) (Marso et al. 2016b).

Lixisenatide

The Evaluation of Lixisenatide in Acute Coronary Syndrome (ELIXA) trial enrolled patients with type 2 diabetes and a recent history of myocardial infarction or hospitalization for unstable angina (Fig. 32.4) (Pfeffer et al. 2015). An exploratory analysis of ELIXA, which included 4441 participants with normoalbuminuria (UACR <30 mg/g), 1148 participants with microalbuminuria, and 389 participants with macroalbuminuria, investigated the percentage change in albuminuria and eGFR according to baseline albuminuria status, and examined the time to new-onset macroalbuminuria and doubling of serum creatinine. After adjustment for traditional risk factors such as HbA1c, lixisenatide was shown to reduce the progression of albuminuria in macroalbuminuric participants (−39.18%; 95% CI: −68.53 to −9.84; $p = 0.0070$). It was also associated with a lower risk for new-onset macroalbuminuria adjusted for baseline, and on-trial HbA1C (HR: 0.808; 95% CI: 0.660–0.991; $p = 0.0404$ and HR: 0.815; 95% CI: 0.665–0.999; $p = 0.0491$, respectively). There were no differences in eGFR decline between treatment groups (Muskiet et al. 2018).

Exenatide

The Exenatide Study of Cardiovascular Event Lowering (EXSCEL) trial was a large cardiovascular outcome study, enrolling a total of 14,752 patients with type 2 diabetes with or without previous cardiovascular disease (Holman et al. 2017). The primary outcome was a cardiovascular composite that included death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke. While kidney-related outcomes were not reported with the primary trial findings, results for additional prespecified microvascular analyses were recently published (Bethel et al. 2020). After median follow-up period of 3.2 years, the mean change in eGFR from baseline was found to be similar in the exenatide and placebo groups. New-onset macroalbuminuria was noted in 2.2% and 2.5% of participants in the exenatide and placebo groups, respectively (HR: 0.87; 95% CI: 0.70–1.07; $p = 0.19$) (Bethel et al. 2020). Another recently reported *post-hoc* analysis comparing the effects of twice-daily exenatide versus titrated insulin glargine on kidney function and albuminuria in patients with type 2 diabetes without overt nephropathy, likewise was not shown to affect kidney function decline or progression of albuminuria (Muskiet et al. 2019).

Glucagon-Like Peptide-1 Receptor Agonist Trials: Ongoing Kidney-Outcome Studies

In consideration of the benefits observed in the GLP-1 RA trials summarized, several key studies are ongoing that will shed additional light on the potential benefits of GLP-1 receptor agonism on kidney-related outcomes, in individuals with moderate-to-severe kidney disease. The Effect of Semaglutide Versus Placebo on the Progression of Renal Impairment in Subjects with Type 2 Diabetes and Chronic Kidney Disease (FLOW) is an

ongoing randomized clinical trial expected to complete in August 2024 (Clinicaltrials.gov 2019). An estimated 3160 participants will be enrolled and randomized to treatment with weekly injectable semaglutide or placebo. The overall objective of FLOW is to determine the effect of semaglutide on the progression of CKD in patients with type 2 diabetes. Enrolled participants will have renal impairment defined by:

1. An eGFR $\geq$50 and $\leq$75 mL/min/1.73 m^2 and UACR >300 and <5000 mg/g; or
2. An eGFR $\geq$25 and <50 mL/min/1.73 m^2 and UACR >100 and <5000 mg/g.

Participants will additionally be treated with a maximally titrated or tolerated ACE inhibitor or ARB. FLOW will examine time to first occurrence of a composite of eGFR decline of $\geq$50% from baseline, ESRD, or death from kidney or cardiovascular disease, as well as prespecified secondary outcome measures (annual rate of change in eGFR, time to occurrence of all-cause death, time to occurrence of each individual component of the primary composite outcome and relative change in UACR).

Putative Mechanism of Observed Kidney Outcomes

The exact mechanisms responsible for the observed kidney protective effects are subjects of ongoing inquiry. Benefits are likely exerted through influences on modifiable risk factors such as glucose reduction, blood pressure control, and weight loss, as well as direct biological effects on the kidney. The distribution of GLP-1 receptor in kidney is still under investigation, but receptors have been detected in arterial vasculature, glomerular capillaries, endothelial cells, macrophages, juxtaglomerular cells, and cells of the proximal tubules (Fujita et al. 2014; Kodera et al. 2011; Schlatter et al. 2007; Korner et al. 2007; Pyke et al. 2014).

Addition of a GLP-1 RA to background antihyperglycemic therapy leads to additional reductions in HbA1C, ranging from −0.3% to −1.9%, compared to controls in the clinical trials evaluating cardiovascular safety (Pfeffer et al. 2015; Marso et al. 2016a, b; Madsbad 2016). In patients with moderate-to-severe chronic kidney disease (CKD) at stages 3 and 4, active treatment with insulin glargine and dulaglutide resulted in similar reductions in HbA1c (Tuttle et al. 2018a).

Treatment with liraglutide or semaglutide has been associated with SBP reductions of approximately 2–5 mmHg compared to placebo or active treatment with insulin or a sulfonylurea (Sun et al. 2015a). Unfortunately, this effect is blunted or absent in people with moderate-to-severe kidney disease (Tuttle et al. 2018a; Bode 2012).

GLP-1 RAs additionally promote reductions in waist circumference and body weight, with weight reductions of approximately 3 kg on average achieved with GLP-1 RA treatment when compared to other glucose-lowering treatments (Vilsboll et al. 2012; Potts et al. 2015; Sun et al. 2015b). Moreover, the weight loss effect with GLP-1 RA treatment is preserved in patients with CKD (Tuttle et al. 2018a; Davies et al. 2016).

Some of the proposed direct effects on the kidney include alteration in fluid and electrolyte metabolism, through reduction of Na^+/H^+ exchanger 3 (NHE3)-dependent proximal tubule sodium reabsorption, and decrease in sodium bicarbonate and water reabsorption. This is the probable mechanism behind natriuresis and diuresis observed in rats, mice, and humans following GLP-1 receptor activation (Farah et al. 2016; Skov et al. 2013, 2016).

GLP-1 has general anti-inflammatory effects, which may protect the kidney from inflammatory events that induce histological changes and perturb glomerular hemodynamics (Lee and Jun 2016; Deb et al. 2017). Treatment with dulaglutide lowers serum levels of C-reactive protein (CRP) by approximately 1 mg/L, and with exenatide by a mean of 0.5 mg/L (Bunck et al. 2010; Ferdinand et al. 2014). A meta-analysis of randomized controlled trials with GLP-1 RA treatment in patients with type 2 diabetes found an approximately 2 mg/L reduction in serum CRP (Mazidi et al. 2017). In experimental

DKD models, GLP-1 RA treatment exhibits anti-inflammatory and antioxidative effects, resulting in protection from endothelial injury and reduction of proteinuria (Park et al. 2007; Kodera et al. 2011; Hendarto et al. 2012). Plausible candidates for the anti-inflammatory and anti-oxidative mechanisms are increased production of cyclic adenosine monophosphate (cAMP) and protein kinase A (PKA). Even the downstream target of cAMP and PKA activation is unclear. The probable candidate is NAD(P)H oxidase, a major source of oxidative stress in DKD (Jha et al. 2014; Dieter et al. 2018).

In rats, liraglutide has additionally been shown to attenuate oxidative stress, expression of transforming growth factor–beta and fibronectin, and reduce albuminuria (Hendarto et al. 2012). Furthermore, exenedin and liraglutide infusions in rats and humans prevent macrophage infiltration, and inhibit release of proinflammatory cytokines from macrophages, decrease protein levels of intercellular adhesion molecule-1 (ICAM-1) and type IV collagen, decrease TGF-β1 and TGF-β1R expression with inhibit activation of downstream Smad3 and ERK1/2 signaling, activating nuclear factor-κB in kidney tissue (Kodera et al. 2011; Hogan et al. 2014).

Future Perspectives

Major organizations such as the American Diabetes Association (ADA) now recommend GLP-1 RAs with proven cardiovascular benefits be considered for use in patients with indicators of high risk or established atherosclerotic cardiovascular disease, CKD or heart failure independent of baseline HbA1C or individualized glycemic targets (American Diabetes Association 2020). The multitude of biological effects exerted include antihyperglycemic effects, weight loss, and blood pressure reduction.

In addition, a mounting body of knowledge indicates that the GLP-1 RAs address the principal pathomechanism of DKD through their anti-inflammatory, antioxidant, and antifibrotic effects. AWARD-7 suggested that dulaglutide attenuates eGFR decline and progression of albuminuria in patients with type 2 diabetes and moderate-to-severe CKD, providing the first evidence to suggest a benefit of GLP-1 receptor agonism on kidney disease progression in this population (Tuttle et al. 2018a). Additional evidence is needed, however, to determine GLP-1 RAs impact on kidney outcomes in at-risk patients, and effects on cardiovascular risk in this group of patients. Findings from ongoing clinical trials, such as FLOW, will continue to inform our understanding of the role of GLP-1 RAs in patients with established kidney disease. Hopefully, ongoing trials will confirm GLP-1 RAs as one of the most promising therapeutic interventions, to mitigate the risk of development and progression of DKD.

The Epidemiology of the Diabetes: Depression Comorbidity in Brazil—Inequality and Interaction

33

Finn Diderichsen

Contents

Abstract

Type 2 diabetes has worldwide increasingly become a disease clustering among the low educated. The steep negative gradient of disability across levels of education among both men and women, contrasts with a positive gradient for both diabetes and obesity among men. It is found that both diabetes and depression clusters among the low educated, and the two disorders also cluster to each other. The effect of diabetes on disability is much stronger among people also suffering from depression, and that interaction is particularly remarkable among men. It is also stronger among low educated, particularly among low-educated women.

The unequal prevalence of diabetes is partly due to a similar patterning of obesity, but it is

J. Faintuch and S. Faintuch (eds.), *Obesity and Diabetes*, https://doi.org/10.1007/978-3-030-53370-0_33

found that there exists a differential susceptibility, in which the association between obesity and diabetes is stronger among the low educated. That seems partly due to higher susceptibility to obesity among those suffering from comorbid depression.

There is thus evidence not only of a vicious circle between diabetes—depression—obesity—diabetes, but the actual impact on people's daily life and capability of these comorbidities, is also aggravated by an interaction between the two disorders and with low socioeconomic status. Diabetes and depression thus show a pattern of syndemics in the context of large social inequalities of Brazil.

Poverty · Disability · Depression · Diabetes · Social inequality · Disease burden

Introduction: Why Diabetes and Depression?

Some comorbidities are more interesting and important than others—for populations and for patients. The combination of diabetes and depression is one of them. For at least five reasons. Both disorders occur with high and—and for diabetes at least—increasing prevalence. They have both substantial effect on disability and disease burden. Thirdly, both occur with considerable class and gender disparities, in patterns that however differs across populations and social contexts. The two disorders tend further not only to co-occur but also to cluster—i.e., suffering from one of the disorders increases the risk of having the other. Finally, there is evidence that they might interact, i.e., one disease influence the course and consequences of the other.

The research interest in this comorbidity has been extensive. The first published paper on the association between diabetes and depression came in 1949, and since 2010 the annual number of publications is 100–200 (Sweileh 2018). Most of them from high-income countries. In this chapter we shall, with data from the latest Brazilian Health Survey (PNS 2013—see Box 33.1), analyse the social epidemiology of diabetes, and examine how depression is associated with the occurrence, social disparities, and consequences of diabetes.

Box 33.1 Analysis of the Brazilian National Health Survey (PNS 2013)

We use the latest Brazilian National Health Survey PNS 2013 (Szwarcwald et al. 2014). It is a cross-sectional household survey designed with a three-stage random sampling procedure. The census tracts are the primary units, the households are the second-stage units, and one resident per household aged 18 years or older is the third-stage unit. The sample includes 81,357 households. A total of 8.1% did not want to participate or could not be contacted. Interviews on health issues were carried out with 60,202 individuals. The survey was approved by the *Comissão Nacional de Ética em Pesquisa* (CONEP—National Commission of Ethics in Research—no. 328,159). PNS 2013 is thus a large survey with sufficient size for the power-demanding interaction analyses; however, it is cross-sectional, which limits any attempt to draw causal inferences.

Disability is here measured as self-reported consequence of long-term diseases. Disability is based on questions raised for each of 13 different chronic disorders (including one "other diseases" category): "to what degree the disease or its complications limit daily activities including work. Those who answer "moderate, serious, or very serious" to at least one of these questions are classified as having *disability*, i.e., limiting activities due to illness. The basic individual exposure is the highest level of *education* achieved.

Prevalent *diabetes* is based on an affirmative answer to the question: 'Has any

(continued)

Box 33.1 (continued)

doctor told you have diabetes?' Compared to laboratory measurements with Hba1c levels >6.5% or medication self-report, it seems to underestimate the prevalence (Malta et al. 2019). Symptoms of depression are based on the patient health questionnaire—9 (PHQ-9 scale) with a sum-score ranging from 0 to 27. Having moderate or severe depressive symptoms (*Depression*) is defined as scoring ten or higher. For the regression analysis, Generalized Linear models with binomial distribution were used in IBM SPSS v25. Associations are thus measured in absolute terms as risk-difference (RD) in percentage units of prevalence. We have chosen this measure of associations since it is more policy relevant and adequate for estimating interaction. The size of interactions between two exposures is estimated as the difference in disease prevalence between those exposed to both compared to those exposed to none, minus the sum of the effects of single exposures. Some confounders are included in the regression model as indicated under the tables, but several other potential confounders are not included since they are not collected in the survey. We have applied weights to adjust for sampling stratification and differential non-response in the survey (Szwarcwald et al. 2014).

Diabetes: Increasingly a Disorder of Poverty

Diabetes is often described as a disease of modernization, including industrialization and urbanization. In upper middle-income countries like Brazil where these processes develop faster than elsewhere, the diabetes prevalence is increasing approximately 2% annually (NCD RisC 2016a). The industrialization of food production and global shift in diets, with growing marketing and consumption of foods and beverages with added sugars and salt, refined carbohydrates, grain-based desserts and savoury snacks, has hit low- and middle-income countries harder than in the industrialized North, and Latin America earlier than many other regions (Popkin et al. 2012; Popkin and Reardon 2018). Time and energy use on physical activity linked to work, home production, travel and leisure time activities have also changed, and contributed to the rise in obesity and type-2 diabetes (Ng and Popkin 2012).

These changes are universal, but the effects on obesity and diabetes have differed, not only between countries at different economic levels, but also within countries between men and women, and between different socioeconomic groups. Diabetes shows, in both European (Espelt et al. 2012; Imkampe and Gulliford 2011) and some Asian countries (Kim and Nam 2017), increasing disparities and occurs now with steep social gradients, even in welfare states with relatively small socioeconomic inequalities (Agardh et al. 2011). In Brazil, increasing educational inequalities in diabetes have also been observed in the period 1998–2013 (Beltran-Sánchez and Andrade 2016), a period when income inequality in Brazil was declining (see Box 33.2). In that sense, diabetes has become more a disease of poverty than a disease of modernization (Mendenhall 2019).

Box 33.2 The Brazilian Context

Brazil is a middle-income country with a gross domestic product per capita that is 7 times lower than in the US and 4.5 times higher than in India. It experienced in the years 1990–2014 a strong economic growth, where income inequality and poverty declined sharply. Since 2015 these indicators have however pointed in the opposite direction with growing inequalities. Brazil implemented since 1990 a fast-expanding public health service programme (SUS) that generated access to care nationwide, but in particular for poor populations in the North of Brazil. Specific

(continued)

Box 33.2 (continued)

programmes for child health and for the control of non-communicable diseases (NCD) like diabetes and hypertension have been implemented. The human development index (HDI) is a composite index of human development, including measures of education, income and longevity. The average HDI of Brazil increased from 0.611 in 1990 to 0.759 in 2017. There are however still large inequalities between Brazilian states. In 2010, HDI varied from 0.631 in Alagoas in the North East region (similar to Honduras), to 0.824 in the Federal District where Brasilia is located (similar to Argentina). These differences in HDI thus correspond to more than 25 years' development in Brazil. States with high HDI tend also to be more industrialized, urbanized and with higher average income. They have at same time smaller income inequalities. Epidemiologically, Brazil has experienced a very fast decline in communicable disorders and, as elsewhere, a slowly increasing prevalence of many NCDs, including diabetes.

The social epidemiology of depression is much less clarified, particularly in low and middle-income countries. There is no strong evidence that the prevalence of depression is actually increasing (Ferrari et al. 2013), but several studies from Brazil and other middle-income countries have shown higher prevalence among women and among underprivileged groups (Silva et al. 2014; Munhoz et al. 2016; Brinda et al. 2016).

The epidemiological development of diabetes in the Brazilian population has made it a major priority in national health policies, with detailed vertical programs to be implemented in primary care (Almeida-Pititto et al. 2015). When, like in Brazil, 70% of diabetes cases have only primary school or less, policies aimed at tackling the diabetes epidemic must address the growing social inequality in diabetes.

The Social Patterning of Diabetes, Obesity and Depression in Brazil

The empirical analysis in this chapter is based on the latest Brazilian National Health Survey (PNS 2013). See text Box 33.1 for details.

Figure 33.1 shows the age-adjusted prevalence of diabetes, obesity, depression and disability across levels of education for men and women.

In Fig. 33.1, it can be observed that there is a steep educational gradient in prevalence of disability for both women and men. Disability is here measured as moderate-to-severe limitation of daily activities. We have calculated for disability among women the Slope Index of Inequality—SII (Mackenbach and Kunst 1997) as −12.5 percentage points (p.p.), with 95% confidence interval (CI: −14.2; –10.8), and for men as −13.8 (CI: −15.5; –12.3). They confirm significant inequality for these samples. In the Brazilian population, both diabetes and depression (Yokota et al. 2016) are important causes of disability. As many as 36% of diabetics report disability, 48% of those with moderate-to-severe depressive symptoms, and 75% suffer from both.

The steep negative gradient in disability might therefore be influenced by social disparities in the prevalence of diabetes and depression, but many other diseases might play a role too. In Fig. 33.1, it can be seen that there indeed is a negative gradient for diabetes (SII = −7.4; CI: −8.5; –6.2), but only among women. For men the association between education and diabetes is weakly positive (0.6 CI: –0.5; 1.7) When compared to the disability gradient it raises the question, whether the disability consequences of diabetes are stronger among men than women, and in particular for low educated men?

The inequality in diabetes is stronger in the rich (and economically more equal) states in the south of Brazil. Slope index of inequality for diabetes in women is −10.8 (CI: –12.7; –8.9) in these states, compared to −4.4 (CI: −6.4; –2.5) in the poorer (and more unequal) less developed North Eastern states. Even within Brazil the economic development seems to transform diabetes from a disease of modernization increasingly to a disease also of poverty.

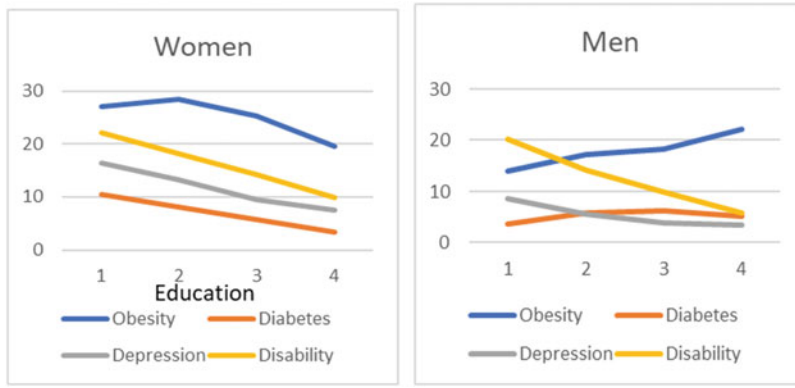

Fig. 33.1 Prevalence (%) of obesity (BMI ≥30), self-reported diabetes, moderate-to-severe symptoms of depression (PHQ-9 ≥ 10) and disability (self-reported moderate to severe limitation of daily activities including work, due to long-term illness). Brazil PNS 2013. Education (1 = less than primary school, 2 = primary school, 3 = secondary school, 4 = tertiary school or higher). Prevalence in percent adjusted for age and state

The curves in Fig. 33.1 raise the question why the association between education and diabetes is so different for men and women. What makes women more susceptible to the protective effect of education on diabetes? It seems in Fig. 33.1 that, at least partly, it could be due to a sex difference in the social patterning of obesity. The educational slope of obesity is negative for women (SII = −10.5 CI: −12.5; –8.5), but positive for men (SII = 7.7 CI: 5.9; 9.5). It would however still not explain that obesity and diabetes are more strongly associated for low-educated women than for others.

Figure 33.1 reveals negative educational gradients for depression with SII = −4.6 CI: –3.5; –5.6) for men, and for women an even steeper gradient with a SII = −9.7 (CI: 8.2; 11.1). As was the case for diabetes, the gradient is stronger in the rich more industrialized states in the South of Brazil, with a SII of −10.6 (CI: –12.9; –8.3) compared to −5.6 (CI: –8.1; –3.1) in the Northeast. Since depression is both a cause and an effect of both obesity and diabetes (Jantaratnotai et al. 2017) the comorbidity with depression might, as we shall see, contribute to some of the questions mentioned here.

To sum up: the simple description of the social patterning of disability, diabetes, depression and obesity in Fig. 33.1 raises at least two questions where the diabetes-depression comorbidity might play a role: (1) Does diabetes have differential consequences in terms of disability across sexes and educational levels? (2) Does obesity have differential effects on diabetes across sexes and levels of education?

Mechanisms of Health Inequalities

These two questions point to two of the generic mechanisms driving disparities in morbidity and disability (Diderichsen et al. 2001). From an ethical point of view, it is relevant to start with the inequality of the disabling consequences of disease. Amartya Sen has argued that if an important quality of human development is greater freedom for people to live the lives they have reason to value, then inequalities in the origins of that un-freedom becomes central. Bad health due to escapable disabilities and premature mortality is a critical source of such un-freedom (Sen 2002).

Differential Consequences

If we go backwards in the causal chain, it is evident that disparities in disability and participation are generated by disparities in underlying morbidities (Schuring et al. 2019). Diabetes and depression are two obvious sources in the Brazilian population, but several other chronic diseases contribute as well, including cardiovascular and musculoskeletal disorders (Malta et al. 2016). Epidemiological studies have since long

Table 33.1 Differential consequences. The interaction between short education (≤ prim educ.) and disease (diabetes or depression) in relation to disability. Percentage points prevalence difference with 95% CI. Adjusted for age and state. Brazil PNS 2013

	Diabetes		Depression	
	Men	Women	Men	Women
≤Prim. educ. + disease	18.3 (16.2;20.5)	24.2 (22.3;26.3)	45.5 (43.3;47.6)	42.7 (41.1;44.4)
≤Prim. educ. 0 disease	6.2 (5.4;7.0)	4.7 (3.8;5.6)	4.9 (4.2;5.7)	2.5 (1.6;3.4)
>Prim. educ. + disease	14.1 (11.4;16.7)	14.4 (11.3;17.5)	31.0 (28.3;33.8)	25.9 (24.0;27.8)
>Prim. educ. 0 disease	0 (ref.)	0 (ref.)	0 (ref.)	0 (ref.)
Interaction educ.*disease	−2.0 (−5.3;1.4)	5.2 (1.6;8.8)	9.5 (6.1;13.0)	14.4 (11.8;16.9)

Prim. educ. Primary education; *ref.* Reference category for the table

indicated that with a given morbidity the rate and degree of disability and participation might differ across levels of education, i.e., *differential consequences* (Burström et al. 2000). That might be a result of not only unequal access to and quality of health care, but also unequal levels of comorbidity and demands at the labour market not compatible with ill-health and short education. Only few studies have analysed the inequalities in disability specifically for diabetes, but they have found clear educational and sex disparities in disability (Ervasti et al. 2016) (Table 33.1).

Table 33.1 unsurprisingly indicates that depression has a very strong association with disability and is stronger than diabetes. The association between disease and disability is more prominent among low educated, particularly for women. That difference is estimated by the interaction between education and disease in the last row of Table 33.1. There are thus indications of *differential consequences* across levels of education—in particular for depression and for women. This may have many explanations. Education might play a role for perceived disability, because the labour market often demands more physical ability among people with low education, and the consequences in terms of reduced workability might therefore be stronger among those suffering from short education (Schuring et al. 2019).

Interacting Comorbidity

Another reason there might be differential consequences of diabetes is the unequal prevalence of comorbid depression, in case depression interacts with diabetes in the effect on disability. Several clinical studies have shown that depression interferes with the care, control, and course of diabetes (Ciechanowski et al. 2000; Pirraglia and Gupta 2007; Petrak et al. 2015). Few studies have however looked at whether there is an interaction between diabetes and depression, in their association with disability (Egede 2004; Kalyani et al. 2017; Diderichsen and Andersen 2019). Table 33.2 demonstrates the interaction.

In Table 33.2, it can be noticed a rather strong interaction between diabetes and depression, particularly among men. We might here have a mechanism contributing to the paradox found in Fig. 33.1, that low-educated men show high levels of disability, however, relatively low prevalence of diabetes and depression. That might thus be due to depression, interfering with the course and consequences of their diabetes.

Clustering

The impact on population health of interaction between disorders will depend on the degree of co-occurrence and clustering. The more clustering there is of two or more disorders to the same individuals, the more opportunities will there be for them to interact. In Brazil, there is indeed a clustering of diabetes and depression. In the alluded-to survey (PNS 2013), the prevalence of diabetes is 6.2% and for depression 7.7%. This means that the prevalence of co-occurrence by chance would be 0.48%. In reality it is 0.92%,

Table 33.2 The interaction between diabetes and depression in relation to disability. Percentage points prevalence difference with 95% CI. Adjusted for age, education and state. Brazil PNS 2013

	Men	Women
+ Diabetes; + depression	65.0 (60.3;69.8)	57.7 (54.2;61.3)
+ Diabetes; 0 depression	9.1 (7.4;10.8)	14.1 (12.4;15.8)
0 Diabetes; + depression	33.8 (32.0;35.6)	32.2 (30.8;33.5)
0 Diabetes; 0 depression	0 (ref.)	0 (ref.)
Interaction diabetes*depression	22.1 (16.8;27.4)	11.5 (7.4;15.5)

ref. Reference category for the table

i.e., 1.9 times higher than expected. This level of clustering has been found in other countries too (Nouwen et al. 2019).

Clustering can be due either to shared causation or to bidirectional causal relationships between the two disorders. As recent reviews have shown, there have been numerous longitudinal studies documenting the bidirectional causal relationship between depression and diabetes (Nouwen et al. 2019; Chireh et al. 2019; Zhao et al. 2019). There is also evidence indicating several shared causes (Chireh and D'Arcy 2019). Shared causation by obesity and short education has been mentioned here, but there are other candidates. A Scandinavian twin study has demonstrated that type 2 diabetes and depression may share a genetic component, albeit with different genetic factors being at play in males and females (Kan et al. 2016).

The dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis is a much-discussed biological link between stress, depression, obesity and type 2 diabetes, even if many mechanistic details are badly understood (Joseph and Golden 2017; Milaneschi et al. 2019). Origins of stress reactions and HPA-dysregulation might therefore be shared, causes, including childhood poverty and maltreatment, generating increased inflammatory vulnerability to the effects of later exposures (Milaniak and Jaffee 2019). Violence, unemployment and living in communities with large income inequalities are examples of particular relevance in Brazil, and might increase stress and thereby both depression and diabetes (Kelly and Ismail 2015; Hammen 2015).

Diseases that cluster and interact with each other and with the social context have been called *syndemics* (Singer et al. 2017). The diabetes/depression comorbidity is an example of a syndemic between non-communicable disorders (Mendenhall et al. 2017; Diderichsen et al. 2019). Mendenhall argues, based on her anthropological studies, that we should consider diabetes invariably in a syndemic context. Poverty and violence are very prevalent in Brazilian slums *('favelas'),* and generate a chronic level of stress that could drive the occurrence of both depression, diabetes and their complications (Mendenhall 2019).

Differential Exposure

If we go a step further back in the causal chains, the inequalities in the incidence of a disease will be driven by unequal distribution of major causes of the disease—i.e., *differential exposure*.

Obesity is the most important cause of type 2 diabetes and might explain a considerable part of the social disparities in diabetes (Smith et al. 2013; Steele et al. 2017). Obesity prevalence has been rising for both men and women in low- and middle-income countries (LMIC) (NCD RisC 2016b); however, the rise has been much more pronounced among low-educated and underprivileged groups, leading to a reversal of the education/obesity relationship from positive in low-income countries to negative in middle- and high-income countries (Jaacks et al. 2019). That trend has been found to be particularly strong among women (Ford et al. 2017). The association between education and body mass index (BMI) seems mainly to be mediated by environmental and psychosocial factors (Blüher 2019; Claassen et al. 2019).

Obesity Patterns in Brazil

As shown in Fig. 33.1, for women in Brazil there is a graded negative association between education and obesity, while it is positive for men. That has not always been the case. In 1975, the association between BMI and income was positive for both men and women in Brazil (Monteiro et al. 2007; Gomes et al. 2019). Since then, the prevalence of obesity has increased faster among low-income than high-income groups for both genders. In the 1990s, the prevalence of obesity actually declined among high-income women. The changing social patterning of obesity clearly plays a major role in the changing patterns of diabetes, but does not fully explain it (Espelt et al. 2012; Kim and Nam 2017). The reason why the profiles in Brazil have become so different for men and women might be due to labour market segregation, as low-educated women to a high-degree work with domestic service, and low-educated men work in agriculture, construction and industry.

Gene Expression and Miscellaneous Mechanisms

Genotype is another underlying cause of type 2 diabetes. Studies so far have not indicated that the genetic risk is associated with education, but they have suggested that education might modify the epigenetic expression, and effect on obesity and diabetes (Liu et al. 2015; van Zon et al. 2017; Frank et al. 2019).

Low birthweight is associated with type 2 diabetes (Knop et al. 2018). Wells has formulated the risk for diabetes as an interaction between low metabolic capacity (influenced by impaired foetal and infant growth), and metabolic load generated by adiposity, sedentary life style and psychosocial stress (Wells 2019). The combination of impaired foetal growth and adult metabolic load is particularly relevant in middle-income countries like Brazil, where changes have happened fast within a lifetime. The health effects of undernutrition early in life and later exposure to obesogenic environments thus represent a dual burden of malnutrition. Fortunately, prevalence of stunting (as a sign of early undernutrition) has declined rapidly in Brazil since the 1970s, and social disparities have been reduced (Monteiro et al. 2010).

Social stress has in several studies been shown to impact on the risk of diabetes, including early adversities (Milaniak and Jaffee 2019) and adult social stress from work (Xu et al. 2017). Poor housing and violence have also been identified as risk factors and potential modifiers of the obesity-diabetes relationship—partly through the metabolic effects of stress (Kelly and Ismail 2015; Volaco et al. 2018; Heraclides et al. 2011).

Stress mobilizes biological responses, including the release of glucose and lipids into the circulation, inflammatory cytokine expression and increased blood pressure. Repeated stress might in the long run generate allostatic load, with dysregulation of glucose metabolism and chronic low-grade inflammation. Stress might in addition influence behaviours, including dietary habits and physical activity (Hackett and Steptoe 2017). Stress can also generate depression, and both stress and depression might work through sleep disturbances in their impact on diabetes (Anothaisintawee et al. 2016).

Differential Vulnerability

As the aforementioned causes might work in the same causal pathway as obesity, they might interact and modify the effect of obesity. Since social stress and childhood adversities are strongly related to education and income, they might generate a *differential vulnerability* to obesity (Diderichsen et al. 2019).

Vulnerability is a concept used in many disciplines with different meanings, and often including many dimensions. One is the lack of capability to change, cope with—or adapt to—determinants of ill health. Since health is a critical constituent of capabilities (Sen 2002), this approach provides a feed-back pathway where ill health and its consequences, through changed capabilities, influence causes and consequences

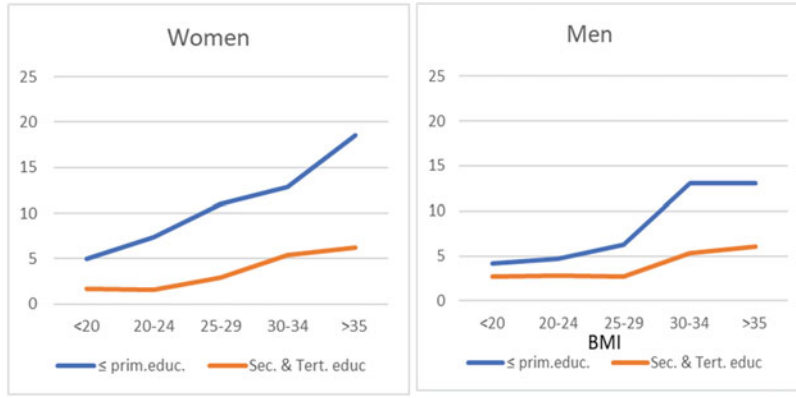

Fig. 33.2 Prevalence (%) of self-reported diabetes (adjusted for age and state) according to BMI stratified for education. PNS Brazil 2013

of disease. Since many different interacting causes in the same pathway might mediate the health effect of social position, the effect of a single cause might differ across social positions, if it interacts with some other cause related to social position—*differential susceptibility*.

It is well known that the association between BMI and type 2 diabetes varies across ethnic groups, with stronger effects among Asian populations (Chiu et al. 2011). Some studies indicate that the obesity-diabetes association is stronger in countries with higher-income levels, compared to low-income countries (Wang et al. 2014). Body fat distribution modifies the BMI-diabetes association and waist circumference has, for the same BMI levels, increased in many countries (NCD RisC 2016b). Stress is associated with increased abdominal adiposity (Surkan et al. 2018) and might contribute to this development.

From an equity point of view, the interesting question is whether the BMI-diabetes association differs across level of education. In Fig. 33.2, data on this are shown for Brazil.

The Impact of Obesity

It can clearly be seen that the association is steeper for the low educated. While ten-point increase in BMI-average is associated with 6 percentage points increased prevalence of diabetes among the low educated, it is only 2–3 percentage points for the better educated. There is in other words an interaction between obesity and short education that can be estimated to 2.6 percentage points (CI: 1.3; 4.0) for women and 4.8 (CI: 3.4; 6.2) for men.

That differential association of BMI and diabetes can be due to interaction between obesity and some other risk factor for diabetes associated with education. The survey we have access to here has measured smoking, dietary habits and physical inactivity and none of them show any interaction with obesity. As the data are cross-sectional, the behavioural factors might act as both causes and effects of diabetes, which makes the interpretation complicated. There is no measure of perceived stress in the PNS, but depression might be an indicator strongly linked with exposure to stress.

Obesity has been found to be associated with depression in a bi-directional causal relationship (Wu and Berry 2018; Stunkard et al. 2003). The relevant question here is to what extent depression modifies the association between obesity and diabetes. Figure 33.3 illustrates that for both men and women there is an interaction between obesity and depression: 3.5 percentage points (CI: 1.4; 5.5) for women and 6.8 (CI: 3.8; 9.8) for men (Fig. 33.3). Similar findings have recently been announced in China (Ning et al. 2019). Since depression is more prevalent among low educated, this might contribute to the differential susceptibility in Fig. 33.2.

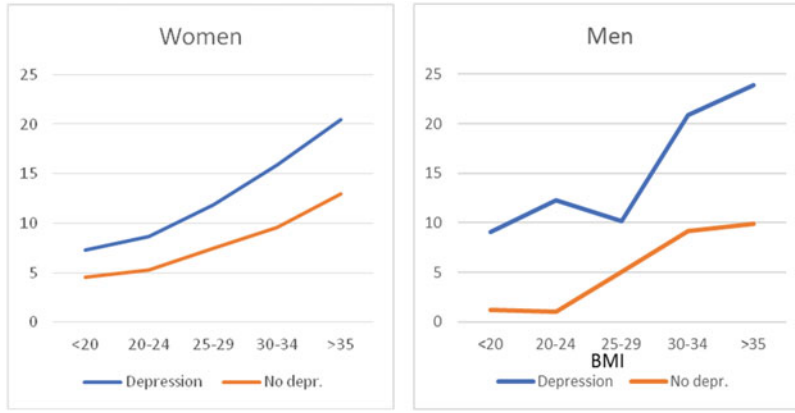

Fig. 33.3 Prevalence (%) of self-reported diabetes (adjusted for age and state) according to BMI and stratified for depression. PNS Brazil 2013

Summarizing

It is well known that the causal sequence of diabetes-depression-obesity-diabetes can create a vicious circle. What this analysis adds is that the disabling effect on people's daily life and activities of the combined diabetes-depression comorbidity is stronger than the sum of each of the two disorders. That interaction between the two disorders is, for underprivileged groups, aggravated by the fact that low education in combination with either diabetes or depression has a strong impact on disability.

We also find that the clustering of two disorders is driven partly by a shared social determination. Being low educated in the highly unequal society of Brazil represents a shared cause of both disorders, particularly for women. Short education also enforces the association of obesity with diabetes, indicating a differential susceptibility to the effect of obesity. We have found the concept of *syndemics* useful when dealing with clustering and interaction, between diseases that mediate the effect of social position on disability. If one disease is associated with low social position, the consequences of another interacting disease might differ across social positions, which means it has differential consequences.

Tackling the vicious circle mentioned here might use different entry points. One is to prevent obesity, which will demand powerful policy initiatives regulating the food industry to produce affordable healthy foods, and planning the physical environment to promote physical activity. Physical activity improves depressive symptoms, insulin sensitivity and glycaemic control. Other entry points are treatment of depression and/or diabetes. A review suggests that treatment of comorbid depression and diabetes is more effective with an integrative approach addressing both conditions together (Darwish et al. 2018).

Most selective serotonin reuptake inhibitor antidepressants have however been found to increase BMI; however, they could on the other hand have a limiting effect on diabetes and complications via reduced depressive symptoms. Several studies on the effect of glycaemic control in diabetes patients with depression or distress have yielded heterogeneous results (Bystritsky et al. 2014). A recent systematic review concluded that psychological interventions with diabetes and elevated diabetes distress, with symptoms of depression and/or anxiety, can improve glycaemic control (Schmidt et al. 2018).

Treatment of obesity might similarly lead to an improvement of depressive symptoms (Sevilla-Gonzalez et al. 2017). Better treatment of depression associated with diabetes is therefore a high priority, and a better understanding of the psychological and physiological mechanisms involved in this comorbidity would be helpful. Diabetes care has improved substantially in recent years in Brazil, but the large inequalities in quality and effect of care still exist (Neves et al. 2018). The

epidemiological patterns shown here for Brazil, and the anthropological research on the diabetes-depression syndemic make it clear that the social and economic context is critical.

Contribution of Hyperglycemia and Unhealthy Diet to Cardiovascular Mortality

34

Jian Zhang and Dong Li

Contents

Abstract

Approximately 463 million adults are living with diabetes worldwide, and another 374 million people are at increased risk of developing type 2 diabetes. Hyperglycemia, one of the significant risk factors for type 2 diabetes mellitus, is also involved in the initiation and progression of major cardiac complications, such as atherosclerotic coronary heart disease. Food as a source of nutrition is closely related to the occurrence of many chronic diseases. A bundle of risk factors has been identified, including a high intake of saturated fat, short on fruits, vegetables, and whole grains, as well as heavy alcohol use. This chapter deals with diabetic care and cardiac mortality due to

Hyperglycemia · Diabetes · Obesity · Cardiovascular risk · Unhealthy diet · Dysglycemia · Dyslipidemia

Obesity, a Risk Factor for Cardiovascular Disease

Epidemiological and clinical evidence demonstrates that obesity will produce a variety of structural and functional adaptations of the cardiovascular system, such as reducing cardiac output and left ventricular systolic function, increases peripheral resistance, left ventricular mass, left ventricular wall thickness, and internal size (Saeedi et al. 2019; Newell et al. 2010; Alpert et al. 2018; Piche et al. 2018). These changes are often associated with high blood pressure and deranged blood lipids, which, in turn, increase the risk of cardiovascular disease (CVD). An unhealthy dietary pattern contributes to obesity (healthy dietary style is shown in Fig. 34.1). Indirect effects are mediated by coexisting cardiovascular risk factors, such as insulin resistance, hyperglycemia, hypertension, and dyslipidemia. As a result, obese people are more likely to develop CVD and manifestations of CVD, especially coronary heart disease (CHD), angina, myocardial infarction (MI), atrial fibrillation, heart failure (HF), and sudden cardiac death (SCD).

Chronic Inflammation

One possible link between diabetes and obesity and subsequent CVD is low-grade inflammation (Duncan et al. 2003). Diabetes and insulin resistance are associated with overexpression of many cytokines in adipose tissue (Shimobayashi et al. 2018). Elevated C—reactive protein (CRP) levels in diabetic patients may be related to endothelial dysfunction. Diabetic patients also suffer from decreased adiponectin secretion, leading to decreased endothelial function (Shimobayashi et al. 2018). Insulin resistance is associated with elevated plasma free fatty acids, which lead to increased triglyceride stores in muscles, increased glucose production in the liver, and increased insulin production in people with type 2 diabetes (Leahy 2005). Insulin resistance in diabetic patients is also associated with hypertrophy of cardiomyocytes and systolic dysfunction (Leahy 2005; Belke et al. 2002).

Dietary Pattern and Its Impact

An unhealthy dietary pattern contributes to obesity (Healthy dietary style is shown in Fig. 34.1). Saturated fats and trans fats will raise cholesterol and low-density lipoprotein (LDL) levels (de Souza et al. 2015; Hooper et al. 2011). Sugar-sweetened beverages are incriminated in overweight, obesity, and may lead to ischemic heart disease (Huang et al. 2014). Higher fruit, vegetable, and fish (omega-3 and omega-6 fatty acids but not fish oil) consumption has been emphasized.

The Mediterranean Paradigm

The Mediterranean diet (higher consumption of fish, legumes, and supplementary nuts or extra virgin olive oil) has been considered one of the healthiest dietary patterns, which proved to reduce CVD mortality by 30%. In this regard eating a diet rich in animal protein, mainly red and processed meat, refined grains, sweets, desserts, and low in fiber, has been linked to an increased risk of cardiovascular death (Chen et al. 2013; Song et al. 2016). Diabetes, high blood pressure, and hypercholesterolemia may be considered intermediate factors in the relationship between dietary patterns and CVD mortality.

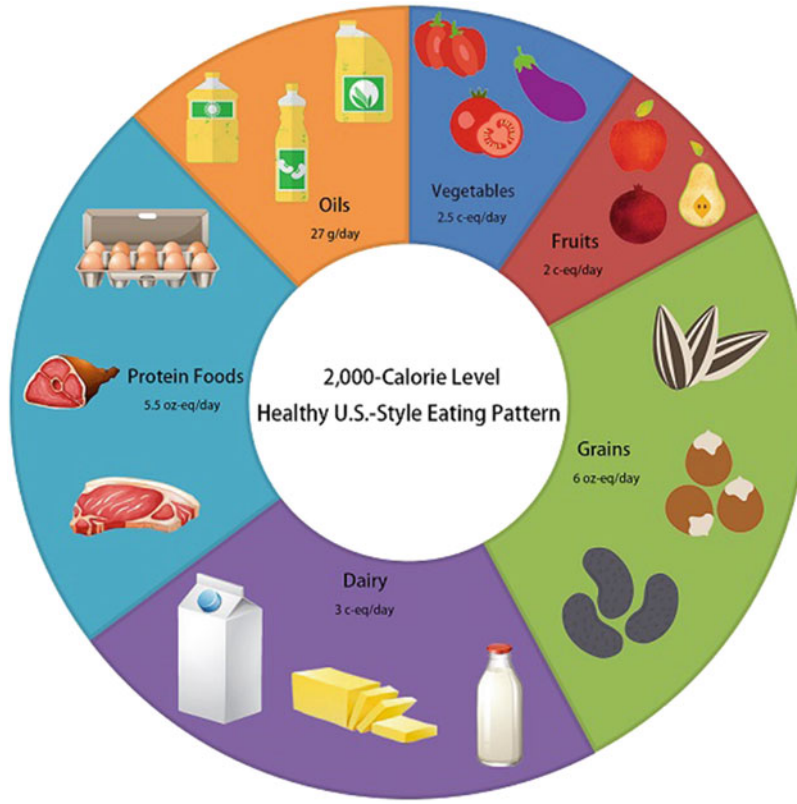

Fig. 34.1 The 2000-Calorie Level of Healthy U.S.-Style Eating Pattern Daily (*2015–2020 Dietary Guidelines for Americans*. 8th Edition). NOTE: Food group amounts shown in cup-(c) or ounce-(oz) equivalents (eq). Oils are shown in grams (g)

Metabolic Disease and Dysglycemia

CVD is a leading cause of death and morbidity in the diabetic population (Matheus et al. 2013). Metabolic syndrome is analogously more prone to CVD events (Ford 2005; Malik et al. 2004; Morrish et al. 2001; Wong 2007). In 2015, the GBD project (Mortality 2015) estimated that diabetes mellitus had become the sixth leading cause of disability worldwide. Approximately 17.7 million people died of cardiovascular disease, accounting for 31% of global deaths, according to WHO. Compared with nondiabetic patients, diabetic patients have a 2–4 times higher risk of cardiovascular disease (Poznyak et al. 2020; Chichareon et al. 2020; Preis et al. 2009). Cardiovascular deaths accounted for 44% of deaths in people with type 1 diabetes and 52% of deaths in people with type 2 diabetes (Morrish et al. 2001). The leading causes of death in diabetic patients include ischemic heart disease, malignant tumors, cerebrovascular disease, and pneumonia/influenza. The most common manifestations of CVD in diabetes are peripheral artery disease (16.2% or more) and heart failure (14.7%), followed by angina and nonfatal MI.

In the SAN Antonio heart study, which followed 4875 patients for 7–8 years, diabetes was significantly associated with increased CVD mortality. The risk of heart failure in diabetes mellitus rose to 40%, compared with an age-adjusted ratio of 2.8 for nondiabetics, representing a two- to threefold elevated risk (Go et al. 2014).

Predisposing Factors tor Type 2 Diabetes

The risk of type 2 diabetes is determined by genetic and metabolic factors, including immutable circumstances such as race, family history,

gestational diabetes history, and age, along with modifiable ones such as obesity, unhealthy diet, insufficient physical activity levels, and smoking. Excess fat is often associated with insulin resistance and is a significant risk factor for type 2 diabetes and CVD (Hardy et al. 2012). Sedentary lifestyle, dyslipidemia, and hypertension affect endothelial dysfunction, which can further accelerate atherosclerosis (Rodriguez-Araujo and Nakagami 2018). Inflammatory markers such as C-reactive protein (CRP) in diabetic patients may also predict further risk for cardiovascular and peripheral artery disease.

Insulin resistance is one of the direct causes of cardiovascular disease. Due to the increase of insulin content in the blood, the dilatation function of the blood vessel wall cannot proceed, increasing the patients' blood pressure. On the other hand, the occurrence of insulin resistance can cause endothelial cell function damage in patients. Besides, insulin resistance also can cause injury of endothelial cells and lead to myocardial ischemia, which is the direct pathogenic factor of several cardiovascular diseases.

The Impact of Dyslipidemia

Dyslipidemia is common in diabetic patients and is associated with an increased risk of CVD (Matheus et al. 2008; Incalza et al. 2018), especially for myocardial infarction, atherosclerotic stenosis, and aortic valve stenosis. A large case-control study involving 52 countries demonstrated that for first myocardial infarction (MI), dyslipidemia was the most critical risk factor (Yusuf et al. 2004). Primary prevention randomized controlled trials (RCTs) evidenced that reducing low-density lipoprotein (LDL) lowers the risk of CVD, which aligned with the range of pretreatment LDL levels (Collins et al. 2016). In a well-designed meta-analysis, the degree of reduction in CVD is proportionate to the degree of lowering of LDL cholesterol, till levels as low as 21 mg/dL (0.5 mmol/L) (Sabatine et al. 2018).

Endothelial Damage

Endothelial cell injury is one of the leading pathways toward cardiovascular disease related to metabolic syndrome. Patients with low lipid metabolism and insulin resistance can prompt fat cells to release free fatty acids, which enter the veins and cause an increase in low-density protein (LDL) in the blood. LDL attaches to endothelial cells in large quantities and causes endothelial cell damage.

General Biomarkers and Novel Technologies

There are several categories of CVD biomarkers (Biomarkers Definitions Working G 2001; Bossuyt et al. 2012; Moons 2010; Braunwald 2008) addressing heart failure (brain natriuretic peptide/BNP, N-terminal BNP/NT-BNP, atrial natriuretic peptide/ANP, suppression of tumorigenicity/ST-2), or atherosclerotic coronary artery disease (troponin T or I, creatinine phosphokinase-MB). Additionally, they can target inflammation (C-reactive protein, interleukin/IL-6, fibrinogen, monocyte chemotactic protein-1, tumor necrosis factor/TNF-a), oxidative stress (isoprostanes), and metabolic conditions (low- and high-density lipoprotein, apolipoprotein/ApoB 100, lipoprotein-associated phospholipase A2, homocysteine, vitamin D, fibroblast growth factor 23, adiponectin, glycated hemoglobin, haptoglobin).

ALT, AST, and cardiac-specific troponin I or troponin T levels are clinically used as surrogate predictive markers in CVD progression and prognosis. For myocardial infarction, the ratio of creatine kinase CK-MB1 to CK-MB2 isoforms is specific and a sensitive predictor. The issue remains for the clinical application of these

cardiac markers (CK-MB, troponin I, and troponin T), and the profiles have an inevitable delay.

New Biomarkers

Novel biomarkers, including cardiac troponins (cTn), cardiac myosin light-chain kinase (cMLCK), and heart-type fatty acid-binding protein (H-FABP), have emerged (Parsanathan and Jain 2020); however, their clinical value has not yet been fully elucidated. Conventional noninvasive anatomical and electrophysiological biomarkers, namely, carotid intima-media thickness (CIMT) and coronary artery calcification (CAC), continue to be investigated. Carotid intima-media thickness can be used in younger populations to predict CVD events. Coronary CT angiography is often used to measure intimal and medial calcification associated with arterial stiffness. CAC is an independent risk factor to predict subclinical atherosclerosis. Additionally, several microRNAs, including miR-126, miR-223, and miR-197, and a panel of 27 single-nucleotide polymorphisms (SNPs) from genome-wide association studies, have been anticipated as biomarkers to predict CVD. However, the gains are arguably modest, and further research is needed to identify new biomarkers and to determine whether multimarker strategies are a viable approach to better risk stratification.

Big Data and the Gut Microbiome

Big data approaches may deliver clinically relevant phenotypes, scalable insights from real-world evidence (biomedical and omics-data) driving disease prediction, and personalized medicine through advanced analytics. The intestinal microorganisms should not be excluded from this target. Previous studies had shown that *Akkermansia muciniphila* has health benefits, such as reducing obesity, glucose intolerance, insulin resistance, as well as fat accumulation in the liver in animal models. In a clinical protocol with overweight and obese insulin-resistant patients, 3- month administration of the pasteurized bacteria (10^{10}/day) was well tolerated and did not interfere with the general microbiome profile. Effectively insulin sensitivity improved, whereas insulin and cholesterol levels, body weight, and additional anthropometric measurements, as well as inflammatory markers all diminished (Depommier et al. 2019).

The Precision Medicine Approach

Large epidemiologic databases, including CVD information are now available, such as the Global Burden of Disease (GBD) Study (UNC Carolina Population Center 2020; Institute for Health Metrics and Evaluation (IHME) 2020; World Health Organization 2018). Along with large-scale observational and clinical trials, these represent a significant step toward the precision medicine concept; however, more is needed in the realm of multi-omics cardiovascular screening. The genotype, endophenotype, and clinical phenotype in commonly seen cardiovascular diseases has been demonstrated to be more heterogeneous than previously believed, thus representing a challenge to the short-term application of the multi-omics concept (Leopold et al. 2020). Nevertheless, advanced machine-learning methodologies applied to available conventional datasets, such as the classification and regression tree (CART) algorithm, are already permitting the highest accuracy and reliability in the diagnosis of coronary artery disease. In a protocol starting with a 55-independent feature diagnostic panel, the 18 best and also just the 10 highest-rated variables, structured within the CART algorithm, already outperformed previously published models (Ghiasi et al. 2020).

Abstract

Gestational diabetes mellitus, characterised as glucose intolerance first recognised during the second or third trimester of pregnancy, which is clearly not type 1 or type 2 diabetes, imposes a significant burden on maternal and neonatal health. Women with gestational diabetes are at an increased risk of subsequent progression to type 2 diabetes, a chronic metabolic disorder associated with multiple comorbidities and reduced life expectancy. This chapter will underline the pathophysiological mechanisms involved in gestational diabetes, review the current guidelines and recommendations for screening and disease management, discuss future prognosis for both mother and child, as well as look into post-partum care strategies to delay or prevent type 2 diabetes onset.

Gestational diabetes mellitus · Diabetes mellitus · Hyperglycaemia · Pregnancy · Pathophysiology · Screening · Diagnosis · Management

Gestational Diabetes: A Growing Problem

Gestational diabetes mellitus is glucose intolerance with onset or first diagnosis during the second or third trimester of pregnancy that is neither pre-existing type 1 nor type 2 diabetes (American Diabetes Association (ADA) 2019a). Widely recognised risk factors for gestational diabetes include non-white ethnicity, advanced maternal age, obesity, excessive weight gain during pregnancy, family history of diabetes, gestational diabetes in prior pregnancy, foetal macrosomia and unexplained stillbirth (Martis et al. 2018). In 2019, the International Diabetes Federation estimated that, on a global scale, 20.4 million or 15.8% of live births were affected by hyperglycaemia in pregnancy, with 83.6% of those cases being due to gestational diabetes (International Diabetes Federation 2019). This prevalence is expected to rise due to trends in physical inactivity and increased caloric consumption, promoting the spread of the global obesity epidemic (Hunt and Schuller 2007).

Pregnancy is by nature a diabetogenic condition as it is associated with a decrease of insulin sensitivity, which is accompanied by a compensatory increase in insulin secretion. The purpose of these metabolic changes is to ensure that adequate levels of glucose and other nutrients are available for the foetus (Di Cianni et al. 2003). However, obesity and inheritance often interfere with these metabolic shifts, leading to inadequate insulin secretion due to the inability of pancreatic β-cells to adapt, and hence women develop gestational diabetes (Di Cianni et al. 2003).

Other Metabolic Features of Pregnancy

In addition to glucose metabolism, pregnancy induces changes in both lipid and protein metabolism. As there is a need for increased glucose and amino acids supply to the foetus, energy production shifts from an anabolic to a catabolic state, promoting the use of lipids instead of carbohydrates as source (Butte 2000). These alterations lead to fat accumulation, as total cholesterol, low-density lipoprotein (LDL) cholesterol, very low-density lipoprotein (VLDL) and triglycerides are all elevated both during second and third trimesters, while high-density lipoprotein (HDL) cholesterol increases in early pregnancy and remains elevated during its whole duration (Butte 2000; Pusukuru et al. 2016). In pregnancies complicated by gestational diabetes, hyperlipidaemia is exaggerated, with an emphasis on the significantly increased triglyceride levels throughout the whole gestational period (Ryckman et al. 2015). With regard to protein metabolism, plasma levels of branched-chain amino acids (isoleucine, leucine and valine) are elevated in women with gestational diabetes, and these alterations are also positively associated with a higher incident risk of type 2 diabetes (Metzger et al. 1980; Tobias et al. 2018).

To date, the complex pathophysiological mechanisms involved in the development of

Table 35.1 ADA guidelines on screening and diagnosis of gestational diabetes

One-step strategy			
The diagnosis of gestational diabetes is made when any of the following plasma glucose values are met or exceeded:			
Fasting: 92 mg/dL (5.1 mmol/L)			
1 h: 180 mg/dL (10.0 mmol/L)			
2 h: 153 mg/dL (8.5 mmol/L)			
Two-step strategy			
First step: A 50-g non-fasting GLT is performed. If plasma glucose levels at 1 h following the load are ≥130 mg/dL, 135 mg/dL, or 140 mg/dL (7.2 mmol/L,7.5 mmol/L, or 7.8 mmol/L, respectively), perform a 100-g OGTT.			
Second step: A 100-g OGTT is performed at fasting. The patient receives a diagnosis of gestational diabetes if at least two of the following four plasma glucose levels (at fasting state and 1 h, 2 h, 3 h during OGTT) are met or exceeded:			
	Carpenter-Coustan[a]	Or	NDDG
Fasting	95 mg/dL (5.3 mmol/L)		105 mg/dL (5.8 mmol/L)
1 h	180 mg/dL (10.0 mmol/L)		190 mg/dL (10.6 mmol/L)
2 h	155 mg/dL (8.6 mmol/L)		165 mg/dL (9.2 mmol/L)
3 h	140 mg/dL (7.8 mmol/L)		145 mg/dL (8.0 mmol/L)

GLT glucose load test, *NDDG* National Diabetes Data Group, *OGTT* oral glucose tolerance test
[a] The 2020 ADA guidelines recommend that if a two-step approach is used, the Carpenter Coustan criteria should be preferred due to lower diagnostic thresholds

gestational diabetes have not yet been fully understood.

Screening and Diagnosis

According to the American Diabetes Association (ADA), screening for gestational diabetes is performed at 24–28 weeks of gestation in women who have no history of pre-existing diabetes, using either the "One-step" 75-g oral glucose tolerance test (OGTT) or the "Two-step" approach using a 50-g (non-fasting) screen, followed by a 100-g OGTT for those who receive a positive result (American Diabetes Association (ADA) 2019a). The 75-g OGTT is performed in the morning, following an overnight fast of at least 8 h, at the fasting state, 1 and 2 h (American Diabetes Association (ADA) 2019a). In the two-step strategy, the patient receives a 50-g non-fasting glucose load test (GLT), glucose measurement is performed at 1 h, and based on the result, a 100-g OGTT is performed (American Diabetes Association (ADA) 2019a) (Table 35.1).

However, there is a lack of universal agreement on both the screening method as well as the cut-off values, used for the diagnosis of gestational diabetes. This often leads to different estimates of disease prevalence across regions, while different populations are being targeted (Behboudi-Gandevani et al. 2019). Table 35.2 highlights the differences between universal screening guidelines for gestational diabetes. The majority of guidelines support the use of a one-step strategy, while some guidelines suggest both a one-step and a two-step approach.

Managing Gestational Diabetes

Glucose Management

Tight glycaemic control is a key step in the management of gestational diabetes (Fig. 35.1). The Fifth International Workshop-Conference on Gestational Diabetes Mellitus (Metzger et al. 2007) recommends the following target blood glucose levels for women with gestational diabetes during pregnancy:

- Fasting <95 mg/dL (5.3 mmol/L) and either
- 1-h postprandial <140 mg/dL (7.8 mmol/L) or
- 2-h postprandial <120 mg/dL (6.7 mmol/L).

Dietary Interventions

Dietary interventions are the primary strategy for the management of gestational diabetes (Fig. 35.1). Following diagnosis, a nutrition plan

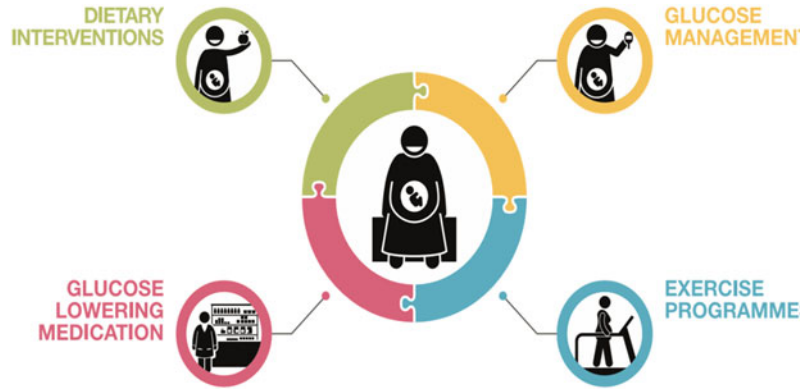

Fig. 35.1 Management of gestational diabetes in pregnancy (Figure created by Michael Bonar, Diabetes Research Centre, Leicester, UK)

is provided to the patient by a registered dietician specialised in gestational diabetes, aiming to achieve sufficient calorie intake for foetal growth and improve maternal health outcomes (American Diabetes Association (ADA) 2019b). Dietary interventions should by no means promote weight loss or excessive gestational weight gain, while they should focus on achieving optimal glycaemic control (Brown et al. 2017). There is no optimal calorie intake for women with gestational diabetes supported by research so far; hence, it is suggested that these women should adhere to the Dietary Reference Intakes for all pregnant women, suggesting a minimum of 175 g of carbohydrates, 71 g of protein and 28 g of fibre (American Diabetes Association (ADA) 2019b).

Overall, medical nutrition guidelines for gestational diabetes recommend adequate protein consumption and selection of low glycaemic-index foods (Tsirou et al. 2019). There are, however, several inconsistencies across the different available medical nutrition therapy guidelines, as recognised by a recent review and critical appraisal, as they often fail to involve patients and dieticians in their development, and be realistic and flexible, while their applicability is low (Tsirou et al. 2019). Future research needs to focus on developing high-quality, evidence-based guidelines that focus on patients, and can therefore be applicable in a realistic clinical setting.

Exercise Programmes

While women with gestational diabetes are first offered dietary interventions, guidelines often recommend the combination of diet and exercise as a more effective approach for disease management (The National Institute for Health and Care Excellence (NICE) 2015; American College of Obstetricians and Gynecologists (ACOG) 2015) (Fig. 35.1). Frequent and sustained exercise can improve insulin sensitivity in skeletal muscle and achieve better glucose control (Martis et al. 2018). Current pregnancy guidelines focus primarily on the prescription of aerobic exercise, and secondarily on resistance strength training (Padayachee 2015). It is generally recommended that the patient should be offered an individualised exercise programme, including moderate-intensity exercise with a duration of at least 20–30 min a day that should be performed daily or on most days of the week, unless there is some contraindication (American College of Obstetricians and Gynecologists (ACOG) 2015). Safe types of physical activity during pregnancy include walking, stationary cycling, swimming and low-impact aerobics (American College of Obstetricians and Gynecologists (ACOG) 2015).

Contraindications to Exercise

There are considerable beneficial outcomes associated with exercise for both the mother and the foetus, while contraindications must be also considered. Performing physical activity in pregnancy can often be hindered due to pregnancy-related pain, as pelvic girdle pain or low back pain prevalence is high and often induces disability (Wu et al. 2004). Contraindications for physical activity during pregnancy as recognised by international guidelines include multiple gestation, pregnancy-induced hypertension or pre-eclampsia, cardiovascular disease, thyroid disease, anaemia, persistent bleeding, premature membrane rupture, premature contractions or labour, and cerclage or incompetent cervix, while a few guidelines recognise morbid obesity, poorly controlled diabetes mellitus, eating disorders and placenta previa as contraindications as well (Evenson et al. 2014).

Glucose-Lowering Medication and Supplements

Women with gestational diabetes who cannot achieve favourable glucose control with lifestyle modifications such as dietary and exercise intervention are administered pharmacological agents (Fig. 35.1). In the United States, ADA recommends insulin as the first-line pharmacological agent (American Diabetes Association (ADA) 2019b). Insulin is administered by either multiple daily injections or continuous subcutaneous infusion. The Food and Drug Administration (FDA) has approved human regular insulin, rapid-acting insulin analogues (lispro and aspart), Neutral Protamine Hagedorn (NPH) long-acting insulin, as well as the long-acting insulin analogue Detemir, classifying them as pregnancy category B, and has established their safety of use during pregnancy (Kintiraki and Goulis 2018).

Oral Therapy

The use of oral medication, including both metformin and glyburide (sulfonylureas), is supported by evidence; however, they are still regarded as a second-line treatment by ADA, as there is a concern about them crossing the placenta, while long-term offspring safety is also questionable (American Diabetes Association (ADA) 2019b). Glyburide has also been linked to both foetal macrosomia and neonatal hypoglycaemia (Malek and Davis 2016; Song et al. 2017). With regard to metformin, it has been found to induce less weight gain compared to insulin; while it has been associated with a lower risk of neonatal hypoglycaemia, it is associated with a higher risk of preterm birth (Balsells et al. 2015; Gui et al. 2013).

Consistently with ADA, the American College of Obstetricians and Gynaecologists (ACOG) guidelines focus on insulin, and they also recommend metformin as well as glyburide (sulfonylureas) as an alternative, while the Fifth International Workshop-Conference in Gestational Diabetes Mellitus focuses on insulin, suggests glyburide as an alternative treatment, and expresses uncertainty about metformin (Metzger et al. 2007; The American College of Obstetricians and Gynecologists (ACOG) 2018). Contrary to that, guidelines by the National Institute for Health and Care Excellence (NICE) recommend metformin as a first-line pharmacological treatment, while insulin is used when there is a contraindication for metformin, and glyburide is also considered an alternative treatment option (The National Institute for Health and Care Excellence (NICE) 2015).

A few advantages of oral medication are the ease of use, wide acceptability as well as lower cost (Ryu et al. 2014). In real-world clinical practice, healthcare professionals need to weigh both favourable outcomes and adverse effects in order to decide upon a treatment option based on the condition of the individual, while more research is required to evaluate long-term treatment-associated outcomes on offspring health.

Vitamins and Other Supplements

The evidence surrounding the efficacy of dietary supplements for the management of gestational diabetes is quite contradicting. A double-blinded randomised controlled trial by Li et al. found that vitamin D supplementation during pregnancy affected by gestational diabetes can improve both fasting plasma glucose and lipid levels (Li and Xing 2016). Contrary to that, results from a recently published systematic review support that there is no adequate evidence on the efficacy of vitamin D supplementation, in improving glucose metabolism or maternal and neonatal outcomes (Rodrigues et al. 2019). Myo-inositol supplementation has drawn research attention over the last few years, with several studies demonstrating its potential in improving insulin resistance in gestational diabetes and reducing the need for insulin treatment (Corrado et al. 2011; Costabile and Unfer 2017; Lubin et al. 2016). The efficacy of both vitamin D and myo-inositol in pregnancy complicated by gestational diabetes needs to be further investigated.

Future Prognosis for Mother and Child

Short-Term Outcomes

A substantial number of maternal complications have been associated, including gestational hypertension and preeclampsia, preterm birth, perineal trauma, caesarean delivery and postpartum bleeding (Kim 2010). With regard to foetal/neonatal health, a diagnosis of gestational diabetes increases the risk of macrosomia, being born large for gestational age, shoulder dystocia, bone fractures, nerve palsy, stillbirth, neonatal hypoglycaemia, hyperbilirubinaemia and respiratory distress syndrome (Martis et al. 2018; Kim 2010).

Long-Term Outcomes

Women affected by gestational diabetes have a nearly 10-fold higher risk of progression to type

2 diabetes than those with a normoglycaemic pregnancy (Vounzoulaki et al. 2020). Incidence of type 2 diabetes has also been reported to markedly increase in the first 5 post-partum years, while it seemed to reach a plateau afterwards (Kim et al. 2002). Among the most common factors associated with an increased risk of progression are the degree of glucose intolerance during pregnancy, maternal age at diagnosis of gestational diabetes, use of insulin during pregnancy, and longer post-partum follow-up periods (Kim et al. 2002).

Cardiovascular, Metabolic and Other Complications

Women with a history of gestational diabetes are at an increased risk of future cardiovascular disease, while they are also more likely to be diagnosed with non-alcoholic fatty liver disease (Goueslard et al. 2016; Foghsgaard et al. 2017), with both these conditions being associated with reduced average life expectancy. A previous diagnosis of gestational diabetes identifies a patient group with a twofold higher risk for future cardiovascular events, and this risk is independent of subsequent progression to type 2 diabetes (Kramer et al. 2019). Additionally, not only glucose, but also mean lipid levels such as total cholesterol, triglycerides, LDL cholesterol, as well as mean systolic blood pressure, are significantly increased in women with previous gestational diabetes (Meyers-Seifer and Vohr 1996).

During pregnancy, women affected by gestational diabetes exhibit impaired microvascular function and skeletal muscle oxygenation as well as blunted cerebral oxygenation, while these impairments can persist in the post-partum period (Dipla et al. 2017; Kintiraki et al. 2018; Vounzoulaki et al. 2019). The impact of gestational diabetes is not limited to physical health but extends to mental health and wellbeing, as women affected by the disease were found to have an over fourfold risk of post-partum depression (Hinkle et al. 2016), with caesarean delivery and gestational weight gain identified as possible risk factors (Nicklas et al. 2013).

Complications of the Newborn

Children are more prone to become overweight or develop metabolic syndrome (Boerschmann et al. 2010; Vääräsmäki et al. 2009), while a recent longitudinal cohort study also demonstrated that exposure to gestational diabetes during pregnancy, diagnosed by 26 weeks of gestation, induces a higher risk of autism spectrum disorder in offspring (Xiang et al. 2015).

Post-partum Screening and Care

Women affected by gestational diabetes during pregnancy require close monitoring in the post-partum period. Post-partum screening is recommended at 4–12 weeks post-partum, using an OGTT (American Diabetes Association (ADA) 2019b). The use of glycated haemoglobin (HbA1c) for post-partum screening is not recommended by ADA, as it can be affected by pregnancy red blood cell turnover or blood loss during labour, while the 75-g OGTT is more sensitive in detecting both prediabetes and type 2 diabetes (American Diabetes Association (ADA) 2019b). If test results are normal, further testing is required every 1–3 years with any recommended glucose test (HbA1c, fasting plasma glucose or OGTT), and frequency is dependent on risk factors such as family history, body mass index (BMI) before pregnancy, and use of insulin or oral medication in pregnancy (American Diabetes Association (ADA) 2019b). Post-partum care in this population mainly focuses on lifestyle modification, pharmacological treatment and breastfeeding (Fig. 35.2).

Diet, Exercise and Metformin

Both lifestyle intervention and metformin have been proven effective in attenuating subsequent progression to type 2 diabetes. Results from the Diabetes Prevention Program Outcomes study have indicated that the cumulative incidence of type 2 diabetes was the lowest in those who received lifestyle intervention, with the onset of

Fig. 35.2 Post-partum management of women with gestational diabetes (Figure created by Michael Bonar, Diabetes Research Centre, Leicester, UK)

diabetes being delayed by about 4 years when lifestyle intervention was implemented and 2 years when metformin was administered compared with placebo (Diabetes Prevention Program Research Group 2009). Similar results were reported from long-term studies conducted in Finland and China (Lindström et al. 2013; Li et al. 2008). In particular, in women with previous gestational diabetes in the Diabetes Prevention Program Outcomes study, both lifestyle intervention and metformin achieved lower rates of progression to type 2 diabetes over a 10-year follow-up period (Aroda et al. 2015).

Another randomised controlled trial implementing lifestyle intervention with a Mediterranean diet and monitored exercise in women with prior gestational diabetes demonstrated that these interventions were associated with lower incidence of impaired glucose regulation and type 2 diabetes (Pérez-Ferre et al. 2015). The efficacy of healthful dietary patterns was also supported by results from the Nurses' Health Study II, where once again, the risk of type 2 diabetes was lower in women who adopted these patterns (Tobias et al. 2012). Lifestyle interventions for the prevention of type 2 diabetes in this high-risk group have been found to be both cost effective and cost saving (Lohse et al. 2011).

Other Oral Drugs

Apart from metformin, troglitazone has been investigated as a potential pharmacological agent and was found to be effective in the prevention of type 2 diabetes in a cohort of Hispanic women with previous gestational diabetes (Buchanan et al. 2002). However, troglitazone was withdrawn from the market in 2000 as it was found to cause hepatotoxicity. In a follow-up of the same patient group where pioglitazone was administered this time, progression rates to type 2 diabetes were once again observed to be lower (Xiang et al. 2006). Previous research has also evaluated the efficacy of acarbose treatment in patients with impaired glucose tolerance and found that it was capable of delaying progression to type 2 diabetes (Chiasson et al. 2002). However, there is a lack of evidence for the efficacy of acarbose for both the management of gestational diabetes during pregnancy and the prevention of type 2 diabetes post-partum.

The Multiple Advantages of Breastfeeding

Breastfeeding should be encouraged among women with previous gestational diabetes, in line with current guidelines (American Diabetes Association (ADA) 2019b). However, breastfeeding is often hindered by the delayed onset of lactogenesis, a cause of both diabetes and obesity that leads to low rates and short duration of breastfeeding (Gunderson 2007). Studies have demonstrated that breastfeeding is associated with reduced post-partum fasting plasma glucose levels in women with previous

gestational diabetes (Shub et al. 2019), while it can also contribute to post-partum weight reduction in this population (López-Olmedo et al. 2016). Overall, women with previous gestational diabetes who breastfeed demonstrate improved glucose metabolism and insulin sensitivity that have the potential of reducing the risk of future type 2 diabetes (Gunderson et al. 2012).

Progression to Type 2 Diabetes

Women affected by gestational diabetes during pregnancy have an established higher risk of developing type 2 diabetes in the future. Common risk factors associated with type 2 diabetes incidence in this population include non-European ethnicity, family history of type 2 diabetes, use of insulin during pregnancy and increased BMI (O'Reilly et al. 2011). The association between non-European ethnicity and higher incidence of type 2 diabetes after gestational diabetes has been extensively investigated and is well recognised (Ignell et al. 2013; Kousta et al. 2006). However, research performed in Caucasian women with previous gestational diabetes, who are considered to be at lower risk, demonstrated that incidence of post-partum dysglycaemia was over 10% in the early post-partum period (6 weeks post-partum), highlighting the importance of close monitoring in all women regardless of their ethnicity (Ogonowski and Miazgowski 2009). Time to development of diabetes is an important factor to consider, as development of type 2 diabetes in the early post-partum period is an indicator of marked defects in β-cell function, potentially attributed to genetic predisposition (Kwak et al. 2013).

The Challenges of Effective Screening

Progression to type 2 diabetes can be effectively delayed or prevented when women with prior gestational diabetes attend post-partum screening, as the latter facilitates risk classification for type 2 diabetes and introduction of preventative interventions. However, studies across the world have demonstrated that post-partum screening attendance is suboptimal in this patient group (Goueslard et al. 2017; Kim et al. 2006; Kwong et al. 2009; Blatt et al. 2011). There are several reasons that can justify the low uptake of post-partum screening. First of all, patient surveys have highlighted that there is limited awareness of the need for screening and low-risk perception about future progression to type 2 diabetes (Minsart et al. 2014; Sterne et al. 2011). In addition to that, time restrictions and child responsibilities have also been identified as potential barriers, while the length and nature of the OGTT can also hinder screening attendance (Minsart et al. 2014; Sterne et al. 2011; Van Ryswyk et al. 2016). Healthcare professionals are often unaware of the importance of recommending post-partum screening (Almario et al. 2008).

E-Health and Postpartum Follow-Up

Results from a randomised controlled trial using postal reminders showed that women who received a reminder were almost nine times more likely to get screened (Clark et al. 2009). An e-mail reminder system is a cost-effective and time-efficient means to improve screening attendance, with a 10% improvement in screening uptake for type 2 diabetes (Halperin et al. 2015). In Belgium, reminder letters and emails demonstrated that this strategy improved screening rates (Benhalima et al. 2017). Again, clinics that utilised reminders were two to three times more likely to successful screening (Peticca et al. 2014). All these studies, however, emphasised the fact that even though screening attendance was improved with the use of reminder systems, it still remained low and suboptimal. Improving screening uptake on a global scale will improve health outcomes in this population.

Summary

As gestational diabetes is a multifactorial disease, similar to type 2 diabetes, early detection should

be a priority to prevent unfavourable health outcomes. In addition to that, these women should be closely monitored in the post-partum period and receive appropriate care designed to attenuate subsequent progression to type 2 diabetes. A multidisciplinary approach should be applied both during pregnancy and post-partum, being flexible and focusing on individual needs. There are several inconsistencies with regard to the identification of women with gestational diabetes due to different screening methods and diagnostic cut-offs used around the world. This introduces barriers in patient care, as different patients are targeted during pregnancy by the different guidelines and consequently followed up in the post-partum period. Future research needs to address both benefits and harms of different screening methods and diagnostic thresholds on maternal and neonatal outcomes, their effect on maternal wellbeing as well as the associated health costs. Finally, future research should also aim to identify post-partum screening barriers and facilitators that will have the potential to improve screening uptake and reduce progression to type 2 diabetes.

Acknowledgments The authors gratefully acknowledge Mr. Michael Bonar for creating the illustrations featured in this chapter as well as Professor Dimitrios G. Goulis for providing advice on this chapter.

Abstract

Gestational diabetes mellitus (GDM) has become increasingly prevalent in the United States, and its impact on adverse maternal and neonatal outcomes necessitates proper screening, management, and follow up. Although there is a lack of consensus on screening methods for GDM, the American College of Obstetrics and Gynecology (ACOG) recommends the two-step approach between 24 and 28 weeks. In contrast, the International Association of Diabetes and Pregnancy Study Group (IADPSG) recommends a one-step approach. Once the diagnosis of GDM has been made, management may consist of nutritional therapy, alone, or in combination with pharmacologic interventions such as insulin, metformin, or less often, glyburide. Close management is warranted in order to avoid adverse maternal and neonatal outcomes, both during delivery and later in life to both mother and infant.

The Growing Prevalence of Gestational Diabetes

Gestational diabetes mellitus (GDM) is well known to increase the risk of adverse outcomes in mothers and infants. Its additional capacity to contribute to potential maternal and pediatric morbidity later in life prompts the importance of investigating the issue from a public health perspective (Ferrara 2007). In the United States, the prevalence of gestational diabetes appears to be increasing. Between 1989 and 2004, rates increased from 1.9% to 4.2%, with the largest increase found in black women younger than 25 (Getahun et al. 2008). More recent data from 2016 have estimated this prevalence to be even larger at 6.0%, which highlights its pervasiveness over the last 25 years (Deputy et al. 2018). Interestingly, the prevalence of GDM has increased concomitantly with the rise of obesity, as well as with the trend toward older maternal age, decreasing physical activity, and more widespread type 2 diabetes (Dabelea et al. 2005; Ferrara 2007).

In the United States, there is increased prevalence of GDM in minority women as compared to non-Hispanic whites. In a study looking at eligible pregnancies from 1994 to 2002, the prevalence of GDM was highest in Asian and Hispanic women, intermediate in African Americans, and lowest in non-Hispanic whites (Dabelea et al. 2005). According to data from 2016, it is highest in non-Hispanic Asian women at 11.1% (Deputy et al. 2018). Studies in both Europe and Australia have shown analogous disparities with higher GDM prevalence in Asian women (Ferrara 2007). An increased incidence in older mothers (Getahun et al. 2008; Deputy et al. 2018) also extends globally, with an Australian study showing that mothers greater than 40 were more than six times as likely to develop GDM, than their 20–24 year old counterparts (Anna et al. 2008).

Additional Influences

In a study from the early 1990s, it was found that advanced maternal age, family history of diabetes mellitus, nonwhite ethnicity, higher BMI, weight gain in early adulthood, and cigarette smoking predicted an increased risk of GDM (Solomon 1997). Another study from the late 1980s had already observed similar conclusions, however, also saw positive correlations between GDM and parity, history of infertility, preterm delivery, and stillbirth (Berkowitz et al. 1992). Table 36.1 is adapted from the CDC and summarizes the variation in GDM prevalence according to a range of selected maternal characteristics (Deputy et al. 2018).

Despite these previous studies, several epidemiological limitations make it difficult to appropriately study trends in GDM, including dispute with regards to diagnostic criteria and screening

Table 36.1 Pre-existing diabetes and gestational diabetes among women with a live birth (USA, 2016)

Features	Previous diabetes mellitus (%)	Gestational diabetes (%)
Age < 20	0.4	1.9
20–29	0.5–0.7	3.3–5.1
30–39	1.4	7.0–9.6
40+	2.1	12.8
Nulliparous	0.8	5.2
Primiparous	0.8	5.9

techniques (Ferrara 2007). For example, while there is clearly a positive association between severe obesity and GDM, the magnitude of the variation is different among studies. This is likely due to the variations in classifications of obesity as well as diagnostic criteria for GDM (Chu et al. 2007).

Screening and Risk Evaluation

The purpose of screening for GDM is to identify healthy individuals who have a high probability of having or developing the disease. However, identifying these individuals can be confounded by women with probable pre-existing diabetes that is diagnosed early in pregnancy. The American Diabetes Association (ADA) defines GDM as "diabetes diagnosed in the second or third trimester of pregnancy that was not clearly overt diabetes prior to gestation" in order to separate pregnant women with undiagnosed type 2 diabetes (American Diabetes Association 2018a). Screening techniques have also adapted to differentiate GDM from pre-existing diabetes. The American College of Obstetrics and Gynecology (ACOG) recommends that overweight or obese women with diabetic risk factors be screened for undiagnosed type 2 diabetes at the initiation of prenatal care. Table 36.2 is adapted from the American College of Obstetricians and Gynecologists Gestational Diabetes Mellitus Practice Bulletin, and it highlights these characteristics (Gestational Diabetes Mellitus 2018). In women where undiagnosed type

2 diabetes is suspected, nonpregnant diabetic diagnostic criteria can be used for detection (American Diabetes Association 2018a).

There is a lack of uniformity among national and international standards for screening and diagnosing GDM (HAPO Study Cooperative Research Group 2008). Currently, two strategies, the one-step and two-step approaches, can be used to screen and diagnosis GDM, but controversy still exists between which strategy is best (Saccone et al. 2020). In a meta-analysis investigating differences in perinatal outcomes between both methods, researchers found that the one-step approach was associated with a lower risk of large for gestational age infant, NICU admission, and neonatal hypoglycemia (Saccone et al. 2020). However, additional studies have argued that the one-step approach will not only increase incidence of GDM, but will also increase direct and indirect healthcare costs (Vandorsten et al. 2013). As such, ACOG supports the two-step approach, but many practitioners will choose the one-step approach if felt more appropriate for their patient populations (Gestational Diabetes Mellitus 2018).

The two-step approach includes an initial screening test followed by diagnostic testing (American Diabetes Association 2018a). In women who have not previously been diagnosed with type 1 or 2 diabetes mellitus, current recommendations suggest that all pregnant women are screened for GDM between 24 and 28 weeks' gestation. This can be done via administration of a 50-g oral glucose solution. This screening tool does not require fasting, and it is followed by a 1-h venous glucose determination (Gestational Diabetes Mellitus 2018). The gestational timing of this screening recommendation results from a United States Preventive Services Task Force systematic review that found insufficient evidence to suggest screening earlier than 24 weeks (Moyer and U.S. Preventive Services Task Force 2014). Cutoffs for positive screening values differ among institutions, but thresholds vary between 130 and 140 mg/dL. Some studies argue that the higher threshold of 140 mg/dL may lead to lower rates of false-positive screening tests and thus prevent unnecessary maternal stress, but no randomized controlled trials have determined one cutoff to be more effective than others (Rumbold and Crowther 2002; Gestational Diabetes Mellitus 2018). Therefore, ACOG recommends providers select a single consistent threshold for the 1-h glucose screening test that best fits their patient population (Gestational Diabetes Mellitus 2018).

Abnormal results on the initial 50-g screening test are followed by a 100-g, 3-h diagnostic oral glucose tolerance test (OGTT). Table 36.3 is adapted from the ACOG Gestational Diabetes Mellitus Practice Bulletin and demonstrates diagnostic threshold serum glucose values set by the National Diabetes Data Group and Carpenter and Coustan. Due to the lack of competitive trials between cutoff values, there is no clear consensus on which values to definitively recommend (Gestational Diabetes Mellitus 2018). Historically, two abnormal values from the 3-h OGTT were needed to diagnose GDM according to criteria established in a 1964 study (O'Sullivan and Mahan 1964). More recent data have come to suggest that even a single abnormal value may also be associated with adverse maternal and neonatal outcomes. A systematic review showed women with one abnormal glucose value still had increased risk for poor obstetric outcomes, similar to those who were diagnosed with GDM (Roeckner et al. 2016). Further research is needed to determine if women with one abnormal value would benefit from evaluation and treatment, but currently ACOG guidelines recommend two abnormal values on the 3-h OGTT to establish a

Table 36.4 International Association of Diabetes in Pregnancy Study Group criteria for diagnosis of gestational or overt diabetes in pregnancy (after oral glucose tolerance test)[a]

Fasting	≥92 mg/dL
1 h	≥180 mg/dL
2 h	≥153 mg/dL

diagnosis of GDM (Gestational Diabetes Mellitus 2018).

In the one-step approach, a 75-g 2-h OGTT is used to identify GDM. When one plasma glucose measurement exceeds the diagnostic threshold, values set by the International Association of Diabetes and Pregnancy Study Group (IADPSG), a diagnosis of GDM can be made (Table 36.4 from IADPSG) (Metzger 2010). In one study using the IADPSG one-step diagnostic criteria, women diagnosed with GDM had increased adverse pregnancy outcomes such as gestational hypertension, pre-eclampsia, and large for gestational age infants (Caissutti et al. 2017). Long-term follow-up of these women showed that a significantly larger group of patients diagnosed with GDM via the one-step strategy developed prediabetes or type 2 diabetes compared to those women diagnosed with GDM via the two-step method (Lowe et al. 2018). Those who oppose the one-step method argue that, by definition, it increases the incidence and healthcare costs associated with GDM and increases the potential for harm with more obstetric and neonatal intervention (American Diabetes Association 2018a; Lowe et al. 2018; Cheung and Moses 2018). However, this increasing incidence in GDM diagnoses via the one-step method could potentially identify a larger pool of women who would benefit from increased screening for disorders of glucose metabolism later in life (American Diabetes Association 2018a). Ultimately, there is no international consensus on which diagnostic method is best, and rising evidence suggests that no one diagnostic criteria exists but, rather, must be adapted locally with population data (Mcintyre et al. 2018).

Of note, screening for GDM using A1C at 24–28 weeks' gestation is not as effective as the glucose-loading test (American Diabetes Association 2018a). Although glycated hemoglobin levels may be beneficial in helping to screen for diabetes that existed before pregnancy, there is no A1C threshold with both good sensitivity and specificity that make it an appropriate screening test for GDM (Moyer and U.S. Preventive Services Task Force 2014).

Classification of Gestational Diabetes

The White Classification system, first established in 1949, attempted to use alphabetical groups to categorize diabetes in pregnancy in a way that allowed clinicians to stratify patients with risk factors for fetal and neonatal mortality. These characteristics included age at onset of diabetes, duration of disease, and the presence or absence of hypertensive disorders, vascular, or renal complications (Sacks and Metzger 2013). Table 36.5 demonstrates the different classes of the 1949 White Classification system (Bennett et al. 2015).

Ambiguity on how to classify cases of GDM leads to confusion among practitioners (Hare and White 1980). The majority of the population of women in which the White Classification was originally based had diabetes antedating pregnancy, primarily type 1 (Hare and White 1980; Bennett et al. 2015). Therefore, the White Classification was never originally intended to be used with GDM. Upon considering diverse obstetric demographics and the complex nature of GDM, the White Classification revision in 1980 created a separate class for GDM (Hare and White 1980). ACOG further expands the GDM class into A1GDM or A2GDM, with the latter requiring pharmacologic therapy to achieve euglycemia (Gestational Diabetes Mellitus 2018). In class A1GDM, nutritional therapy alone is sufficient (Gestational Diabetes Mellitus 2018). Table 36.6 demonstrates an updated classification system that includes the subcategories of GDM (Gilmartin et al. 2008).

Table 36.5 White classification of diabetes in pregnancy: (A) Initial (1949) version and (B) Final (1980) version

(A) Initial 1949 Version	
Class A	Diagnosis of diabetes made on a glucose tolerance test, which deviates but slightly from the normal
Class B	Duration less than 10 y and Onset age 20 y or older and No vascular disease
Class C	Duration 10–19 y or Onset 10–19 y of age or Minimal vascular disease (e.g., retinal arteriosclerosis or calcified leg vessels)
Class D	Duration 20 y or longer or Onset younger than 10 y of age or More evidence of vascular disease, e.g., retinitis, transitory albuminuria, or transitory hypertension
Class E	Calcified pelvic arteries on X-ray
Class F	Nephritis
(B) Final 1980 Version	
Class A	Diet alone, any duration or onset age
Class B	Onset age 20 years or older and duration less than 10 years
Class C	Onset age 10–19 years or duration 10–19 years
Class D	Onset age younger than 10 years, duration over 20 years, background retinopathy, or hypertension (not pre-eclampsia)
Class R	Proliferative retinopathy or vitreous hemorrhage
Class F	Nephropathy with over 500 mg/d proteinuria
Class RF	Criteria for both Classes R and F coexist
Class H	Arteriosclerotic heart disease clinically evident
Class T	Prior renal transplantation

Table 36.6 Updated White classification

A: Abnormal glucose tolerance test at any age or of any duration treated only by diet therapy
B: Onset at age 20 years or older and duration of less than 10 years
C: Onset at age 10–19 years or duration of 10–19 years
D: Onset before 10 years of age, duration over 20 years, benign retinopathy, or hypertension (not preeclampsia)
– D1: Onset before age 10 years
– D2: Duration over 20 years
– D3: Calcification of vessels of the leg (macrovascular disease)
– D4: Benign retinopathy (microvascular disease)
– D4: Hypertension (not preeclampsia)
R: Proliferative retinopathy or vitreous hemorrhage
F: Renal nephropathy with over 500 mg/d proteinuria
RF: Criteria for both classes R and F
G: Many pregnancy failures
H: Evidence of arteriosclerotic heart disease
T: Prior renal transplant
Gestational diabetes
– A1: Controlled by diet and exercise
– A2: Requires insulin

Obstetric and Pharmacologic Management

Ideal glycemic levels in GDM are another topic of controversy, with no controlled trials coming to a consensus on optimal targets (Gestational Diabetes Mellitus 2018). The ADA and ACOG recommend that fasting glucose levels remain below 95 mg/dL, 1-h postprandial levels remain below 140 mg/dL, and 2-h postprandial levels remain below 120 mg/dL (Gestational Diabetes Mellitus 2018; American Diabetes Association 2018b). There are no clinical guidelines establishing accepted frequencies or timing of glucose monitoring. The general recommendations from ACOG suggest glucose monitoring four times a day, including fasting and after each meal (Gestational Diabetes Mellitus 2018). Additionally, postprandial levels are preferred to preprandial glucose values. One randomized study showed that using postprandial levels rather than preprandial to guide therapy allowed for reduced risk of neonatal hypoglycemia, macrosomia, and cesarean delivery (Veciana et al. 1996). Glucose monitoring may be decreased based on clinical discretion, if the patient has achieved appropriate glycemic control with diet (Gestational Diabetes Mellitus 2018; Turok et al. 2003).

Dietary Guidance

As previously mentioned, GDM can be treated using nutritional therapy alone (class A1GDM) or with additional pharmacologic interventions (class A2GDM). Medical nutrition therapy continues to be a central component of GDM management aimed at establishing normoglycemia, maintaining appropriate weight gain in pregnancy, promoting adequate fetal well-being, and preventing ketonemia (American Diabetes Association 2008). Specific nutritional recommendations vary between patients depending on their pre-pregnancy weights and ideal gestational weight gain, however, typically involve a carbohydrate-controlled meal plan (American Diabetes Association 2008). In general, three moderately sized meals and two to four snacks are recommended, with one snack in the evening to prevent ketosis overnight (Gestational Diabetes Mellitus 2018; American Diabetes Association 2008).

Carbohydrates should be dispersed throughout the day and compose 33–40% of total calories, with a minimum consumption of 175 g (American Diabetes Association 2008; Gestational Diabetes Mellitus 2018; Turok et al. 2003). The remaining calories can be distributed between protein (20%) and fats (40%) (Gestational Diabetes Mellitus 2018). The ADA recommends nutritional counseling at the time of diagnosis with a registered dietitian when possible, in order to provide individualization of therapy (Turok et al. 2003). For example, obese women may benefit from moderate caloric restriction to improve glycemic control (American Diabetes Association 2008). Specifics on medical nutritional therapy should be tailored to the patient needs, with collaboration between physicians and registered dieticians in order to achieve optimal outcomes. Exercise also has a part in management, but there are limited randomized controlled trials regarding its role in patients with GDM. ACOG suggestions reflect general diabetes care, aiming for 30 min of moderate aerobic exercise 5 days a week or 150 min total (Gestational Diabetes Mellitus 2018).

Pharmacotherapy

When nutrition and exercise are not sufficient to establish normoglycemia, pharmacologic management is indicated, as is the case in Class A2GDM. A systematic review found no ideal threshold at which to initiate drug therapy (Nicholson et al. 2008). Table 36.7 specifies the glycemic thresholds used by ACOG and ADA (Gestational Diabetes Mellitus 2018; Gilmartin et al. 2008). Both ACOG and ADA prefer the use of insulin to establish normoglycemia in pregnancy, as it does not cross the placenta and is effective in achieving metabolic control (Gestational Diabetes Mellitus 2018; American

Table 36.7 Glycemic thresholds to begin pharmacologic therapy for GDM

ACOG (mg/dL)	ADA (mg/dL)
Fasting ≥95	Fasting ≥105
1 h post-prandial ≥140	1 h post-prandial ≥155
2 h post-prandial ≥120	2 h post-prandial ≥130

Table 36.8 Pharmacotherapy features of special insulins

Regular insulin	30 min–8 h
NPH insulin	1–18 h
Glargine insulin	1–24 h
Detemir insulin	1–26 h
Lispro, Aspart	1 min–5 h

Modified from Gabbe SG, Graves CR. Management of diabetes mellitus complicating pregnancy. Obstet Gynecol 2003; 102(4): 857–868

Diabetes Association 2018b). The initial daily recommended dosage is 0.7–1.0 units/kg and can be divided into multiple injections, to optimally correct trends of hyperglycemia. NPH insulin, insulin glargine, and insulin detemir are acceptable long-acting options, while insulin lispro and aspart have been utilized for short-acting drugs. Table 36.8 is adopted from ACOG and demonstrates the timing of insulin options in pregnancy (Gestational Diabetes Mellitus 2018). Insulin regimens should be individualized to the patient and simplified for optimal results, and physicians should adjust treatment as pregnancy progresses and insulin resistances increases (Turok et al. 2003).

Oral Glucose-Lowering Prescriptions: Metformin

The Society for Maternal Fetal Medicine (SMFM) states that metformin is also a reasonable first-line alternative to insulin, although many women will still need insulin for glycemic control (SMFM Publications Committee 2018). In one meta-analysis comparing the use of metformin versus insulin, metformin use in GDM was associated with less maternal weight gain, less gestational hypertension, and less neonatal hypoglycemia, suggesting that perhaps there is a benefit to using metformin first line rather than insulin (Gui et al. 2013). However, unlike insulin, metformin crosses the placenta, and little is known about long-term outcomes associated with fetal exposure (SMFM Publications Committee 2018). Current studies looking at neurodevelopmental outcomes in 2-year-olds exposed to insulin and metformin in utero, respectively, show comparable results (Wouldes et al. 2017). Another study determined that metformin during fetal life for maternal GDM does not seem to have an impact on growth and body composition of 8-year-old children (Rø et al. 2012).

Other studies present conflicting results. Metformin has been shown to have cord arterial concentrations at almost twice the level of maternal venous concentrations, and research indicates that the fetus is exposed to concentrations comparable with therapeutic levels in adult populations (Vanky et al. 2005). A New Zealand follow-up of children at age 9 exposed to metformin or insulin in utero, showed that metformin-exposed children were found to have higher weights, arm and waist circumferences, and BMI (Rowan et al. 2018). Maternal tolerance to therapy must also be considered, as metformin can be associated with extensive gastrointestinal side effects (SMFM Publications Committee 2018).

Glyburide

Another option is the sulfonylurea glyburide. However, current data suggest that it is inferior to both insulin and metformin (Balsells et al. 2015). Like metformin, glyburide crosses the placenta and concentrates in cord serum, but there is no evidence to date about long-term effects on fetal exposure in utero (SMFM Publications Committee 2018). Also analogous to metformin, many women still may require insulin to achieve glycemic control (Brown et al. 2017). In a 2017 systematic review, glyburide was associated with increased composite neonatal death and serious morbidity as composed to metformin (Brown et al. 2017). Glyburide has also been correlated with higher birth weight and increased frequency of macrosomia and neonatal hypoglycemia as compared to insulin and metformin (SMFM Publications Committee 2018). Consequently, ACOG currently recommends that glyburide not be used first line, as it has not proven equivalent outcomes as compared to insulin and metformin (Gestational Diabetes Mellitus 2018). Despite data that show glyburide is a less effective choice in treating GDM, studies of commercially insured women showed an increase in glyburide use from 7.4% to 64.5% between 2000 and 2011 (Castillo et al. 2014). The increase in use could be attributed to the fact that oral hypoglycemic agents, including glyburide and metformin, have a lower cost and higher patient acceptance compared to insulin, possibly leading to increased patient satisfaction and compliance (SMFM Publications Committee 2018). Ultimately, clinicians are encouraged to counsel patients on the limited long-term safety data when prescribing glyburide (Gestational Diabetes Mellitus 2018).

Antenatal Fetal Testing

Achieving euglycemia is foundational to the management of GDM, but additional obstetric surveillance is also needed to optimize fetal outcomes. Maternal blood glucose levels are a known risk factor for stillbirth in patients with GDM (Mackin et al. 2019). As such, antenatal fetal testing is initiated at 32 weeks for women with poorly controlled GDM or who require pharmacologic management to achieve euglycemia (Gestational Diabetes Mellitus 2018). In women with A1GDM, risks for stillbirth have not been demonstrated, and consequently, ACOG has found inconclusive evidence regarding the need for antenatal fetal testing. Specific practices often vary by institutional guidelines, but in patients who achieve euglycemia via nutritional therapy alone, antenatal testing can generally be implemented later than in women with poorly controlled GDM (Gestational Diabetes Mellitus 2018). Studies have shown that twice weekly nonstress tests were effective in preventing stillbirth, but currently no antepartum surveillance method or frequency has been proven most successful (Kjos et al. 1995; Turok et al. 2003). Other acceptable fetal testing methods include the modified biophysical profile or full biophysical profile (Turok et al. 2003).

Indications for Ultrasonographic Monitoring

Because of the association of macrosomia and GDM, many clinicians use ultrasonography to assess fetal growth in the third trimester, although specific practices vary (Gestational Diabetes Mellitus 2018). The ADA recommends ultrasound measurements of fetal abdominal circumference every 2–4 weeks starting in the early third trimester and encourages clinicians to use this information to guide management (Metzger et al. 2007). In contrast, the International Federation of Gynecology and Obstetrics vaguely suggests "periodic clinical and sonographic growth assessments from diagnosis until term" (Hod et al. 2015). Ultrasonography can also be used to estimate fetal weight, but has been shown to significantly overestimate the prevalence of large for gestational age (LGA) fetuses in women with GDM. In a study comparing estimated fetal weight with actual birth weight,

only 22% of women with a large for gestational age ultrasound diagnosis delivered an LGA neonate (Scifres et al. 2015). Estimated fetal weight via ultrasound has also been found to increase the risk of cesarean delivery (Little et al. 2012). While ultrasound can assist traditional clinical examinations to predict macrosomia, its inherent limitations in the ability to correctly estimate fetal weight account for the variance in obstetrical practices for women with GDM (Johnstone et al. 1996).

Optimal Delivery Time

Timing of delivery is also a challenging topic in GDM, as there is limited quality evidence to support universal guidelines. Delivery practices vary by institution and type of GDM (Gestational Diabetes Mellitus 2018). In Class A1GDM, the timing of delivery should not occur before 39 weeks unless other obstetric complications arise, and expectant management can be utilized through 40 6/7 weeks (Gestational Diabetes Mellitus 2018; Hod et al. 2015). However, some argue that earlier delivery may be indicated when fetal weight is estimated to be greater than 4000 g due to increased risk of shoulder dystocia and subsequent neonatal morbidity (Hod et al. 2015). As previously mentioned, ultrasound's inherent limitations in estimating fetal weight account for discrepancies in its utilization for delivery, and the advantages of this delivery strategy are still debated (Rouse et al. 1997). Clinicians are encouraged to discuss the benefits and risks of elective scheduled deliveries, including cesarean delivery, when there is estimated fetal macrosomia (American College of Obstetricians and Gynecologists' Committee on Practice Bulletins—Obstetrics 2016). For late-term or post-term Class A1GDM pregnancies, induction can be considered to reduce neonatal mortality and maternal morbidity associated with increased cesarean rates (Middleton et al. 2018).

In Class A2GDM that is well controlled, delivery can be considered between 39 0/7 and 39 6/7 weeks (Gestational Diabetes Mellitus 2018). Labor before 40 weeks in women requiring pharmacologic management for GDM may be associated with lower incidence of shoulder dystocia (Lurie et al. 1996). However, management is less clear for women with poorly controlled Class A2GDM, and practices may vary between clinicians and patients (Valent and Caughey 2016). Delivery between 37 0/7 and 38 6/7 weeks may be warranted in these patients (Gestational Diabetes Mellitus 2018). Earlier deliveries in the late preterm should be limited to patients in which aggressive attempts of achieving euglycemia, such as in-hospital therapy, have failed (Gestational Diabetes Mellitus 2018).

Intrapartum Glucose Homeostasis

Intrapartum glycemic monitoring is also necessary in women with GDM in order to avoid neonatal hypoglycemia and associated morbidities that may be caused by maternal hyperglycemia during labor (Ryan and Al-Agha 2013). Class A1GDM women can often be monitored during parturition without the need for additional pharmacologic management for glycemic control (Ryan and Al-Agha 2013). However, women with Class A2GDM often require intrapartum monitoring and pharmacologic intervention, but there is no consensus on specific practices. A recent randomized control trial found that tight maternal glucose control did not result in better outcomes when compared to more liberalized maternal management that allowed for higher maternal glucose levels and less frequent glucose measurements (Hamel et al. 2019). Recommendations from the International Federation of Gynecology and Obstetrics for these women suggest maternal glucose levels of 72–126 mg/dL during labor and delivery to avoid adverse outcomes such as neonatal hypoglycemia, birth asphyxia, and nonreassuring heart rate tracings (Hod et al. 2015).

Complications and Follow Up

Because GDM arises later in pregnancy after organogenesis, it is not associated with the same risks of congenital malformations as pre-existing diabetes (Nold and Georgieff 2004). However, GDM is associated with several short-term and long-term consequences in the fetus and subsequent neonate. The most established ramifications of GDM include large for gestational age, defined as fetal or neonatal weight at or above the 90th percentile for gestational age, and macrosomia, often defined as birth weight greater than or equal to 4500 g (Practice Bulletin No. 173 Summary 2016; Mitanchez 2010). From a physiologic standpoint, this is thought to be due to an increased transplacental transfer of glucose, leading to increased fetal substrate uptake and fetal hyperinsulinemia (Hod et al. 2015). Figure 36.1 highlights the pathophysiology of maternal hypoglycemia on adverse fetal outcomes, including LGA and macrosomia (Hod et al. 2015). In the international, multicenter HAPO study, researchers found that with increasing maternal glucose levels, the frequency of large for gestational age infants increased as well (HAPO Study Cooperative Research Group 2008).

Furthermore, multiple studies have found that increasing maternal hyperglycemia is associated with macrosomia, LGA, and the secondary outcomes associated with macrosomic fetuses such as operative deliveries, postpartum hemorrhage, shoulder dystocia, brachial plexus injury, birth canal tears, and maternal and fetal morbidity (Hod et al. 2015; Kwik et al. 2007; Lazer et al. 1986). However, LGA and macrosomia are multifactorial and are influenced by other factors, such as maternal weight gain. In one study looking at the effects of maternal glucose levels and weight gain on fetal macrosomia risk, 29.3% of women with GDM who gained more than

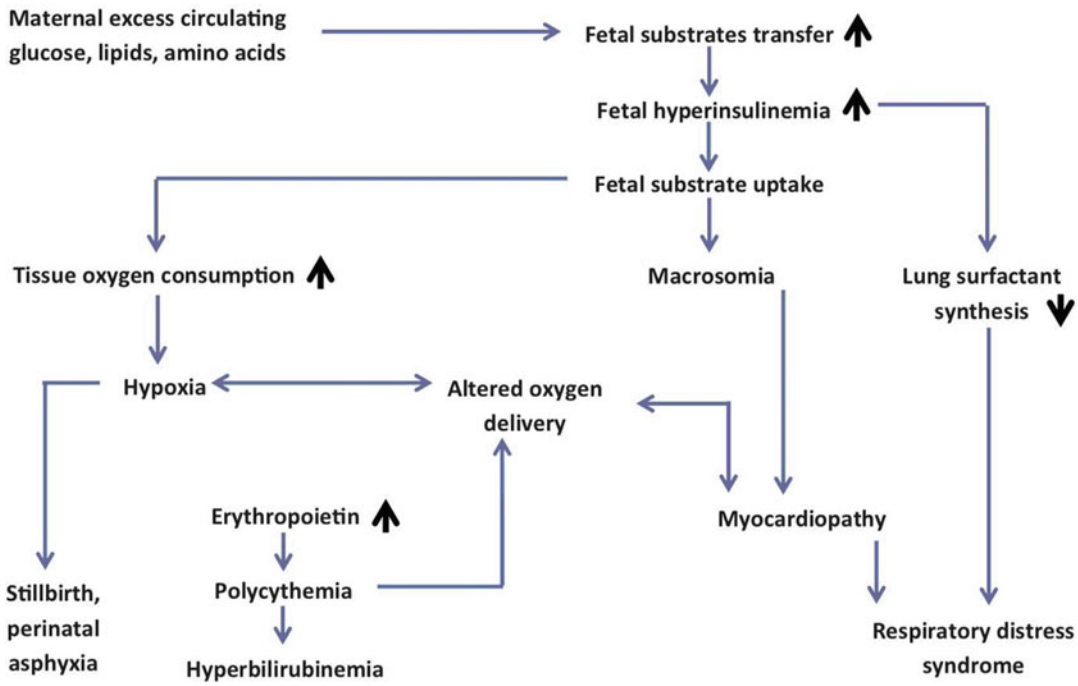

Fig. 36.1 Fetal and neonatal complications arising from intrauterine exposure to maternal hyperglycemia (Modified from: Hod M, Kapur A, Sacks DA, Hadar E, Agarwal M, Di Renzo GC, Cabero Roura L, McIntyre HD, Morris JL, Divakar H. The International Federation of Gynecology and Obstetrics (FIGO) Initiative on gestational diabetes mellitus: A pragmatic guide for diagnosis, management, and care. Int J Gynaecol Obstet. 2015;131 (Suppl 3):S173–211)

40 pounds had a macrosomic newborn compared to only 13.5% of women with GDM who gained appropriate pregnancy weight (Hillier et al. 2009). While confounding factors may influence the association between GDM and fetal size, maternal hyperglycemia remains an important risk factor for LGA and macrosomia.

Additional Neonatal Aberrations

Morbidities associated with GDM include fetal hyperinsulinemia and beta cell hyperplasia, neonatal hyperbilirubinemia, hypoglycemia, polycythemia, and increased intensive neonatal care (HAPO Study Cooperative Research Group 2008; Turok et al. 2003; Hod et al. 2015). Respiratory distress in neonates has also been reported as a complication to GDM in some studies, but the ALPS trial argues that newborns of GDM mothers were not more likely to have severe respiratory complications (Hod et al. 2015; Werner et al. 2018). Similarly, some studies argue that there is an increased risk of stillbirth in GDM mothers, but the association with maternal hyperglycemia is debated (Gestational Diabetes Mellitus 2018).

Long-Term Complications

These include higher risks of obesity, impaired glucose metabolism, and diabetes later in life. Some postulate that this occurs through epigenetic changes in developmental programming. Fetal exposure to maternal hyperglycemia in utero can lead to modification of phenotypic expression in newly formed cells, and in the third trimester, this can lead to aberrant proliferation of fetal adipocytes and muscle cells along with hyperplasia of pancreatic beta cells and neuroendocrine cells. Some argue this physiologic basis to the long-term effects is seen in offspring born to GDM mothers (Hod et al. 2015).

Maternal Complications

Women with GDM are at increased risk of developing pre-eclampsia with increasing risks at higher levels of maternal hyperglycemia (HAPO Study Cooperative Research Group 2008; Joffe et al. 1998). There are risks for developing hypertensive disorders during pregnancy, even after adjusting for potential confounding factors (Joffe et al. 1998). Cesarean delivery is another potential maternal morbidity with 25% of GDM mothers who require pharmacologic therapy undergoing cesarean delivery compared to 9.5% of controls (Gestational Diabetes Mellitus 2018). However, potentially the most concerning maternal consequences of GDM are the long-term associations with cardiometabolic disorders. In women with a previous diagnosis of GDM, 32.9% went on to develop metabolic syndrome within 5–10 years (Varner et al. 2017). Additionally, a history of GDM has been established as a risk factor tor types 1 and 2 diabetes. One study found that younger ages, the need for pharmacologic management, and positivity of autoantibodies in women with GDM predicted a higher risk of subsequent progression to type 1 diabetes (Jarvela et al. 2006).

Type 2 diabetes is a well-known consequence of GDM, with an incidence of almost 20% after 9 years and an estimated 70% within 22–28 years (Feig et al. 2008; Gestational Diabetes Mellitus 2018). Obesity intensifies this risk, as it does in the general population (Baptiste-Roberts et al. 2009). GDM has also been found to be an independent risk factor for long-term cardiovascular morbidity (Kessous et al. 2013).

Diagnostic Work Up and Long-Term Care

Following delivery, screening for diabetes, impaired fasting glucose levels, and impaired glucose tolerance is recommended in all women

with GDM between 4–12 weeks postpartum (Gestational Diabetes Mellitus 2018). This is generally done through a fasting plasma glucose and 75-g, 2-h oral glucose tolerance test (Gestational Diabetes Mellitus 2018). Follow up is critical in identifying these women, as many randomized controlled trials have shown the benefit of early interventions such as diet and exercise or pharmacologic therapy, in delaying or preventing type 2 diabetes in women with abnormal glucose tolerance (Kitzmiller et al. 2007). Additionally, women with GDM who have persistent undiagnosed hyperglycemia have high risks in additional pregnancies, including major congenital malformations with maternal hyperglycemia during the first trimester. These risks can be mitigated by early preconception treatment (Kitzmiller et al. 2007). Long-term follow up is essential, and testing is recommended every 1–3 years if initial oral glucose tolerance testing is normal (American Diabetes Association 2018b). However, while routine follow up is critical in recognizing women who have progressed to diabetes, other therapies are available to intervene before diabetes develops.

In a randomized, controlled clinical trial, both metformin and intensive lifestyle therapies were found to be efficacious in reducing the incidence of diabetes by approximately 50%, in women reporting a history of GDM (Ratner et al. 2008). Lifestyle changes may also be effective in reducing future cardiovascular morbidity as well (Kitzmiller et al. 2007). Finally, women with a history of GDM should be counseled on the importance of breastfeeding and its protective role in preventing childhood obesity and maternal diabetes (Hod et al. 2015). Ultimately, a multidisciplinary approach between obstetricians, family physicians, internists, pediatricians, and other health care providers is needed to optimize long-term health outcomes in these women.

Ongoing Studies and Future Directions

Research is still needed in stratification of risk factors to adequately determine high-risk patients who need early pregnancy screening. Additionally, the need exists to develop portable and low-cost point of care testing strategies, to make universal screening for GDM a realistic possibility in areas with limited resources, and the US Preventive Services Task Force maintains that there is a need to look for screening methods that are simpler to use than the current recommendations, such as glycosylated hemoglobin measurement (Final Recommendation Statement [Internet] 2019). Intervention studies regarding optimal glucose control for best outcomes, and pharmacologic studies identifying the efficacy and long-term effects of glucose medications are other areas of future research. Long-term cohort studies following both women with GDM and their children are advised, to determine longitudinal repercussions of diabetes in pregnancy.

Current research being published from the ADA seeks to address many of these issues, such as the effectiveness of metformin in GDM to the economic burden of GDM. Meanwhile, other organizations, such as FIGO, highlight many of the aforementioned research needs, alongside appeals for greater international research collaboration to address these knowledge gaps (Hod et al. 2015).

Abstract

It has long been recognized that diabetes is associated with a high cardiovascular risk, although this is not the same in all patients. Diabetes frequently coexists with other risk factors that will enhance this cardiovascular risk, including hypertension, dyslipidemia, and platelet dysfunction. Treatment of all these risk factors is essential to lower the risk in both primary and secondary cardiovascular prevention settings. The choice of antidiabetic agent may also impact this risk, as some classes have been shown to decrease cardiovascular mortality and others will increase the risk of

Introduction

It has always been recognized that patients with diabetes have a higher risk of vascular disease, especially cardiovascular complications. These complications are the main cause of death (Dal Canto et al. 2019). Adults with diabetes have 2–4 times increased cardiovascular risk compared to adults without diabetes, despite falling mortality rates in both groups (Rawshani et al. 2018). This trend in reduction in mortality rates is present especially in high-income countries, but not as clear in the middle-to-low-income countries (Dal Canto et al. 2019). On average at the age of 60, patients with diabetes and no cardiovascular disease will have a life expectancy of 6 years less, and those with diabetes and cardiovascular disease will have a 12-year shorter life expectancy (The Emerging Risk Factor Collaboration 2015). This increased risk will be present in patients either with type 1 or type 2 diabetes, and some reports indicate that the relative risk is even higher for type 1 diabetes (Lee et al. 2019).

Since the report by Haffner et al. (1998), diabetes has been considered a high cardiovascular risk group similar to a nondiabetic secondary prevention group. However, other studies have challenged this concept (Afkarian et al. 2016; Schneider et al. 2016). Although patients with diabetes have a higher cardiovascular risk compared to patients without diabetes, this risk can vary with each patient.

High-Risk Groups

Several characteristics will identify subgroups that have a higher risk. These include the presence of microvascular complications such as retinopathy (Sabanayagam et al. 2019), microalbuminuria (Ninomiya et al. 2009), chronic kidney disease (glomerular filtration rate of less than 60 cm^3/min) (Afkarian et al. 2016; Sabanayagam et al. 2019), smoking (Rawshani et al. 2018), and suffering from diabetes for more than 15 years (Hu et al. 2001). Most of these risk groups will also have microvascular alterations that will further increase the risk of macrovascular complications. Recent guidelines support this, recommending risk stratification within patients with diabetes that will tailor treatment goals (Consentino et al. 2019).

There are several reasons as to why patients with diabetes have a higher cardiovascular risk. First, insulin resistance may lay common pathways that will lead to hypertension, diabetes, and cardiovascular disease. Therefore, there is a very close link between hypertension and diabetes. Long-term hyperglycemia may lead not only to microvascular disease but also to changes in the vascular bed, inflammation, lipid oxidation, and an accelerated atherosclerotic process. Additionally, patients with diabetes may develop diabetic cardiomyopathy that will further increase the risk of cardiovascular disease and heart failure. Furthermore, platelet dysfunction is common in patients with diabetes mellitus, and this increases the risk of atherothrombosis and cardiovascular events.

Hypertension

Around 50–80% of patients with diabetes also have hypertension (Chen-Ku et al. 2019; Whelton et al. 2018). Hypertension is a strong factor that increases cardiovascular risk.

Wang et al. (2017) demonstrated that patients with higher insulin levels (as a marker of insulin resistance) have a higher prevalence of hypertension. Insulin resistance will lead to arterial stiffness due to the deposition of extracellular matrix in the artery walls. Smooth muscle cells will generate more reactive oxygen species that will lead to endothelial dysfunction, and there is also an activation of the renin angiotensin system in adipocytes (D'Elia and Strazzullo 2018).

Several proposed mechanisms may link hypertension and diabetes. Insulin resistance leads to an increase in the sympathetic tone, which causes an increase in heart rate, cardiac output, and vascular resistance. Furthermore, there is some evidence that renal tubular cells will have a higher expression of SGLT-2 cotransporters that will lead to a higher sodium retention. This increase of sympathetic tone may lead to an activation of the renin angiotensin system, with higher levels of angiotensin II that will promote vasoconstriction, myocardial fibrosis, salt and water retention.

Additionally, chronic stress may also lead to increased sympathetic activity. The stimuli of alpha 1 receptors generate water and salt retention and insulin resistance. Furthermore, stimuli of alpha 2 receptors in the pancreas will inhibit insulin secretion, which may lead to hyperglycemia. An increased sympathetic tone will enhance ventricular ejection force increasing blood pressure, and if this is sustained for more than 48 h, it can lead to an adaptation of baroreceptors and therefore chronic hypertension (Saxena et al. 2018).

Some studies have shown that in renal tubular cells, intracellular hyperglycemia will increase SGLT-2 expression. A higher-salt diet will also increase tubular SGLT-2 expression (Elliott et al. 2016). Renal tubular cells will increase SGLT2 expression when exposed to norepinephrine, at least in in vitro models. An increase in SGLT2 activity will lead to greater tubular sodium and glucose reabsorption, an additional mechanism that links hypertension and diabetes.

Patients with diabetes are more salt sensitive than healthy adults. Renal response to insulin is maintained in insulin-resistance states, leading to greater renal sodium reabsorption (Uzu 2017).

All of these mechanisms may explain the close correlation between diabetes and hypertension. Hypertension will accelerate the development and progression of microvascular disease (UKPDS 1998). Also, hypertension is a risk factor for vascular complications in diabetes, as patients diagnosed with diabetes and hypertension will have a higher risk of cardiovascular and cerebrovascular complications, along with heart failure (Rawshani et al. 2018). Peripheral artery disease is another vascular complication associated with the presence of hypertension (Mohammedi et al. 2016).

Dyslipidemia

The usual lipid profile that presents in patients with insulin resistance and diabetes is characterized by high triglycerides, low HDL, and an increase in small dense LDL particles. This is also called atherogenic dyslipidemia. In insulin-resistance states, there is a higher efflux of free fatty acids from adipocytes and, under these stimuli, hepatic VLDL production is increased. Since insulin is a coactivator of lipoprotein lipase, when there is insulin resistance there is a decrease in the activity of this enzyme. The increased number of triglyceride-rich lipoproteins competes for a saturable process of lipoproteinlipase-mediated clearance, leading to a greater number of remnant lipoproteins particles (Stahel et al. 2018). Meanwhile, hepatic lipase activity is not affected and it will hydrolyze triglycerides and phospholipids of these remnants, leading to smaller, denser particles of VLDL, VLDL remnants, and LDL, which are more atherogenic (Miksztowicz et al. 2012). On the other hand, there is an increased cholesterol ester transfer protein (CETP)-mediated lipid exchange between HDL and VLDL particles, leading to triglyceride enrichment of VLDL particles, which is a preferred substrate by hepatic lipase, yielding HDL remnants that are cleared by renal glomerular filtration leading to low HDL levels (Stahel et al. 2018).

Diabetes is also characterized as a state of increased production of reactive oxygen species that will oxidize LDL particles, making them more atherogenic. Oxidized LDL particles are easily captured by macrophages, leading to the development and progression of the atherosclerotic plaque. Higher levels of angiotensin II and sympathetic activity will also contribute to the

generation of reactive oxygen species (Low Wang et al. 2016).

The role of dyslipidemia in microvascular complications is controversial. The data that support that dyslipidemia treatment will decrease the progression of microvascular complications is not very clear yet. On the other hand, the evidence in favor of statins in cardiovascular and cerebrovascular complications is very clear and strong.

Diabetic Cardiomyopathy

Diabetic cardiomyopathy is defined as the presence of a myocardial structural or functional abnormality in the absence of hypertension, atherosclerotic, or valvular disease. A more recent definition by the American Heart Association and the European Society of Cardiology states that it is a clinical condition, where there is ventricular dysfunction without coronary atherosclerosis and hypertension (Jia et al. 2018). This makes the clinical diagnosis of this entity difficult since the absence of atherosclerosis must be demonstrated, and this often requires invasive tests. Therefore, the true prevalence of diabetic cardiomyopathy is unknown.

Several pathophysiologic mechanisms may explain this condition. Two of the most accepted mechanisms are related to insulin resistance and hyperglycemia. Insulin resistance, as stated previously, will lead to higher levels of free fatty acids (FFA). These FFA will lead to the activation of different pathways, including ceramides that will generate cardiac hypertrophy. Hyperglycemia, through different mechanisms, including the polyol pathways, may promote myocyte proliferation and hypertrophy.

The classic paradigm states that diabetic cardiomyopathy will present initially as diastolic dysfunction (heart failure with preserved ejection fraction), and later will progress to dilation of the left ventricle and a fall in cardiac output (heart failure with reduced ejection fraction). It has long been recognized that patients with diabetes will have a higher risk of heart failure, and this risk is related to both disease duration and degree of hyperglycemia (Erqou et al. 2013). When we look at the data from the cardiovascular outcome trials, it has been shown that heart failure hospitalization rates were at least the same or even more frequent as the rates of ischemic strokes, cardiovascular deaths, or noncardiovascular deaths (Wiviott et al. 2019). Recent trials have also shown that SGLT-2 inhibitors have a great impact on heart failure, and this has raised the awareness and discussion of the importance of heart failure in patients with diabetes.

There are several mechanisms by which hyperglycemia may lead to contractile dysfunction (Zamora and Villena 2019):

- Hexosamine biosynthetic pathway leading to prolonged calcium transients.
- Activation of the protein kinase pathway that will promote cardiac hypertrophy.
- Advanced glycosylation end products pathway with an increase in RAGE expression that promotes oxidative stress, the formation of irreversible crosslinks, fibrosis, collagen deposition, production of inflammatory cytokines and growth factors.
- Polyol flux pathway that will end up in cell apoptosis.

In insulin-resistance states, there is higher free fatty acid efflux from the adipose tissue, leading to a higher fatty acid oxidation in the myocardium. An increase in mitochondrial activity will increase reactive oxygen species formation, and thus, increasing angiotensin I receptor expression (Zamora and Villena 2019).

Platelet Dysfunction

There are several mechanisms by which platelets are dysfunctional in patients with diabetes mellitus, and these mechanisms may also contribute to a higher rate of atherothrombotic events compared to patients without diabetes (Ferreiro and Angiolillo 2011):

- Hyperglycemia may lead to P-selectin expression, activation of PKC and decreased membrane fluidity, by glycation of surface proteins.
- Deficient insulin action by insulin resistance may lead to impaired response to nitric oxide and PGI2 and increased intracellular calcium.
- Associated conditions such as obesity, dyslipidemia, and inflammation may lead to platelet activation.
- There is also upregulation of $P2Y_{12}$ signaling and oxidative stress.

Clinical Features of Vascular Disease in Patients with Diabetes Mellitus

Atherosclerotic Disease

Hypertension and atherogenic dyslipidemia will lead to an accelerated atherosclerotic process and a higher risk of myocardial infarction, stroke, and peripheral artery disease. The burden of disease is not only greater, but it will also be present at a younger age. Other traditional risk factors such as smoking will further enhance this risk. Clinical presentation of atherosclerosis may differ from that of patients without diabetes.

It has also been demonstrated that patients with any profile of vascular disease will have a higher risk of developing vascular diseases in other beds. There is a high frequency of coexistence of different vascular diseases, such as coronary and cerebrovascular disease (Steg et al. 2007).

Coronary Artery Disease

Coronary artery disease may present classically as stable angina, unstable angina, or myocardial infarction. Silent ischemia is more frequent in patients with diabetes compared to the general population. Also, plaque burden tends to be more diffuse. When revascularized, the rate of restenosis is greater and faster in patients with diabetes (Makrilakis and Liatis 2017).

As mentioned previously, some patients with diabetes are at higher risk of coronary artery disease. These circumstances are called risk enhancers and they are outlined in Table 37.1 (Grundy et al. 2019a).

Guidelines do not support routine screening of coronary artery disease either with a stress test, coronary angiogram, or CT angiography if the patient is asymptomatic. In asymptomatic patients, the way to prevent cardiovascular disease is to have a very strict risk factor control, which will be discussed later on.

Clinical suspicion for coronary disease should be very high. Since patients with diabetes can present with silent ischemia, the presence of dyspnea or heart failure obliges to rule out coronary disease. Also, the frequency of atypical chest pain is greater. Therefore, all chest pain in patients with diabetes makes it mandatory to rule out the presence of coronary artery disease.

Cerebrovascular Disease

Strokes are one of the leading causes of morbidity and mortality in patients with diabetes mellitus (Rawshani et al. 2018). Patients with diabetes

Table 37.1 Risk enhancers for coronary artery disease in patients with diabetes mellitus

Long duration of diabetes (≥10 years for patients with type 2 diabetes mellitus or ≥20 years for type 1 diabetes mellitus)
Albuminuria ≥30 μg of albumin/mg of creatinine
Estimated glomerular filtration rate <60 mL/min/1.73 m^2
Retinopathy
Neuropathy
Ankle brachial index (ABI) <0.9

mellitus have a higher risk of stroke and this is considered in risk scores such as CHA_2DS_2-VASc (Lip et al. 2010). This risk is further enhanced especially by the presence of hypertension, and to a lesser extent dyslipidemia.

Stroke treatment does not differ. Whenever possible, thrombolysis should be performed in ischemic stroke.

Regarding stroke prevention, if the patient has atrial fibrillation, diabetes mellitus, and an additional risk factor, anticoagulation is recommended. Otherwise, stroke prevention should follow guidelines as in the general population, where blood pressure and lipid control are essential.

Peripheral Artery Disease

The risk of peripheral artery disease is inherently higher in patients with diabetes mellitus. The presence of this condition increases the risk of complications associated with diabetic foot disease, lower-extremity amputation, cardiovascular disease, and mortality (Nativel et al. 2018). When defined by abnormal ankle brachial index (ABI), its prevalence may be up to 20% (Selvin and Erlinger 2004), becoming greater with advanced age and diabetes duration.

A small percentage of patients with peripheral artery disease presents with intermittent claudication. In some patients, these symptoms may be confounded with those of diabetic neuropathy and other conditions such as statin-associated myopathy. The symptoms of intermittent claudication may not always be as classically described, and sometimes it may be only lower-extremity myalgia. Any deterioration of either walking quality or speed, as well as fatigue, pain, cramps, discomfort or burns in buttocks, thighs, calves, or feet should raise the suspicion of peripheral artery disease, especially when triggered by exercise and quickly relieved with rest (Nativel et al. 2018).

Different guidelines recommend peripheral artery disease screening, initially with an exhaustive interview, and palpation of pedal pulses (American Diabetes Association 2020). The first line of noninvasive tests when signs or symptoms of lower-extremity artery disease become present, should be the brachial-ankle index. This is a very simple, low-cost test that may be performed in the office and should be conducted at least once a year. If ABI is less than 0.90, it is highly suspicious of peripheral artery disease. The lower the index, the more critical the obstruction. ABI of over 1.4 is also considered abnormal indicating calcified and stiffened arteries. If a low ABI is present, hypertension and lipid treatment goals will change, as this will deem the patient as having a higher risk of other atherosclerotic vascular events (Grundy et al. 2019a; American Diabetes Association 2020).

Treatment

To prevent cardiovascular risk in primary prevention, or lower the risk of a new vascular event in secondary prevention, the main objectives are to control risk factors, including smoking, hypertension, dyslipidemia, and glucose homeostasis.

Lifestyle Modification

Lifestyle modification is the initial approach in all patients with diabetes mellitus, regardless of cardiovascular risk, presence of microvascular complications, or duration of diabetes. However, there have been few trials that have evaluated the impact of lifestyle intervention in cardiovascular endpoints. UKPDS compared intensive pharmacologic intervention with conventional lifestyle intervention, achieving a difference in glucose control favoring pharmacologic intervention. Yet the achieved reduction in cardiovascular events in favor of the pharmacologic intervention group is not evidence that lifestyle interventions are ineffective (UK Prospective Diabetes Study (UKPDS) Group 1998a).

LOOKAHEAD (2007) showed that patients treated with intensive lifestyle modifications achieved an initial reduction in weight and waist circumference, which was paired with an improvement in glucose and blood pressure

control. However, this was not sustained in the long term and therefore it was not associated with a decrease in cardiovascular disease. However, the group that was treated with intensive lifestyle modifications required fewer medications (statins, antihypertensive drugs) to achieve different targets (Look AHEAD Research Group 2013).

Hypertension

Early studies have shown that lowering blood pressure will decrease not only cardiovascular disease but also any diabetes-related endpoint (Emdin et al. 2015). It seems that from a cardiovascular perspective, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARB), diuretics, calcium channel blockers, and beta blockers have similar efficacy in reducing cardiovascular events. However, there may be small differences as shown in some meta-analyses, where thiazides are more effective in decreasing heart failure and stroke risk, calcium channel blockers may increase heart failure risk (compared to ACE inhibitors or ARB), and ACE inhibitors and ARB are more effective than beta blockers in stroke and cardiovascular events (Chen et al. 2018).

What has long been debated is the blood pressure treatment goal. Guidelines recommend different targets, especially of systolic blood pressure. Table 37.2 summarizes the blood pressure targets recommended by different professional groups.

Few trials have directly compared blood pressure targets specifically in patients with diabetes. Most data are derived from subgroup analysis. In the UKPDS (1998), lower blood pressure was associated with a lower risk of any diabetes-related endpoints, including cardiovascular disease. However, this lower blood pressure group achieved on average 144/82 mmHg, compared to the less intensive group (154/87 mmHg). In the ACCORD-BP trial, a systolic blood pressure target of 140 mmHg is mentioned, as compared to a target of 120 mmHg. Overall, no difference was observed in cardiovascular events except a slightly lower rate of stroke in the lower blood pressure target group, however, with a higher risk of adverse events, including renal failure and postural hypotension (ACCORD Study Group 2010a).

A meta-analysis (Emdin et al. 2015) has focused on the benefits of starting antihypertensive drugs if initial systolic blood pressure was greater than 140 mmHg compared to less than 140 mmHg. In general, if antihypertensive drugs are started when systolic blood pressure is less than 140 mmHg, only the risk of stroke and development of microalbuminuria were decreased. No difference was observed in myocardial infarction, heart failure, or other cardiovascular events.

Table 37.2 Blood pressure treatment goals recommended by different professional groups

American Diabetes Association (2020)	
High cardiovascular risk (existing atherosclerotic cardiovascular disease or 10-year atherosclerotic disease risk ≥15%)	<130/80 mmHg
Lower cardiovascular disease (10-year atherosclerotic cardiovascular risk <15%	<140/90 mmHg
American Association of Clinical Endocrinologists (AACE) (2019)	
Patients with diabetes mellitus	<130/80 mmHg
European Society of Cardiology (2019)	
Patients with diabetes mellitus	120–130 mgHg Systolic blood pressure, diastolic 70–80 mmHg
Older people (>65 years)	Systolic 130–139 mmHg
Patients at high risk of a cerebrovascular event	Systolic <130 mmHg
American College of Cardiology/American Heart Association (2018)	
Patients with diabetes mellitus	<130/80 mmHg

State of Art

If we want to summarize current treatment recommendations, a blood pressure of less than 140/90 mmHg is recommended for most patients with diabetes mellitus. For those at higher risk such as secondary prevention or having multiple cardiovascular risk factors, a target of less than 130/80 mmHg should be adopted. If overt proteinuria is present, even lower blood pressure targets may be recommended to decrease the magnitude of proteinuria. Therefore, there is not one single blood pressure cutoff point, and this should be individualized.

There is very scarce evidence regarding blood pressure goals in patients over 80 years of age. The only trial performed specifically in this group, the HYVET trial, reached a blood pressure goal of 150/90, and this was associated with a reduction in mortality and cardiovascular events (Beckett et al. 2008). Current guidelines do not make different recommendations based on patient age.

Dyslipidemia

Statins are the gold standard in lipid-lowering therapies. They have been demonstrated to be efficacious in primary and secondary cardiovascular disease prevention (Costa et al. 2006), and the benefit does not differ in patients with diabetes compared to the general population (Cholesterol Treatment Trialists' (CTT) Collaborators 2008).

In primary prevention, CARDS (2004) and HPS-diabetes (2003) included patients with diabetes over 40 years of age with an additional risk factor such as retinopathy, microalbuminuria, hypertension, or smoking. In both of these trials, intervention with either atorvastatin in a dose of 10 mg daily or simvastatin in a dose of 40 mg daily, respectively, decreased the rate of major adverse cardiovascular events (MACE).

In secondary prevention, subgroup analysis of trials (2010) that compared high-intensity versus low-intensity statin showed that patients with diabetes had benefits similar to patients without diabetes.

In the IMPROVE-IT trial (2018), high-risk patients treated with ezetimibe combined with simvastatin compared to simvastatin monotherapy demonstrated a reduction in MACE. Subgroup analysis showed some heterogeneity, where patients with diabetes showed a greater reduction in MACE compared to patients without diabetes. So, it seems that patients with diabetes may derive greater benefits from this combination. However, we must interpret these data with caution since it is a subgroup analysis.

Fibrate Combination

Much has been debated about the role of fibrates either as monotherapy or combined with statins in patients with diabetes. It seems very straightforward that if typical dyslipidemia associated with diabetes is characterized by high triglycerides and low HDL, fibrates should confer beneficial cardiovascular effects. In the FIELD trial (2005), fenofibrate compared to placebo, had the same rate of cardiovascular events. However, there was greater use of statins in the placebo group compared to the fenofibrate group, and this may have attenuated the differences and final cardiovascular results. In the ACCORD-lipid trial (2010b), fenofibrate combined with simvastatin was compared to simvastatin monotherapy and did not show a significant difference in cardiovascular events. Once again, subgroup analysis showed heterogeneity and some benefit, in those patients whose initial triglycerides levels were over 204 mg/dL and HDL of less than 34 mg/dL. On an individual basis, each one of these trials did not show a statistically significant reduction in cardiovascular disease. However, a Cochrane systematic review concluded that fibrates were associated with a slight decrease in cardiovascular events, although not in total mortality (Jakob et al. 2016). Currently, several trials are evaluating the benefit of fenofibrate combined with statin specifically in patients with diabetes, high triglyceride, and low HDL levels.

Omega 3 Fatty Acids

The REDUCE-IT (2019a) trial evaluated the use of a dose of 2 g twice a day of icosanpent ethyl compared to placebo in patients at high cardiovascular risk already taking statins, with high triglycerides (135–500 mg/dL), low HDL (less than 40 mg/dL), and LDL below 100 mg/dL, and showed a decrease in cardiovascular events.

Subgroup analysis of the cardiovascular trials with PCSK9 inhibitors alirocumab and evolocumab (Sabatine et al. 2017) in secondary prevention showed the same benefit in patients with diabetes as in the general population.

State of the Art

Guidelines recommend different LDL targets based on different risks in patients with diabetes (Table 37.3). In those patients without microvascular disease and long-standing diabetes (less than 10 years in type 2 diabetes and 20 years in type 1 diabetes), LDL of less than 100 mg/dL is recommended. In those with microvascular disease and/or long disease duration LDL, the target of less than 70 mg/dL should be sought after. If the patient has an established cardiovascular disease or multiple uncontrolled risk factors or chronic kidney disease, LDL less than 55 mg/dL is recommended. Initial therapy should be statins, and if on the maximally tolerated dose, ezetimibe can be added and then a PCSK9 inhibitor.

Antiplatelet Therapies

Patients with diabetes mellitus have higher platelet reactivity and are also prone to thrombotic events that contribute to their higher atherosclerotic cardiovascular risk. Despite this

Table 37.3 Lipid management recommendations by different professional groups

American Diabetes Association (2020)	
Patients with a 10-year atherosclerotic cardiovascular risk >20%	High-intensity statin (to achieve an LDL reduction of >50%)
40–75 years and those over 75 years without atherosclerotic cardiovascular disease	Moderate-intensity statin (to achieve an LDL reduction of 30–50%)
Patients with atherosclerotic cardiovascular disease on a statin with controlled LDL but with elevated triglycerides (135–499 mg/dL)	Add eicosapent ethyl to statin therapy
American Association of Clinical Endocrinologists (2019)	
Extreme risk (diabetes and established clinical cardiovascular disease)	LDL less than 55 mg/dL, apoB <70 mg/dL
Very high risk (diabetes plus major atherosclerotic risk factor such as hypertension, family history, low HDL, smoking or CKD 3/4)	LDL less than 70 mg/dL, apoB <80 mg/dL
High risk (diabetes without other major risk and/or age less than 40)	LDL <100 mg/dL, apoB <90 mg/dL
European Society of Cardiology (2019)	
Very high risk (atherosclerotic cardiovascular disease either clinical or by imaging, diabetes, and target organ damage, >2 risk factors, early onset of type 1 diabetes of long duration, over 20 years)	LDL less than 55 mg/dL
High risk (diabetes without target organ damage, with diabetes of more than 10 years or other additional risk factors, CKD stage 3)	LDL less than 70 mg/dL
Moderate (young patients with diabetes, T1DM less than 35 years, T2DM less than 50 years with duration of diabetes fewer than 10 years without other risk factors)	LDL less than 100 mg/dL
American College of Cardiology/American Heart Association (2019b)	
In patients with atherosclerotic cardiovascular disease	High-intensity statin to lower LDL >50%
Very high-risk patients (history of multiple atherosclerotic cardiovascular diseases or 1 major atherosclerotic disease plus multiple high-risk conditions such as diabetes)	LDL <70 mg/dL
Patients with diabetes and 40–75 years of age and LDL over 70 mg/dL	Start moderate-intensity statin
Patients with diabetes and 40–75 years of age and LDL over 70 mg/dL at higher risk, especially those with multiple risk factors or those 50–75 years of age	Start high-intensity statin therapy

pathophysiologic mechanism, various recent meta-analyses and trials have shown that aspirin is ineffective in decreasing total mortality and cardiovascular deaths in primary prevention, although there is a slight decrease in myocardial infarction, transient ischemic attack, and stroke. However, there is a higher risk of major bleeding, intracranial bleeding, and gastrointestinal bleeding (Abdelaziz et al. 2019). Therefore, current guidelines do not recommend the routine use of antiplatelet therapy in diabetes, except in patients with multiple risk factors at high risk of cardiovascular events (American Diabetes Association 2020).

In patients with established cardiovascular disease, antiplatelet therapy is effective in decreasing the risk of a new vascular event. A meta-analysis by the antithrombotic Trialist's Collaboration (2009) showed that aspirin was associated with a 20% reduction of major coronary events.

An unanswered question is who should receive dual antiplatelet therapy beyond the first 12 months after cardiac revascularization. The THEMIS-PCI trial (Bhatt et al. 2019b) showed that patients with diabetes and previous percutaneous coronary intervention (PCI), had fewer cardiovascular events when treated long term with aspirin plus ticagrelor; however, patients without PCI did not benefit from this dual therapy. There was no difference in total or cardiovascular mortality. Patients that were treated with dual antiplatelet therapy had a higher risk of major bleeding, and this must be considered when deciding who should receive dual antiplatelet therapy in the long term.

Glucose-Lowering Therapies and Cardiovascular Disease

Glucose Lowering and Cardiovascular Disease

Decreasing Hba1c will lead to a reduction in cardiovascular disease in the long term, however not in the short term. In patients recently diagnosed with either type 1 or type 2 diabetes, UKPDS (2008) and EDIC (2005) showed a reduction in cardiovascular events in the long term. Therefore, glucose control still is important not only to decrease microvascular events but also cardiovascular disease.

In patients with long-term diabetes or established cardiovascular disease, VADT (2009), ACCORD (2008), and ADVANCE (2008) showed that a lower Hba1c target did not decrease cardiovascular events in the short term. When all these trials were pooled in a meta-analysis, it showed that intensive glucose control was associated with a decrease in total coronary heart disease and nonfatal myocardial infarction, however not cardiovascular mortality (Ray et al. 2009). In the ACCORD trial, the intensive treatment group had a higher mortality rate, especially in those patients that started with a higher Hba1c, and who despite multiple treatment optimization strategies were not able to lower Hba1c (Riddle et al. 2010).

Hypoglycemia

One of the caveats of lowering glucose is the risk of hypoglycemia. There have been different studies (Kosiborod et al. 2008) that have shown that hypoglycemia, especially severe hypoglycemia, is associated with a higher rate of cardiovascular mortality. Several mechanisms may explain this link. First, hypoglycemia may lead to electrocardiographic changes, including QT prolongation, and this will make the patient prone to ventricular arrhythmias (Nuryani et al. 2012). Second, during hypoglycemia there is a release of catecholamines, and this may lead to plaque instability and acute coronary events. Third, severe hypoglycemia leads to seizures or loss of consciousness; this may trigger hypoxia, thus precipitating acute coronary events. There is evidence that hypoglycemia in the coronary care unit is associated with chest pain and ECG changes (Desouza et al. 2003). Strategies that lead to lower hypoglycemia risk should be sought, including drug treatment choice, patient education, and dose titration (including insulin and sulfonylureas).

Glucose-Lowering Agents and Cardiovascular Disease

Two classes of drugs have proven to reduce major adverse cardiovascular events and mortality: SGLT2 inhibitors and GLP-1 receptor agonists.

Three SGLT2 inhibitors have been evaluated in cardiovascular outcome trials, empagliflozin, canagliflozin, and dapagliflozin. Inclusion criteria and baseline characteristics differ in these trials and may explain why there are some differences in results. A meta-analysis (Zelniker et al. 2019) showed that overall, in the secondary prevention group, these drugs decreased MACE, especially cardiovascular mortality and heart failure hospitalization. It seems that in patients with multiple risk factors but without established cardiovascular disease, there was no benefit in MACE reduction although there were benefits in heart failure. Also, there were benefits in renal endpoints.

A more recent trial (Perkovic et al. 2019) performed in patients with diabetes and proteinuria showed that canagliflozin 100 mg daily, not only decreased progression of renal disease but also lowered cardiovascular disease, including the primary prevention cohort. In this trial, cardiovascular endpoints were secondary. Dapagliflozin has been recently evaluated in patients with heart failure and an ejection fraction of less than 40%, with and without diabetes, showing a significant reduction in heart failure hospitalization and total mortality. This benefit was observed in patients both with and without diabetes (McMurray et al. 2019).

GLP-1 receptor agonists are a very heterogeneous group. These agents can be classified according to their structure, either based on human GLP-1 (such as liraglutide, semaglutide, albiglutide, or dulaglutide), or based on exendin-4 (exenatide and lixisenatide). Cardiovascular outcome trials have been published with almost all of these agents. Trials with agents based on exendin-4 structure have been neutral in MACE. On the other hand, agents based on human GLP-1 have shown a reduction in MACE and in some of them, all-cause mortality (Marso et al. 2016a, b). Most of these trials have shown benefits in atherosclerotic cardiovascular events, such as myocardial infarction (Hernandez et al. 2018), revascularization (Marso et al. 2016b), and stroke (Marso et al. 2016b; Gerstein et al. 2019) especially in patients at high risk with established cardiovascular disease. The only trial that has shown a benefit in patients in the primary prevention is REWIND with dulaglutide (Gerstein et al. 2019). This is the only trial with enough power to show a benefit in primary prevention settings, and also has had the longest follow up. All GLP-1 receptor agonists have proven to be neutral in heart failure.

Other Antidiabetic Molecules

Metformin is one of the oldest antidiabetic agents. It has been backed up by clinical experience, safety, and low cost. However, there are not that many randomized controlled trials with enough power to evaluate its cardiovascular benefit. UKPDS (1998b) selected patients that were overweight to be randomized to metformin, and not the entire cohort. In this setting, a reduction in myocardial infarction was shown, and this benefit was maintained on the long-term follow-up.

There has been some concern regarding the cardiovascular safety of sulfonylureas since the results of the UGP. Recently, some trials have shown that the newer-generation sulfonylureas seem to be safer. Although not its primary endpoint, in the ADOPT trial (Kahn et al. 2006) in recently diagnosed patients with type 2 diabetes, glyburide had a lower rate of cardiovascular events compared to both metformin and rosiglitazone, although this was mainly due to a lower rate of heart failure. ADVANCE (2008) evaluated a lower Hba1c control based on gliclazide compared to conventional therapy, and the results on cardiovascular endpoints were neutral. TOSCA.IT (2017) randomized patients to pioglitazone or sulfonylureas (mostly glimepiride and gliclazide) and showed comparable rates of cardiovascular events. CAROLINA (2019) was a randomized controlled trial comparing glimepiride and linagliptin, and showed no difference in cardiovascular events. So, it seems that at

least gliclazide and glimepiride are neutral in cardiovascular events and comparable to pioglitazone or a DPP4 inhibitor. However, all of these trials also showed a higher rate of hypoglycemia and weight gain with sulfonylureas.

Thiazolidinediones increase the risk of heart failure. Rosiglitazone, albeit initial concerns about its cardiovascular safety, seems to be neutral. Several studies with pioglitazone have shown some benefit in atherosclerosis compared to glimepiride. The primary endpoint of PROACTIVE (2005), the cardiovascular outcome trial of pioglitazone, did not show any clear benefits. The classic MACE was a secondary endpoint in this trial and showed a statistically significant reduction.

DPP-4 inhibitors have been thoroughly evaluated in cardiovascular outcomes. All of them, either in primary or secondary prevention, have been neutral in cardiovascular events. Saxagliptin in the SAVOR trial (Scirica et al. 2014) showed an increase in heart failure hospitalization and alogliptin in the EXAMINE trial (Zannad et al. 2015) showed the same trend, although it did not reach statistical significance. There is no clear explanation of the reason why these two agents may differ from the other ones in the group and confer a higher risk of heart failure. Subgroup analysis in both of these studies showed that this increase in hospitalization for heart failure was present, especially in those patients with higher baseline NT-proBNP levels and without a known history of heart failure.

Insulin Effects

Despite pathophysiologic mechanisms that may link insulin to an increased risk of cardiovascular events, this has not been supported by trial results. Some preclinical data showed insulin accelerating atherosclerosis, water, and salt retention. No trials have evaluated the cardiovascular safety of human insulins. In the UKPDS (1998a), the treatment with human insulin in order to achieve a lower blood glucose control was associated with a decrease in any diabetes-related endpoints, including cardiovascular disease. However, there was a difference in Hba1c in both groups, so it is impossible to discern if the benefit was due to insulin per se or to glucose control. Insulin glargine was compared to placebo in the ORIGIN trial (2012) and showed to be neutral in cardiovascular events. Insulin degludec was compared to insulin glargine in the DEVOTE trial (Marso et al. 2017) and showed similar cardiovascular results. Although DIGAMI (Malmberg 1997) showed initial benefits in acute coronary syndrome with intravenous insulin treatment, this was a small trial. When a larger cohort was investigated, the results were not replicated (Malmberg et al. 2005). Therefore, it seems that insulin is neutral from a cardiovascular standpoint.

In summary, blood glucose control is important to reduce cardiovascular events in the long term. SGLT-2 inhibitors decrease MACE, cardiovascular mortality, renal endpoints, and heart failure. GLP-1 receptor agonists based on human GLP-1 structure decrease atherosclerotic endpoints and mortality. There is some evidence of cardiovascular benefit with metformin. Pioglitazone, saxagliptin, and it seems that alogliptin as well, may increase heart failure hospitalization. Newer-generation sulfonylureas seem to be neutral in cardiovascular events, and the same applies to DPP4 inhibitors. Upon all this evidence, a recent guideline (Consentino et al. 2019) has moved SGLT-2 inhibitors and GLP-1 receptor agonists as first-line treatment in those patients at high cardiovascular risk or with established cardiovascular disease, instead of metformin. All other guidelines still recommend metformin as first-line therapy, and then SGLT-2 inhibitors or GLP-1 receptor agonists especially in patients with established cardiovascular disease, favoring SGLT-2 inhibitors if there is heart failure or chronic kidney disease.

Multifactorial Intervention

Few trials have evaluated the benefits of multifactorial intervention and cardiovascular outcomes. STENO-2 trial randomized patients with type 2 diabetes and microalbuminuria to two groups, one with a strict multifactorial control (total cholesterol less than 190 mg/dL, triglycerides less than 150 mg/dL, blood pressure less than 140/85 mmHg, Hba1c less than 6.5% and aspirin)

compared to a less strict control (total cholesterol less than 250 mg/dL, triglycerides less than 195 mg/dL, blood pressure less than 160/95 mmHg, Hba1c less than 7.5%, no routine aspirin use). In the initial report, they showed a great reduction in all diabetes-related endpoints, including microvascular and macrovascular disease (Gaede et al. 2003). On follow up, they pointed out a delay of 7.9 years in the median of mortality and 8.1 years in the appearance of cardiovascular events in the intensive control group, with a risk reduction of 62% regarding cardiovascular events (Gaede et al. 2016).

Bariatric and Metabolic Surgery

There is evidence that bariatric surgery is better compared to optimal medical management, not only in diabetes remission but also in cardiovascular risk factors. However, in the STAMPEDE trial, there was no reduction in cardiovascular events in the bariatric surgery group, probably due to the small number of participants (Schauer et al. 2017). Yet major international associations endorse continued attention to bariatric and metabolic interventions, as an important option for all patients with class III obesity (BMI $\geq$40 kg/m^2), with or without overt diabetes, for those with class II obesity and diabetes (BMI 35.0–39.9 kg/m^2) who do not respond to conventional glucose-lowering therapy, and even in case of just class I obesity patients (BMI 30.0–34.9 kg/m^2), for those who are refractory to optimal antidiabetic treatment (BMI cutoff 2.5 kg/m^2 lower for Asian patients, in all categories) (Rubino et al. 2017).

Contents

Abstract

The joint position statement by the American Diabetes Association (ADA) and the American Heart Association (AHA) supports the use of high-intensity sweeteners (HIS) or commonly referred to as non-nutritive sweeteners (NNS), replacing sugar-sweetened beverages (SSB) among individuals with prediabetes and diabetes. There is much heterogeneity in results regarding the use of HIS in the literature. Nonhuman models have previously demonstrated obesogenic and carcinogenic potential with high utilization of HIS. However, to date, there is inconsistent evidence regarding HISs and their impacts on obesity and diabetes. In a few well-controlled studies, there appear to be inconsistent effects of HIS on metabolic syndrome. This chapter will describe the different available HISs in the United States. The effects on appetite, taste receptors, and glucose homeostasis will be explored. Furthermore, a review of the potential health impacts from consuming HIS,

Introduction

One main contributing factor to the obesity pandemic has been an increased intake of energy-dense foods leading to an imbalance between energy consumption and energy expenditure, contributing to the tripling of obesity prevalence worldwide between 1975 and 2016 (World Health Organization 2019). The increasing prevalence of obesity and overweight has also extended into children and adolescents between the ages of 5 and 19, rising from 4% in 1975 to over 18% in 2016 (World Health Organization 2019). These 18% of obese and overweight children and adolescents accounted for over 340 million individuals (World Health Organization 2019).

High-intensity sweeteners (HIS) have been around since the end of the nineteenth century after saccharin was serendipitously discovered (Parker 1978). Human epidemiological studies and animal feeding studies, suggesting that HISs may dysregulate energy balance and cause metabolic syndrome, challenge the traditional belief that these substitutes only deliver a pleasant sweet taste without bringing any negative consequences.

High-Intensity Sweeteners

The United States Food and Drug Administration (FDA) has reviewed scientific data and approved six products to be considered as safe high-intensity sweeteners (HIS) to be used in food products: acesulfame potassium (Ace-K), aspartame, neotame, advantame, saccharin, and sucralose. In addition to these six, there are two substances on which FDA has received Generally Recognized as Safe (GRAS) notices; they are *Siraitia grosvenorii Swingle* (Luo Han Guo/monk fruit) fruit extracts (SGFE) and certain high purity steviol glycosides purified from the leaves of *Stevia rebaudiana Bertoni*. The FDA did not question the notifier's GRAS notices under the intentional condition of use (Food and Drug Administration 2019). Table 38.1 summarizes the acceptable daily intake determined by the FDA and the intensity of each sweetener.

Under the FDA's definition, all eight of these sweeteners are considered as non-nutritive sweeteners, except aspartame (Food and Drug

Table 38.1 Names of high-intensity sweeteners (HIS), regulatory status by the FDA, acceptable daily intake, and intensity (2019)

Names of high-intensity sweetener (HIS)	Regulatory status by the FDA	Acceptable daily intake (kg of body weight, per day) (mg/kg)	Intensity (compared to sucrose)
Saccharin	Approved	15	200–700×
Aspartame	Approved	50	200×
Acesulfame-K	Approved	15	200×
Sucralose	Approved	23	600×
Neotame	Approved	23	7000–13,000×
Advantame	Approved	32.8	20,000×
Steviol Glycosides	GRAS notified	4[a]	200–400×
Siraitia grosvenorii (Luo Han Guo) swingle fruit extracts (SGFE)	GRAS notified	Not specified	100–250×

[a]Determined by the Joint FAO/WHO Expert Committee on Food Additives (JECFA); *FAO* Food and Agriculture Organization of the United Nations

Table 38.2 Professional organizations and their views on sugar substitutes

Association/committee	Snapshot of position statements/recommendations
American Diabetes Association (ADA) (2020) Evert (2019)	→ Replace sugar-sweetened beverages (SSBs) with water as often as possible → When sugar substitutes are used to reduce overall calorie and carbohydrate intake, people should be counseled to avoid compensating with the consumption of additional calories from other food sources → Using sugar substitutes does not make an unhealthy choice healthy; rather, it makes such a choice less unhealthy → ADA supports the American Heart Association science advisory: There is not enough evidence to determine whether sugar substitute use definitively leads to a long-term reduction in body weight or cardiometabolic risk factors, including glycemia
Dietary Guidelines for Americans (2015–2020) USDA (2015)	→ Replacement of sweetened beverages with beverages containing sugar substitutes will reduce caloric intake in the short term → The effectiveness of long-term weight management is uncertain → Sugar substitutes are considered safe for the general population → FDA determined that even for high consumers of these sugar substitutes, their consumption is less than the acceptable daily intake level
Position of the Academy of Nutrition & Dietetics (2012) Fitch and Keim (2012)	→ Nutritive and non-nutritive sweeteners are considered safe as long as consumers do not exceed the federal recommendations on daily consumption → The overall diet plan should be considered along with sugar-substitute-containing products

Administration 2019). Aspartame is a nutritive sweetener since it contains more than 2% of caloric content in the same amount of sugar. These high-intensity sweeteners have been commonly referred to as sugar substitutes, non-nutritive sweeteners, low-calorie sweeteners, or artificial sweeteners. People include HIS in their foods for various reasons. Some may choose to consume HIS in foods and drinks to achieve improved glucose control or their goal weight, while others may enjoy the taste and are not concerned with the presence of HIS.

A joint position statement between the ADA and AHA on HISs, published originally in 2012, states that HIS can be utilized to reduce caloric and carbohydrate consumption for overall diabetes control and to obtain a healthy body weight (Gardner et al. 2012). Table 38.2 has a summary of professional organizations and their positions on HIS.

HIS: Beyond Calorie Restriction

Glucose homeostasis is mainly regulated by hormones and food composition (Björck et al. 1994). However, scientists suspect many other possible factors that can affect the blood glucose control process, including stress level, hot water immersion, environmental factors, body fat mass, and timing of food consumption (Patel and Abate 2013; Leicht et al. 2019; Singh et al. 2019; Yang et al. 2020). As the use of HIS is becoming more widespread in recent years, scientists question the possible adverse effects of these substances on the human body. High-intensity sweeteners are used to replace sugar in drinks or foods to lower the caloric and carbohydrate content.

Interactions with Sweet Taste Digestive Receptors and Insulin Secretion

The preference for sweetness may be innate; however, some studies have demonstrated that this preference may have been conditioned and shaped by the individual's experiences (Ventura and Mennella 2011). It was suspected by scientists that the sweet taste receptor, known as T1R2/T1R3, can be reduced in responsiveness and sensitivity to sweet taste when conditioned to long-term HIS exposure. This adaptation, in

turn, would promote the dissociation between sweet taste and caloric content of drinks/foods, causing weakened cephalic responses (Schiffman et al. 1981). As shown in rats, the weakened cephalic response could cause a higher caloric intake. This chain of reaction had led to the hypothesis of HIS indirectly causing weight gain (Davidson et al. 2011).

Swithers and colleagues found that rats taking glucose tolerance tests after ingestion of saccharin-sweetened supplements had a higher glucose level than those who took glucose-sweetened supplements (Swithers et al. 2012). The authors suggested that HIS interfered with the typical relationship between sweet taste and calories suppressing glucagon-like peptide-1 (GLP-1) release, which could potentially alter glucose homeostasis (Swithers et al. 2012). This study supported the theory by Deutsch that when rodents consumed HIS long-term, the cephalic response triggered by sweet taste was weakened (Deutsch 1974). A few human studies on sweet taste receptors in the oral cavity and cephalic-phase insulin release (CPIR) demonstrated mixed results (Teff et al. 1995; Just et al. 2008; Ford et al. 2011). There were no changes in plasma insulin and blood glucose levels among groups that tasted water, sucrose, saccharin, and aspartame, when comparing pre- and post-stimulus area under curves (Teff et al. 1995). In another study, tasting saccharin increased insulin level ($p = 0.031$); however, there was no significant change in blood glucose levels ($p > 0.12$) (Just et al. 2008).

HIS on Sweet Taste Receptors in the GI Tract

Jang et al. (2007) showed that human duodenal L-cells expressed sweet taste receptors, the taste G-protein gustducin, and several other taste transduction elements (Jang et al. 2007). The gut L-cells are responsible for releasing GLP-1 when appropriate. In the gut of mice, sweet taste receptors behave very similar to the oral taste receptors, and the L-cells also express α-gustducin (Jang et al. 2007). When an antagonist to the sweet taste receptors and α-gustducin are present in mice, incretin response is impaired. In vitro, HIS can induce secretion of incretins through the T1R3-dependent mechanism (Jang et al. 2007). It is proposed that in mice, the sweet taste receptors in the gut respond to both nutritive foods (glucose and sucrose) and HIS (sucralose) to affect the release of incretins, increasing SGLT-1 expression and thus potentially altering glucose homeostasis (Margolskee et al. 2007).

HIS and Insulin Response

Previous human studies showed a lack of consensus on the clinical implications of HIS on glucose homeostasis (Sylvetsky and Rother 2016). In healthy adult subjects ($n = 22$), examining the effects of 240 mL of diet soda (sucralose and acesulfame-K) vs. carbonated water, followed by a 75-g glucose tolerance test, diet soda with glucose consumption showed a significantly higher GLP-1 secretion compared to carbonated water with glucose consumption ($p = 0.003$), but no differences in glucose ($p = 0.64$) and insulin levels (at 20 min, $p = 0.20$; at 25 min, $p = 0.28$) (Brown et al. 2012). Interestingly, the same authors did a similar study 3 years later in youths with T1DM ($n = 9$), T2DM ($n = 10$), and healthy controls ($n = 25$), consuming diet soda with glucose compared with drinking carbonated water with glucose. They found that GLP-1 levels increased significantly in T1DM ($p = 0.02$) and healthy control subjects ($p = 0.029$) groups, but without change in the group with T2DM ($p = 0.92$). Glucose and C-peptide levels showed no significant differences between the consumption of the two beverages in any group (Brown et al. 2012). These results indicate that people with T2DM, compared to healthy subjects or people with T1DM, may express a different incretin effect when exposed to HIS or other ingredients in the diet soda used in this study.

Another study compared sucralose, aspartame, and water with glucose consumption between

adults with newly diagnosed drug-naïve T2DM (Temizkan et al. 2015). The healthy control group that consumed sucralose had a significantly lower ($p = 0.002$) glucose level compared to the group that drank water before a glucose tolerance test, with no difference between consuming aspartame and water ($p = 0.53$) (Temizkan et al. 2015). GLP-1 was significantly higher ($p = 0.04$) with a sucralose preload compared with a water preload in the healthy control group (Temizkan et al. 2015). Results in subjects with T2DM did not show the same level of difference. In both healthy subjects and subjects with T2DM, the total area under the curve (AUC) for insulin (healthy $p = 0.29$, T2 $p = 0.07$) and c-peptide (healthy $p = 0.87$, T2 $p = 0.46$) were not statistically different between the three consumption settings (Temizkan et al. 2015). Other studies on healthy human subjects have shown a similar result of no significant difference in glycemia and insulin response (Ford et al. 2011; Ma et al. 2010; Wu et al. 2012, 2013). When healthy subjects were studied using HIS (aspartame and sucralose groups) daily for 2 weeks, the total AUC for glucose, insulin, active GLP-1, and leptin were similar to the baseline values (Ahmad et al. 2020).

Discrepancies in Obese Subjects

Pepino and colleagues found that with a preceding sucralose consumption, the glucose tolerance test showed significantly higher plasma glucose concentrations ($p = 0.03$), a greater incremental increase in insulin area under the curve ($p < 0.03$), a greater peak insulin secretion rate ($p < 0.02$), and a decrease in insulin clearance ($p = 0.04$) with no significant difference in plasma active GLP-1 concentrations ($p = 0.72$) (Pepino et al. 2013). A more recent study comparing healthy normal weight and obese individuals ingesting sucralose prior to oral glucose tolerance test (OGTT), resulted in increased glucose AUC in both weight groups; while insulin response to sucralose decreased in healthy weight participants (within 20–40 min) and raised in obese participants (within 90–120 min) (Nichol et al. 2019).

Impact on Appetite

To achieve the "calorie-saving" goal through the consumption of HIS-sweetened items, one must refrain from compensatory energy intake throughout the day. The potential mechanisms relating to appetite and food intake affected by HIS include cephalic phase stimulation, nutritive and osmotic effects, gut peptide response, palatability, informed use leading to overconsumption, loss of signal fidelity, activation of reward systems, and training the palate/learning to like the familiar (Mattes and Popkin 2009). It has been concluded that these potential mechanisms of HIS causing an increase in appetite or food intake were disproved based on the available evidence, or were inconclusive due to insufficient evidence. For example, although adding HIS to products without calories may enhance appetite, the same effect was not observed when HIS was consumed with an energy source (Mattes and Popkin 2009).

The methodologies used in controlled feeding experiments and free-living trials have added complexities, to demystifying the extent of other food item intake due to the consumption of HIS (Gardner et al. 2012). Since controlled feeding experiments cannot simulate real-world situations, such investigations may or may not exhibit an effect on future calorie intake caused by HIS. Education is needed to disseminate that HIS-containing products can assist in weight management only if utilized to replace full-calorie food items, and also if the energy deficiency created for which is not compensated. Many factors exist in the real world, contributing to food choice and calorie intake, so the amount of food consumed after HIS consumption might be confounded by reverse causality (e.g., future intake of higher-calorie food items as a compensation for the previous HIS-containing items) (Gardner et al. 2012).

Glucose Homeostasis

Studies do not support the speculation that HIS stimulates incretin responses. Sucralose, similar

to glucose, administered via an intragastric infusion under a fasted state in healthy humans did not stimulate the release of insulin, GLP-1, or gastric inhibitory polypeptide (GIP), thus not compromising gastric emptying (Ma et al. 2009). Sucralose delivered intraduodenaly also in fasted healthy humans, did not affect concentrations of postprandial blood glucose, GLP-1 release, or amount of glucose absorption in the small intestine (Ma et al. 2010). Lastly, GLP-1, insulin, or glucose concentration was also not impacted in healthy human subjects with a fasted state after sucralose being administered orally (Ford et al. 2011), or aspartame, acesulfame K, or sucralose being intragastrically infused (Steinert et al. 2011). In disagreement with such findings, a study done in young, healthy adults revealed that the consumption of HIS in the form of a diet soda before a glucose load, led to a significant increase in GLP-1 secretion but not in insulin or glucose levels (Brown et al. 2009).

Energy Intake

Energy intake has been included as an outcome (either primary or secondary) in experiments comparing HIS vs. caloric sweeteners used in beverages and foods. For example, de la Hunty and colleagues conducted a meta-analysis (de la Hunty et al. 2006), concluding that aspartame was able to create an energy deficit, with 68% of which uncompensated for 24 h, and the energy deficit lasted until the next period of consumption. On the other hand, with the four studies in this meta-analysis examining the effects via beverages alone, the energy deficit created was 85% uncompensated in the subsequent 24 h post-HIS consumption (de la Hunty et al. 2006). These results suggest that substituting sugar-sweetened beverages with HIS-containing beverages might result in a higher calorie net reduction than doing the same in foods.

In a crossover design, when subjects consumed sucrose-sweetened (full calorie) beverages, a lack of energy intake compensation was observed. When HIS-containing beverages were consumed, a net reduction in energy intake was achieved through consuming HIS (Van Wymelbeke et al. 2004). In contrast, a 1-month study generated a similar total energy intake between sugar-containing soft drinks and aspartame-containing soft drinks among normally weighted adults (Reid et al. 2007).

Impact on Body Weight Management

An increased BMI, according to a meta-analysis of 30 cohort studies ($n = 405{,}907$), may be associated with routine consumption of HIS (Azad et al. 2017). However, the same meta-analysis demonstrated an inconsistent effect of HIS on BMI in seven randomized control trials (RCTs) ($n = 1003$) (Azad et al. 2017). A smaller recent RCT ($n = 100$) demonstrated that two doses of aspartame ingested per day did not affect body weight among healthy lean adults (Higgins et al. 2018). A common myth is that those who consume higher amounts of HIS also consume higher total calories. However, no caloric difference was demonstrated in a 24-h dietary recall study of ($n = 14{,}098$) American adults that consumed HIS versus no HIS in the National Health and Nutrition Examination Survey (NHANES) (Malek et al. 2018).

In a smaller study of older adults ($n = 749$), a linear dose-response increase between HIS-soda consumption and waist circumference occurred (Fowler et al. 2015). A longitudinal cohort study of Hispanics between 12 and 18 years old ($n = 98$) determined that chronic HIS consumers compared to controls had higher total body fat at baseline and 1-year follow-up (Davis et al. 2018). The children with higher levels of HIS consumption also had higher total energy and carbohydrate consumption. In the UK Millennium Cohort Study, children between 7 and 11 years of age were longitudinally studied to examine the association between HIS consumption and adiposity over 4 years (Laverty et al. 2015). Daily

consumption of HIS was associated with higher body fat (+1.18 kg/m^2, 95% confidence intervals: 0.81, 1.54).

Impact on Blood Glucose Management

When BMI is adjusted in both the Nurses' Health Study II ($n = 116{,}000$ women) (Malik et al. 2019) and the Health Professionals Follow-Up Trial ($n = 40{,}000$ men) (de Koning et al. 2012), there is no significant increase in type 2 diabetes mellitus (T2DM) development with HIS intake. Before adjusting for BMI, the Nurses' Health Study II had a 35% higher risk of developing T2DM and 40% higher in the Health Professionals Follow-Up Trial (Malik et al. 2019; de Koning et al. 2012). Higher consumption of HIS in the Health Professionals Follow-Up Trial is hypothesized to be in reaction to weight gain, which is associated with increasing T2DM risk (Malik et al. 2019).

In a double-blind, randomized crossover trial of 60 adults with healthy BMI and without diabetes (Bonnet et al. 2018), all participants underwent a 4-week washout period and then consumed two cans of aspartame and acesulfame K per day or unsweetened, no-calorie beverage for 12 weeks. There was no significant effect on insulin sensitivity or secretion. A recent RCT ($n = 100$) confirmed that two doses of aspartame ingested per day did not affect insulin levels, resting leptin, glucagon-like peptide-1, or gastric inhibitory peptide after 12 weeks among healthy lean adults compared to baseline levels (Higgins et al. 2018).

Other Diseases or Abnormalities

Carcinogenesis

The National Cancer Institute issued a statement affirming the use of HIS is not associated with cancer in humans (National Cancer Institute Website 2019). In many animal models, however, HISs have been shown as carcinogenic agents. Soffritti and colleagues found that after aspartame was administered to Sprague-Dawley rats ($n = 900$) at 0, 80, 400, 2000, 10,000, 50,000, and 100,000 ppm from 8 weeks old to natural death, both male and female mice had increased incidences of cancer (e.g., leukemia and lymphoma), and increased carcinomas of the renal pelvis and ureter were found in female mice (Soffritti et al. 2005). Another study showed a similar result, where male ($n = 457$) and female mice ($n = 396$) were divided into five groups and given different amounts of sucralose (0, 500, 2000, 8000, and 16,000 ppm) from 12 days post-gestation to entire lifespan (Soffritti et al. 2005). The dose-related incidence of malignant tumors/neoplasms was found significantly higher in male mice given doses at 2000 and 16,000 ppm.

However, in a controlled protocol with mice (Mann et al. 2000), three groups of male ($n = 52$) and female ($n = 52$) animals were given a sucralose-containing diet at concentrations of 3000, 10,000, and 30,000 ppm for 104 weeks. The incidence of any tumors was not found to be increased in the sucralose group.

Disruption of Gut Microbiota

An increased ratio between Firmicutes and Bacteroidetes as well as an increase in *Lactobacilli* spp. have been identified following the consumption of HIS, and this composition mirrors that of obese organisms (Suez et al. 2014; Nettleton et al. 2016). As known, aberrations in the gut microbiota have been associated with the development of obesity, diabetes, metabolic syndrome, and cardiovascular disorders (Kho and Lal 2018).

For some, the phenomenon of metabolic endotoxemia could underlie such shifts. This is a low-grade inflammatory response caused by gut dysbiosis (Cani et al. 2007). Lipopolysaccharides (LPS) released from dead bacteria in the gut are taken into the circulatory system, binding to cluster of differentiation (CD)-14 proteins, nucleotide oligomerization domains (NODs), and Toll-like receptors (TLRs) on macrophages and dendritic cells (Tanti et al. 2013). CD14 proteins are modulators in animals for insulin sensitivity, directly linked to hyperglycemia, hyperinsulinemia, and weight gain (Liauchonak

et al. 2019). Overproduction of inflammatory cytokines after the activation of the immune cells could trigger subsequent signaling pathways in metabolic cells to operate, ultimately leading to insulin desensitization, downregulating of proteins for glucose transport, and other metabolic effects (Cani et al. 2007).

Cardiovascular and Kidney Disease

The Nurses' Health Study revealed that an increased risk for both coronary heart disease (CHD) and chronic kidney disease (CKD) was associated with the consumption of more than two diet sodas per day, when compared to consuming fewer than one diet soda per month (Fung et al. 2009). After controlling for weight, this association disappeared (Fung et al. 2009; Lin and Curhan 2011). Risks for specific medical conditions only existed when HIS was consumed in beverages (did not include foods with HIS).

Total and Cardiovascular Mortality

A study published in early 2019, including 37,716 men and 80,647 women, examined the relationship between the long-term use of SSBs and HIS, and the risk of mortality in the United States (Malik et al. 2019). A higher risk for total and cardiovascular disease mortality was unearthed (Malik et al. 2019). Besides, a significant association between mortality and HIS consumption was identified in females via cohort-specific analyses, urging further research (Malik et al. 2019).

Reverse causation may explain some of the inconsistencies within the data (Fitch and Keim 2012; Dugan et al. 2019). For example, overweight or obese individuals are more likely to consume HIS-containing foods and beverages. The same population is also more likely to develop type 2 diabetes mellitus (Fitch and Keim 2012; Dugan et al. 2019). Based on the ADA/AHA joint position statement, HIS can safely be used to replace sugar-containing beverages and products. However, due to the inconsistent results in some studies, water may be the best first choice beverage for those attempting to lose weight. More research is needed to fully understand the consequences of long-term HIS consumption.

Ongoing Studies and Future Perspectives

Sylvetskym et al. (2016) suggest eight methodological areas to consider in future studies, which are:

1. Population selection
2. Control group
3. Habitual consumption of HIS
4. Variation among HIS
5. Consumption route
6. Secondary study outcomes other than weight
7. Eucaloric versus lower calorie consumption
8. Translational research

Studies that include a broad range of age, gender, body weight, and race/ethnicity subjects would be helpful for interindividual variations (Sylvetsky et al. 2016). Few studies are evaluating HIS in the perinatal period, children, and elderly (Sylvetsky et al. 2016). A control group in HIS research is often lacking. Many lack controls using water, unflavored seltzer water, or foods without sweetener (Sylvetsky et al. 2016). HIS is mostly examined in the setting of weight loss/management. More reviews on HIS in a population not restricting calories would be helpful.

Evaluating the effects of HISs in specific patient groups with metabolic diseases and underlying inflammatory states would clarify the microbial alterations associated with the disease states (Sylvetsky et al. 2016). Studies that compare the effects of different types of HIS are needed, since, for example, aspartame, sucralose, and stevia may have different impacts on postprandial glycemia, obesity, and other secondary outcomes. Also, most individuals that consume HISs would obtain them from a variety of products (e.g., tea, coffee, sodas, and foods). Further studies should include multiple

HIS-containing products, which will translate into a more real-world representation and application (Toews et al. 2019).

Personalised Molecular Feedback for Weight Loss

39

Shilpa Tejpal

Contents

Abstract

Exercise, drugs and all sorts of dietary plans are typical weight loss options that overweight or obese individuals are offered, besides more radical actions such as bariatric surgery. However, weight loss is sometimes incremental, especially at the very start of a regimen and this often leads to the people dropping-out of a dietary programme. Hence, there is a need to understand and identify biomarkers that are affected over a short interval, and use them to provide quantitative biofeedback on the efficiency of a diet. It would also allow personalised optimisation of dieting parameters with relevance to short term.

Keywords

Obesity · Biomarker · Molecular feedback · Personalised information

This chapter has been adapted from Shilpa Tejpal, Metabolic Profiling and Identification of Biomarkers for Weight Loss, University of Warwick, Warwick Medical School, April 2019.

Importance of Quantitative Biomarkers of Weight Loss

The worldwide prevalence of obesity has nearly tripled between 1975 and 2016 (González-Muniesa et al. 2017; Data and Statistics 2015). Obesity is associated with several comorbidities such as type 2 diabetes, cardiovascular diseases (CVDs), sleep apnoea, metabolic syndrome and certain types of cancer (Abdelaal et al. 2017). Obesity is an incredibly complex disease that is associated with metabolic, genetic and behavioural deregulations. They should be studied in combination with environmental factors, socio-economic status, behaviour, education and genotype. All these factors affect caloric intake, thermogenesis, lipid utilisation, nutrient turnover and differential fat storage in tissues (Hruby and Hu 2015).

Several blood and physical markers are used to measure weight loss, such as hip/waist ratio, BMI, body fat and/or weight for physical markers, along with high-density lipoprotein (HDL), low-density lipoprotein (LDL) and fasting glucose in serum. In most diets, the weight lost is rapidly regained after the end of the diet (the "yo-yo" effect); therefore, investigating possibilities to use molecular information to predict whether the weight is kept off on a long-term is an interesting question. There is a range of approaches available to lose weight from surgical or drug-based interventions to different diet programmes.

Weight loss plans involve following a certain diet regime and/or monitoring net caloric intake. To date, no dietary intervention combines molecular measurements with digital technology, tracking life-style parameters such as food intake or exercise, despite the availability of several food tracker apps and websites. All weight loss programmes give a broad description of the diet plan, which is often arbitrary. In addition, every individual has a different metabolism and responds differently to a diet plan (Tejpal et al. 2019a). Thus, personalised optimisation of the diet plan needs to be understood to determine how diet parameters can be adapted to an individual's metabolism.

Advantages and Limitations of Internet and Mobile Resources

Technological support available to help with weight loss includes diet trackers and activity monitors. These resources provide information on nutrition profile and/or caloric content of different food items. They also allow to maintain records of different meals eaten in a day. Other types of devices such as activity monitors record heart rate, number of steps taken in a day, physical activity levels, sleep patterns and blood pressure. There are also several support networks available like Weight Watchers and Slimming World. A support network is a platform where people trying to lose weight come together sharing their stories, challenges, victories, feelings, and providing support to others to help achieve their goals. People also share their food recipes, diet plans and physical activity routines on such networks. Such platforms help people to remain enthusiastic, motivated, set goals, track progress and stay engaged in the weight loss plan being followed by them (Soeliman and Azadbakht 2014). Many studies have shown that dieting is more successful when supported by social interactions, such as exercising with a friend or dieting as a group (Higgs and Thomas 2016; Lemstra et al. 2016).

Dietary Tracking

Tracking and recording eating patterns is a well-known method for effective weight management (Liu et al. 2011, 2012). Traditionally, people used paper forms of the dietary questionnaire, which were considered tiring (Moshfegh et al. 2008). Nowadays, there are several internet (Inc A 2016; Abel et al. 2001) and mobile versions for personal tracking of food eaten (Vereecken et al. 2005; 24th European Congress on Obesity (ECO2017) 2017). Mis-reporting of food intake is a well-known problem (Moshfegh et al. 2008; Conway et al. 2003) in any platform because of its dependency upon honesty, motivation and self-awareness (Liu et al. 2012). There can be under-reporting of the food intake due to

unconscious bias of an individual (Scisco et al. 2011). Energy expenditure on the other hand can potentially be tracked without bias using activity monitors, but they do not provide a direct link to weight loss. They may show the number of steps walked or run, calories consumed and/or heartbeat/min (Shilpa Tejpal et al. 2019). Even if a device that accurately measures caloric intake and expenditure is widely available, the information may not be sufficient to motivate users to make changes in their behaviour that would result in weight loss. Also, these devices are not 100% tailored to an individual. They only give an estimate of the calories burnt based on weight and height, sometimes including gender and age, but they do not include any information on fat distribution or hormonal patterns. This information is therefore generic and thus there is need for identification of biomarkers to provide tailored feedback. This may help us understand as to why some individuals fail and/or find it difficult to lose weight, despite of keeping records of food eaten in a day (Teixeira et al. 2012).

Biomarkers for BMI and Adiposity

BMI is often used to identify overweight (25–29.9 kg/m^2), obesity (≥30 kg/m^2) and severe obesity (≥40 kg/m^2); however, it may not be the most efficient method as it is unable to provide information about body fat distribution (Obesity W. Obesity Classification 2019). For example, elderly people lose muscle with age making BMI a less accurate indicator of body composition (Adab et al. 2018). BMI can be complemented with waist circumference (WC) or biometric impedance measurements, which gives a better representation of adiposity distribution to differential fat under the skin (subcutaneous) and intra-abdominal (visceral) (Seven et al. 2016). According to the National Institute for Health and Care Excellence (NICE) guidelines, WC >94 cm (male) and WC ≥85 cm (females) indicates a higher deposition of visceral fat (Obesity W. Obesity Classification 2019). Biometric impedance involves estimation of body composition, particularly body fat. The health risk associated with obesity is identified by combining these methods, as shown in Table 39.1.

Table 39.1 Identification of risk level for obesity related co-morbidities by combining BMI and Waist Circumference

BMI (kg/m^2)	Waist circumference (cm)	Risk of co-morbidities
<18.5	<94 (men) <85 (women)	Low
	≥94 (men) ≥85 (women)	Average
18.5–22.9	<94 (men) <85 (women)	Average
	≥94 (men) ≥85 (women)	Increased
23–24.9	<94 (men) <85 (women)	Increased
	≥94 (men) ≥85 (women)	Moderate
25–29.9	<94 (men) <85 (women)	Moderate
	≥94 (men) ≥85 (women)	Severe
≥30	<94 (men) <85 (women)	Severe
	≥94 (men) ≥85 (women)	Very severe

Each BMI category in association with waist circumference is used to identify the risk for developing obesity related co-morbidities (Obesity W. Obesity Classification 2019)

Normal adipose tissue expresses anti- and pro-inflammatory regulators to allow functioning of adipose tissue (Deng et al. 2016). Interleukin (IL) 4 is a major anti-inflammatory regulator that controls the expression of T helper (TH) type 2 cells, regulatory T cells (Tregs) and macrophages. Macrophage phenotype is divided into groups, namely classically activated macrophages (M1) and alternatively activated macrophages (M2). Expression of M2 macrophages by IL4 promotes systemic insulin sensitivity in lean mice (Odegaard et al. 2008; Ricardo-Gonzalez et al. 2010). Many pro-inflammatory marker levels increase with higher adiposity. A cross-sectional meta-study has found association between C-reactive protein (CRP), a marker for systemic inflammation, and free fat mass (Cox et al. 2015; Choi et al. 2013; Eagan et al. 2010). Increased levels of CRP and triglyceride (TG) are found in overweight women in comparison to normal weight women (Klisic et al. 2014). With nutrition overload, lipid activation and increased energy storage, there is a switch from M2 to M1 (Deng et al. 2016).

Adipocytes secrete adipokines such as leptin and adiponectin, which have opposing effects on immune cell functions. Leptin has pro-inflammatory effects and increases with elevated nutrition uptake and stimulates production of IL 1, 6 and 12, and tumour necrosis factor α (TNFα), while adiponectin has anti-inflammatory effects and decreases with excess adiposity (Deng et al. 2016). The overexpressed pro-inflammatory cytokines are found in obese individuals, and one-third of total circulating concentrations of IL-6 originate from adipose tissue (Ellulu et al. 2017). Levels of IL 6 decrease after 12 months of bariatric surgery in morbidly obese patients (Illán-Gómez et al. 2012). The abundant energy substrates in obesity lead to increased reactive oxygen species (ROS) signalling and mitochondrial dysfunction (McMurray et al. 2016). This is also associated with decreased insulin sensitivity (McMurray et al. 2016). c-Jun N-terminal kinases (JNK) and nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) are regulated by ROS and are associated with obesity-induced insulin resistance (Finkel 2011).

Metabolomic Markers

Several metabolomics studies involving untargeted proton (^{1}H) nuclear magnetic resonance spectroscopy (NMR) and ion exchange chromatography (IEC), on obese human and mice urine samples, have identified metabolites associated with BMI and adiposity (Elliott et al. 2015; Du et al. 2013), summarised in Fig. 39.1.

Biomarkers for Foods and Drinks

Double-labelled water (water with isotopes of deuterium and oxygen 18) is used to measure energy expenditure (EE) in an individual (Potischman and Freudenheim 2003). Urine samples are collected to determine the rate of disappearance of each isotope from the body via mass spectrometry. This disappearance rate is further used to indirectly calculate carbon dioxide production to estimate total EE. EE is lower in obese and overweight population in comparison to healthy individuals. To be in an energy balance, energy intake (EI) should be equal to EE. Increased EE is associated with under-reporting of food intake. Urine nitrogen is used as a biomarker for protein intake through dietary means (Bingham 2003). Constant dietary intake over longer periods is also associated with daily nitrogen turn-over and excretion (Bingham 2003). Hydrocarbons in breath are used as a means to measure lipid peroxidation. Peroxidation of *n*-6 and *n*-3 fatty acid releases pentane and ethane, respectively, into breath (Mayne 2003). Supplementation with β carotene reduces breath pentane levels significantly (Gottlieb et al. 1993). Markers for α and β carotene, lycopene and β-cryptoxanthin are correlated with serum cholesterol levels (Fraser et al. 2016). Biomarkers for different foods include *N*-methylnicotinic acid (NMNA), a niacin-related (vitamin B3) metabolite marker for coffee drinking (Lang et al. 2011), proline betaine for citrus fruit consumption (Heinzmann et al. 2010), and *O*-acetyl carnitine for red meat intake (Mozaffarian et al. 2011).

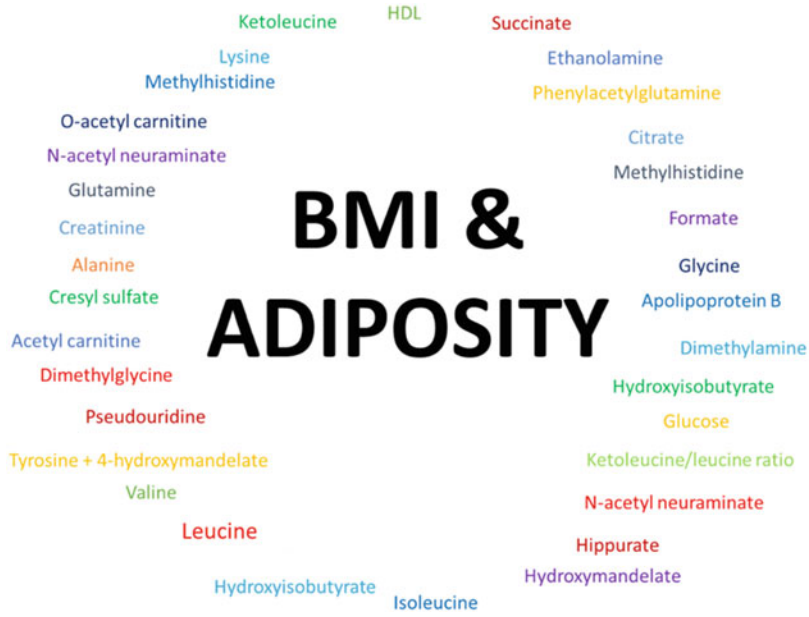

Fig. 39.1 Urinary metabolic signatures of BMI and Adiposity in urine. The information for the metabolic signatures was obtained from (Bouatra et al. 2013)

Phytotherapeutic Interventions

Food components can modulate hunger, satiety and EE. In particular, benefits of plant bioactive compounds on metabolism have become a focus of multidisciplinary studies; and several plant extracts are studied in the prevention of obesity (Lu et al. 2013). Based on their nutritional value, such extracts have physiological benefits and reduce the risk of chronic diseases (Estaquio et al. 2008; Liu et al. 2004). Phenols, anthocyanins and tannins, found in tea, berries and peas, have been demonstrated to decrease lipids, through the inhibition of lipase activity (Sergent et al. 2012). Starch with high glycaemic index is associated with weight gain (Scribner et al. 2007, 2008) by causing increased insulin secretion (Aller et al. 2011).

Diets rich in protein from vegetables (e.g., legumes) induce satiety and suppress intake and appetite by increasing the hormone peptide tyrosine (PYY) and decreasing ghrelin (Nilsson et al. 2013; Lonnie et al. 2018). Raspberries decrease serum glucose, insulin levels, leptin and body weight in mice fed high-fat diet (Prior et al. 2010). Citrus fruit species are associated with decreased inflammation and reduced oxidative stress markers in humans (Coelho et al. 2013). Other studies have found bergamot, grapefruit and orange juice to be associated with decreased total cholesterol, low density lipoprotein (LDL) and glucose concentration in humans (Mollace et al. 2011; Dow et al. 2012; Aptekmann and Cesar 2013). Similar results have also been found in rats after lemon juice administration (Oboh et al. 2015). To summarise, the different plant-based compounds that are present in foods are shown in Table 39.2.

Appetite Regulation

Appetite can be expressed in terms of physical behaviour, peripheral physiology and central nervous system functions (Stafleu et al. 2004). People stop eating due to absence of hunger or because they feel full (Mook and Votaw 1992). Diet-induced thermogenesis (DIT) is the amount of energy used above the basal rate during the breakdown of food in the body. DIT and satiety

Table 39.2 Bioactive compounds currently prescribed or investigated to treat obesity (Solas et al. 2016)

Molecule	Mechanism
Appetite	
Saponins (gingenoside)	Satiety
Fibre and polysaccharides (diverse)	
Terpenes (geniposide)	
Steroidal glycosides (P57A53)	
Polyphenols (proantho-cyanidins)	
Proteins (diverse)	
Energy expenditure	
Alkaloids (capsaicin)	Thermogenesis
Flavonoids (diverse)	
Polyphenols (catechin)	
Fatty acids (MUFA, PUFA, ...)	Beta-oxidation lipolysis/anti-lipogenesis
Curcumin	Induction of brown fat-like phenotype
Metabolism	
Saponins (astragaloside IV, gingenoside)	Lipase inhibition, fat depletion
Fibre	Lipid uptake reduction; reduction of energy dietary value; secretion of anorectic peptides
Pseudo-tetrasaccharide, acarbose	Amylase inhibitor
Polysaccharides (diverse)	Fat depletion
Alkaloids (berberine betaine, piperine, capsaicin)	Browning fat depletion
Polyphenols (resveratrol, proanthocyanidins, epicatechin, diverse from tea)	Adipogenesis inhibition; fat depletion and absorption lipase/amylase inhibition

The table describes the different compounds, their source and mechanism of action

are positively correlated and DIT decreases hunger (Westerterp-Plantenga et al. 1997, 1999; Crovetti et al. 1998). Ghrelin is also associated with hunger. Infusion of ghrelin in healthy subjects leads to enhanced appetite and energy intake levels (Wren et al. 2001). Plasma concentration for ghrelin decreases after administration of glucose (Mizuta et al. 2002) and carbohydrates, (Matthys et al. 2003) but there is no suppression after high-fat administrations (Matthys et al. 2003; Klok et al. 2007). Insulin and glucose are therefore indirectly related to satiety. Neuropeptide Y and Agouti-related protein (AgRP) are located in the hypothalamus, their expression is activated in conditions of fasting and negative energy balance, and they increase the hunger level (Schwartz et al. 2017). Pro-opiomelanocortin (POMC) neurons release the similarly named anorexic neuropeptide that reduces food intake (Schwartz et al. 1997).

Molecular Biomarkers in the Real World

Angiotensin-Converting Enzyme

To find a marker for long-term weight loss, a panel of biomarkers was tested before and after an 8-week diet, and weight loss maintenance was determined after 6 months (Wang et al. 2011). In this study, angiotensin-converting enzyme (ACE) was shown (amongst the extensive blood profiling for diverse protein and steroid hormones) to be the only potential predictor for sustained weight loss (Wang et al. 2011). At the end of the 8-week intervention, individuals with weight loss displayed decreased ACE concentration (~12%) (Wang et al. 2011), which supports the previously reported decreased ACE activity in overweight/obese adults after dieting (Engeli et al. 2005; Harp et al. 2002). ACE is a zinc

metallopeptidase enzyme involved in the conversion of angiotensin (Ang) I to angiotensin II (Wang et al. 2011; Brewster and Perazella 2004; Tejpal et al. 2019b). Ang I is obtained by cleavage of angiotensinogen (AGT) with the help of renin. Ang II is well known for its role in increased blood pressure and retention of salt and water (Brewster and Perazella 2004).

Lactate and Insulin

A molecular feedback approach to assist dieting efforts and behavioural responses of people using a web- and mobile-based application was investigated. Skipping a meal in a day regardless of which one resulted in consistent weight loss for that day, in comparison to control days in which any number of meals was allowed. Insulin, ACE and lactate levels in urine showed correlations to BMI, caloric patterns and weight difference (Tejpal et al. 2018, 2019a).

Lactate is the by-product of glucose utilisation by the organs and tissues during hypoxia or glycolysis (Arriarán et al. 2015). It helps to modulate oxygen release in hypoxic tissues and acts as a substrate for gluconeogenesis (Frayn et al. 1990; Kerckhoffs et al. 1998). It also acts as a substrate for lipogenesis in liver and other tissues (Kevin O'Hea and Leveille 1969; Granata et al. 1976; Lopaschuk et al. 1992). Release of lactate in adipose tissue is often attributed to hypoxia, acidosis and stress (Lee Dong et al. 2015; Sestoft et al. 1982). Lactate production is known to increase in vitro in large adipocytes from obese animals, and can reach up to 50–70% of glucose metabolised (Crawford et al. 2010). Indeed, baseline lactate concentrations are higher in obese subjects as compared to lean subjects (Newby et al. 1990).

Insulin is a small-peptide hormone, whose secretion is stimulated by increased levels of glucose in blood (Saltiel and Kahn 2001). Insulin regulates blood glucose homeostasis by increasing glucose uptake in muscles and fat cells and inhibiting its production in liver (Saltiel and Kahn 2001). It varies with food intake in terms of meal composition, timing and quantity (Van Cauter et al. 1992; Stevenson et al. 2005; Scheer et al. 2009). Moreover, its concentration and action are under circadian regulation, giving rise to "afternoon diabetes" (Van Cauter et al. 1992; Scheer et al. 2009; Jarrett and Keen 1969). This finding has been used to suggest that diet plans should incorporate meal timing (Hampton and Johnston 2014) with the breakfast meal being the largest meal, as opposed to the most common behaviour of highest food consumption in the evening (Hampton and Johnston 2014; Gill and Panda 2015). Indeed, it is shown that a high-carbohydrate breakfast promotes greater weight loss than a diet low in carbohydrates by reducing food cravings and increased satiety (Jakubowicz et al. 2012, 2013; Almoosawi et al. 2013).

Ongoing Investigations and Future Perspectives

A large-scale 2-week PREDICT study involving 1100 UK and US adults (60% twins) studied the effects of markers such as blood glucose, fat and insulin to genetics, environment, meal timing, exercise, sleep and gut microbiome. Even for the same meal, the blood markers hugely varied in different individuals. This variation is partially explained by genetic factors corresponding to 50%, 30% and 20% for glucose, insulin and triglyceride, respectively. The identical twins have only 37% of shared gut microbiome, which is only 2% more than the percentage shared by two unrelated individuals (When it Comes to Food, One Size Doesn't Fit All! 2019). Less than 40% of variations between individuals eating the same caloric load are explained by the nutrients content on food labels (Cutler 2019). Time of the meal also affects the individuals' responses.

The data are being used by ZOE company together with universities (ZOE 2019) to develop a machine learning algorithm that will predict a person's response to the food eaten. Another large-scale study has been launched at the Swiss Federal Institute of Technology named Food & You. The aim of the study is to confirm the theory that individuals respond differently to the same meal eaten, as based on the blood glucose measurements (Stéphanie Milliquet 2019). It is a

digital study conducted entirely online, where participants record their daily food intake for 2 weeks on MyFoodRepo. They also use a smartwatch or an app to track their physical activity and sleep. Blood sugar levels are also monitored, and a stool sample is collected once to analyse gut microbiome. The data collected will then be used to generate an algorithm that can predict blood sugar levels after a meal.

Personalised Nutrition

An individual having a potato chip triggering a six times higher triglyceride peak, can be steered towards a low-fat snack option based on the personalised information. The current guidelines are based on the questionnaire filled by individuals. The information provided can be mis- or under-reported creating a bias in the data generated. A detailed view of metabolic differences, wearable sensors and machine learning can help structure the personalised guidance options for people.

Abstract

Starting in the 1990s, multiple organizations have published guidelines to address the management of children and adolescents with obesity and diabetes. As the rates of obesity continued to escalate, the guidelines have been constantly evolving to keep up. Significant obstacles include the paucity of controlled trials in children, the bias against managing obesity as a disease in general and especially in children, and the dichotomy in treatment from family based behavioral treatment with modest outcomes to much more aggressive treatment such as surgery. To date, medical options for children with obesity are limited. In this chapter, we chronicle the evolution of the guideline-based management of children with obesity over the past 30 years. We will also review policy on the management of type 2 diabetes in children and adolescents, the incidence of which has increased along with the incidence of severe obesity in children. We will then discuss emerging issues.

Keywords

Obesity · Type 2 diabetes · Guidelines · Children · Adolescent · Algorithm

Background

Childhood obesity is a growing global health problem. One in every three children is either overweight or obese. Management of this chronic debilitating condition has evolved over the past 30 years. Initially, prevention and diagnosis was the focus of management of this developing health crisis. Discussion of the treatment of children and adolescents suffering with obesity emerged as it became apparent that prevention and diagnosis was not going to address the child or adolescent living with obesity. Currently, almost every pediatric health problem is impacted by the coexistence of obesity, even those problems that historically have been associated with low body mass indices (BMI), i.e., type 1 diabetes mellitus.

Management of the pediatric child with obesity has been directed by various publications providing recommendations, guidance, and policy. It has been 22 years since the publication of the first guidance on the management of this complex childhood disease. The field continues to progress with new research and experience, yet suffers from a lack of randomized controlled clinical trials, a continual struggle to find clinical resources to manage this population, and a growing complacency with the existence of obesity in children among both the health care community and the general population.

Overview of Existing Guidelines and Recommendations

Several medical organizations that are focused on the health of children have published guidance on the assessment and management of children with obesity, including the Department of Health and Human Services, the American Academy of Pediatrics (AAP) Institute of Healthy Childhood Weight, the Children's Hospital Association, the Endocrine Society, Pediatric Endocrine Society, and the Obesity Medical Association. Guidelines have also been developed to guide the management of type 2 diabetes (T2DM). In 2013, the AAP published a clinical practice guideline addressing this topic and in 2018 the American Diabetes Association published a position statement.

The timeline for the recommendations and policies on the management of children with obesity and type 2 diabetes published to date is described now and represented in Fig. 40.1.

The first recommendation on the management of children with obesity was published in 1998, when the Department of Health and Human Services convened a committee of pediatric obesity experts (Barlow and Dietz 1998). The AAP updated the 1998 recommendation in 2007 (Barlow et al. 2007), this time using an Expert Committee comprising representatives from 15 professional organizations, appointed experienced scientists, and clinicians in three writing groups. In 2015, the AAP published an update to the 2007 recommendation and called it the "Algorithm for the Assessment and Management of Childhood Obesity in Patients 2 Years and Older" (Institute for Healthy Childhood Weight 2015) (Table 40.1).

In 2014, the Children's Hospital Association published a "consensus statement reviewing management of conditions associated with obesity" (Estrada et al. 2014). In 2017, the Endocrine Society published their "Clinical Practice Guideline: Pediatric Obesity—Assessment, Treatment, and Prevention: An Endocrine Society Clinical Practice Guideline" (Styne et al. 2017), which was an update to their previous publication in

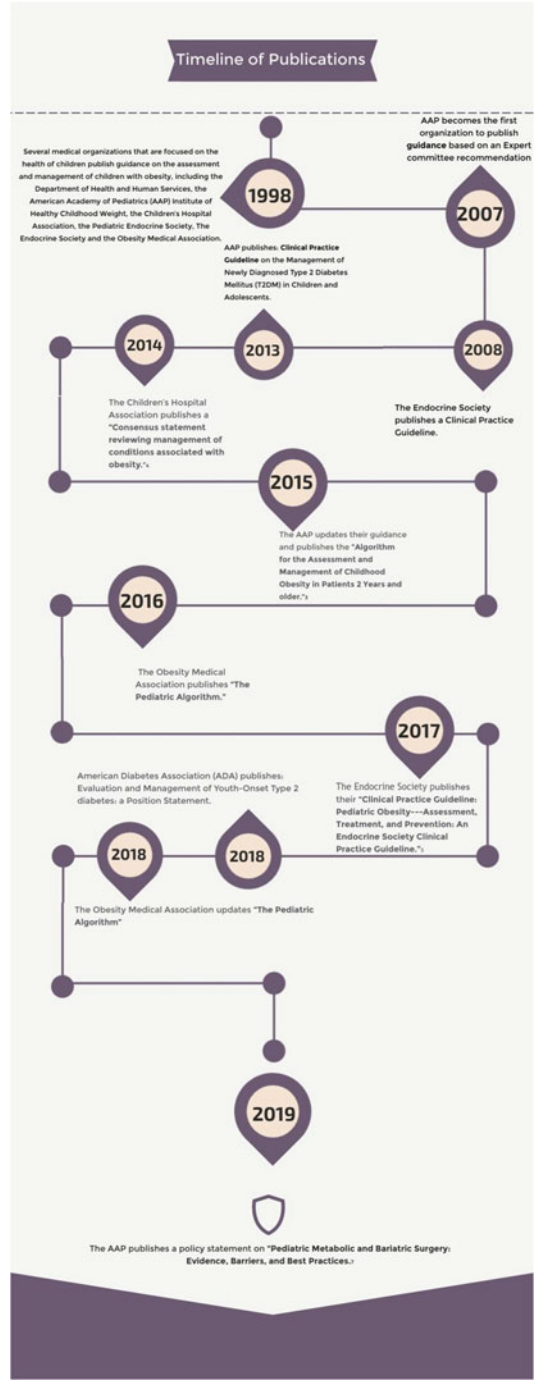

Fig. 40.1 Timeline of publications for recommendations on management of children and adolescents with obesity

2008 (August et al. 2008). In 2016, the Obesity Medical Association published "The Pediatric Algorithm," which was updated in 2018 (Cuda

Table 40.1 Characteristics of recommendations on management of children and adolescents with obesity

	Format	Target audiences	Data source	Discussion of comorbidities	Discussion of management	Discussion of surgery
Maternal and Child Health Bureau 1998	Committee Recommendations	PCPs	Clinical and research experience of the committee members	Minimal	Minimal	None
AAP 2007/2015 Recommendations/ Algorithm	Evidence-based review 2007/ Staged approach	PCPs	Extensive reference	Minimal	Minimal	Minimal
CHA 2014 Consensus Statement	Expert opinion	PCPs	Extensive references	Limited to dyslipidemia, elevated ALT, hypertension, and PCOS	Behavior/family based intervention	None
Endocrine Society 2008/ 2017 CPG	Evidence-Based Review 2017	PCPs and Subspecialists	Extensive references plus 2 systematic reviews	Extensive	Mostly behavior/ Family-based intervention	Minimal
OMA 2016/2018 Algorithm	Evidence-based review 2106/2018	PCPs, pediatric obesity centers and specialists	Extensive references	Extensive	Behavior/ Pharmacotherapy/ Surgery	Some
AAP policy statement on metabolic and bariatric surgery	4 Lead authors from the AAP section on obesity	PCPs, pediatric obesity centers, and subspecialists	Limited references	Limited	Multidisciplinary care/surgery	Extensive

et al. 2016). In 2019, the AAP published a policy statement on "Pediatric Metabolic and Bariatric Surgery: Evidence, Barriers, and Best Practices" (Armstrong et al. 2019).

Publications providing guidance on type 2 diabetes in children and adolescents were developed in 2013 (AAP) (Copeland et al. 2013) and in 2018 (American Diabetes Association) (Arslanian et al. 2018). The 2013 AAP Clinical Practice Guideline was developed in response to the "rapid emergence" of type 2 diabetes, frequently a complication of obesity, which, up until this time, had rarely been seen in children. The 2018 ADA position statement added to the body of knowledge based on new results from two large studies done in adolescents with type 2 diabetes.

The Maternal and Child Health Bureau, Health Resources and Services Administration: 1998 Obesity Evaluation and Treatment—Expert Committee Recommendations

This first recommendation addressing children with obesity reviewed the assessment, medical complications, indications for referral to an obesity specialist, evaluation, and treatment of children with BMI $\geq$ the 85th percentile. At the time of the compilation of this document, data from the National Center for Health Statistics reported a rate of one in five children as being overweight. BMI was characterized by overweight, at risk of overweight, and not at risk for overweight. Triceps skin folds measurement was recommended for the assessment of the degree of overweight. Much of the document focused on the child whose BMI is between the 85th–94th percentile, as this was likely the group presenting most frequently for evaluation at the time. Dietary approach centered on easy ways to reduce caloric intake and the Committee noted that the Food Guide Pyramid was the most helpful guide to healthy eating. Discussion of complications was brief and focused on identifying orthopedic conditions, pseudotumor cerebri, sleep disorders, polycystic ovary syndrome, acanthosis nigricans, hypertension, and dyslipidemia. There was no discussion as to the management of these complications and only a cursory mention of referring children with suspected diabetes to a pediatric endocrinologist. Treatment was centered on family-based behavioral therapy, with provider realization of weight stigma and the need for chronic care.

AAP Guidance: 2007 Expert Panel and 2015 Algorithm for the Assessment and Management of Childhood Obesity in Patients 2 Years and Older

The 2007 recommendation was notable for an evolution from simple identification of obesity to universal screening and assessment, consistent preventive health messages, and early intervention. The hallmark of the 2007 Expert Panel Recommendation was the concept of staged management, with the first stage in primary care and progressing to multidisciplinary care and then to tertiary care at suggested intervals if no clinical improvement. In the 9–10 years since the publication from the Maternal and Child Health Bureau, the prevalence of obesity in children had increased from one in five to closer to one in four, leading to the recommendation for universally assessing children for obesity in primary care settings. The Expert Panel also suggested a change in terminology as compared to the prior recommendation: the term "obesity" should be applied to those children with a BMI $\geq$ the 95th percentile or $\geq$30 kg/m^2, whichever is lower, and "overweight" applied to the 85th–94th percentile, replacing the category of "at risk for overweight." A discussion of the increasing prevalence of severe obesity was included, but no specifics in relation to level of BMI given.

The 2007 Expert panel indicated that management should start with the least intensive stage and progress through the stages based on response to treatment, age, BMI, health risks, and motivation (Barlow et al. 2007). This recommendation goes into more depth on the identification and management of complications and includes problems not previously discussed to

include nonalcoholic fatty liver disease, type 2 diabetes, hypothyroidism, Cushing Syndrome, psychiatric disorders, and a very brief mention of genetic syndromes.

The AAP 2015 Algorithm was based on the 2007 Expert Committee Recommendations plus "new evidence and promising practices" (Institute for Healthy Childhood Weight 2015). This two-page document provided a succinct reference for office use.

The four stages discussed are: Prevention Plus, Structured Weight Management, Comprehensive Multi-Disciplinary Intervention, and Tertiary Care Intervention. Progression through the stages is generally at 3–6-month intervals if the child experiences no improvement in BMI/weight status. Treatment is primarily behavior change involving the family. Treatment is targeted to the primary care clinic during the first two stages. At Stage 3, the management moves to a Pediatric Weight Management Clinic/Multi-disciplinary team and the intensity of the care increases. Stage 4 continues in the Pediatric Weight Management Clinic but now involves consideration of the use of medications and bariatric surgery in addition to more frequent and intensive multidisciplinary care.

The 2007 and 2015 guidance included recommendations for laboratory screening: fasting glucose and fasting lipid profile, ALT and AST. According to these publications, the clinical utility of measuring vitamin D and fasting insulin was yet to be determined. These publications also suggest that although there are no guidelines, the age at which laboratory screening should be considered was 2 years of age.

AAP Clinical Practice Guideline on the Management of Newly Diagnosed Type 2 Diabetes Mellitus (T2DM) in Children and Adolescents: 2013

This guideline was developed by a partnership between the AAP, Pediatric Endocrine Society (PES), the American Academy of Family Physicians (AAFP), American Diabetes Association, and the Academy of Nutrition and Dietetics. The document specifically addressed children of ages 10–18 who met the criteria for type 2 diabetes. This publication recommends the use of insulin for those children with HbA1c >9% or blood glucose concentrations greater than 250 mg/dL or in ketoacidosis. For other children with type 2 diabetes, metformin in combination with lifestyle modification was recommended although the partnership recognized that insulin or insulin with metformin can be used in those with more modest levels of hyperglycemia. At the time of this publication, the results of the TODAY (Treatment Options for type 2 Diabetes in Adolescents and Youth) trial were becoming available. Evidence from this trial suggested that metformin in combination with lifestyle management was superior to metformin alone and also suggested that metformin in combination with rosiglitazone was superior to management with metformin alone. However, all groups showed poor glycemic control over time.

The Children's Hospital Association Consensus Statement: 2014

The Consensus statement was developed over a 3–4 year period by an expert committee work group. It was designed to be a management tool for primary care providers. The consensus statement included input from experts working in 25 pediatric obesity centers, a review of literature and existing guidelines, and consultation with pediatric subspecialists.

The consensus statement reviewed screening tests and endorsed the tests recommended by the AAP expert panel and commented that 50–80% of pediatric obesity centers also measure HbA1c, vitamin D 25 OH levels, TSH with reflex-free T4, and fasting insulin. This statement also noted that >80% of pediatric obesity centers refer children for sleep studies who have suggestive symptoms and performed evaluation of PCOS in females

with irregular menses and/or signs of hyperandrogenism.

The consensus statement includes treatment guidelines for abnormal LDL and/or triglyceride levels as well as elevated ALT levels, and a recommendation for the management of elevated blood pressure according to existing guidelines at the time of this work. Of note, in 2017, the AAP published an updated clinical practice guideline on the management of children with hypertension (Flynn et al. 2017). Finally, the consensus statement discusses the management of polycystic ovarian syndrome in the context of normal blood glucose levels, prediabetes, and type 2 diabetes.

Endocrine Society Clinical Practice Guideline: 2017 Pediatric Obesity—Assessment, Treatment, and Prevention: An Endocrine Society Clinical Practice Guideline

The Endocrine Society CPG (Styne et al. 2017) was developed using the grading of recommendations, assessment, development, and evaluation approach. The 2017 publication was an update to the publication of the original guidelines in 2008 (August et al. 2008). In addition, two systematic reviews were done to support the guideline: (1) Treatments of Pediatric Obesity: An Umbrella Systematic Review, and (2) The Association of Weight Loss and Cardiometabolic Outcomes in Obese Children: Systematic Review and MetaRegression. The first review looked at data from 133 randomized controlled trials with 30,445 patients. The second review focused on changes in lipids, liver function tests, blood pressure, HbA1c, and fasting blood glucose in children with obesity.

The CPG discusses the diagnosis, prevalence, laboratory evaluation, comorbidities, genetic obesity syndromes, activity recommendations, sleep hygiene, screen time, family involvement, school-based and comprehensive behavioral change interventions, breast feeding of infants, dietary guidance that follows the guidelines of the American Academy of Pediatrics and the US Department of Agriculture, psychosocial issues, pharmacotherapy, and metabolic and bariatric surgery. Each section starts with the recommendation followed by a discussion of the values, evidence and finally, remarks.

The Obesity Medical Association: 2018 Pediatric Obesity Algorithm

A cooperative group from Obesity Medical Association analyzed the evidence concerning diagnosis, evaluation, and management, aiming to provide comprehensive practical help to the healthcare professions. The initial version of the Pediatric Obesity Algorithm was launched in 2016 with an expanded and updated version published in 2018.

American Diabetes Association (ADA): Evaluation and Management of Youth-Onset Type 2 Diabetes—A Position Statement: 2018

This ADA Position statement (Arslanian et al. 2018) starts with a discussion on the differences between onset of type 2 diabetes in youth vs. onset in adulthood. It notes that youth demonstrate greater insulin resistance for any degree of adiposity and greater insulin secretion for any degree of insulin resistance. In addition, this position statement recommends testing for pancreatic autoantibodies to exclude the possibility of autoimmune type 1 diabetes as well as genetic evaluation for monogenic diabetes if suggested by clinical presentation.

Due to the recognition of the low rate of hypoglycemia in youth with type 2 diabetes, including those on insulin, the ADA recommends that HbA1c be $<7\%$ for those on oral agents alone. Increasing evidence for rapidly progressive disease due to loss of beta cell function suggests that even lower HbA1c targets may be necessary.

Recognizing that lower-income and minority youth are the most affected, the ADA

recommends culturally sensitive educational materials, assessment of the patient in his or her social context, and preconception counseling.

However, the ADA also recommends a weight loss strategy designed to achieve a 7–10% decrease in excess weight. This should be done through intensive weight management despite the finding in the TODAY (Treatment Options for Type 2 Diabetes in Adolescents and Youth) trial (Flynn et al. 2017) of no long-term difference between those who achieved ≥7% weight loss with lifestyle management and those who were only on metformin monotherapy.

In regards to pharmacotherapy, the only difference between the ADA position statement and the AAP CPG in 2013 was that insulin was recommended if the HbA1c was ≥8.5% instead of 9%. More recently, liraglutide has been recommended for use in adolescents with type 2 diabetes and has shown positive effects on HbA1c, weight status, and fasting plasma glucose (Tamborlan et al. 2019). This was not however mentioned in the ADA position statement as the data were not yet published. Metformin use was recommended for all youth with type 2 diabetes and HbA1c < 8.5%; however, a median time to treatment failure was noted to be a short 11.8 months. The ADA notes that not enough data exist to recommend early use of insulin in an attempt to preserve beta cell function.

The ADA discusses the use of bariatric surgery if the adolescent has uncontrolled hyperglycemia and a BMI ≥35 kg/m^2. However, they also note that 13% of adolescents required a second procedure and an additional 13% required an endoscopic procedure (Inge 2017).

The ADA Position Statement discusses early management of hypertension, albuminuria, screening for neuropathy, retinopathy, evaluation for NAFLD, screening for obstructive sleep apnea, treatment for polycystic ovarian syndrome, and testing and management of dyslipidemia. The discussion of these complications includes concern about the more rapid progression than seen in adults as well as more rapid progression than seen in youth with type 1 diabetes.

AAP Policy Statement: 2019 Pediatric Metabolic and Bariatric Surgery—Evidence, Barriers, and Best Practices

This AAP Policy Statement (Armstrong et al. 2019) reviews the outcomes from several studies on relatively small cohorts of adolescents with severe obesity who have had surgical procedures. The majority of the patients had Roux-en-Y gastric bypass. Outcomes were impressive with average reductions in BMI between 27–29%, and significant resolution of comorbidities at 3 years. Comparison groups of adolescents who were managed with lifestyle all experienced increases in BMI. Surgical complications were reported as infrequent (15%) in the early postoperative period. Eight percent had major perioperative complications. The Policy recommends that surgery be considered at a BMI of 35 kg/m^2 with complications or 40 kg/m^2 with or without complications. Barriers to care are discussed. A disparity of care between groups with lower socioeconomic status and minority race or ethnicity and those with average or high socioeconomic status and white race is noted. Other barriers mentioned include providers who are reluctant to refer their patients for surgery and lack of insurance coverage. The Policy notes that care should occur in a multidisciplinary setting that can provide high-quality pediatric metabolic and bariatric surgery.

Issues with the Guidelines/Recommendations

We have reviewed the existing guidelines and recommendations. The following discussion considers emerging issues of importance in the field of pediatric obesity medicine.

Media Use

AAP Council on Communications and Media policy statement (American Academy of Pediatrics Council on Communications and Media

2016) reviewed publications on television, videos, and mobile or interactive technologies. Below age 2 years adult participation is essential, and excessive media use could be damaging. Below 18 months nothing besides video-chatting should be allowed. Within the bracket of 18–-24 months only selected programs and apps should be considered, always in the presence and with assistance of grown ups. Beyond age 2, 1 h or less per day of appropriate movies or videos could be permitted. Bedtime curfew starting 1 h before sleep, with removal of all electronic devices, is another precaution.

Public policy has been historically oriented toward prevention of childhood obesity. Virtually no public policy addresses the treatment and management of the 30% of children and adolescents suffering with obesity. Even attempts to limit marketing to children are difficult to enforce, although in September 2019 the Center for Digital Democracy was able to pass the Children's Online Privacy Protection Act (COPPA) directed at You Tube, which is the first policy limiting media targeted at children. Unfortunately only children aged 12 and younger receive pop ups directing them to You Tube Kids, which is supposed to be a "safer platform for children" (The Children's Online Privacy Protection Act 2019).

Failure to Address the Dramatic Increase in Youth Onset Type 2 Diabetes

The prevalence of youth onset Type 2 diabetes has dramatically increased over the past 20 years, largely as a result of the dramatic increase in youth with obesity and in particular, in youth with severe obesity. According to a recent consensus report (Arslanian et al. 2018) on youth-onset type 2 diabetes, evidence suggests that type 2 diabetes in children is different not only from type 1 diabetes but also from type 2 diabetes in adults. Although type 2 diabetes in youth more closely resembles the pathophysiology in adults with insulin resistance and nonautoimmune beta cell failure, youth-onset type 2 diabetes displays unique features, including rapidly progressive beta cell decline as well as accelerated development of diabetes complications. Several large studies have contributed to most of what we know about youth-onset Type 2 diabetes: The SEARCH for Diabetes in Youth Study (Hamman et al. 2014), the TODAY (Zeitler et al. 2007; TODAY Study Group 2013) (Treatment Options for type 2 Diabetes), and the RISE (Zeitler 2019; Buse et al. 2018) (Restoring Insulin Secretion Study). Unfortunately, these trials have shown that youth who develop type 2 diabetes suffer a more aggressive, rapidly progressive decline in beta cell function as compared to older adults with new-onset type 2 diabetes. In RISE, youth with prediabetes or recently diagnosed type 2 diabetes had 50% lower levels of insulin sensitivity as compared to adults with similar age-adjusted BMI. Not surprisingly, insulin secretion was two- to threefold greater in adolescents as compared to adults. Importantly, even with treatment with either metformin or insulin (glargine), beta cell function significantly declined in 12–15 months from baseline. Despite this, treatment options for type 2 diabetes in adolescents have been extremely limited to two FDA-approved drugs: insulin and metformin, with the recent addition of GLP-1 agonist liraglutide, and the promotion of healthy lifestyles.

The trials mentioned here strongly point to the need to correct dysregulation of glucose and fat metabolism before children and adolescents develop prediabetes and then progress to diabetes. Since progression occurs in spite of pharmacotherapy, weight management becomes the front line of defense against the progression of glycemic dysregulation. The cornerstones of pediatric weight management are diet and lifestyle modification. However, this is usually approached with a "balanced diet," which while typically includes a decrease in carbohydrate consumption from baseline, may not be enough to effect an increase in insulin sensitivity. To date, there is no universal guidance for how to change carbohydrate consumption to effect insulin sensitivity, and each child has a unique level of insulin resistance. Parents and children are mostly focused on a decrease in %BMI or actual weight instead of an increase in insulin sensitivity when

the most critical part of their child's treatment could be the prevention of glycemic dysregulation. Historically, we have poorly defined management of this increasingly common complication and we are witnessing the consequences.

The Lack of Pharmacotherapeutic Options for Children and Adolescents

Pharmacotherapy for adults with obesity is a mainstay of treatment. Six medications are currently FDA approved for use in adults with BMI $\geq$ 30 kg/m^2 or those who are overweight (BMI $\geq$ 27 kg/m^2) with obesity-related complications. These medications are covered by most insurance plans for adults, defined as those 18 years or older. However, the only weight loss medication approved by the FDA for children or adolescents is orlistat ($\geq$12 years), and its use is curtailed by significant gastrointestinal side effects. Phentermine is approved for use in older adolescents >16 years of age. No other medications are approved by the FDA for weight loss under the age of 18. There are very limited data on the safety and efficacy of the use of these medications in children and adolescents. Over the past 5 years, pediatric obesity medicine experts have increasingly used weight loss medications "off label." As a group, pediatricians have long used medications "off label," so much so that the American Academy of Pediatrics published a Policy Statement in 2014 on "Off-label Use of Drugs in Children" (AAP Policy Statement 2014). The cardinal principle for the use of off-label medication is to ensure that the benefit of using the medication outweighs the risk.

Evolution of the use of medication (other than orlistat or phentermine) to treat obesity in children and adolescents began in 2012 and 2013 when two studies looked at the use of metformin and lifestyle intervention vs. just lifestyle intervention. Although the results were reported as statistically significant, the weight loss reported was relatively small: 1.3 kg/m^2 and 1.07 kg/m^2 (Mauras et al. 2012; Kendall et al. 2013). Likewise, a trial using a GLP 1 receptor agonist in 2013 only showed a 1.13 kg/m^2 placebo subtracted difference (Kelly et al. 2013).

Pediatric obesity medicine specialists face additional barriers to the use of weight loss medications other than lack of FDA approval. A significant barrier is the lack of insurance coverage for medications leading to out-of-pocket expense for the family. Because of this problem, pediatric obesity medicine specialists who have determined that the use of weight loss medication outweighs the risk default to using phentermine, which is relatively inexpensive to purchase, and with topiramate, which can be prescribed and covered by insurance since it is a medication approved by the FDA for other use in the pediatric population. Similarly, the combination of buproprion and naltrexone or lisexamfetamine (approved in 2015 for use in adults or use for binge-eating disorder) are used. Recently (August 2019), the use of liraglutide was approved for children and adolescents 10 years of age or older, but for the indication of T2DM, not for weight loss.

Metformin is commonly used in the population of children and adolescents, although approved by the FDA only in pediatric patients 10 years of age or older with T2DM. However, many obesity medicine specialists prescribe metformin for PCOS or severe insulin resistance with or without impaired glucose tolerance. Multiple trials (McDonagh et al. 2014; Khokhar et al. 2017; Kaplowitz 2017) have shown that a small amount of weight loss is associated with the use of metformin, especially in the first few months after starting the medication.

Obstacles to Bariatric Surgery in the Adolescent with Obesity

Although the rate of weight loss surgery in adolescents with severe obesity has been increasing, it is still very low. Bariatric surgery in adolescents with severe obesity has been found to be effective in decreasing excess weight and improving comorbidities. However, data on the long-term efficacy and safety of adolescent bariatric surgery are limited. Real barriers to this

treatment modality exist. The leap from behavioral management to surgery is too drastic for many families. In addition, although the recent Policy statement from the AAP endorses bariatric surgery as a safe and effective strategy for youths with severe obesity, there are few studies on optimal timing, best preoperative and postoperative care, and adjunctive (including behavioral and medication) therapy. This compounds the lack of insurance coverage, reported as less than half the coverage in adults of similar BMI and comorbid status, the lack of multidisciplinary weight management programs with a surgical tract or referring relationship to a bariatric surgical program, and the low socioeconomic status of many of the adolescents with severe obesity who meet criteria for surgery (Armstrong et al. 2019).

Forty three percent of the adolescents who start the process of evaluation for bariatric surgery made it through the process in one retrospective chart review of 145 adolescent patients (Brode et al. 2018). This statistic is similar to the surgical completion rate for adults. Previous adult studies have found an association between attrition and psychological factors. Interestingly, the study in adolescents by Brode et al. found no difference in assessed psychological factors between those adolescents who completed the program and had surgery and those who did not complete the program. Specifically, there were no differences in current psychotropic medication use, utilization of outpatient therapy, current substance use, or previous inpatient hospitalization for a psychiatric condition. In addition, a recommendation by the clinical team for initiation of psychological treatment did not accurately predict completers vs. noncompleters. Male sex was a significant predictor of noncompletion of surgery, but the reason for this was not clear.

Another significant issue is the management of the change in diet required after surgery in the setting of low-income and minority youth with severe obesity who get a significant amount of their daily nourishment from publically funded meals. Modifying Federally funded School Breakfast and Lunch meals even with a signed letter from a medical provider for a "special diet" is extremely challenging. The new AAP policy advises the consideration of weight loss surgery in adolescents with BMI down to 35 kg/m^2. This will include many adolescents who are fully involved in normal activities, such as sports teams, school clubs, and social events. Many of the adolescents are expected to make "healthy choices." Following a restrictive diet in these situations will be challenging at best.

To complicate matters further, there is a lack of even a basic understanding on the management of adolescents with severe obesity, with or without weight loss surgery. There are no studies detailing dosage of behavioral modification or pharmacotherapy before or after surgery. In addition, studies involving the relative benefit of bariatric surgery performed during adolescence compared to young adulthood (18–25 years old) are needed (Ryder et al. 2018). Historically, pediatricians have been very reticent to use weight loss medications in adolescents with severe obesity. It is difficult to imagine that they will feel more comfortable with managing adolescents with obesity as they progress through the rest of their adolescence post surgery.

Few Programs Providing Multidisciplinary Treatment for Youth with Obesity

In a prospective study collecting data from 31 pediatric weight management programs across the United States, early BMI reduction in the first month of treatment was significantly associated with greater long-term BMI reduction at 6 and 12 months ($\geq$5% BMI reduction from baseline) in adolescents with obesity-seeking treatment (Gross et al. 2019). However, the availability of large multidisciplinary weight management programs with Stage 3 Comprehensive Multi-Disciplinary Intervention and Stage 4 Tertiary Care Intervention is limited with large sections of certain states devoid of Obesity Medicine specialists, particularly those with pediatric obesity experience. In a review of 16 studies from 1995 to 2017 (Zolotarjova et al. 2018) analyzing the effects of multidisciplinary interventions on weight loss and health outcomes in children and

adolescents with morbid obesity, positive weight loss results were observed in numerous studies with younger children having a greater reduction in BMI z-score in comparison to adolescents. Authors noted the importance of early incorporation of multidisciplinary interventions in obesity treatment in addition to the lack of standardization of obtaining parameters. Of note, cardiovascular risk parameters were only investigated in three of the studies with improvements noted in this limited subset, and only some of the studies analyzed the effects of intervention on psychosocial well-being. In addition, few reported long-term follow-up outcome measures, limiting the utility of the findings in regards to sustainability and effectiveness of measure studies with a more standardized approach warranted.

Recognition of Rare Variants of Obesity

Obesity is a heterogeneous multifactorial disease, which results from the interrelationship between behavioral, environmental, and genetic factors. Although the genetic causes underlying obesity remain largely unknown, genetic factors are estimated to account for 40–70% of the obesity predisposition of an individual (Zhao and Grant 2011; Ranadive and Vaisse 2008; Serra-Juhe et al. 2019). There are syndromic causes for obesity; however, obesity is often not accompanied by specific phenotypes. There are rare genetic variants affecting several genes such as LEP, LEPR, MC4R, PCSK1, and POMC found in nonsyndromic patients (Serra-Juhe et al. 2019), and it has been estimated that 7% of patients with severe pediatric obesity may have rare abnormalities of chromosomes and/or highly penetrant genetic mutations (Styne et al. 2017; Farooqi and O'Rahilly 2008). MC4R deficiency is the most common monogenic form of obesity accounting for 2–5% of severe obesity in adult and pediatric populations.

Genome-wide association studies (GWAS) have found strongly associated genomic variants with a number of loci reported from GWAS analyses of adult BMI and obesity also having a role in obesity in pediatric populations. Genome-wide approach has revealed genes that underlie the pathogenesis of childhood obesity (Zhao and Grant 2011). Understanding the genetics of childhood obesity is vital in the prevention and treatment of pediatric cases in order to provide families with individualized follow-up and genetic counselling as well as therapeutic approaches for genetic causes of obesity (Chesi and Grant 2015). Although the GWAS approach provides a more comprehensive strategy to locate causal genes related to obesity, the challenge arises from lack of availability of such resources for most patients undergoing evaluation, and limited GWAS-related reports specific for childhood obesity, with most studies uncovering loci in the adult context (Zhao and Grant 2011).

Failure to Recognize the Burden of Risk Factors as Children with Obesity Become Young Adults

Many studies have addressed the presence of risk factors in children and adolescents with obesity. These studies document increased incidence of metabolic syndrome, hypertension, and glycemic dysregulation with increasing severity of obesity. Likewise, in the past two decades, the incidence of cardiovascular disease in young adults (18–50 years) has been steady or has increased, while the incidence of cardiovascular disease in adults over 50 has decreased. A higher BMI in young adulthood has a long-term negative effect on blood pressure and heart structure. These observations suggest that we may see an increase in cardiovascular disease as this younger population ages. Obesity in youth is a major contributing factor to this problem. Not only in developed countries, but also in undeveloped countries, the prevalence of obesity in childhood has increased. In the US, the proportion of children (aged 12–19 years) with a healthy BMI declined between 1999 and 2013, and is now appearing to level off between 65–70%. As children with a body mass index percentile at the >95th percentile have a greater chance of maintaining obesity into adulthood, appropriate counseling and lifestyle modifications to families is needed to

prevent the known complications of excess weight gain. The goals of treatment involve the prevention and reduction of the risk of obesity-related sequelae with improvement of health outcomes. A weight loss of 5–10% has been associated with improvement in comorbidities (Kumar et al. 2019).

Other risk factors associated with obesity that directly contribute to cardiovascular disease are physical inactivity, hypertension, diabetes, dyslipidemia, and dietary intake.

In the US, physical activity levels continue to decline in children, and especially in adolescents. Hypertension rates in children with obesity increase as adiposity increases. Prevalence varies between 3.8–24.8% in studies of children with obesity, as compared to the prevalence of 3.5% in the general population. Furthermore, lack of a nocturnal dip in blood pressure is characteristic of children with obesity (Flynn et al. 2017). The increase in incidence of Type 2 diabetes was discussed earlier in this chapter. In the last 40 years, lower triglyceride levels and higher HDL levels have been seen in the general population, but not so in children and adolescents with obesity. In addition, older adults have demonstrated greater improvement in lipid levels than younger adults.

A decrease in the dietary intake of trans fats, total fat, and saturated fat has occurred in the US over the past 30 years. However, these changes were not as profound in children aged 12–19 years as they were in those older than 19 years. NHANES noted that those with a low socioeconomic status, African Americans or Mexican Americans did not have an improvement in dietary fat. In particular, excessive consumption of sugar sweetened beverages and processed meat was strongly associated with cardiometabolic disease–related mortality.

Conclusions

Rates of obesity in children and adolescents have dramatically increased over the last 40 years. In particular, the prevalence of severe obesity continues to climb. Lower socioeconomic and minorities are at highest risk. Management of this global health crisis has not kept up and now younger adults are suffering unprecedented rates of type 2 diabetes and early cardiovascular disease. Family-based behavioral therapy for those children at highest risk requires access to multidisciplinary care in pediatric obesity centers. Such centers are not available in large areas of the country, receive poor institutional support, and often have long waiting times to be seen in the center. An extraordinary amount of time commitment from the family is expected to meet the >25 h of patient contact hours over a 6-month time frame recommended by the USPSTF (US Preventive Services Task Force 2010). The leap from medical treatment to surgical is extreme for many families and insurance coverage is not universal. Randomized controlled trials are necessary to establish optimal treatment.

Type 2 Diabetes: An Unresolved Disease 41

Sarah Cuschieri

Contents

Abstract

The existence of diabetes has been reported for centuries dating back to the Egyptian period. As years passed, scientists have identified the pathophysiology of this disease and its management. Diabetes is a multifactorial disease and different types of diabetes have been reported. Even though this is a disease of antiquity, its prevalence has been on the rise, and it is a currently a global epidemic as well as public health emergency. Different stakeholders (ranging from the medical professional, to policy makers and governmental bodies) need to work together to prevent health inequalities and control this growing epidemic.

Diabetes: A Historical Disease

Diabetes mellitus was recognized around 1550 BC by the Egyptians, between 400 and 500 BC by Hindu pioneers Charaka and Sushruta, as well as by Aretaeus of Cappadocia, in the first century AD. In Greek diabetes means syphon, suggesting the constant elimination of urinary fluid by severely affected patients (International Diabetes Federation 2017; Tattersall 2010).

The pioneer to describe serum hyperglycaemia and the association with sugar in urine was Matthew Dobson from Liverpool, way back in 1775 (Dobson 1776). In 1797 the surgeon John Rollo applied the adjective 'mellitus', meaning 'honey-like' in Latin, to the already established 'diabetes'. Furthermore, he concluded that the serum sugar was originating from vegetables being digested in stomach, and hence proposed a diet high in animal produce as a treatment option for this condition (Rollo 1797). It was in 1815 that glucose was identified as being the leading sugar in the diabetic urine, paving the way for chemical testing, instead of less elegant dipping a finger and tasting it. However, it was only a century later, between 1913 and 1915, that the physician Ivar Christian Bang established a practical micro-method to measure glucose, contributing to the introduction of the glucose tolerance test (Tattersall 2010).

During the same era, the pathophysiology of diabetes was being explored. It was in 1869 that Paul Langerhans made the great discovery that the pancreas parenchyma included 'islands' of different cells (Langerhans 1869). Later on, these 'islets of Langerhans' were reported to be responsible for pancreatic secretions (Laguesse 1893). In the 1900s, the pancreatic secretion was named 'insulin' and was utilized as an injectable treatment for diabetes (De Meyer 1904; Banting et al. 1922). It was in January 1922 that Banting and Best conducted the first human experiment on an adolescent, using injectable insulin. The biological abnormalities and the clinical symptoms related to diabetes were reverted back to normal, making this experiment successful (Banting et al. 1922). However, in the 1930s, it was reported that not every diabetic patient had a positive outcome following injectable insulin. There were those 'sensitive' and 'insensitive' to insulin therapy (Himsworth 1939). The various diabetes classifications and types will be discussed in later sections.

Diabetes management was refined over the years. Designer insulins *lispo*, *aspart*, *glargine* and *detemir* allow custom-tailored prescriptions. The 'insulin pen' made its way in 1981 by John Ireland, which made the management of serum glucose by insulin more acceptable to patients (Paton et al. 1981). Oral hypoglycaemic agents came around in the 1940s, when sulphonylureas were found to be insulin secretagogues and were manufactured (De Franco et al. 2015). Later in 1960 Metformin was introduced on the European market (Tyberghein and Williams 1957). Since then, different classes of oral and injectable hypoglycaemic agents appeared, such as glitazones, glucose-like peptide 1 (GLP-1) agonists, and dipeptidylpeptidase-4 (DPP-4) inhibitors.

Diabetes: A Disease of Many Faces

Himsworth in 1936 pioneered in suggesting the presence of different types of diabetes (Himsworth 1939). Over the years, various expert committees attempted to classify the different forms of diabetes. In 1965, age of onset was considered as the determining factor for the type of diabetes a person develops. The World Health Organization (WHO) divided diabetes into 'Juvenile-onset' and 'Maturity-onset' disease. This classification changed in 1976 to 'Insulin-dependent diabetes mellitus' (IDDM) and 'non-insulin-dependent diabetes mellitus' (NIDDM) (National Diabetes Data Group 1979). However, a revised classification was proposed by the American

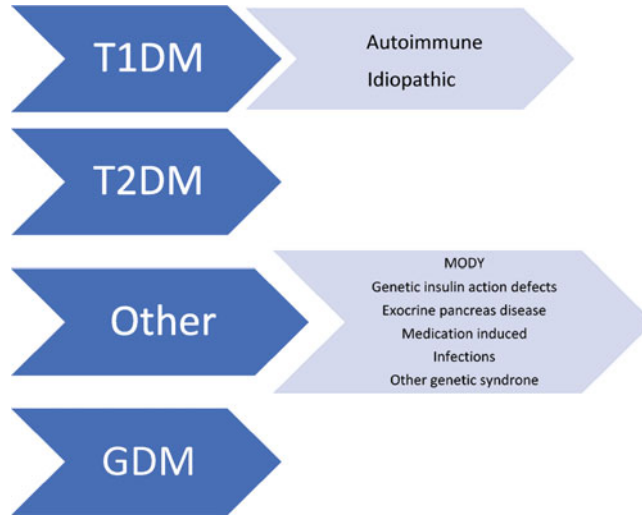

Fig. 41.1 The consensus between ADA (1997) and WHO (1999) aetiological classification of glycaemia disorders (The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus 1997; World Health Organisation Consultation Group 1999) *T1DM* Type 1 diabetes mellitus, *T2DM* Type 2 diabetes mellitus, *MODY* Mature onset disease of the young, *GDM* Gestational diabetes

Diabetes Association (ADA) in 1997 and seconded by the WHO later on in 1999 (The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus 1997; World Health Organisation Consultation Group 1999), as seen in Fig. 41.1.

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus (T1DM) affects individuals usually before 35 years, and is characterized by severely reduced or absent pancreatic beta cells. Hypoinsulinaemia and episodes of acute diabetes ketoacidosis are the usual features. These individuals require insulin therapy for life. Two sub-sets of T1DM have been identified: (1) Autoimmune and (2) Idiopathic. Autoimmune attack of the pancreas is more common in Europids. Autoantibodies, including anti-glutamine acid decarboxylase (anti-GAD), anti-insulin and/or islet cell antibodies are usually detected on presentation (Alberti 2010; Libman et al. 2011). On the other hand, the idiopathic T1DM is more common in non-Europid populations, with the loss of beta cell function but absence of autoantibodies. However, these individuals still have episodes of ketoacidosis and require exogenous insulin for survival (Alberti 2010; Libman et al. 2011).

Neonatal Diabetes

Neonatal diabetes is conventionally diagnosed around 3–6 months of age, in the absence of any autoantibodies (Shield et al. 1997). Two types are present: transient and permanent. The transient type is a rare condition, and is associated with intrauterine growth retardation and the inheritance of two chromosome homologs from the father alone (Sperling 2006a; von Mühlendah and Herkenhoff 1995). Diabetes during adulthood is a risk in this population (Metz et al. 2002). The latter type of neonatal diabetes has been associated with activation of KCNJ11 potassium channel subunit, by Kir 6.2 gene mutation, along with ABCC8 (sulfonylurea receptor 1) and insulin promoter factor (IPF-1) mutations (Sperling 2006b). The treatment of choice for neonatal diabetes is sulphonylureas.

Latent Autoimmune Diabetes of Adults (LADA)

LADA is mostly detected at age 35 or older, along with the presence of GAD autoantibodies. The characteristics of LADA consist of an overlap between type 1 and type 2 phenotypes, with an ultimate exogenous insulin dependence (Tuomi et al. 1993).

Maturity-Onset Diabetes of the Youth

Maturity-onset diabetes of the youth (MODY) is composed of a collection of autosomal dominated inherited disorders that usually present before the age of 25 years. A history of Hyperglycaemia in the family is very common. MODY is non-insulin dependent since it results from a single genetic defect in the beta cell function, rather than the presence of insulin resistance (Tattersall 1974, 1998).

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) is a hyperglycaemic state that presents during pregnancy. At-risk mothers undergo diabetes screening through an oral glucose tolerance test around 28 weeks. Risk factors for GDM include previous GDM, increase in maternal age, type 2 diabetes mellitus in the close family, previous macrosomic babies, and obesity (Metzger et al. 2007; Chan et al. 2002) The plasma glucose level normally goes down to normal levels postpartum, yet the possibility of subsequent type 2 diabetes should not be neglected.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus (T2DM) is the dominant modality. It is a heterogeneous disease suffering from the impact of environmental and genetic influences. The genetic inheritance is mainly linked to the beta cell function, differently from acquired factors connected to insulin resistance (Tuomilehto et al. 2001).

Insulin sensitivity of the beta cells determines glucose homeostasis. Exhaustion of beta cell output along with insulin resistance results in persistent hyperglycaemia. Increased free fatty acid levels, especially small dense LDL-C and triglycerides, are similarly observed during insulin resistance and hyperglycaemia, making T2DM individuals at a higher cardiovascular risk (Cobb et al. 2013).

Type 2 Diabetes Mellitus: A Spectrum of Dysglycaemic Profiles

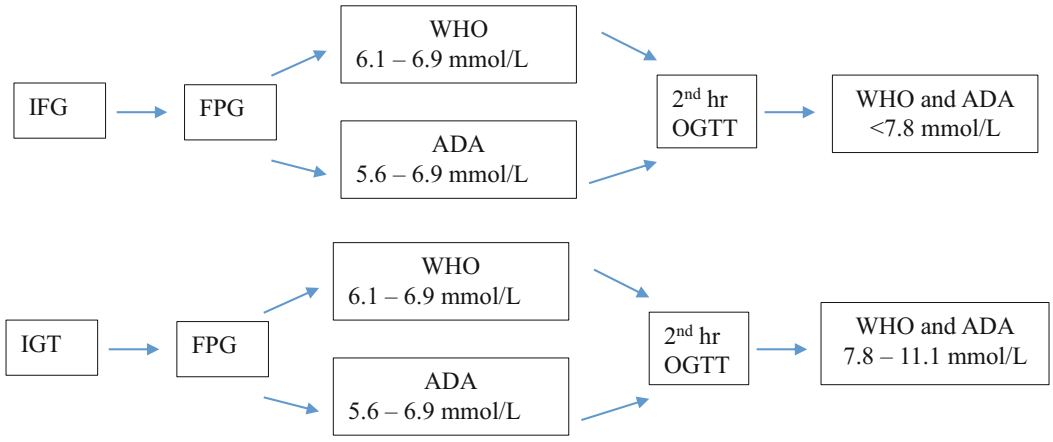
The hyperglycaemia state can be described as a spectrum of phenotypes with the end stage being full-blown type 2 diabetes mellitus (T2DM). However, in most individuals prior to reaching this state, a mild asymptomatic hyperglycaemic profile would be present and only picked up on screening.

Impaired Glucose Regulation

A raised plasma glucose level mildly above the normal baseline (>7 mmol/L) is considered as impaired glucose regulation or pre-diabetes. This hyperglycaemic state is still considered as a metabolic condition originating from a combination of pancreatic beta cell dysfunction (primary or secondary) and insulin resistance. Subsequent type 2 diabetes, cardiovascular and dyslipidemic comorbidities cannot be ruled out (Alberti 1996).

Impaired glucose regulation is divided into two different hyperglycaemic states: impaired fasting blood glucose (IFG) and impaired glucose tolerance (IGT). The underlying pathophysiology for both hyperglycaemic states is insulin resistance; however, the site where this occurs varies. Hence, the method of diagnosis also varies. Impaired glucose tolerance (IGT) is investigated by an oral glucose tolerance test (OGTT), with 7.8–11.0 mmol/L of glucose after 2 h. It is uncommon in women >60 years.

IGT signals peripheral insulin resistance of the skeletal muscle, with minimal effect on the liver. In contrast, impaired fasting blood glucose (IFG) points towards hepatic insulin resistance with a normal peripheral pattern. In fact, during an OGTT, there is severe impairment of the first phase of insulin response, but insulin secretion



IFG – Impaired fasting glucose
IGT – Impaired glucose tolerance
FPG – Fasting plasma glucose
WHO – World Health Organization
ADA – American Diabetes Association
OGTT – Oral glucose tolerance test

Fig. 41.2 Different diagnostic criteria for pre-diabetes (American Diabetes Association 2018; World Health Organization 2006) *IFG* Impaired fasting glucose, *IGT* Impaired glucose tolerance, *FPG* Fasting plasma glucose, *WHO* World Health Organization, *ADA* American Diabetes Association, *OGTT* Oral glucose tolerance test

improves during the second phase. This condition is more common in men across all age groups; however, prevalence tends to plateau in the middle age (Kanat et al. 2012). The diagnostic criteria for IFG include fasting glucose and OGTT. Disagreements are present between international organizations with regard to the diagnostic cut-off criteria, as seen in Fig. 41.2.

Such disagreements are also present for the cut-off point for the glycated haemoglobin (HbA1C). The World Health Organization (WHO) and International Diabetes Federation (IDF) recommend 6.0–6.5% for high-risk individuals (Kilpatrick et al. 2009). The American Diabetes Association (ADA) considers this state with an HbA1C between 5.7–6.4% (American Diabetes Association 2018). In order to establish a clinical diagnosis of both IFG and IGT, it is important that a repeat OGTT is performed within 3 months of the initial diagnosis. This is essential since a substantial proportion of these individuals would have already developed type 2 diabetes.

During impaired hyperglycaemic states, lifestyle interventions or else initiation of Metformin could reduce the risk of developing type 2 diabetes by about 58% (Tuomilehto et al. 2001; Hamman et al. 2006; Eriksson and Lindgärde 1991; Diabetes Prevention Program Research Group et al. 2009; Lindström et al. 2003; Pan et al. 1997; Ramachandran et al. 2006).

Type 2 Diabetes Mellitus Profile

A multilevel approach is depicted in Fig. 41.3 (Susser 1996).

Early Life Genetics and Epigenetics

The risk to develop type 2 diabetes mellitus can initiate from the intra-uterine period. It has been reported that a hyperglycaemic foetal environment predisposes to insulin resistance, obesity and T2DM in adulthood (Jiang et al. 2013). This

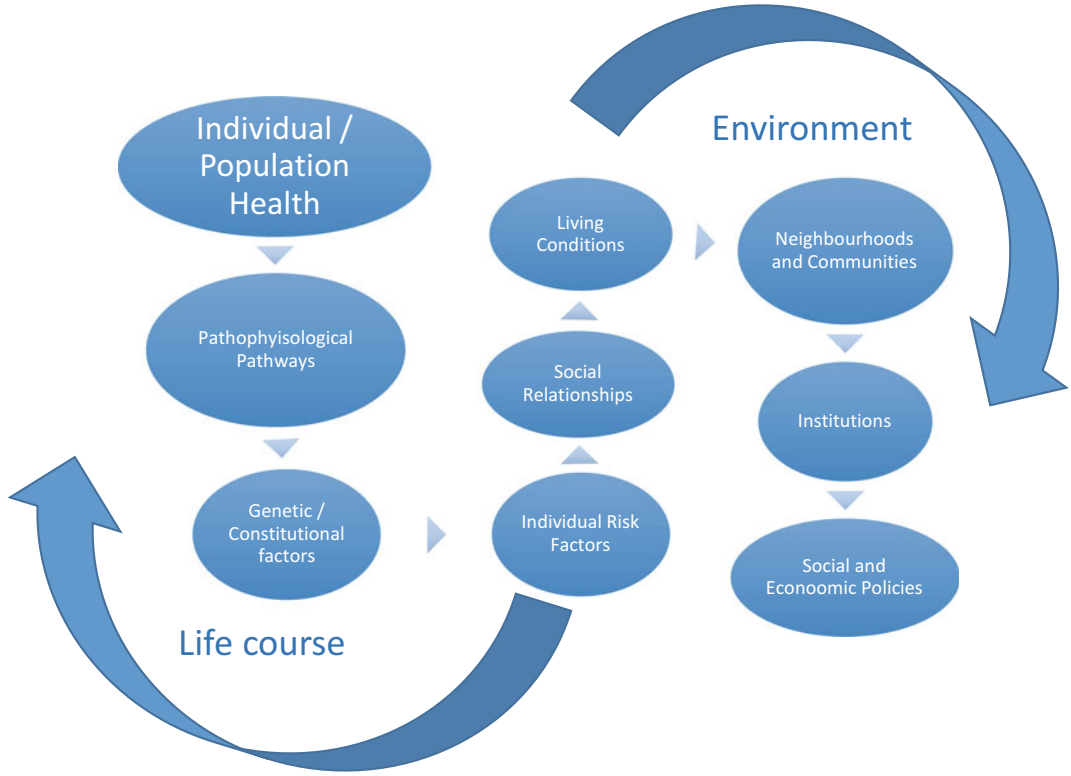


Fig. 41.3 Diabetes mellitus ecologic paradigm over the life course (Kaplan et al. 2000)

is followed by early-life growth trajectories amalgamated with interactions between non-modifiable (genetics) and modifiable (environment) factors that have an effect on insulin resistance, beta cell function and obesity (Kahn et al. 2006; Sladek et al. 2007; Alberti et al. 2006). The birth weight of the child is also a determinant for future T2DM. The *thrifty phenotype hypothesis* suggests that low birth weight following inadequate nutrition in utero leads to biological programming later on in life with a susceptibility to developing T2DM (Randle et al. 1963). On the other hand, the *theory of an association* reported by McCarthy suggests that an association between diabetes and low birth weight is due to pleotropic genes, related to both foetal growth and diabetes onset (McCarthy 1998).

Genetic Element

Twin studies have reported that there is a genetic linkage for the development of T2DM. Monozygotic twins were reported to have a concordance rate of 90%, with a 37% concordance rate for dizygotic twins (Newman et al. 1987; Beck-Nielsen et al. 2003). A person born to one parent afflicted by T2DM has a 40% lifetime risk of progressing to the same condition (Köbberling and Tillil 1982). A number of single-nucleotide polymorphisms (SNPs) have been identified that contribute to the basis for the genetic susceptibility for T2DM (Cuschieri 2019a). Inappropriate lifestyle can also induce diabetes-susceptible genotypes.

Diagnostic and Screening Testing

The T2DM diagnostic tests are the same as the screening tests for this disease. In 2006 a consensus was reached between WHO, IDF, and ADA, endorsing the same diagnostic cut-off points, as seen in Fig. 41.4.

Obesity

Excess adiposity (obesity) is one of the leading contributing factors to the diabetic epidemic. Both diseases have underlying insulin resistance and inflammatory pathways. The high adiposity status arises from body fat deposition following unhealthy dietary habits, sedentary lifestyles as well as genetic predispositions. The social determinates of health should not be overlooked in the context of obesity, with low socioeconomic status being associated with high adiposity (Cuschieri 2019b). Furthermore, for most of the countries, the typical population living environment is obesogenic in nature, predisposing individuals to unhealthy habits.

Diabetes: From Historical Curiosity to a Serious Epidemic

The (T2DM) burden across different sectors includes disability; morbidity; diminished life expectancy; reduced quality of life; individual and national financial losses; loss of human and social capital; and ultimately increase in mortality (Ali et al. 2010). On evaluating European diabetes-related deaths in 2017, significant mortality rates can be observed across the different countries, as seen in Table 41.1.

A large proportion of this burden is originating from the global ageing of the population. In turn, this has an effect on both the individual and the country level, with an increase in economic burden across healthcare systems. As a matter of fact, this can be observed in Table 41.2, where the mean diabetes expenditure per diabetic person across the European countries was compared for the years 2015 and 2017 (International Diabetes Federation 2015, 2017). Actions targeting the ageing population with appropriate preventive

interventions and strategies are required. Furthermore, it has been reported that this growing T2DM epidemic is occurring hand in hand with the also exponentiating obesity prevalence, as seen clearly in Table 41.3. Hence targeting both conditions is imperative.

Adapted from WHO Global Observatory data and International Diabetes Federation Atlases (International Diabetes Federation 2017; Cuschieri 2019b; World Health Organization n.d.)

Preventive Screening

The backbone structure for screening criteria was established in 1968 by Wilson and Jungner, to which T2DM fits perfectly. This is because T2DM is a serious disease, with frequent comorbidities and shortened expectancy of life. Diabetes screening tests are relatively cheap with no adverse effects (Evans et al. 2011; Wilson and Jungner 1968). Alas, the setting up of population-based preventive screening has been debated over the years even though diabetes has been a growing disease, affecting both the paediatric and adult population. In 2003, the World Health Organization suggested that if the prevalence of undiagnosed T2DM was very high in a population with an associated cardiovascular disease risk, then population level screening would be beneficial and recommended (International Diabetes Federation 2017). Furthermore, a pan-European population-based screening study (ADDITON—Europe) investigated whether a T2DM screening programme was feasible using a multi-stage screening protocol. The researchers concluded that although this may be challenging, a screening protocol is feasible to implement at a population level (van den Donk et al. 2011). One needs to keep in mind that when screening for T2DM, individuals suffering from impaired fasting blood glucose (IFG) and impaired glucose tolerance (IGT) would be picked up (depending on the screening protocol implemented).

Given the possibility of future T2DM, more adherent follow-up is advised when compared to normoglycaemic individuals. They may be initiated on lifestyle interventions or medication in order to prevent the conversion of their glycaemic status to full-blown diabetes. Hence, screening for T2DM may be visualized as sustaining an added increase in economic burden on the healthcare system. Over time, preventive screening would have a positive outcome on healthcare systems, mortality and morbidity of at-risk individuals, with an increase in productivity and sustainability of the country's economic growth.

Contents

Abstract

Most critically ill patients develop hyperglycemia, the degree of which is associated with mortality. However, randomized controlled trials investigating tight glucose control have found a divergent impact on morbidity and mortality, possibly explained by differences in glucose targets, monitoring and titration tools, and nutritional strategies. In patients receiving parenteral nutrition early in the course of critical illness, tight glucose control has shown to be effective and safe when performed with a validated protocol, including accurate glucose measurements. The optimal blood glucose target remains unclear for patients not receiving early parenteral nutrition, and may differ according to the premorbid diabetes status. Efficacy and safety of tight glucose control can be improved by

using validated decision-support software, continuous glucose monitoring and closed-loop insulin delivery, although widespread implementation of these technologies is precluded by the ongoing controversy on the topic, the added cost, and, for some devices, lack of measurement accuracy.

Glucose targets · Intensive insulin therapy · Intensive glucose monitoring · Tight glucose control · Closed-loop glucose control · Continuous glucose monitoring · Hypoglycemia risk · Hypoglycemia prevention

Introduction

The stress response evoked by severe medical illnesses, major trauma, and surgery induces profound metabolic and endocrine alterations, including insulin resistance and resultant hyperglycemia. Numerous observational studies in different subgroups of critically ill patients have shown a clear relationship between spontaneous (i.e., untreated) blood glucose concentrations and subsequent mortality risk, whereby the risk of mortality is lowest in patients with blood glucose in the normal, age-adjusted fasting range, and progressively increases with more severe hyper- and hypoglycemia (Fig. 42.1) (Falciglia et al. 2009; Kosiborod et al. 2005; Egi et al. 2008). In patients with pre-existing diabetes, a similar U-shaped relationship between blood glucose and outcome has been observed, although the curve appears flattened and somewhat shifted to the right. However, whether such associations reflect a causal relationship between blood glucose concentrations and outcome cannot be deducted from observational studies. Indeed, the higher mortality risk in patients with more severe hyperglycemia and hypoglycemia could equally be explained by increased illness severity in these patients, with inherently an increased mortality risk.

Hyperglycemia and Outcome: A Causal Relationship or Not?

Assessment of causality can only be performed by a randomized controlled trial in which patients are randomized to treating stress hyperglycemia

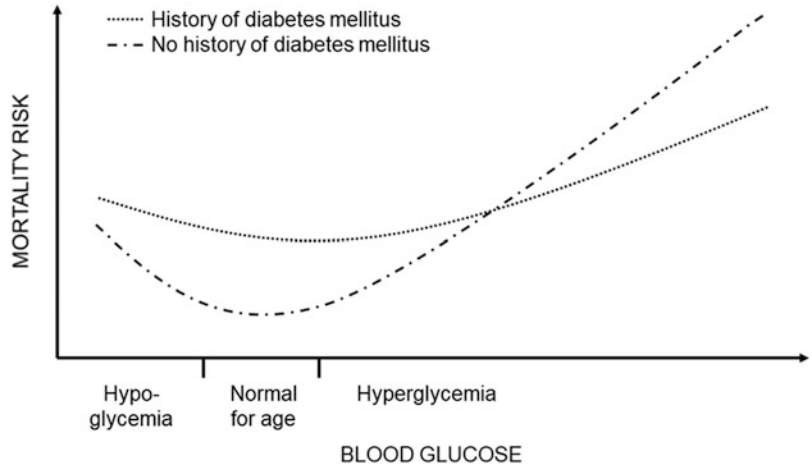

Fig. 42.1 Association of blood glucose concentrations with outcome. In critically ill patients, numerous observational studies have revealed a U-shaped relationship between upon-admission and mean blood glucose concentrations and the risk of mortality, with the lowest mortality risk associated with normal-for-age fasting blood glucose concentrations in patient without pre-existing diabetes. In patients with pre-existing diabetes, the curve is flattened and the nadir somewhat shifted to the right

versus tolerating this condition up to a certain threshold. Randomized controlled trials (RCTs) on this topic have yielded conflicting results, however (Van den Berghe et al. 2001, 2006a; Vlasselaers et al. 2009; Finfer et al. 2009; Brunkhorst et al. 2008; Preiser et al. 2009; Annane et al. 2010; Kalfon et al. 2014; Macrae et al. 2014; Agus et al. 2012, 2017a; Bilotta et al. 2007, 2009; Jeschke et al. 2010).

In three pioneer RCTs performed in Leuven, Belgium, which were performed in the context of early use of parenteral nutrition, strictly targeting the normal, age-adjusted fasting range of blood glucose (80–110 mg/dL [4.4–6.1 mmol/L] for adults, 50–80 mg/dL [2.8–4.4 mmol/L] for infants, and 70–100 mg/dL [3.9–5.6 mmol/L] for children older than 1 year) with insulin therapy, an intervention labeled as tight glucose control, was compared with tolerating hyperglycemia up to the renal threshold (215 mg/dL [11.9 mmol/L]) (Van den Berghe et al. 2001, 2006a; Vlasselaers et al. 2009). The latter threshold was standard care at that time, since more severe hyperglycemia may induce obvious complications, including osmotic diuresis and associated fluid shifts. In the Leuven RCTs, altogether having included 3448 patients, tight glucose control significantly improved morbidity and mortality of critically ill adults and children.

Indeed, among others, the intervention reduced the incidence of acute kidney injury and critical illness polyneuropathy, facilitated weaning from mechanical ventilation, and reduced the incidence of infectious complications, hereby reducing dependency on intensive care, risk of mortality, and costs for healthcare (Van den Berghe et al. 2001, 2006a, b, c; Vlasselaers et al. 2009; Hermans et al. 2007). Importantly, the mortality benefit was maintained on the long-term and in critically ill children, patients had slightly improved neurocognitive outcome 4 years after randomization, despite the increased incidence of severe hypoglycemia (Ingels et al. 2006; Mesotten et al. 2012). Mechanistic studies performed by the Leuven research group attributed the benefit to prevention of cellular glucose overload and associated toxicity, rather than to glycemia-independent effects of insulin (Ellger et al. 2006; Vanhorebeek et al. 2009a, b; Gunst and Van den Berghe 2016). Inspired by the clear benefit of a seemingly "simple" intervention, glucose control strategies were soon implemented in many centers, albeit with varying targets. Subsequently, several implementation studies and small single-center RCTs confirmed clinical benefit by implementing tight glucose control (Bilotta et al. 2007, 2009; Jeschke et al. 2010; Krinsley 2004; Lecomte et al. 2008). However, clinical benefit was not confirmed in multicenter RCTs, and the largest multicenter RCT until now, the NICE-SUGAR study ($n = 6104$), found excess mortality by tight glucose control (Finfer et al. 2009; Brunkhorst et al. 2008; Preiser et al. 2009; Annane et al. 2010; Kalfon et al. 2014; Macrae et al. 2014; Agus et al. 2012, 2017a). As a result, tight glucose control remains debated, and clinical practices vary widely (Gunst and Van den Berghe 2016; Marik 2016; Niven et al. 2015; Krinsley and Preiser 2019).

Harm by Iatrogenic Hypoglycemia?

All RCTs on tight glucose control have shown a significantly increased risk of hypoglycemia (Van den Berghe et al. 2001, 2006a; Vlasselaers et al. 2009; Finfer et al. 2009; Brunkhorst et al. 2008; Preiser et al. 2009; Annane et al. 2010; Kalfon et al. 2014; Macrae et al. 2014; Agus et al. 2012, 2017a; Bilotta et al. 2007, 2009; Jeschke et al. 2010). This has been a concern for clinicians, since prolonged, severe hypoglycemia may be life threatening. Moreover, in a secondary analysis of the NICE-SUGAR study, the investigators attributed the excess mortality by the intervention to an increased risk of hypoglycemia (Finfer et al. 2012). However, increased incidence of hypoglycemia has also been found in RCTs showing benefit of tight glucose control (Van den Berghe et al. 2001, 2006a; Vlasselaers et al. 2009; Bilotta et al. 2007, 2009; Jeschke et al. 2010). Moreover, in a nested-case control study of patients included in the pediatric Leuven RCT, iatrogenic severe hypoglycemia did neither associate with

increased biomarkers of neuronal damage nor with impaired neurocognitive outcome (Mesotten et al. 2012; Vanhorebeek et al. 2010). The prevention of hyperglycemia during glucose reperfusion in the Leuven RCT may have played a role, since hyperglycemia during glucose reperfusion is also potentially deleterious (Vanhorebeek et al. 2010; Suh et al. 2007).

In this regard, an animal model has shown that neuronal death was triggered by glucose reperfusion rather than by hypoglycemia per se (Suh et al. 2007). Hence, although prolonged, severe hypoglycemia is harmful and should be avoided, it remains unclear whether short-term iatrogenic hypoglycemia by itself impairs outcome. Nevertheless, confirmation of this hypothesis would require an RCT, which is ethically not justifiable. Hence, one cannot exclude the possibility that iatrogenic hypoglycemia may have offset some of the benefit of tight glucose control in the Leuven RCTs. Therefore, hypoglycemia should be prevented and treated early, while carefully avoiding rebound hyperglycemia.

How to Explain the Discrepant RCT Results?

Most likely, the outcome differences across subsequent RCTs relate to methodological differences among the trials. Indeed, on several key points, the protocols of the Leuven RCTs and subsequent multicenter RCTs substantially differed (Table 42.1). Three key differences include different blood glucose targets in the randomization groups, different protocols to monitor glucose and administer insulin, and different feeding protocols (Van den Berghe et al. 2009).

Differences in Blood Glucose Targets

The pioneer Leuven studies had a worldwide impact on blood glucose control practices (Niven et al. 2015). The shift in standard care drove researchers of subsequent RCTs to compare tight glucose control no longer with tolerating hyperglycemia up to the renal

Table 42.1 Key differences between the pioneer Leuven RCTs and subsequent multicenter RCTs

	Leuven RCTs	Multicenter RCTs
Glucose target		
Control group	<215 mg/dL	In general <180 mg/dL
Intervention group	80–110 mg/dL (adults); 70–100 mg/dL (children older than 1 year); 50–80 mg/dL (infants)	80–110 mg/dL (regardless of age)
Glucose measurement		
Measurement site	Predominantly arterial	Variable; venous and capillary measurements in some RCTs
Measurement device	Predominantly blood gas analyzer	Variable; potentially inaccurate glucometers in some RCTs
Insulin administration		
Infusion practice	Continuous intravenous infusion	Variable; boluses allowed in some RCTs
Dose adjustment	Well-trained nurses, allowing intuitive decision making	Variable; strict, unvalidated protocols in some RCTs
Nutritional management	Full feeding in acute phase of critical illness (including early PN)	Variable

To convert mg/dL to mmol/L, divide by 18
PN parenteral nutrition, *RCT* randomized controlled trial

threshold, but to a lower, intermediate target [in general <180 mg/dL (<10 mmol/L)]. Hence, in most subsequent studies, including NICE-SUGAR, the comparison was different (Finfer et al. 2009). As a result, the difference in achieved blood glucose concentrations was generally much smaller than in the Leuven RCTs, whereby some RCTs may have been underpowered to detect a benefit of tight glucose control. However, this does not explain the observed harm in NICE-SUGAR.

Aggregating the RCT evidence, one could argue that targeting an intermediate range of blood glucose would be optimal. However, no large RCT has directly compared such intermediate target with tolerating hyperglycemia up to the renal threshold. Conversely, a secondary analysis of the adult Leuven RCTs has suggested a dose-dependent effect of blood glucose lowering on outcome. Indeed, regardless of randomization, patients with blood glucose in the tight range had better outcome than patients with blood glucose in the intermediate range, which suggests that tight glucose control may be preferred (Van den Berghe et al. 2006b). Moreover, apart from a different glucose target in the control group, other methodological differences may equally explain the increased mortality risk in NICE-SUGAR (Van den Berghe et al. 2009).

Not only the glucose target in the control group differed between the RCTs. In the pediatric multicenter RCTs on tight glucose control, the target in the intervention group differed as compared to the Leuven RCT (Vlasselaers et al. 2009; Macrae et al. 2014; Agus et al. 2012, 2017a). Indeed, in Leuven, the target range in the intervention group was age-adjusted and lower than in adults, to account for the lower fasting blood glucose concentrations in healthy infants and children (Vlasselaers et al. 2009). In contrast, in the pediatric multicenter RCTs, the higher, adult target was used in the intervention group (Macrae et al. 2014; Agus et al. 2012, 2017a). Consequently, the achieved difference in blood glucose in pediatric multicenter RCTs was considerably lower than in Leuven. Indeed, whereas the mean achieved difference in blood glucose between both randomization groups was 34 mg/dL (1.9 mmol/L) and 45 mg/dL (2.5 mmol/L) for infants, respectively, older children included in the Leuven RCT, the mean difference was 7 mg/dL (0.4 mmol/L), 9 mg/dL (0.5 mmol/L), and 14 mg/dL (0.8 mmol/L) in subsequent multicenter RCTs (Agus et al. 2017b). Hence, the hypothesized effect size, which was extrapolated from the Leuven RCT, was probably not realistic. Consequently, these RCTs were likely underpowered (Gunst and Van den Berghe 2017). Nevertheless, one pediatric multicenter RCT suggested a potential benefit of tight glucose control in the high-risk subgroup of noncardiac surgery patients (Macrae et al. 2014).

Different Protocols to Monitor Glucose and Administer Insulin

Second, the protocol whereby tight glucose control was realized, substantially differed between the consecutive RCTs. In contrast to the Leuven studies, in which the glucose control protocol was well standardized, protocols of some subsequent RCTs, including NICE-SUGAR, lacked standardization (Van den Berghe et al. 2009). Standardization, including frequent, accurate glucose measurements and a validated insulin protocol, is likely important to prevent and early treat hypoglycemia. In Leuven, glucose measurements were predominantly performed on arterial blood using a blood gas analyzer, which results in a fast and accurate measurement of blood glucose (Van den Berghe et al. 2001, 2006a; Vlasselaers et al. 2009). Insulin was administered by continuous intravenous infusion through a central venous line, without administering boluses. The insulin dose was titrated by experienced nurses using a guideline that allowed intuitive decision making. Overall, the Leuven protocol led to a high time-in-target range, and a lower incidence of hypoglycemia than in NICE-SUGAR (Van den Berghe et al. 2009).

In NICE-SUGAR, the lack of standardization with regard to glucose measurements and insulin titration may have increased the risk of the intervention (Gunst and Van den Berghe 2016). Indeed, in contrast to Leuven, a variety of point-

of-care glucometers were allowed, as were capillary and venous glucose measurements. This may have resulted in a substantial number of inaccurate glucose measurements. In this regard, a center participating in NICE-SUGAR has reported problematic inaccuracies with the glucometer used at that time, with measurement errors up to 100 mg/dL (5.6 mmol/L) (Cembrowski et al. 2010; Scott et al. 2009). Likewise, capillary and venous glucose measurements are potentially inaccurate, especially in patients with shock and in patients receiving intravenous glucose, respectively (Van den Berghe et al. 2009). Consequently, inaccurate glucose measurements in NICE-SUGAR may have led to undetected episodes of prolonged and severe hypoglycemia, which could explain the excess mortality.

Moreover, inaccurate glucose measurements could have increased glucose variability, which is also associated with impaired outcome (Krinsley et al. 2013; Bagshaw et al. 2009). The risk of hypoglycemia in NICE-SUGAR, both detected and undetected, and of large glucose fluctuations, was potentially aggravated by the insulin administration protocol. Indeed, in contrast to Leuven, insulin boluses were allowed on top of continuous infusion (Finfer et al. 2009). Moreover, insulin was titrated using a strict and unvalidated if-then algorithm. Altogether, these methodological differences between trials indicate that safe and effective implementation of tight glucose control requires a well-standardized and accurate protocol that includes frequent, accurate glucose measurements and a validated insulin protocol.

Different Feeding Protocols

A third important difference between the subsequent glucose control RCTs is the difference in feeding protocols, which is explained by the long-lasting lack of solid evidence on critical care nutrition (Casaer and Van den Berghe 2014). Indeed, for a long time, artificial feeding practices have been based on observational studies and expert opinion. In the Leuven RCTs on tight glucose control, all patients received early parenteral nutrition when enteral nutrition was insufficient to meet the caloric target, which was in line with the European feeding guidelines at that time (Singer et al. 2009). In subsequent multicenter RCTs, feeding protocols differed. In NICE-SUGAR, although not protocolized, on average much less parenteral glucose was administered in the acute phase of critical illness (Finfer et al. 2009). This feeding strategy by itself reduces the degree of hyperglycemia. Recently, two large multicenter RCTs have demonstrated that early parenteral nutrition prolonged intensive care dependency in both critically adults and children, also when feeding-induced hyperglycemia is treated (Casaer et al. 2011; Fivez et al. 2016). Hence, contemporary feeding guidelines now no longer recommend early initiation of parenteral nutrition (Singer et al. 2019).

Apart from attenuating the degree of hyperglycemia, the current feeding practice of withholding early parenteral nutrition also increases the risk of hypoglycemia when tight glucose control is aimed for (Casaer et al. 2011; Fivez et al. 2016). Currently, no large RCT has investigated whether tight glucose control is still beneficial, when performed with a validated protocol, including accurate glucose measurements, in the absence of early parenteral nutrition. A meta-analysis of existing RCTs suggested that the outcome benefit of tight glucose control was only present in RCTs having administered larger amounts of intravenous glucose in the acute phase of critical illness (Marik and Preiser 2010). However, this meta-analysis did not correct for other methodological differences between the included trials. In contrast, a secondary analysis of the adult Leuven RCTs found benefit by tight glucose control also in patients in the lowest tertile of parenteral glucose administration (Van den Berghe et al. 2006b). Hence, in patients not receiving early parenteral nutrition, it currently remains unknown whether stress hyperglycemia should be tolerated up to a certain threshold or treated using a

validated protocol. This is being investigated in the multicenter Tight versus Liberal Blood Glucose Control in Adult Critically Ill Patients (TGC-fast) study, which is currently enrolling patients (clinicaltrials.gov, NCT03665207).

Toward Precision Medicine?

Apart from the methodological differences between the RCTs, one could also question whether the divergent results could be explained by inclusion of different patient subgroups. However, the NICE-SUGAR study, including mixed intensive care unit (ICU) patients, did not find a subgroup in whom there was a differential impact of the intervention (Finfer et al. 2009). Likewise, secondary analyses from the adult Leuven RCTs found benefit in all subgroups, with the possible exception of diabetes patients (Van den Berghe et al. 2006b).

Do Diabetes Patients Benefit from More Loose Blood Glucose Control?

Observational studies have shown that the relationship between spontaneous blood glucose concentrations and outcome differs between patient subgroups (Falciglia et al. 2009; Kosiborod et al. 2005; Egi et al. 2008). Indeed, in particular, in patients with pre-existing diabetes mellitus, the U-shaped curve is somewhat flattened and the nadir shifted to the right (Fig. 42.1). This may suggest that patients with pre-existing diabetes mellitus may benefit from less tight glucose control during ICU stay, and that acutely lowering chronic hyperglycemia may be harmful. Although there is some physiological rationale to support this hypothesis, there is no clear RCT evidence to support it. A pooled analysis from the adult Leuven studies found that the mortality benefit of tight glucose control was only present in the subgroup of nondiabetes patients (Van den Berghe et al. 2006b). However, the incidence of acute kidney injury and critical illness polyneuropathy was numerically lower in the group receiving tight glucose control, also in the subgroup of diabetes patients. Likewise, several multicenter RCTs, including NICE-SUGAR, found no different effect of the intervention in diabetes patients versus nondiabetics (Finfer et al. 2009; Brunkhorst et al. 2008; Kalfon et al. 2014).

An Individualized Target?

Observational studies in diabetes patients have indicated that the relationship between blood glucose and outcome differed according to the estimated antecedent blood glucose control (Egi et al. 2011; Plummer et al. 2014). Indeed, the lowest mortality risk was found to associate with blood glucose concentrations close to the average preadmission level, as estimated from upon-admission hemoglobin A1c (Egi et al. 2011; Preiser et al. 2018). Likewise, a study in hospitalized patients has suggested that relative hyperglycemia upon admission, as reflected by an increased ratio of the upon-admission blood glucose to the estimated average blood glucose concentration before hospital admission, may be a better predictor of outcome than absolute hyperglycemia (Roberts et al. 2015). This suggests that the ideal blood glucose target in critical illness may depend on the average preadmission blood glucose concentration.

Nevertheless, confirmation of this hypothesis requires confirmation by an RCT. Published RCTs have not separately reported on outcome in diabetes patients with and without good antecedent glucose control. The multicenter CONTROLING trial was designed to address this knowledge gap. The investigators randomized critically ill patients to individualized blood glucose treatment versus standard care (clinicaltrials.gov, NCT02244073). In the intervention group, the individualized target was calculated based on the upon-admission hemoglobin A1c level. The study was terminated prematurely by the data safety monitoring board. At the time of submission of this manuscript, no results have been published yet.

Strategies to Optimize Glucose Control

The conflicting results between the consecutive RCTs illustrate that tight glucose control is not a "simple" intervention that is easy to implement, but an intervention that requires a validated and accurate glucose control protocol and a skilled nursing team, with prevention of hypoglycemia and large glucose fluctuations.

Decision-Support Software

To further improve the quality and safety of tight glucose control, several computerized algorithms have been developed, with varying design and performance (Salinas and Mendez 2019; Chase et al. 2018). The Leuven research group has developed a computerized algorithm—the LOGIC-Insulin software—based on the experiences of the nurses in Leuven (Van Herpe et al. 2013). The algorithm takes into account demographic data, as well as data on steroids, nutrition, and trends in blood glucose, and consequently advises on the insulin dose and glucose bolus (in case of hypoglycemia), and on the time of the next glucose measurement. In the single-center randomized LOGIC-1 study, the software was found to be superior to nurse-guided tight glucose control, with a higher time in blood glucose target range and virtually no episodes of hypoglycemia (Van Herpe et al. 2013).

Subsequently, the software was validated in a multicenter RCT, which demonstrated a similar high performance in the different centers, with a higher time in target range than in the nurse-controlled group, and without increasing the risk of hypoglycemia (Dubois et al. 2017). Apart from the LOGIC-Insulin algorithm, also other algorithms have shown to improve the time in blood glucose target range, without increasing the risk of hypoglycemia (Salinas and Mendez 2019; Chase et al. 2018). Hence, implementing such algorithms could greatly improve the efficacy and safety of tight glucose control, especially in centers not experienced with tight glucose control.

Continuous Glucose Monitoring

Likewise, (near-)continuous glucose monitoring (CGM) could theoretically improve the quality of tight glucose control. However, the use of subcutaneous sensors measuring interstitial glucose, which are often used in ambulatory patients with diabetes, is complicated in critically ill patients because of potential inaccuracies due to edema and poor capillary perfusion, as well as to the non-negligible time lag between systemic and interstitial glucose concentrations (van Steen et al. 2017). Therefore, intravascular sensors have been developed, and several devices currently have regulatory approval (van Steen et al. 2017). Despite this, most devices do not meet the very strict requirements of point accuracy, as set by a group of critical care experts (Finfer et al. 2013). Theoretically however, this drawback could be overcome by trend accuracy (Bochicchio et al. 2019; Righy Shinotsuka et al. 2016). Nevertheless, the limited durability and added cost of a CGM device, as well as the current controversy about the benefit-risk ratio of tight glucose control, preclude widespread implementation of CGM (Krinsley et al. 2017).

Closed-Loop Glucose Control: The Artificial Pancreas

Theoretically, the ultimate solution for high-quality glucose control is the implementation of closed-loop insulin delivery systems, which combine CGM with automated, software-controlled insulin delivery. Recent RCTs have demonstrated improved glucose control as compared to standard care, by closed-loop insulin delivery in ambulatory and hospitalized diabetes patients (Bally et al. 2018; Brown et al. 2019; Boughton et al. 2019). However in these patients, interstitial glucose sensors were used and insulin was administered subcutaneously, which is potentially hazardous in critically ill patients. To the best of our knowledge, only one company has an available closed-loop system that combines intravascular blood glucose measurement, venous in this case, with venous administration of insulin

(Salinas and Mendez 2019; Okabayashi et al. 2014). Interestingly, the system has been tested in a single-center RCT, in which intermediate glucose control was compared to tight glucose control guided by the closed-loop device, in patients receiving early parenteral nutrition. As compared to the control group, closed-loop glucose control improved clinical outcome (Okabayashi et al. 2014). However, apart from not being commercially available in most countries, the limited durability, extra cost, and controversy about tight glucose control may preclude clinicians to use such device (Salinas and Mendez 2019; Krinsley et al. 2017).

Conclusion

The optimal blood glucose target for critically ill patients remains unclear. When performed in the context of parenteral nutrition administered early in the course of critical illness, and with use of a validated protocol, including accurate glucose measurements, tight glucose control has shown to be effective and safe. The impact of tight glucose control, when performed with a validated protocol in the context of not administering parenteral nutrition in the acute phase of critical illness, remains unclear. The use of clinically validated decision-support software may improve the quality of glucose control and decrease the incidence of hypoglycemia.

There is insufficient evidence to use different blood glucose targets in subgroups of critically ill patients, with the potential exception of poorly controlled diabetes patients, who might benefit from less strict control. In the absence of new evidence, it seems prudent to avoid severe hyperglycemia, hypoglycemia, and large glucose fluctuations for all critically ill patients. A large RCT is currently ongoing to test the impact of tight glucose control in the context of omitting early parenteral feeding, and with use of accurate measurements and a validated insulin-titration computer-guided algorithm (clinicaltrials.gov, NCT03665207).

Acknowledgments JG and GVdB receive a research grant from the Research Foundation—Flanders (FWO; T003617N). JG receives a research grant from the University of Leuven (C24/17/070) and a postdoctoral research fellowship supported by the Clinical Research and Education Council of the University Hospitals Leuven. GVdB receives structural research financing via the Methusalem program funded by the Flemish government through the university of Leuven (METH14/06) and a European Research Council Advanced Grant (ERC-2017-ADG-785809).

Abstract

Recent advancements in continuous glucose monitoring (CGM) represent a novel and untapped resource to optimize behavior change interventions for the prevention and treatment of type 2 diabetes and obesity. In this chapter, we provide a brief history about CGM and evidence supporting its use, including nontraditional indications (people with type 2 diabetes and nondiabetic populations). We then discuss current applications for CGM as a tool for dietary modification, physical activity behavior change, and weight control

J. Faintuch and S. Faintuch (eds.), *Obesity and Diabetes*, https://doi.org/10.1007/978-3-030-53370-0_43

as well as insights on the theoretical basis for using CGM as biological feedback to motivate lifestyle behavior change. The chapter concludes with a discussion on the future opportunities for CGM as a wearable lifestyle behavior change tool for the treatment of obesity and diabetes.

Keywords

Wearable electronic device · Smartphone diabetes apps · Glucometer · Insulin pump · Glucose-monitoring device · Type 2 diabetes · Type 1 diabetes · Obesity · Technology-supported lifestyle intervention

At least 38% of U.S. adults are obese (Flegal et al. 2016) and nearly 30 million U.S. adults have diabetes—more than 90% of these patients are diagnosed with type 2 diabetes mellitus (T2DM) (Centers for Disease Control and Prevention 2017). In 2015, 1.5 million new cases of diabetes were diagnosed and another 84 million individuals were estimated to have prediabetes (Centers for Disease Control and Prevention 2017). Projections suggest that by 2050 one in three adults will be affected by this life-limiting chronic condition (Boyle et al. 2010). In 2017, the total estimated cost of diabetes was $327 billion, including $237 billion in direct medical costs (American Diabetes A 2018). These costs are expected to rise to more than $622 billion by 2030 (Rowley et al. 2017).

Among patients with T2DM, glycated hemoglobin (HbA1c) levels are a key indicator of glucose control. Elevated HbA1c levels are associated with all-cause mortality and the risk of cardiovascular disease and cancers of the colon and rectum, stomach, pancreas, breast, and liver (de Beer and Liebenberg 2014). Lowering HbA1c levels to 6.5–7% significantly benefits health outcomes. Efforts to improve diet and exercise remain the foundation of glycemic management (Davies et al. 2018). Meta-analyses demonstrate that intensive lifestyle interventions can reduce HbA1c by 0.29–0.54% (Martos-Cabrera et al. 2020); however, less encouraging results have also been observed (Usman et al. 2018).

Barriers to HbA1c Reductions

The gold standard lifestyle intervention protocol for T2DM management, which was implemented in the Look AHEAD trial, showed favorable results in overweight and obese adults with T2DM; however, 45% of participants were unable to achieve group weight loss goals (>7% reduction) and nearly 50% were unable to reduce their HbA1c to <7% (Pi-Sunyer et al. 2007). Furthermore, it is widely accepted that intensive lifestyle interventions like Look AHEAD require tremendous patient commitment and are resource intensive. In fact, an early evaluation of the National Diabetes Prevention Program, which was the programmatic foundation for Look AHEAD, show that less than 20% of delivery costs ($139 of $800 per beneficiary) are reimbursed (Ritchie and Gritz 2018). More effective and less resource- and time-intensive interventions that significantly improve glycemic control in patients with T2DM need to be considered.

Continuous Glucose Monitoring

CGM is a method of tracking glucose levels 24 h a day, and is often used in place of point-of-care glucometers for self-monitoring of blood glucose (SMBG). Users of CGM technology wear a small, transdermal (or implantable) sensor that measures glucose concentrations in interstitial fluid for an extended wear time (typically 3–14 days). Glucose readings are transmitted wirelessly to a receiver or compatible smart device, where they are displayed continuously or when the user scans the sensor as in flash glucose monitoring. The benefit of CGM versus SMBG is that the displayed data include current glucose levels as well as historical trends. Having information about the rate and direction of change in glucose levels helps inform treatment decisions.

CGM Use in Type 1 Diabetes

It has been more than two decades since the first CGM system was approved by the FDA in 1999

for the management of (type 1) diabetes. Advancements in glucose-monitoring technology made over the past 20 years (i.e., increased sensor duration, improved accuracy, and reduced mean absolute relative difference/MARD to <11%) have continued to revolutionize diabetes management, such that CGM is now widely accepted for the management of T1DM (Didyuk et al. 2020). Several diabetes organizations have reviewed the literature on the appropriate use of CGM in T1DM management and concluded it is a useful educational and disease management tool (Carlson et al. 2017). CGM aids patients and clinicians to visualize the important role that diet, exercise, stress management, and diabetes medications can have in managing diabetes, and facilitates effective shared decision making as part of standard clinical care (Carlson et al. 2017). The most recent CGM innovations take diabetes treatment to an even more exciting level—insulin pump-CGM combinations and closed-loop systems. These two systems provide patients access to insulin pump and CGM data in one device and automatically adjust insulin levels, respectively.

Continuous Glucose Monitoring in Type 2 Diabetes

Indications for using CGM have only begun to be addressed outside of T1DM (Carlson et al. 2017). The relatively high cost-to-benefit ratio, lack of standardized format for displaying results, and uncertainty on how best to use CGM data to make therapeutic decisions have kept CGM from widespread use in T2DM (Kompala and Neinstein 2019; Petrie et al. 2017). Currently, CGM has only been approved by the FDA for use by patients with T2DM who are on an intensive insulin regimen. One reason for the limited approval of CGM for T2DM is there have been few controlled studies of CGM use in T2DM. A recently published meta-analysis found only seven, qualified randomized controlled trials that tested the utility of CGM in patients with T2DM (Ida et al. 2019). Results indicated that HbA1c levels and time spent with hypoglycemia were significantly lower in the CGM group as compared to the SMBG group. Despite the limited number of trials, results demonstrate the feasibility and efficacy of using CGM for T2DM management. As a testament to this potential, the American Association of Clinical Endocrinologists consensus is that more frequent use of CGM in T2DM is anticipated to increasingly replace SMBG (Garber et al. 2019).

Continuous Glucose Monitoring in Nondiabetic Populations

It is anticipated that future generations of commercially available body worn sensors, including CGM, will have the capability to monitor various health-related biological measures. The earliest examples of this are wearable heartrate monitors that, years after their introduction to the market, became a standard feature on most smartwatches and activity trackers targeted toward the health-conscious consumer. More recently, some activity trackers have features to track sleep by actigraphy, heart rate, pulse oximetry, electrocardiogram, and respiration. As CGM becomes smaller and more affordable, health-conscious consumers who are interested in the "quantified self" will have the power to push the existing wearable sensor market to make glucose monitoring available to a wider consumer base. If this is the case, however, there are key questions about the utility and feasibility of glucose monitoring in nondiabetic populations that will become important to companies that distribute CGM.

Variability of Glucose Concentrations in Nondiabetic Populations

In nondiabetic populations, glucose levels are believed to remain within the normal range of 70–100 mg/dL. If glucose levels stray out of this range, the amounts of insulin and glucagon produced by the pancreas are adjusted to bring them back into this range. Despite this, research shows that glucose concentrations have substantial variability among nondiabetic populations despite lacking sizable changes in magnitude typically seen in people with diabetes. CGM data

from 57 healthy individuals without a prior diagnosis of diabetes, followed for 2–4 weeks (Hall et al. 2018), showed highly variable intra- and interpersonal patterns of fluctuation. Participants were categorized into low variability, moderate variability, and severe variability based on their CGM data. These glucose patterns were found to be correlated with clinical and metabolic parameters, including HbA1c and triglyceride concentrations.

In another pilot analysis with 13 healthy adults (92% overweight/obese) who wore a CGM, an average of three hyperglycemic events (defined as glucose level >140 mg/dL) occurred across 5 days, and the average mean amplitude of glycemic excursion (MAGE) was 2.2 mmol/L or 40 mg/dL (Liao et al. 2018). This is similar to other studies where the average MAGE ranged from 1.96 to 2.2 mmol/L, or 35–40 mg/dL in healthy individuals (Monnier et al. 2006; Zhou et al. 2011) vs. typically >4 mmol/L or >70 mg/dL in diabetics (Zhu et al. 2019). Analyses of blood samples also show a positive association between HbA1c and 24-h glucose average estimated from CGM data, as well as the frequency of acute hyperglycemic events over the monitoring period. In summary, variability in glucose pattern can be detected by CGM devices in the nondiabetic populations and has clinically relevant implications.

Acceptability of CGM in Nondiabetic Populations

How acceptable is CGM for those with T2DM as a replacement for SMBG and for those without diabetes to wear such a device, particularly given the invasiveness of the current models? Whelan and colleagues (Whelan et al. 2019) showed that adults ($n = 45$) aged ≥40 years who were at moderate-to-high risk of T2DM (determined by the Leicester Risk Assessment) were willing to wear and engage with a CGM (Freestyle Libre/www.freestylelibre.com) for as long as 6 weeks. A majority of the participants in the study found the CGM comfortable to wear. Participants also expressed an interest in the information about glucose fluctuations provided by the CGM. Similarly, among 30 healthy adults (73% women, 67% overweight/obese, aged 24–64 years) who wore a CGM (Dexcom G4/www.dexcom.com) and a waist accelerometer, and recorded all eating events using a smartphone app for 7 days, >90% participants agreed that the CGM device was easy to use and provided information of interest (Liao and Schembre 2018).

Another pilot intervention study recruited insufficiently active adults with overweight or obesity ($n = 19$, 84% women, aged 26–55 years, 84% racial minorities). Seventy-four percent of the participants had elevated fasting blood glucose (between 100–125 mg/dL) at their baseline visit. This pilot intervention involved a 10-day self-monitoring period with a CGM (Freestyle Libre) (Liao et al. 2020). All participants agreed that the CGM was easy to use, and more than 90% agreed that the CGM provided information that was of interest to them. All participants also expressed an interest in receiving messages that provide an interpretive summary of their glucose patterns, and how they are associated with their eating and activity behaviors.

Continuous Glucose Monitors as Lifestyle Behavior Change Tools

Through January 2018, only six studies using real-time CGM to promote health-related behaviors, including dietary intake and physical activity, for weight control and HbA1c reductions were published (Ehrhardt and Al Zaghal 2019).

Dietary Modification

The standard-of-care practice for preventing and treating T2DM includes nutrition therapy. According to the American Diabetes Association (Marathe et al. 2017), the primary goals of nutrition therapy for adults with T2DM are to promote and support healthful eating patterns that achieve and maintain a healthy body weight, and to attain individualized glycemic control. However, determining when and what to eat is the most challenging part of treatment for patients (Marathe et al.

2017). Nutrition therapy requires education that is traditionally provided by a registered dietitian who has specialized training in diabetes-specific medical nutrition therapy. Dietitian-delivered nutrition therapy has been associated with improvements in glycemic control as evidenced by 0.5–2% reductions in HbA1c (Marathe et al. 2017). However, many private clinical practices and community clinics are unable to support a full-time dietitian. Further, patients from larger healthcare institutions, where access to certified diabetes educators is more prevalent, are often not referred to nutrition therapy by their primary care provider or they are unwilling to follow through with the referral. As such, the lack of education or continued education is a key barrier to disease management.

Food Diaries and Glucose Monitoring Feedback

As an adjunct to medical nutrition therapy, self-monitoring of glucose levels and food journaling is the standard recommendation for diabetes self-management. Food journaling most often requires a person to record all food and beverages consumed for multiple days. The strategy of documenting the consumption of food throughout the day and correlating it to its caloric or carbohydrate value can encourage an individual to incorporate healthier food choices, through accountability and the ability to identify and modify problem areas. As an additional benefit, journaling is believed to help those who regularly monitor glucose levels to identify how specific foods might cause their levels to fluctuate (Neithercott 2011); however, manually or digitally recording monitored glucose levels before and after each and every meal and snack, to determine what foods cause glucose spikes, is burdensome and cognitively taxing. Dietary self-monitoring, even using digital technology, is highly burdensome and does not lead to significant or sustained changes in behavior (Parkin et al. 2015).

Smartphone Apps

Popular mobile nutrition apps rely solely on tracking calories eaten—a highly unreliable and tedious task, and they most often do not provide feedback relevant to diabetes management. A vast majority of these diet trackers (e.g., MyFitnessPal, FitBit) lack the ability to personalize behavior change guidance, and have subsequently had lackluster effects on improving dietary intake (and physical activity) among users (Husain and Spence 2015). Furthermore, digital journaling tools have not yet been optimized to function with more advanced glucose monitoring technology. Applications that have been designed specifically for diabetes management (e.g., Glooko, mySugr) are similarly suboptimal. A majority, if not all of the existing diabetes self-management mobile apps, are limited in their function as a glucose and diet tracker for carbohydrate counting, and often require manual data entry (Darby et al. 2016). No existing diabetes management tools provide, to patients or providers, automated and personalized guidance on lifestyle behaviors (e.g., diet, exercise, weight control) that are based specifically on person-specific glucose response data (Darby et al. 2016).

The Contribution of CGM Devices

CGM offers users the ability to visualize the effect food has on glycemic responses (Freeman and Lyons 2008). It is hypothesized that comparing postprandial glucose excursions to foods consumed at usual meal times that have similar carbohydrate composition can provide important insights to patients on how to modify dietary behaviors in an effort to manage HbA1c levels. Using CGM data to motivate changes in dietary intake can be done in real time or retrospectively, but it relies greatly on one's ability to collect and interpret the data. The use of real-time CGM to improve glycemic control among people with T2DM has been of recent interest.

A recent systematic review and meta-analysis included five randomized controlled trials with th aim of supporting the use of CGM among people with T2DM (Janapala et al. 2019). Each study looked at the impact of CGM vs. SMBG on HbA1c. A significant pooled mean difference in HbA1c of –0.25% (–0.45, –0.06) favored CGM. However, only one study provided real-time dietary guidance. In a sample of patients ($n = 65$) with poorly controlled T2DM

(8% < HbA1c < 10%), Yoo and colleagues (Yoo et al. 2008) used real-time CGM once a month for 3 days over a period of 12 weeks. Real-time dietary instructions to patients were to "take in little amounts of food" in response to hyperglycemic alarms (>300 mg/dL). Dietary habits were assessed using food diaries covering 3 days of meals at baseline and 3 months later. While the real-time CGM group showed significant reductions in total energy intake over time, the difference was not significantly greater than the SMBG group. Each of the other studies relied on the patients to interpret the CGM data and respond accordingly (e.g., modify future meals that previously resulted in elevated postprandial glucose excursions).

Periodical Guided Analysis of CGM Records

An alternative method of providing behavioral guidance to CGM users is to examine CGM data and behavioral data retrospectively, with a trained health care provider. Retrospective CGM involves the use of a CGM for a predetermined monitoring period. During the monitoring period, which usually spans 3–10 days, patients wear a CGM and record foods consumed and meal times as well as other behavioral data (e.g., exercise and medication). The CGM data are later accessed by the patient's physician and compared with the behavioral data. Physicians skilled in the interpretation of the data can offer behavioral instructions to the patient with the goal of improving clinically relevant outcomes (e.g., time spent in range, HbA1c).

Research examining the impact of retrospective CGM on clinical outcomes is limited (Alfadhli et al. 2016; Lee et al. 2019; Mohan et al. 2016). Rarely, if at all, do these studies describe recommendations made to patients regarding diet or other lifestyle behaviors. None of the studies assessed changes in dietary intake. Only one study (Lee et al. 2019), which conducted 90 min pattern management-based diabetes education sessions in the group randomized to retrospective CGM ($n = 30$) vs. the control group ($n = 30$), assessed perceived changes in self-care behaviors, including diet, as well as self-efficacy (to eat a healthy diet). Scores on both diet measures were significantly improved in the CGM group vs. the control group over the 6-month study period, despite there being no significant differences in changes in HbA1c over time between the groups.

Physical Activity Behavior

CGM-based physical activity counseling in intervention settings, which aims to draw the connection between physical activity and improved glucose control, has been shown to increase physical activity. (Allen et al. 2008, 2011). In healthy individuals, associations were found between sedentary time, physical activity, and glucose variability (e.g., standard deviation/SD and MAGE) in free-living settings (Kingsnorth et al. 2018). Leveraging this type of information, Liao and colleagues tested a pilot intervention that featured the use of CGM (Liao et al. 2020). In this study, sedentary overweight and obese adults ($n = 19$) completed an in-person physical activity education session, followed by a 10-day self-monitoring period with a CGM and a Fitbit (www.fitbit.com). During the physical activity education session, participants received materials about the benefits of physical activity and an overview of different types of physical activity. Participants were also presented with a web-based glucose simulator that demonstrated how physical activity (i.e., walking) an impact glucose levels during the day. After the education session, participants were given a Freestyle Libre CGM to wear for the next 10 days.

Participants were instructed to obtain a glucose reading each morning upon waking, each night before going to sleep, and at least two other times throughout the day by scanning the CGM sensor with the reader. Upon scanning, the reader displays the current glucose level and a graph showing 8 h of glucose history, with an arrow indicating the directional trend. Participants were encouraged to observe how their daily glucose patterns were influenced by their behaviors (e.g., eating and exercising). The study tested whether participants increased their motivation to change

their physical activity behavior after completing this intervention by examining stages of change. As described in the transtheoretical model, individuals will go through six stages of change when adopting a behavior: precontemplation (not intending to make changes), contemplation (thinking about making changes), preparation (developing plans to make changes), action (actively engaging in the new behavior), and maintenance (keep engaging in the new behavior for an extended period of time).

The study used the Exercise Stages of Change—Continuous Measure URICA-E2 psychometric questionnaire, to assess the different stages of change with the assumption that physical activity behavior is typically a dynamic process that moves between different stages (Lerdal et al. 2009). Compared to preintervention, participants scored lower in the contemplation stages and higher in the action stage at postintervention (ps $<$ 0.05; see Fig. 43.1) suggesting improvements in motivation to be physically active.

Weight Control

Eating in response to hunger facilitates energy homeostasis as an intermediary step in weight regulation (Feig et al. 2018). Yet, in today's permissive food environment, many eating events are unrelated to energy depletion. Rather, they are predicted by nonphysiological determinants of food intake, such as the hedonic properties of palatable foods (Blundell and Finlayson 2004; Lowe and Butryn 2007); individual differences in hedonic eating behavior (e.g., emotional eating) (Schembre et al. 2009; Schembre 2011); sensitivity to food rewards (Cornier 2009, 2011; Versace et al. 2016; Versace and Schembre 2015); and impulsivity and self-control (Batterink et al. 2010; French et al. 2012; Meule et al. 2014; Nederkoorn et al. 2006). Eating behaviors not regulated by physiological signals of hunger and satiety have been empirically linked to weight gain (Bryant et al. 2008; McCrory et al. 2002; Provencher et al. 2003).

Research has shown that people with obesity are hypersensitive to interoceptive signals of hunger and may eat when glucose levels, an indicator of available short-term energy, remain elevated (Schembre and Huh 2014; Schembre et al. 2020), and thus may be less likely to distinguish physiological hunger from their hedonic desire to eat without help (Ciampolini et al. 2013; Ciampolini and Sifone 2011; Jospe et al. 2015; Taylor et al. 2015). Teaching people to self-regulate their energy intake by differentiating between physiological hunger and their hedonic desire to eat without hunger is an empirically supported weight-control strategy (Bacon et al. 2002, 2005; Daubenmier et al. 2016; Gletsu-Miller and McCrory 2014; Kristeller 2005; Kristeller et al. 2006). These data provide a strong evidence base for developing weight control interventions that use glucose monitoring to self-regulate energy intake for the prevention and management of obesity and diabetes.

Hunger Training

Hunger Training teaches people to eat only when their real-time glucose level is at or below a pre-established threshold that reflects a fasted state (Jospe et al. 2015, 2017). The scientific premise of hunger training does not require glucose to be a valid proxy for hunger. Rather, in order to promote energy balance, energy intake should not occur when glucose levels remain elevated. Hunger Training has more recently been conceptualized as a form of intermittent fasting called inter-meal fasting (Schembre et al. 2020).

Historically implemented using glucometers, Hunger Training has been validated in normoglycemic men and women as an effective weight loss method (Ciampolini et al. 2010b; Jospe et al. 2015, 2017). In overweight individuals, as little as 2–4 weeks of hunger training—without additional diet or physical activity guidance—results in weight loss of 7% within 5 months (Ciampolini et al. 2010b) and as much as 1.7% in only 2 weeks (Jospe et al. 2015). When Hunger Training was combined with a single

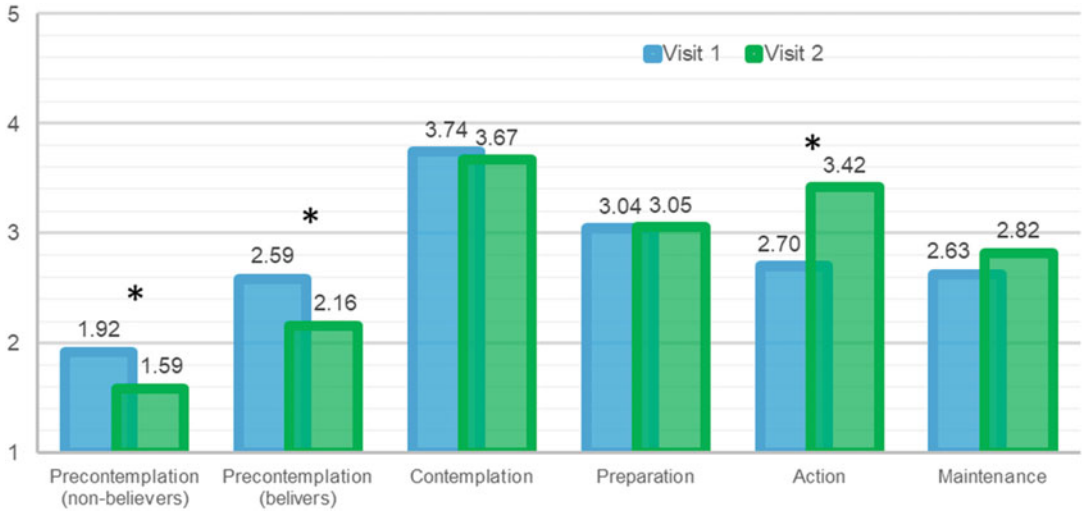

Fig. 43.1 Mean score for each stage of change, captured by the Exercise Stages of Change—Continuous Measure (URICA-E2), before and after a physical activity intervention ($n = 19$) that features a 10-day CGM monitoring. Asterisks indicate a significant difference in mean scores by a two-tailed paired-sample *t*-test

session of diet and physical activity advice and used consistently, it resulted in weight reductions of 13 kg in males and 5 kg in females at 6 months (Jospe et al. 2017). Participants expressed that hunger training increased their awareness of hungry versus nonhungry eating, improved their ability to recognize feelings of hunger and satiety, and reduced their number of eating occasions (de Bruin et al. 2019).

Hunger Training is as successful for weight loss with CGM devices as it has been with traditional glucometers (Jospe et al. 2020). However, CGM resulted in better adherence to the Hunger Training protocol, with patients generally preferring the ease and convenience of CGM, as well as the detailed feedback that it enables (de Bruin et al. 2019). Future behavior change interventions should consider using CGM instead of glucometers to encourage better adherence.

Restored Glucose Homeostasis

Recommendations to eat at lower glucose levels are generally consistent with preprandial glycemic targets (80–130 mg/dL) recommended by the ADA to manage HbA1c levels among people with diabetes (American Diabetes A 2017). Relatedly, interventions like Hunger Training that use blood glucose as a feedback tool have been shown to have favorable effects on glycemic control, insulin sensitivity, and beta-cell function among normoglycemic individuals (HbA1c $< 5.5\%$) (Allen et al. 2011; Ciampolini et al. 2010a; Kempf et al. 2013; Virdi et al. 2013; Yoo et al. 2008) that are comparable to outcomes of traditional lifestyle interventions for adults with T2DM (Huang et al. 2015; Pillay et al. 2015; Terranova et al. 2015).

Theory-Based Insights on Using CGM as Biological Feedback to Motivate Lifestyle Behavior Change

The use of CGM in health behavior interventions facilitates biological feedback (biofeedback), a designated behavior change technique (Abraham and Michie 2008; Michie et al. 2018). By definition, biofeedback reflects the collection of physiological or biochemical data using a monitoring device that is interpreted by an outside agent who provides feedback to prompt or motivate a desired behavior or behavior change. Traditionally, biofeedback referred to a therapeutic approach that used wearable sensors to monitor and provided real-time feedback on various physiological processes once thought to be

involuntary (e.g., heart rate, brain waves, body temperature, muscle contraction). The goal of biofeedback therapy was to teach patients to alter their physiological activity through changes in thinking, emotions, and behavior for the purposes of improving health. Here we are conceptualizing the use of "biofeedback" differently, while maintaining many of the operational characteristics (e.g., providing real-time feedback to users of wearable sensor technology) and end goals (improving health). Specifically, we propose that CGM can be used to provide real-time feedback on the body's acute biological response to health behaviors (i.e., dietary intake and physical activity) and mood states (i.e., psychological stress) that impact acute changes in glucose concentrations, and that this feedback can be used to motivate behavior changes that can have short- and long-term impacts on related health outcomes, if maintained (Schembre et al. 2016).

Consistent with health behavior change theories, it is hypothesized that biofeedback acts as a cue to action (Health Belief Model) (Saghafi-Asl et al. 2020) and increases a person's intrinsic motivation (self-determination theory (Deci and Ryan 2012)) to adopt or maintain a desired behavior change. It is further hypothesized that biofeedback increases someone's perceived susceptibility to acquiring a disease. More specifically, biofeedback about indicators of disease progression (e.g., glucose values and diabetes) could arouse feelings of vulnerability that increase one's intrinsic motivation to take preventive actions (Self-Determination Theory). The experience of Liao and colleagues (Liao et al. 2020, described earlier) showed that among sedentary overweight and obese adults, a brief educational session demonstrating the acute impact of physical activity to reduce glucose levels with simulated CGM data, increased motivation to be physically active.

Future Opportunities for Continuous Glucose Monitorings

The use of CGM for the management and prevention of T2DM is currently hindered by the relatively high cost-to-benefit ratio and uncertainty on how best to use CGM data to make therapeutic decisions (Kompala and Neinstein 2019; Petrie et al. 2017). Manufacturers are hard at work with a goal of reducing the cost of CGM in an effort to expand their market.

CGM can be used to aid dietary choices and nutrition education, for instance, to show how various food choices and portion sizes influences glucose, to increase physical activity and, possibly, to improve sleep and stress management.

There are also research opportunities to optimize understanding of CGM results, which can be overwhelming for some patients (Hilliard et al. 2019; Kruger et al. 2019; Ritholz et al. 2010). Strategies are needed to assist patients with the meaningful interpretation of CGM data in an effort to make health behavior changes that impact on glycemic control.

Abstract

Along with the classic intragastric balloon, several endoscopic bariatric therapies (EBTs) are currently available in clinical practice: aspiration therapy, transpyloric shuttle, gastric reduction techniques, metabolic procedures focused on the small bowel, among others. The aim of this chapter is to summarize the current evidence on EBTs and to provide a glimpse into the future of the endoluminal treatment of obesity and metabolic disorders.

Keywords

Obesity · Overweight · Endoscopy · Aspiration therapy · Intragastric balloon · Bariatrics · Type 2 diabetes

Introduction

The interventional gold standard for severe obesity has long been bariatric surgery as it promotes sustainable weight loss and improvement of obesity-related comorbidities (Colquitt et al. 2014; O'Brien et al. 2019).

As obesity escalates, the number of bariatric surgeries also rises. Recent data showed a total of 685,000 bariatric procedures worldwide in 2016 (Angrisani et al. 2018). However, this number is tiny in the face of the many hundreds of millions of patients currently suffering from the disease.

In this context, novel alternatives to bariatric surgery are certainly needed. As such, endoscopic bariatric therapies (EBTs) have recently become a field of interest in most interventional endoscopy groups. Initially, EBTs were mainly composed of space-occupying devices, mimicking the intragastric balloon. However, creative procedures have been proposed over the last 20 years and EBTs currently entail gastric aspiration, gastric reduction methods, endoscopic bypass liners, duodenal mucosal resurfacing, and magnetic partial jejunal diversion.

Gastric Aspiration: Aspire Assist®

The AspireAssist™ is a modified percutaneous gastrostomy device composed of a discreet external port (Fig. 44.1) and a large fenestrated 15-cm-long intragastric tube. The external port connects to a portable aspiration device that allows removal of around 30% of the recently ingested food (Sullivan et al. 2013).

Initially, two noncontrolled series assessed weight loss outcomes at 1 year and both reported excess weight loss (EWL) around 50% (Sullivan et al. 2013; Noren and Forssell 2016). In 2016, the U.S. Food and Drug Administration (FDA) approved the AspireAssist™ after the publication of an American randomized multicenter controlled trial. The study enrolled 171 patients for either aspiration therapy (AT) plus lifestyle intervention versus lifestyle intervention alone in a 2:1 ratio. The technical success rate was 97% (111 of 114 attempts). At hour, the mean EWL and total weight loss (TWL) were 31.5 ± 26.7% and 12.1 ± 9.6% for the AT group versus 9.8 ± 15.5% and 3.5 ± 6.0% for the control group, respectively ($p < 0.001$). The authors also reported amelioration of HbA1c, triglycerides, and low-density lipoprotein levels,

Fig. 44.1 The external port of the AspireAssist™ device. It should be connected to a portable aspirator to partially remove the recently ingested food

reduction in systolic and diastolic blood pressure, and an increase in high-density cholesterol.

The serious adverse events (SAEs) rate was 3.6%, namely, one case of severe abdominal pain, one patient with peritonitis, one gastric ulcer, and one case of port malfunction requiring tube replacement (Thompson et al. 2017). More recently, the same group published the 4-year follow-up results from this cohort. Among the 58 patients who continued in the study, 43 withdrew the AT before completing 4 years. The reasons for withdrawal were either meeting weight loss goals (25 cases) or insufficient weight loss (18 cases). For the 15 completers, the mean %TWL was 18.7 ± 11.7 and the %EWL was 50.8 ± 31.9%. The most common adverse events after the first year were peristomal inflammation and persistent fistula. The latter was ten times more frequent from years 2 to 4 than during year 1 (Thompson et al. 2019).

In another series, Nyström et al also reported 4-year data from a post-market European registry study (Nystrom et al. 2018). Five centers gathered data from 201 individuals undergoing AT. All patients presented a BMI of at least 35 kg/m^2 and had failed conservative weight loss therapies. The mean %TWL at 1, 2, 3, and 4 years were 18.2 ± 9.4% (n = 155/173), 19.8 ± 11.3% (n = 82/114), 21.3 ± 9.6% (n = 24/43), and 19.2 ± 13.1% (n = 12/30), respectively. There were 42 postprocedural AEs, namely, 12 gastric leaks, 10 stomal irritation/granulation tissue, 9 infections or possible infections, 8 buried bumpers, and 3 tube dislodgments.

Current data suggest AspireAssist™ therapy is effective and safe in addressing moderate-to-severe obesity. Nonetheless, it does not seem a perennial therapy and there are still little data on weight maintenance after removal of the device.

Space-Occupying Devices: Intragastric Balloon (IGB)

The intragastric balloon (IGB) is the oldest and the most commonly employed endoscopic bariatric therapy. It is an effective but mainly transitory method to control obesity. Its most attractive advantage is the minimal risk for major complications (Sallet et al. 2004). Besides primary treatment, it may also serve as a bridging therapy to bariatric surgery for patients at high surgical risk (e.g., superobese individuals) (Dumonceau 2008).

Since the early 1980s, when the pioneer air-filled Garren-Edwards Gastric Bubble was firstly released, several modifications have been implemented on the IGBs. Such refinements have been mainly tailored by the experts' suggestions from a conference held in Tampor Springs, in 1987.

Currently, different models of IGBs are available for clinical use. Most are silicone-based spheres, either water or gas-filled (Fig. 44.2), adjustable or nonadjustable, including single, double, or triple balloons. Some IGBs require endoscopic placement, whereas there are IGBs that circumvent such procedure. All devices demand endoscopic removal after 6- or 12-month indwelling.

IGB therapy provides EWL of around 30% and AWL varying from 4 to 28 kg. Patients with higher BMIs tend to present more remarkable results (Imaz et al. 2008). Sham-controlled studies have demonstrated statistical superiority of IGB versus control regarding absolute weight loss, %TWL, and BMI reduction (Moura et al. 2016). A recent meta-analysis has also proven that water-filled balloons provide better weight

Fig. 44.2 The nonadjustable liquid-filled 12-month indwelling intragastric balloon

loss compared to the air-filled ones in a non-head-to-head comparison (Saber et al. 2017). Of note, however, not all patients undergoing IGB implantation lose weight satisfactorily. Up to 40% fail to achieve adequate outcome (defined as % TWL < 10% or %EWL < 25%). Early removal, early adaptation to restrictive symptoms, de novo dietary disorders (e.g., binge eating) could explain such high clinical failure rates (Dumonceau 2008).

Type 2 Diabetes

Chan et al. investigated the impact of this therapy on glycemic levels in non-insulin-dependent overweight patients. The authors demonstrated a significant reduction in HbA1c levels (8.6–7.3%), and the proportion of patients presenting glycemic levels over 100 mg/dL dropped from 50% before IGB to 12% after treatment. Moreover, 58% of the patients had hypertriglyceridemia before IGB versus only 19% after the treatment. Serum transaminases also sharply dropped with the treatment (Chan et al. 2008).

Regarding bridging therapy to bariatric surgery, strong data support IGB as an effective and safe modality (Busetto et al. 2004). Some studies have also demonstrated the bridging sleeve gastrectomy (SG) as an alternative to the IGB in this scenario. However, even less invasive surgeries such as the laparoscopic SG have higher complication rates than most endoscopic techniques, which renders the IGB an attractive option (Genco et al. 2005).

A recent meta-analysis found that nausea and vomits are the most frequent adverse events. A subgroup analysis demonstrated that water-filled balloons elicit symptoms more frequently than the air-filled ones (Trang et al. 2018); however, they seem to be more effective in terms of weight loss (Saber et al. 2017). A large series with more than 2000 procedures showed an overall AEs rate of 2.8%, including rare cases of perforation (0.19%) and gastric outlet obstruction (0.76%) (Genco et al. 2005).

Transpyloric Shuttle® (TPS)

The Food and Drug Administration (FDA) has recently approved the TPS (BARONova Inc, San Carlos, CA) for marketing. Its mechanism of action is intermittent gastric outlet obstruction rather than simple space restriction. The device is composed of two different-sized silicone-based bulbs connected by a flexible tether. The large bulb anchors in the pylorus to prevent migration, while the smaller one stays in the duodenum. Consequently, the device remains in a transpyloric fashion, and the antral pump intermittently dislocates the large bulb to allow transient food passage (Fig. 44.3).

Patients (10 each) were compared in a 3-month vs. 6-month TPS treatment. Three-month patients presented mean EWL and TWL of 25.1 ± 14% and 8.9 ± 5%, respectively. Six-month patients had mean %EWL and AWL of 41 ± 21.1% and 14.5 ± 5.8%. However, 10 patients (50%) presented gastric ulcers, two requiring early removal (Marinos et al. 2014). Such an elevated rate fostered refinements in the device focused on safety improvement.

Recently, a multicenter double-blind trial (NCT02518685) enrolled 270 patients in a 2:1 ratio to receive TPS treatment or sham. The

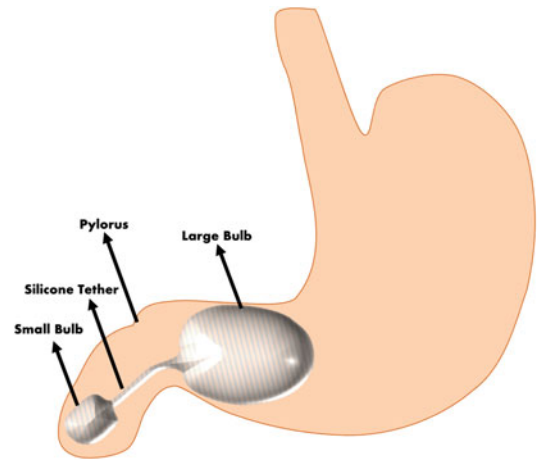

Fig. 44.3 Schematics of the Transpyloric Shuttle device in place

upgraded TPS provided greater TWL than sham at 1 year (9.5% [8.2, 10.8] vs. 2.8% [1.1, 4.5], $p < 0.0001$). Sixty-seven percent of the TPS cohort achieved the predetermined goal of ≥5% TWL. Furthermore, there was a mean BMI reduction of 3.5 kg/m^2 for treated patients versus 1.01 kg/m^2 in the sham group ($p < 0.0001$). Ten percent of patients required early removal (before 12 months). There were no bleeding or perforation cases despite a 10% gastric ulcer rate. Only 2.5% were considered serious adverse events (Rothstein et al. 2018).

In spite of the relatively good performance of the TPS at promoting weight loss, the ulceration and early removal rates are still elevated.

Gastric Reduction: Endoscopic Sleeve Gastroplasty (ESG)

To perform an ESG, an endoscopic-suturing device—the Apollo Overstitch™—is attached to a therapeutic double-channel gastroscope and delivers full-thickness stitches (Fig. 44.4). The suturing pattern varies among centers; however, most perform running sutures from the anterior to the posterior wall passing through the greater curvature, and then back to anterior where the suture is finally cinched (Brunaldi and Galvao Neto 2019). Recently, some authors have also employed reinforcing interrupted stitches in-between the running sutures. The procedure is performed in an antrum-fundus direction, preserving the fundus. That creates a fundal pouch that possibly delays gastric emptying and enhances weight loss by improving satiety (Abu Dayyeh et al. 2017). The final aspect is sleeve-like anatomy with a prominent fundal pouch (Fig. 44.5).

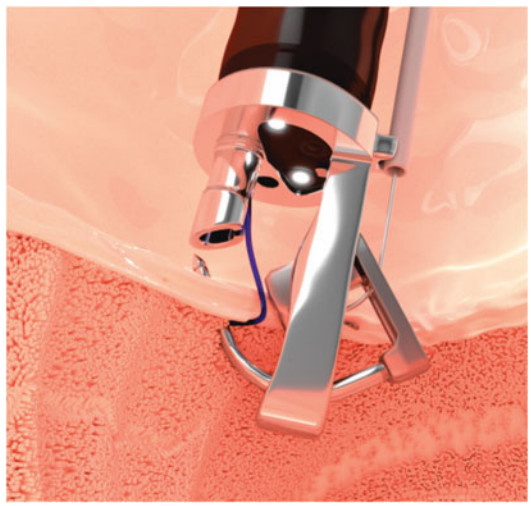

Fig. 44.4 The Apollo Overstitch full-thickness endoscopic suturing device

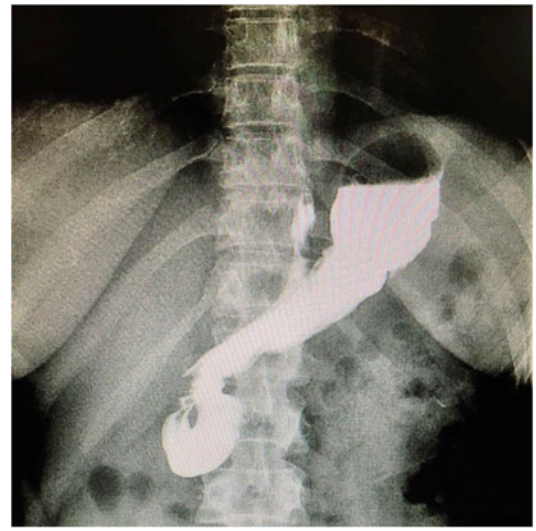

Fig. 44.5 An upper gastrointestinal series showing the endoscopic sleeve gastroplasty anatomy at 3 months postoperatively

Abu Dayehh et al. first described the ESG procedure in 2013 (Abu Dayyeh et al. 2013). Initially, simple interrupted stitches were employed, but as the experience grew worldwide, the technique was refined to the current running suture. Kumar et al. recently summarized such evolution in a comprehensive multicenter series (Kumar et al. 2018).

The ESG is probably the most promising transoral gastric-reduction procedure addressing obesity. Since its first description in 2013, several studies with more than 1500 cases have been reported in the world, including Brazil (Galvao-Neto et al. 2016), USA (Sharaiha et al. 2015), India (Bhandari et al. 2019), Saudi Arabia (Alqahtani et al. 2018), and Spain (Lopez-Nava et al. 2017).

To date, the largest series was published by Alqahtani et al. in 2018 (1000 ESG patients from a single center). Baseline BMI and age were 33.3 ± 4.5 kg/m^2 and 34.4 ± 9.5 years, respectively. Procedure time was 61 ± 16 min, and patients were routinely discharged on the same day. Most complained of mild postoperative abdominal pain and nausea (92.4%), but all symptoms were controlled with oral medications. Twenty-four patients (2.4%) were readmitted due to severe abdominal pain (8), postprocedural bleeding (7), perigastric collection with pleural effusion (4), or postprocedural self-limited fever (5). There was neither mortality nor emergency interventions. Patients presented TWL of 13.7 ± 6.8% (n = 369/423), 15.0 ± 7.7% (n = 216/232), and 14.8 ± 8.5% (n = 54/63) at 6, 12, and 18 months, respectively. All 28 cases of hypertension, 13 of the 17 cases of diabetes, and 18 of the 32 cases of dyslipidemia had complete remission by the third month. During follow-up, eight patients were revised to sleeve gastrectomy due to weight loss failure, and five underwent redo ESG due to weight regain (Alqahtani et al. 2018).

Lopez-Nava et al. have published the longest follow-up to date. In an international multicenter series of 248 cases, the authors reported TWL of 18.6% [95% CI: 15.7–21.5], which was similar for all the three participating centers (p = 0.7). In a linear regression analysis, they found that weight loss at 6 months highly predicted weight maintenance and weight loss at 24 months, thus pointing to an important early-on treatment predictor of poor long-term outcome (Lopez-Nava et al. 2017). A congress abstract reported even longer-term data, with AWL of 18.7 kg (10–27.3) and TWL of 14.5% (8.2–20.9) at 5 years. Patients achieved the nadir weight at 24 months and presented a mean weight regain of 2.4 kg by the final follow-up (Hajifathalian et al. 2019).

In a meta-analysis of 8 studies comprising 1772 procedures, TWL was 15.1% [14.29, 16], 16.4% [15.16, 17.82], and 17.1% [14.64, 19.66] at 6, 12, and 18–24 months, respectively. The AEs rate was as low as 2% (Hedjoudje et al. 2020). Even though there are no controlled data yet, retrospective studies have shown ESG to be superior to IGB (Fayad et al. 2019), and similar to laparoscopic sleeve gastrectomy (LSG) in mildly obese individuals (Novikov et al. 2018).

Currently, a Chinese study is comparing ESG to the LSG (NCT03124485). A multicenter open-label trial comparing ESG to lifestyle intervention is also going on. At the end of a 1-year follow-up, patients from the control group will be allowed to cross over to undergo ESG. Eight centers in the USA are participating, and the enrollment goal is 200 not morbidly obese individuals (BMI ≥30 and ≤40 kg/m^2) (MERIT Trial NCT03406975).

POSE (Primary Obesity Surgery Endoluminal)

The primary obesity surgery endoluminal (POSE) method employs a platform initially developed for natural orifices surgery/NOTES (IOP®, USGI Medical, San Clemente, CA), in order to plicate the fundus and distal body.

Before addressing primary obesity procedures, the IOP system had been tested and approved for gastrointestinal tissue apposition. In this sense, endoluminal cholecystectomy (Swanstrom et al. 2008), gastrotomy closure (Sclabas et al. 2006), repair of gastro-gastric fistulas (Raman et al. 2011), transgastric appendectomy (Horgan et al. 2011), and remodeling of gastrojejunal anastomosis in weight regain (Borao et al. 2010) have been reported.

The IPO is a four-channel working platform that allows the passing of different instruments, including a gripper with a suture cutter, a tissue-driven propeller, a suture anchor catheter, and a channel for a thinner endoscope. It allows the delivery of full-thickness plications under endoscopic guidance. The original POSE procedure (Fig. 44.6) consisted of two parallel lines of 4–5 plications each in the gastric fundus, followed by an additional three or four on the greater curvature of the distal gastric body (Kumar 2017). Therefore, this procedure aims at impairing

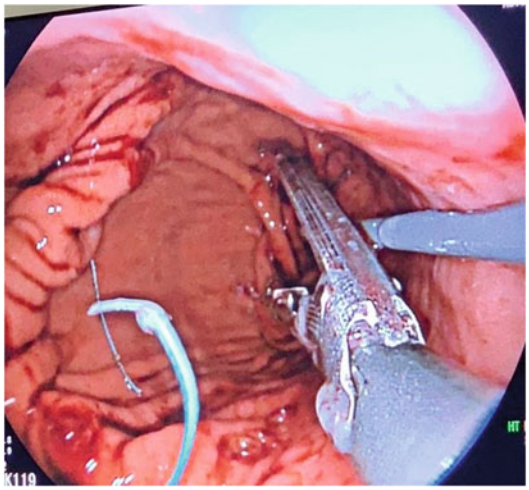

Fig. 44.6 The original POSE procedure. On the left side of the image, note the last fundal plication line. On the right side, the plication line on the greater curvature of the distal body

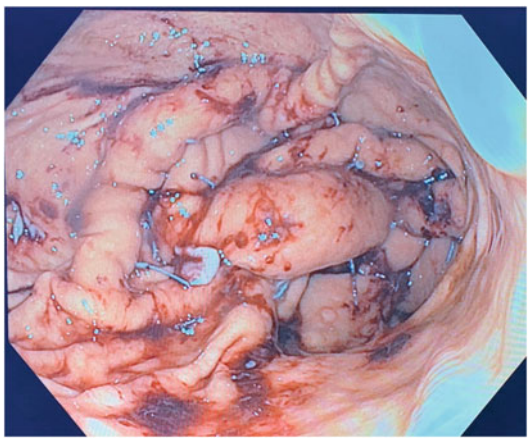

Fig. 44.7 The endoscopic final appearance of the POSE 2.0 procedure

gastric accommodation by reducing the gastric fundus (Kumar 2017).

After exciting results from noncontrolled studies (Espinos et al. 2013; Lopez-Nava et al. 2015), a large multicenter sham-controlled trial failed to demonstrate significant weight loss with the original POSE procedure (Sullivan et al. 2017). In "the ESSENTIAL trial" with 332 moderately obese patients, at 20 months, TWL was only 4.95 ± 7% in the procedure group versus 1.30 ± 5.5% in the sham group ($p < 0.0001$). Only 41% of patients presented TWL ≥5% at the final follow-up. Despite the statistical superiority, the intervention group did not achieve predetermined thresholds of 5% TWL and responders' rate of 50%.

A newly developed procedure—POSE 2.0—aims at delaying gastric emptying rather than impairing accommodation (Fig. 44.7). There are a few ongoing studies that might become available soon.

Endomina Method

The European regulatory agency—the Conformité Européen—has already approved the triangulation platform named Endomina® (Endotools S.A., Gosselies, Belgium) for clinical use. This is an incisionless single-use device that allows full-thickness suturing to promote gastric volume reduction.

Probably, the most attractive feature of the Endomina is that it attaches to any standard gastroscope, exempting the need for specific endoscopes. However, it requires two operators to deliver stitches: the first controls the handles of the device, while the other manipulates the scope. The procedure begins with a regular upper endoscopy followed by the placement of two guidewires in the duodenum. Then, the endoscope is removed and the platform is gently introduced over the guidewires. The endoscope is finally inserted and fixed to the system, while the guidewires are retrieved (Cauche et al. 2013; Huberty et al. 2019).

Using a 5Fr preloaded needle, the system creates an apposition of opposing walls along the greater curvature from the antrum to the fundus. Bipolar coagulation at the suturing sites has also been employed to enhance the durability and strength of the plication. The total duration of the procedure varied from 126 to 147 min in the first published series (Huberty et al. 2017; Wallstabe et al. 2018).

To date, three human studies assessing the efficacy and safety of the Endomina method have been published. All studies involved a Belgian center that helped develop both device and

procedure. Huberty et al. published the first-in-man study in 2016 enrolling 12 obese patients. At 6 months AWL, TWL, and BMI reduction were 10.9 ± 7.3 kg, 11 ± 8%, and 3.9 ± 2.3 kg/m^2, respectively. No serious adverse events were reported (Huberty et al. 2017). The following series demonstrated similar results, but slightly worse outcomes at a longer-term (Wallstabe et al. 2018; Huberty et al. 2018). Controlled data are still lacking, and the real therapeutic potential of the Endomina method is yet to be determined.

Metabolic Procedures: Duodenal Mucosal Resurfacing (Fractyl®)

The duodenal mucosal resurfacing (DMR) is based on the hypothetical central role of the duodenum in regulating glycemic homeostasis. Gut hormones produced by the normal duodenum possibly stimulate the surrounding endocrine pancreatic tissue and systemic insulin receptors, thus helping control serum glucose levels. This is called the incretin effect. Conversely, in patients with type 2 diabetes (T2D), alterations in the proximal bowel epithelium could impair such paracrine and endocrine network, leading to systemic insulin resistance and glucose intolerance (Moran-Atkin et al. 2013). Animal and human studies suggest that bypassing the duodenum improves T2D, which is unrelated to weight loss (Kindel et al. 2009; de Jonge et al. 2013). This observation corroborated the so-called foregut hypothesis and fostered the development of endoscopic alternatives to surgical bypass—such as the DMR.

The DMR procedure promotes a catheter-based hydrothermal ablation of the superficial duodenal mucosa (Fig. 44.8) (de Moura et al. 2019). After re-epithelization, new cells are expected to be healthier and more efficient at producing and releasing incretin hormones, thus improving diabetes control.

The first-in-man trial enrolled 44 individuals to undergo the DMR procedure in a 6-month follow-up study. Patients experienced a reduction of 1.2% in HbA1c (Rajagopalan et al. 2016).

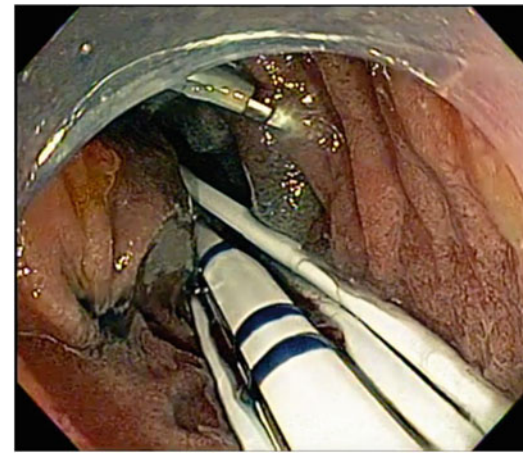

Fig. 44.8 The Duodenal Mucosal Resurfacing procedure. The catheter has two blue external marks 1 cm apart that allow the endoscopic guidance for insertion. On the top of the figure, there is an endoclip demarcating the level of the major papilla. Distally, the duodenal mucosa has already been injected with saline plus methylene blue and superficially ablated (whitish mucosa)

One-year data from a multicenter study with 46 patients showed not only a reduction in HbA1c, but also improvement in fasting plasma glucose and HOMA-IR score. However, 52% of the patients experienced at least one AE related to the procedure, of which one was considered a serious AE (van Baar et al. 2020). Currently, there is an ongoing large multicenter sham-controlled trial with a crossover design (NCT02879383).

Duodenal Jejunal Bypass Liner/DJBL (EndoBarrier®)

This is an endoluminal device composed of three main parts: the anchor, the liner, and the delivery system. The anchor has a large nitinol-based opening with bidirectional barbs for fixation. The liner is a 62-cm-long impermeable fluoropolymer sleeve that avoids contact of the food with the duodenal mucosa (Fig. 44.9). The delivery system is a single-use device preloaded with the implant.

The rationale of the DJBL is based not only on the foregut hypothesis, but also on the hindgut

Fig. 44.9 The duodenal jejunal bypass liner device

hypothesis. The latter advocates that the presence of intact bile acids and undigested food in the distal gut triggers the release of incretin hormones (Verdam et al. 2011; Penney et al. 2015). Therefore, bypassing the duodenum with an impermeable liner precludes contact of the food bolus with a possibly impaired duodenal mucosa (foregut hypothesis), and delivers chyme into the distal gut (hindgut hypothesis).

Tarnoff et al. published the first animal study on DJBL in 2008. Six pigs underwent endoscopic deployment of the device and presented significant lower rates of weight gain compared to control animals (0.42 kg/day vs. 0.23 kg/day, $p = 0.01$) (Tarnoff et al. 2008).

Since the first human experience in 2009 (Rodriguez-Grunert et al. 2008), five randomized studies have already been published. Most report a significant impact on HbA1C levels and some also describe amelioration of metabolic parameters. A recent systematic review comprising all RCTs showed a mean reduction by 1.3% in HbA1c levels at the explant. Such a result outweighed by 0.9% the control group. Accordingly, HOMA-IR decreased by 4.6 [2.9, 6.3] (Jirapinyo et al. 2018).

In time, however, the high incidence of SAEs undermined the routine adoption of the DJBL. Some series reported up to 68% of severe complications, including liver abscesses and cholangitis (Forner et al. 2017; Quezada et al. 2018). Recently, Betzel et al. published a systematic review on AEs related to the DJBL and found 891 reports from 1056 procedures. Thirty-three were considered SAEs, including 11 liver abscesses (Betzel et al. 2018). Probably, the sharp anchoring barbs were responsible for most of the related complications, as they ulcerate the duodenal wall, thus creating a solution of continuity that allows bacterial translocation and injures surrounding vessels.

Such an AEs rate deterred further studies on the DBJL, culminating in withdrawal from the market. New prototypes with different anchoring strategies as well as devices deployed in the stomach are under development and might be available soon.

Endoscopic Magnetic Partial Jejunal Diversion/EMPJD

This is also based on the hindgut hypothesis, which is observed after surgical ileal interposition or biliopancreatic diversion. The technique involves the deployment of two self-assembling magnets (one anterograde and the other retrograde), that should be driven to couple across the wall of two intestinal segments. The magnetic compression deters the blood flow leading to round necrosis that works as a wide anastomosis a week after coupling. Usually, the magnets are uneventfully expelled during defecation (Ryou et al. 2011).

The proof-of-concept study was first published in 2016. Five pigs underwent EMPJD however due to the particular anatomy of the porcine intestine, the only possible anastomosis was jejunocolonostomy. The average duration of the procedure was 14.7 min. At 3 months, the authors typically found a 3.5 cm-wide epithelized anastomosis. The animals undergoing EMPJD presented significant weight stabilization compared to litter-paired control pigs (Ryou et al. 2016).

In the Czech Republic, 11 obese individuals who failed conservative weight loss methods were selected to undergo EMPJD. After 12 attempts, 10 cases were technically successful. Per protocol, all procedures were laparoscopy-guided. The laparoscopic forceps was used to assist coupling if sole endoscopic manipulation was not successful. Eight out of ten cases required

laparoscopic assistance for coupling magnets. Upper endoscopy confirmed broad anastomoses at 2, 6, and 12 months (Machytka et al. 2017).

Mean TWL was 8.2%, 10.6%, and 14.6% at 3, 6, and 12 months, respectively. Accordingly, EWL was 21.7%, 28.3%, and 40.2%. Diabetic patients experienced a distinct reduction in HbA1c at 12 months compared to baseline (7.8 vs. 5.9). There were significant reductions in postprandial insulin at 2 and 6 months, and a significant increase in PYY at 2 months (Machytka et al. 2017).

Currently, there is an ongoing open-label trial settled in Argentina. As the sole endoscopic coupling of magnets incurs substantial technical difficulties, this method shall be converted to a combined surgical-endoscopic procedure shortly.

Bariatric Embolization: A Possible Non-surgical Option for Weight Reduction

45

Muhammad A. Latif and Clifford R. Weiss

Contents

Abstract

Gastric arterial embolization has historically been used to treat gastrointestinal hemorrhage. After the discovery of the appetite-inducing hormone, ghrelin, gastric fundal embolization or bariatric embolization has gained importance for weight reduction. Although still in initial experimental stage, the only effective nonsurgical intervention for reduction of ghrelin is bariatric gastric embolization. Preliminary findings from early single-arm clinical trials have demonstrated that bariatric embolization results in significant decrease of plasma ghrelin levels and leads to weight loss.

It is a safe, novel, promising technique that has the potential to be an alternative procedure to surgery for patients with body mass index between 30 and 40. Common side effects include transient epigastric pain, nausea, vomiting, and stomach ulcers.

Keywords

Bariatric embolization · Left gastric artery embolization · Ghrelin · Weight loss · Appetite-stimulating hormone

Introduction

The World Health Organization recognizes obesity as a global epidemic (Afshin et al. 2017; WHO 2000; Caballero 2007), and in 2013, the American Medical Association (AMA) categorized obesity as a separate disease entity with multiple pathological aspects, requiring a variety of surgical and nonsurgical interventions (A.M.A. Recognizes Obesity as a Disease 2019; Kosti and Panagiotakos 2006). In a recent report of countries of the Organization of Economic Cooperation and Development (OECD), including the United States, one child out of five was found to be overweight or obese (OBESITY Update 2014). Obesity is a risk factor for type 2 diabetes mellitus (T2DM) (Al-Goblan et al. 2014), cardiovascular diseases (CVD) such as hypertension (DeMarco et al. 2014), stroke, and coronary heart disease (Jin 2013), gall bladder disease (Everhart 1993), and cancer (endometrial, breast, prostate, colon) (Stone et al. 2018), resulting in increased risk of disability or premature death (Smith and Smith 2016; Abdelaal et al. 2017). Obesity is also linked with nonfatal diseases, including gout, respiratory conditions (chronic obstructive pulmonary disease, asthma, obstructive sleep apnea) (Poulain et al. 2006), gastro-esophageal reflux disease, osteoarthritis, and infertility. There are also serious psychosocial health implications of obesity due to societal prejudice against obesity (Simon et al. 2006).

Current Techniques

The mechanisms of weight loss for bariatric surgeries such as Roux-en-Y gastric bypass, sleeve gastrectomy, and gastric banding include restricting meal size, inhibiting nutrient absorption, and altering gastrointestinal hormones involved in metabolic homeostasis (Elder and Wolfe 2007; Beckman et al. 2010; Cummings et al. 2002; Karra et al. 2010; O'Rourke et al. 2006; Paxton et al. 2013; Sumithran et al. 2011). Surgical and endoscopic bariatric interventions can be associated with short- and long-term complications (Neff et al. 2013) (Table 45.1). Leaks, stenoses, bleeding, and venous thromboembolic events (VTE) are listed in the early postoperative period (Lim et al. 2018). Late surgical complications include band slippage, band erosion, megaesophagus or pseudoachalasia, gallstone disease, perforation, bleeding, small bowel obstruction, and internal hernia (Lim et al. 2018).

Role of Interventional Radiology

Recently, there have been advancements in interventional radiology to treat obesity as a minimally invasive alternative (Neff et al. 2013). Current radiological interventions include percutaneous computed tomography (CT)-guided cryovagotomy (Prologo et al. 2019) and image-guided gastric fundal embolization (bariatric embolization) (Arepally et al. 2007). Percutaneous CT-guided cryovagotomy involves the use of cryoablation to freeze the posterior vagal trunk located at the base of the esophagus, which normally transmits the hunger signal from the stomach to the brain (Prologo et al. 2019). Bariatric embolization is a minimally invasive, image-guided procedure that targets the appetite-stimulating endocrine functions of the gastric fundus (Gunn and Oklu 2014; Madoff 2013).

Table 45.1 Current surgical, endoscopic, and interventional radiology methods for weight reduction

Specific category	Procedure detail	Proposed mechanism of action for obesity	Benefits	Risks	% Of 1 year weight loss
Roux-en-Y gastric bypass	Small, upper gastric pouch connected to small bowel; larger lower "remnant" pouch;	Reduction of gastric size with resulting decrease in appetite	Rapid weight loss; No device inside the body; Quick improvement in comorbidities (Diabetes and hypertension)	Long healing; Nutrient absorption Dietary restrictions; Irreversible, possible surgical complications	31.2
Sleeve gastrectomy	Resection of the stomach to decrease its size	Reduction of gastric size with resulting decrease in appetite	Rapid weight loss; No device inside the body; Short recovery time	Irreversible procedure Complications, including leak, bleeding, etc.	25.2
Adjustable gastric band	Inflatable silicone device laparoscopically placed around the top portion of the stomach to decrease food consumption	Reduction of gastric size with resulting decrease in appetite	Lower risk of complications No cutting of the stomach Short hospital stay	Infection , erosion, complications Several adjustments Gradual weight loss	13.7
Biliopancreatic diversion with duodenal switch (BPD/DS) (Baltasar et al. 2001)	Duodenal switch with a vertical subtotal gastrectomy and pylorus preservation	Reduction of gastric size; decrease in appetite;	Drastic, significant weight loss	Dumping, osteoporosis Poor nutrition bleeding, infection, hernia	70.1 (% EWL) [a]
Endoscopic sleeve gastroplasty (accordion procedure) (Sharaiha 2017)	Endoscopic suturing device to reduce stomach size	Reduction of gastric size with resulting decrease in appetite	No incisions, Low cost, Outpatient procedure	Bleeding, leak, venous thrombosis, pulmonary embolism	20
Transpyloric shuttle (TPS)	Silicone rubber balloon endoscopically placed in the stomach for 12 months	Decreased food absorption and appetite	Nonsurgical, Longer effect, Significant weight loss	Bleeding, infection, tearing of the esophagus or stomach	9.5
Endoluminal magnetic partial jejunal diversion	Endoscopically placed magnet for intestine diversion	Nutrients, digestive fluids circumvent part of the small bowel	Significant weight loss	Vitamin deficiencies Abdominal distension Diarrhea Constipation Vomiting	14.6
Bariatric Embolization (Hafezi-Nejad et al. 2019)	Embolization of the LGA	Decrease in ghrelin and appetite	Safe with no major complications	Gastric ulcer/ ischemia/ perforation, splenic infarction, acute pancreatitis	8.7

(continued)

Table 45.1 (continued)

Specific category	Procedure detail	Proposed mechanism of action for obesity	Benefits	Risks	% Of 1 year weight loss
Percutaneous CT-guided cryovagotomy	Argon gas used to freeze the posterior vagal trunk located at the base of the esophagus	Disruption of the hunger signal from the stomach to the brain	No data available	No data available	No data available

[a]The percent of excess weight loss or %EWL (i.e., [initial weight–actual weight/actual weight–ideal weight] × 100) is accepted as a good measure of end results, and %EWL > 50 is considered a success

Basis of Bariatric Embolization for Weight Loss

Appetite and Ghrelin Production

Ghrelin is an orexigenic hormone secreted predominantly by the stomach (Druce et al. 2004; Strader and Woods 2005; Inui et al. 2004; Inui 2001). Ghrelin-producing cells are located in the fundus of the stomach, and directly stimulate appetite resulting in weight gain (Hayashida et al. 2001; Takiguchi et al. 2012). It has been shown by Maksud et al. that ghrelin-forming cells have higher density and expression in the stomach mucosa of obese patients (Maksud et al. 2011). Because of the unique nature of this hormone and its effect on appetite, multiple approaches to modulate ghrelin production have been attempted; however, no direct clinical technique has been shown to be successful (Cummings and Shannon 2003; Hu et al. 2005; Murray et al. 2003; Loftus et al. 2000; Wren et al. 2001). In 2007, Arepally et al. (2007, 2008) described an endovascular procedure that directly targeted the gastric fundus and its function. In this investigation, gastric artery chemical embolization (GACE) was performed by injecting a liquid sclerosing agent, sodium morrhuate, into the main left gastric artery (LGA) with fluoroscopic guidance, resulting in a decrease in the plasma level of ghrelin.

Stomach as an Endocrine Organ

Ghrelin is the only hormone that stimulates food intake. Discovered by Kojima et al. (1999), it activates the growth hormone secretagogue receptor in the hypothalamus or anterior pituitary. Ghrelin inhibition on the central nervous system is promptly followed by anorexia and loss of weight (Hu et al. 2005; Loftus et al. 2000). In humans ghrelin injection elicits hunger and enhanced caloric intake (Cummings et al. 2001).

The tendency to recover lost weight after dieting could be partially explained by rebound ghrelin elevation (Strader and Woods 2005). After meals ghrelin decreases in the normal however not in most obese individuals, potentially triggering hyperphagia (English et al. 2002).

Anatomy of the Gastric Fundus

Seven parts are admitted in the stomach: cardia, fundus, antrum, pylorus, lesser curvature, greater curvature, and incisura angularis. The neuroregulatory pathway involved in satiety and appetite stimulation is fundamentally located at the fundus (Cummings et al. 2002, 2005; Frühbeck et al. 2004; Tritos et al. 2003), which contains 10–20 times more ghrelin than the duodenum, which is second (Druce et al. 2004; Inui et al. 2004). The left gastric artery perfuses the

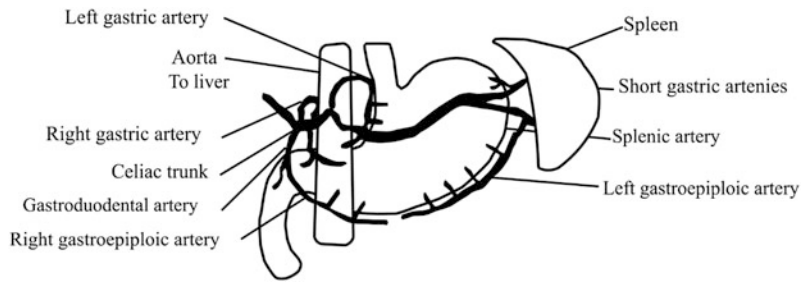

Fig. 45.1 Normal arterial supply of the stomach

fundus (Fig. 45.1), and it is amenable to percutaneous endovascular catheterization.

The short gastric arteries, and the gastroepiploic artery, which have different origins, have a more modest participation. Gastric arterial embolization is effective in cases of bleeding and is also safe, as existing vascular arcades prevent unplanned ischemia.

Ghrelin Suppression After Gastric Bypass Surgery

Since gastric bypass surgery isolates the gastric fundus from ingested nutrients, ghrelin profiles are shown to be lower by 77% compared to those in controls (Murray et al. 2003; Cummings et al. 2005; Nakazato et al. 2001; Okumura et al. 2002). Furthermore, the normal diurnal pattern of ghrelin is interrupted, and the meal-initiated fluctuations are blunted (Murray et al. 2003; Cummings et al. 2005).

Bariatric Embolization

Gastric embolization, previously used for hemorrhage only, could target the appetite-stimulating endocrine functions of the gastric fundus (Madoff 2013; Lu et al. 2014; Loffroy et al. 2010, 2015; Gunn and Oklu 2014). Spherical embolics (300–500 μm) are delivered via a transcatheter approach into the LGA (Madoff 2013). Fundal mucosal ischemia depresses the production of ghrelin (Paxton et al. 2013; Sumithran et al. 2011; Arepally et al. 2007, 2008). Weight and ghrelin response were documented in both animals (Arepally et al. 2007, 2008; Bawudun et al. 2012) and humans (Bin et al. 2018; Kim et al. 2018; Kipshidze et al. 2015; Syed et al. 2016; Weiss et al. 2017).

Patient Selection

Patients with BMI between 30 kg/m^2 and up are the typical candidates. In case of GI disease (stomach or duodenum ulcer, cancer) or local radiation therapy, exclusion applies. It is not known whether bariatric surgery is safe and feasible after bariatric embolization. Future bariatric surgery should be preoperatively discussed with the patients.

Vascular Access

Transfemoral or transradial arterial access are available. The transradial approach looks more feasible and safe (Pirlet et al. 2019).

Embolic Agents

Historically sodium morrhuate was employed; however, better options are now in the market (Arepally et al. 2007). Bead block microspheres (300–500 μm) (www.bostonscientific.com), polyvinyl alcohol (PVA) particles (500–700 μm) (www.cookmedical.com), and embosphere microspheres (300–500 μm) (www.merit.com) are preferred (Vaidya et al. 2008). Spherical embolics of 300–500 μm size are conventionally injected (Table 45.2). Microspheres are biocompatible, hydrophilic, nonresorbable particles produced from an acrylic polymer and impregnated with porcine gelatin (No Title 2019; Kshirsagar and Saudagar 2016).

Table 45.2 Clinical trials for bariatric embolization

Title	Acronym, status, results	Eligibility	Interventions	Embolic agent	Phase	Cases	Locations
Bariatric Embolization Trial for the Obese Nonsurgical	BET-ON, Not yet recruiting, No results available	Obesity Weight Loss Body Weight Morbid Obesity (BMI >40, or BMI >35 with medical comorbidities)	LGA embolization	450 μm Embozene microparticles	Phase 1	5	University of Calgary, CA
Bariatric Embolization of Arteries for the Treatment of Obesity	BEAT Obesity, Completed, Has results	Morbid Obesity (BMI between 40 and 60)	LGA/LGEA embolization	Artificial Embolization Device Embosphere Microspheres	Not applicable	20	Johns Hopkins Hospital, Baltimore, MD, USA
Bariatric Embolization of Arteries for the Treatment of Nonalcoholic Steatohepatitis	None available, Not yet recruiting, No results available	Obesity Weight Loss Body Weight Nonalcoholic Steatohepatitis Nonalcoholic Fatty Liver Disease (NAFLD) (BMI >35)	LGA/LGEA embolization	Embosphere microspheres	Not applicable	8	Saint Louis University, Saint Louis, Missouri, United States
Bariatric Embolization of Arteries in Obese Patients with HCC to Allow Salvage Liver Transplantation	None available, Suspended, No results available	Obesity Weight Loss Hepatocellular Carcinoma Hepatitis Cirrhosis (BMI >35)	LGA embolization	Embosphere Microspheres	Not applicable	8	Saint Louis University, Saint Louis, Missouri, United States
Transradial Selective Catheterization of the Celiac Artery in Obese Patients	None available, recruiting, No results available	Obesity (BMI >30)	Transradial celiac artery angiography	Feasibility , safety of transradial angiography of the celiac artery	Not Applicable	54	Quebec Heart & Lung Institute (IUCPQ-UL), Quebec City, Quebec, CA
Gastric Artery Embolization Trial for Lessening Appetite Nonsurgical	GETLEAN, Unknown, Ni results available	Obesity (BMI >40)	LGA embolization	300–500 μm Bead Block	Not applicable	5	Dayton Interventional Radiology, Dayton, Ohio, United States
Bariatric Embolization for Morbid Obesity	BAEMO, Unknown, Initial results available	Morbid Obesity (BMI >30)	LGA embolization Healthy diet and exercise	500–710 μm PVA (COOK Inc, Bloomington IN, USA)	Phase 3	50	Zhongda Hospital, Southeast University, Nanjing, Jiangsu, China
Gastric Arterial Embolization for Weight Loss	None available, Unknown, No results	Obesity (BMI >40, or BMI >35 with medical comorbidities)	LGA embolization Embolization of gastroepiploic artery	150–250 μm PVA particles	Not applicable	10	Martin Simons, University Health Network, Toronto, CA
Bariatric Embolization of Arteries with Imaging Visible Embolics	(BEATLES), Recruiting, No results available	Obesity Morbid Obesity Weight Loss (BMI >35)	LGA embolization	Bariatric embolization, imaging-visible embolics	Not applicable	59	Johns Hopkins Hospital Baltimore, MD, USA

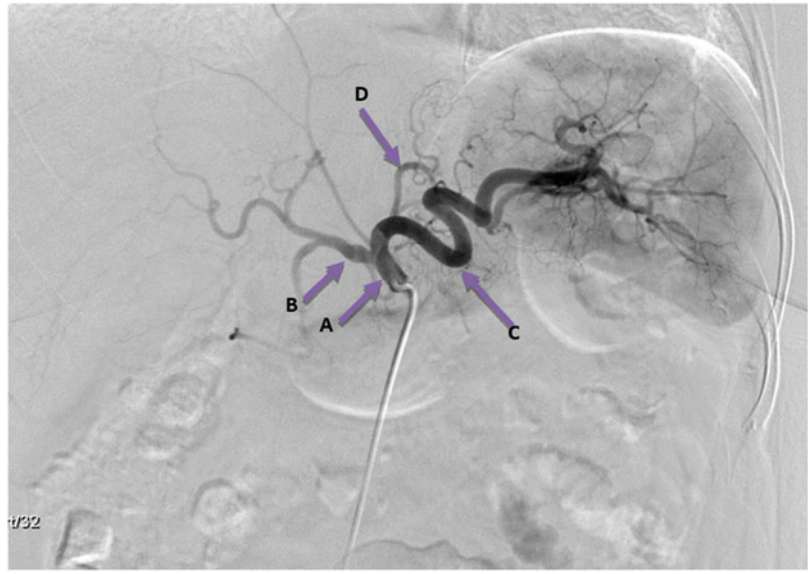

Fig. 45.2 Left gastric artery embolization procedure in a 54-year-old female with morbid obesity. Celiac artery angiogram showing Celiac artery (arrow *A*), Common Hepatic artery (arrow *B*), Splenic artery (arrow *C*), and Left Gastric Artery (arrow *D*)

The exact choice will depend on the arterial anatomy, angiographic findings, types of embolization (localized, proximal, or segmental), duration of occlusion desired, the need for tissue viability, and the patient comorbidities (Lubarsky et al. 2009, 2010; Shin 2012). Bead block microspheres, used in other contexts (Liaw et al. 2012), are a valid option (Kipshidze et al. 2015; Syed et al. 2016). Polyvinyl alcohol (PVA) agents are also a possibility (Bin et al. 2018; Pirlet et al. 2019) (Fig. 45.2).

In the BEAT Obesity trial, 300–500 μm-calibrated embospheres were technically feasible, well tolerated, and followed by short- or intermediate-term weight loss (Weiss et al. 2019). Experimentally smaller microspheres show greater weight gain suppression and fundal ghrelin expression, but with more gastric ulceration (Fu et al. 2018). Radio-opaque embolic beads (Mikhail et al. 2018) have advantages regarding intraprocedural monitoring of target and nontarget embolization, and postprocedural evaluation of embolization (Duran et al. 2016; Thompson et al. 2018). Other embolic agents are listed in Table 45.3 (Gunn and Oklu 2014; Brown et al. 2016; Anton and Rahman 2015).

Table 45.3 Different types of embolic agents

Embolic agents types			
	Permanent		
Temporary	Nonabsorbable microparticles	Mechanical embolic agents	Liquid embolic agents
Gelatin sponge	Polyvinyl alcohol particles (spherical and non-spherical)	Pushable coils	N-butyl-2-cyanoacrylate
Oxidized cellulose and microfibrillar collagen	Tris-acryl gelatin microspheres	Liquid coils	Ethylene vinyl alcohol copolymer
Thrombin	Embozene microspheres	Detachable coils	
		Vascular plugs (covered and non-covered)	

Radiation Dose

Fluroscopic dose follows the recommendations of the Society of Interventional Radiology (SIR), American College of Radiology (ACR), American Association of Physicists in Medicine (AAPM), and National Council on Radiation Protection and Measurements (NCRP) (Stecker et al. 2009; Miller et al. 2004; Radiology AC of 2015; Mahesh 2012; Balter et al. 2012). There is no evidence of skin burns from bariatric embolization in the Beat Obesity trial, and interventions usually take less than 1 h (Weiss et al. 2017).

Post-procedure Immediate Care

Gastric ulcer is a risk, and proton pump inhibitors are recommended before and after the procedure. A subsequent overnight admission can be needed in circumstances of nausea, vomiting, or epigastric pain.

Long-Term Metabolic Effects

Nejad et al. have shown 8.1% weight loss in 1 year (Hafezi-Nejad et al. 2019), less than the 13.7–31.2% outcome after surgical intervention (Arterburn et al. 2018). However, bariatric embolization is more safe and effective especially for patients who have contraindications (Gunn and Oklu 2014; Bin et al. 2018; Hafezi-Nejad et al. 2019; Stahl and Malhotra 2019), or are not interested in bariatric surgery.

Combination Therapy with Clinical and Surgical Maneuvers

The inclusion of diet control and exercise could contribute to weight control on a longer term. Embolization is not proposed as a replacement for bariatric surgery, but as a complementary method to facilitate weight loss with lifestyle modification.

Ongoing Human Trials and Other Lines of Investigation

There are only few clinical trial results for weight reduction, along with others in the recruitment phase (Table 45.2). Most of the safety data have been derived from studies to treat gastrointestinal hemorrhage.

Progress in Noninvasive Beta-Cell Mass Imaging

46

Bluma Linkowski Faintuch and Salomao Faintuch

Contents

Abstract

Beta-cells play a decisive role in regulating glucose homeostasis, via insulin synthesis and release. Beta cell maintenance (mass, architecture, survival) and function (insulin release) are central to type 2 diabetes (T2D), in which the pancreas is technically normal to begin with. Yet progressive loss of beta cells tends to occur with disease progress, due to glucolipotoxicity and additional mechanisms. Many candidate probes for beta cell imaging have been designed based on the screening of genomic, SNP, or proteomic β cell databanks, but no consensus on the ideal probes has yet been reached. Monitoring the beta-cell mass requires a reliable method for noninvasive utilization. Despite the non-negligible challenges, many advances have been reached in preclinical studies, and human trials are going on.

Introduction

In physiological conditions, concentrations of blood glucose are stable within a relatively narrow range, despite large fluctuations in intake (intermittent meals, night fasting) as well as consumption (mild office or household activities, hard-working jobs or sports, sedentary periods, sleeping).

Insulin secretion, dependent on pancreatic beta cell population and function, is often more critical than insulin resistance in T2D, despite the strong association between insulin resistance and obesity, the most frequent precipitant of diabetes onset (Fig. 46.1) (Ashcroft and Rorsman 2012).

Beta cell insults include cytokine-induced inflammation, obesity and insulin resistance, and saturated fat and free fatty acids (FFA), along with hyperglycemia itself. A progressive decline of beta cell function leads to beta cell exhaustion. Even incretin-mimicking drugs like glucagon-like peptide 1 receptor agonists, well-regarded worldwide for their excellent clinical response in T2D, can induce exhaustion in some contexts (Van Raalte and Verchere 2016).

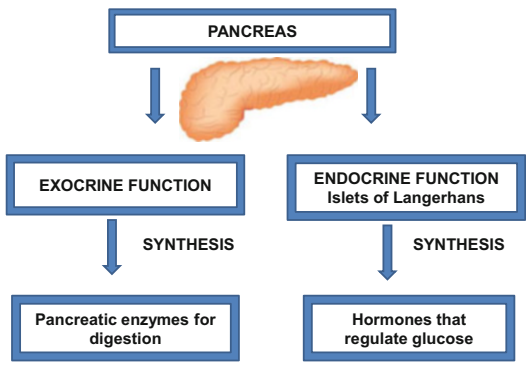

Fig. 46.1 Pancreas and its functions

Main Chronic Disorders Related to Beta-Cells

The fundamental nononcological diseases precipitated by beta-cell aberrations are type 1 and type 2 diabetes. Obesity is intimately related although it should not be listed among the consequences as it is obviously one of the causes of dysglycemia, along with genetics, epigenetics, aging, glucolipotoxicity, and other mechanisms (Li et al. 2020a). Incidentally the interplay with obesity is complex, with different clusters of obese patients exhibiting patterns of insulin responsivity, secretion, and resistance that range from the perfectly healthy to the highly deranged (Li et al. 2020b).

In the course of obesity, both insulin sensitivity and β-cell function tend to decrease (Li et al. 2020a, 2020b). In a healthy organism, there is a continuous feedback relationship between the β-cells and the insulin-sensitive tissues. If adipose tissue, liver, and muscles exhibit a larger glucose turnover, this will lead to a parallel and proportional increase in insulin supply.

Glucotoxicity

Should insulin resistance ensue, β-cells will be overworked in order to maintain the same normal levels of glucose. At some moment pancreatic β-cell demise could occur, partly as a consequence of glucotoxic effects of persistently elevated blood glucose. Further decompensation of glucose homeostasis, potentially leading to prediabetes of full-blown type 2 diabetes, should be anticipated. Reduced proliferation and enhanced beta cell apoptosis have been recognized for some time in T2D (Li et al. 2017).

Lipotoxicity

Plasma nonesterified fatty acids (NEFA) levels play a major role in insulin release, yet the continuous exposure to them interferes with glucose-stimulated insulin secretion pathways, and can

result in reduced insulin biosynthesis. Insulin resistance and failure of the compensatory mechanisms of β-cells further contribute to increased amounts of NEFAs. Indeed adipose tissue release of NEFAs into plasma is inhibited by the antilipolytic action of insulin.

During metabolic syndrome and obesity, it is possible to measure both glucose-specific and NEFA-specific insulin resistance, which are clearly different from normal. The combined effect of lipotoxic increases in plasma NEFA levels and the rise of glucose levels might produce the typical combined outcome glucolipotoxicity (Walker et al. 2020).

β-Cell Mass in Human Obesity

In nondiabetic subjects, obesity is associated with a modest expansion of β-cell mass, in parallel with the α-cell mass, so that the proportional elevation of both glucagon and insulin is maintained in this bihormonal, multifaceted disease (Ellenbroek et al. 2017).

Adiposity and particularly ectopic fat in the pancreas, liver, muscle, and other glucose recipient organs will exacerbate insulin resistance, which subsequently impairs beta cell function. Obesity also increases insulin demand; therefore, hyperfunction of beta cells may ultimately exhaust them, as a result of beta cell dysfunction (Cerf 2013).

In those individuals who develop diabetes, beta cell physiological compensation declines due to hyperglycemia resulting in a persistent progressively increasing metabolic load that could be further influenced by aging and an eventually adverse genetic profile.

Current mathematical models try to integrate such diverse factors as fasting plasma glucose, insulin, leptin, glucagon, nonesterified fatty acids (NEFA), and very-low-density lipoprotein triglyceride (VLDLTG), as well as muscle, hepatic, and pancreatic lipids, fat mass, and mass of β-cells. Combined with dietary pattern, the model is likely to predict the trajectory to both fat and lean T2D (Hassell Sweatman 2020).

Beta Cell Mass in T2D

As alluded to, beta cell mass shrinks in T2D; however, differences between lean and overweight/obese diabetics are not remarkable (41% and 38% decrease, respectively). Duration of disease is a robust and widely recognized driver in such circumstances, with 24% reduction in subjects with less than 5 years after diagnosis, versus 54% in those with over 15 years of overt diabetes (Rahier et al. 2008; Butler et al. 2016).

Rodent Versus Human β Cells

The vast majority of experimental investigations concerning beta cell imaging are conducted in rodents. This has been a hindrance for clinical translation, as major anatomical and functional differences separate these nonhuman species from patients (Kang et al. 2020). It is worth emphasizing this point, as nominally successful animal techniques continuously appear, without sufficiently highlighting such critical detail.

Cell Types

Pancreatic islet cells are not dissimilar between man and rodents: β, α, δ, ε, and pancreatic polypeptide cells (Fig. 46.2).

Yet microvascularization, cytoarchitechture, and composition of cell clusters, which are merely histological arrangements yet with significant functional impact, pursue conflicting models.

In rodents, 80% of the islets consist of insulin-expressing β cells, forming a core surrounded by other cell types. In turn, only 50–60% of the islet cells are of the β variety in humans, and their distribution is scattered. About 30% are glucagon-producing α-cells, along with small proportions of δ-cells (somatostatin), γ—or PP cells (pancreatic polypeptide), and ε-cells (ghrelin) (da Silva Xavier 2018). Additional differences in the cells concern calcium ion

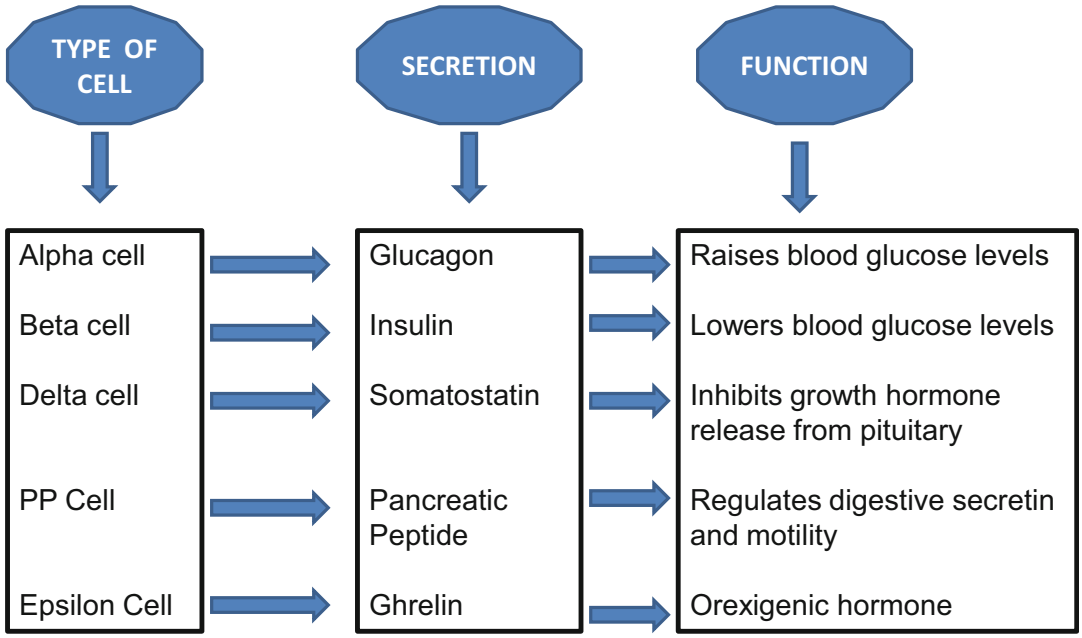

Fig. 46.2 Composition of pancreatic islets

oscillation, and the main transporter for glucose uptake, which is GLUT2 in rodents and GLUT1 in humans. In addition to functional differences (Johnston et al. 2016), such architecture interferes with imaging profiles (Murakami et al. 2019) (Fig. 46.3).

As a result, species-specific expression level and islet distribution of beta cells are inevitable during imaging procedures with positron emission tomography (PET) and single-photon emission computed tomography (SPECT), complicating the interpretation of such diagnostic resources

Beta-Cell Imaging

In front view, the adult pancreas measures about 3.0 cm at the head, 2.5 cm at neck and body, and 2.0 cm at the tail (these values are not applicable to old persons, given the age-related atrophy of the gland). The pancreatic islets constitute 1–2% of this mass and are widely scattered throughout the pancreatic parenchyma. Given an estimated total number of 3.2–14.8 million islets, and an individual diameter of 30 μm to >400 μm, total islet volume could reach 0.5–2.0 cm^3. This is not a sufficiently large size for single islet identification, and a challenge even for global tracing given their widespread distribution in a much larger host organ, yet with specific cell probes, collective beta cell imaging can be envisaged (Huang et al. 2018).

Histological Estimations

Histometric techniques for beta cell mass calculation are well established. Most commonly, islet beta-cell area is defined on pancreatic tissue sections and extrapolated for total pancreatic volume. Yet, no routine clinical application will emerge as multiple biopsies would be required, entailing the risk of pancreatitis, bleeding, pseudocysts, and other serious complications. Such approach is useful as a gold standard, for experimental validation of imaging procedures (Linnemann et al. 2014).

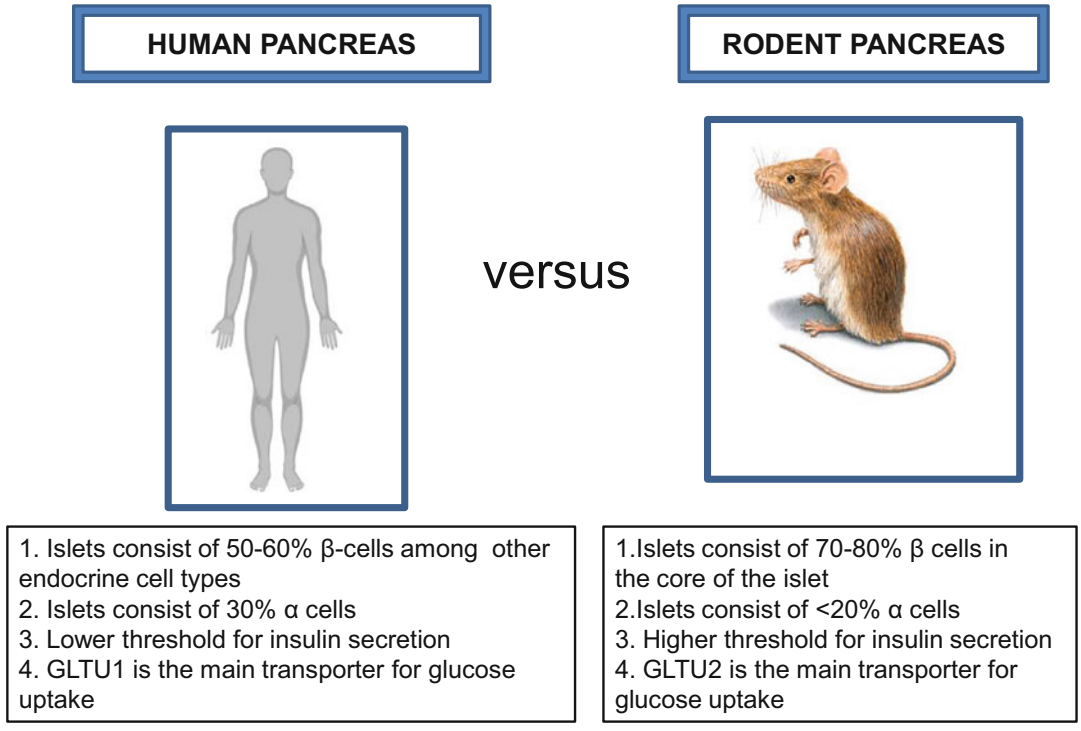

Fig. 46.3 Differences between human and rodent islets

Noninvasive Imaging of Pancreatic β Cells

Diagnosis of beta-cell loss or dysfunction in different phases of diabetes would be conspicuously helped by imaging of the beta cell mass (BCM). Interventions aiming at preservation or regeneration of beta-cells, based on incretin analogs or cell therapy techniques, could be directly monitored. These include cell-based immunomodulatory approaches for type 1 diabetes (Black and Zorina 2020)

As alluded to, when diabetes is diagnosed, a significant proportion of insulin-secreting pancreatic β cells are already dysfunctional or destroyed (Rahier et al. 2008; Butler et al. 2016). Early evaluation of BCM could entail better preservation procedures, in order to prevent such often irreversible loss.

Single Diagnostic Tools

Optical Imaging

Bioluminescence tomography (BLT), fluorescence molecular tomography (FMT), and optical projection tomography (OPT) are not employed yet in the clinical setting, however, have been successful in experimental protocols.

Optical methods rely on the detection and image acquisition of natural or notably induced light emission from a known biological source, with a particular wavelength. Fluorescent proteins have been used for a long time to track cells and proteins, both in vitro and in vivo.

Also, the enzyme luciferase has been transfected to isolated human beta cells, acting as a source of bioluminescence (Kracht et al. 2018). However, no translational applications are foreseen for this complicated intervention in the near future.

Fluorescent probes, after excitation at a specific wavelength, emit an optical signal. Fluorophores range from 510 nm to 900 nm, with better penetration at longer wavelengths. Despite the fact that fluorescence alone is not feasible yet for pancreatic β cell tracking in vivo, encouraging results were announced with a hybrid technique, combining a fluorescence probe with a radioactive marker (18 F). In animals, this enabled the successful identification of pancreatic beta cells with the help of a PET scan (Kang et al. 2019).

Magnetic Resonance Imaging (MRI)

This classic tool uses strong magnetic fields to excite hydrogen atoms. These emit radio frequency signals that can be detected by a receiver and transformed into an image.

MRI contrast agents suffer from limited sensitivity of the systems, and the MRI signal is difficult to quantitate in absolute numbers, in order to calculate the β cell mass. As classic computed tomography and other traditional methods, it lacks specificity and resolution power for the challenge represented by beta cells (Kang et al. 2019).

Radiopharmaceutical Imaging

The physical basis for nuclear medicine imaging is the detection of radiation emitted from a radioactive isotope (biological marker). Many tracers have been tested within the context of pancreatic β cells, particularly monoclonal antibodies and peptides, targeting β cell specific antigens, receptors, or its major secretion molecule, namely, insulin. Table 46.1 lists imaging agents studied in experimental conditions for PET or SPECT imaging of pancreatic beta cells, and radiolabeled with a variety of radioactive isotopes, along with MRI protocols.

Single Photon Emission Computed Tomography (SPECT)

Based on γ-ray-emitting radiotracers, this is one of the most valued nuclear medicine technologies. It offers a high diagnostic sensitivity in the picomolar range, something desirable when dealing with pancreatic islets and related molecules. Combination with computed tomography (SPECT/CT), it could be endowed with the right assessment qualities for BCM, as discussed now.

Combined Diagnostic Tools

Fusion Imaging linking functional and anatomic imaging data via PET/MRI, PET/CT, SPECT/CT, or PET/fluorescence probe, could bypass the weaknesses of single methods by means of methodological synergies, thus paving the way for clinically relevant information (Singh et al. 2017).

Table 46.1 Summary of the main targets and imaging agents

Target	Imaging agent	Type of imaging
VMAT2 Vesicular monoamine transporter 2 neutrotransmission	^{11}C-DTBZ ^{18}F-FP-DTBZ	PET
β-Cell surface antigen	^{111}In-IC2 (mAb)	SPECT
Gangliosides on the plasma membranes of pancreatic β cells	^{125}I-R2D6 (mAb)	SPECT
Dopamine receptors (D2 and D3)	^{11}C-PHNO ^{11}C-5-HDP	PET
GLP1R Glucagon-like-peptide 1 receptor	^{18}F-(Nle14,Lys40)-exendin-4 ^{111}In-DTPA-Lys40-exendin-3 ^{177}Lu-Do3A-VS-Cys40-exendin-4	PET SPECT SPECT
TMEM 27 Transmembrane protein 27	^{89}Zr-8/9 mAb	PET
ZnT8 protein Zinc transporter 8	^{125}I-Ab31 ^{125}I-exendin 4	SPECT
GPR44—Pancreatic protein GPR44 antagonist	11C-AZ12204657	PET
FXY-D2ya	Gd-DOTA-P88	MRI
Zn +@	Gd-DOTA-diBPEN	MRI
Ca+2 Channel	MnCl2	MRI

PET/MRI

PET-MRI is one of these promising approaches. The contrast for MRI was manganese (Mn), an ion gated by voltage-dependent calcium channels, involved in insulin secretion by pancreatic beta cells, along with radiolabeled exendin-4 for PET, a glucagon like peptide 1 receptor agonist, which stimulates beta cell metabolism. In vivo quantification of β-cell function and mass was thus achieved (Michelotti et al. 2020).

SPECT/CT

Creative diagnostic interventions were recently developed in mice, with potential for future use in humans. In one model, pancreatic alpha and beta cells were traced by a dipeptidyl peptidase 6 (DPP6) antibody (nanobody "4hD29"). Subsequent SPECT/CT investigation allowed identification of implanted human pancreatic islet cells in mice. The possibility of employing PET/CT for the same purpose is also envisaged (Demine et al. 2020).

Glucagon-like peptide 1 analog exendin-4, radiolabeled with Indium 111, has been proposed for specific quantification of BCM, by means of a SPECT/CT protocol. Preliminary results in diabetic mice were very positive (Murakami et al. 2019) (Fig. 46.4).

Clinical Trials

A trial was conducted a couple of years ago, using an 18F-FP DTBZ (fluoropropyl-dihydrotetrabenazine) marker, with the aim of evaluating an islet imaging technique and measuring BCM, in both prediabetes and diabetes, compared to healthy obese volunteers (Cline et al. 2018). This marker binds to vesicular monoamine transporter type 2 (VMAT2), which is

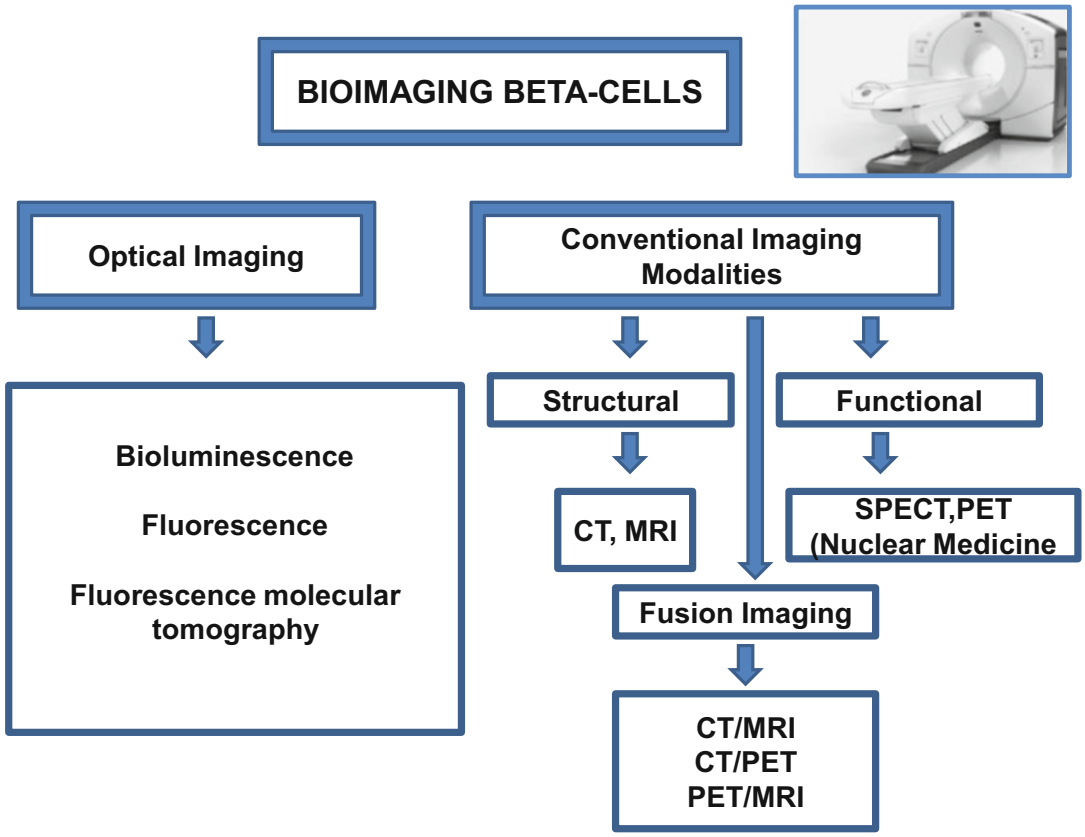

Fig. 46.4 Tools to bioimage beta-cells

expressed by insulin-secreting beta cells. Results were consistent with the hypothesis, and suggested that measured loss of BCM contributed to deficient insulin secretion in humans with type 2 diabetes. Binding potential had previously been tested in type 1 diabetes and repeatable values were observed, anticipating its interest in this population as well (Freeby et al. 2016).

This line of investigation didn't receive unblemished acclamation. In a relatively widely cited criticism by investigators from the University of Pennsylvania, it was recommended that PET scanning be reserved for more substantial cell masses, or for highly concentrated clusters, such as occurring after beta cell transplantation, or hyperinsulinism/insulinoma. The limit for effective PET detection is stated as 8–10 cm^3, something incompatible with islet cell size and histological distribution (Alavi and Werner 2018). Nevertheless the authors stood their ground, in face of their results, and of continuous advances in PET imaging technology (Gotthardt et al. 2018).

Cancer Staging with 18F-FDG PET/CT in Hyperglycemic Patients

47

Monica Finessi, Virginia Liberini, and Désirée Deandreis

Contents

Abstract

In oncology positron emission tomography/computed tomography (PET/CT) is a standard imaging procedure for cancer staging, restaging, treatment monitoring, and radiation therapy planning. Despite the availability of many radiotracers, 18F-fluoro-2-deoxy-2-D-glucose ([18F]FDG) is still the most used for most cancers staging.

Hyperglycemic conditions, antidiabetic oral medications, or insulin can have an impact on [18F]FDG PET/CT scan accuracy. A correct knowledge of how these conditions influence [18F]FDG distribution is fundamental for patients management before [18F]FDG PET/CT. International PET/CT guidelines propose protocols for patients' adequate preparation and therapy management before [18F]FDG administration, in particular with regard to diabetic patients.

Clinical Importance of 18F FDG PET/CT in Cancer Staging

In oncology positron emission tomography/computed tomography (PET/CT) is a standard procedure, commonly used in several cancers for staging, restaging, treatment monitoring, and radiation therapy planning. Despite many radiotracers being available, according to different applications, 18F-fluoro-2-deoxy-2-D-glucose ([18F]FDG) is the most widespread. Focusing on cancer TNM staging, local tumor (T) extension is frequently a prerogative of morphological imaging such as CT scan or MRI to evaluate local extension, but [18F]FDG PET can help in a better tumoral mass characterization, especially identifying necrotic or fibrotic areas inside the tumoral mass to guide biopsy or locoregional treatment. Furthermore [18F]FDG is a very important tool for lymph-node (N) and distant metastases (M) detection: baseline [18F]FDG PET/CT is fundamental to assess tumor burden, which not only is a prognostic factor but also is fundamental to plan the optimal therapeutic strategy (Gallamini et al. 2014).

Indications in Lymphomas

[18F]FDG PET/CT is recommended in disease staging in several tumors, in particular both in Hodgkin lymphoma (HL) and in [18F]FDG-avid non-Hodgkin lymphoma (NHL) subtypes. [18F]FDG PET/CT improves the accuracy of staging both for nodal and extranodal sites, allowing a staging change (sometimes upstaging) in 10–30% of patients, in particular for a better definition of splenic involvement and for its high sensitivity in the case of bone marrow involvement: in the case of bone marrow [18F]FDG PET/CT uptake in HL, bone marrow biopsy is in fact no longer indicated (Cheson et al. 2014). In the case of LH or [18F]FDG-avid NHL, [18F]FDG PET/CT is fundamental also in response to therapy assessment to define complete or partial response, stable or progressive disease using a 5-point scale (Deauville score), based on [18F]FDG lesion uptake compared to background (Cheson et al. 2014).

Carcinoma and Adenocarcinoma

[18F]FDG PET/CT has demonstrated a pivotal role also in several [18F]FDG-avid solid tumors. Despite T extension being often provided by conventional imaging (CT, MRI), PET/CT scan could provide additional information: for example solitary pulmonary solid nodules greater or equal to 8 mm can safely be considered benign if the PET-CT scan is negative (Madsen et al. 2016). On the other hand, in the case of advanced NSCLC the main advantage of [18F]FDG PET/CT is the assessment of tumor spread to the pleura (Gallamini et al. 2014). In the case of breast cancer, despite [18F]FDG PET/CT not being recommended for staging localized disease, evidences support its use in locally advanced breast cancer based on improved regional and distant staging, and also for its prognostic role, as baseline tumor glycolytic activity is associated with biological behavior and prognosis (Caresia Aroztegui et al. 2017).

The fundamental role of [18F]FDG PET/CT in solid tumors staging has been widely demonstrated in N and M assessment. For example in the case of NSCLC, [18F]FDG PET/CT is superior to contrast-enhanced CT (CeCT), by adding metabolic information able to disclose morphologically undetectable nodal dissemination: despite this superiority the sensitivity of PET-CT is in general insufficient to rule out mediastinal lymph node metastasis (Madsen et al. 2016) and surgical staging remains the standard (Gallamini et al. 2014). In the case of advanced breast cancer, the imaging-guided sentinel lymph node biopsy with ^{99m}Tc-colloid remains the gold standard, but the high positive predictive value of [18F]FDG PET/CT ($\geq$90%) could guide an axillary lymph node dissection in

the case of axillary node uptake (Gallamini et al. 2014).

In the case of melanoma staging, [18F]FDG PET/CT could add clinical information for patients with palpable or macroscopic locoregional nodal metastasis: approximately 60% of patients with locoregional nodal metastasis will develop distant metastases (Perng et al. 2015). In M detection, there's no doubt on [18F]FDG PET/CT leading role, and it is widely supported by international guidelines. For example, in NSCLC no curative-intent treatment should be planned until a PET-CT scan has excluded occult distant metastases (Madsen et al. 2016) or, in the case of melanoma, numerous studies have shown that FDG PET/CT can detect M parameter with high sensitivity (86%) and specificity (91%) (Perng et al. 2015).

Tumor Uptake and Hyperglycemia

Several conditions can impact [18F]FDG PET/CT accuracy, first of all peculiar tumor [18F]FDG avidity related to tumor aggressiveness, histology, and metabolism. Hyperglycemia is the second most important condition that can impact [18F]FDG PET/CT scan results, and an accurate knowledge of [18F]FDG uptake mechanism and management of patient glycemic status before performing the exam are pivotal to obtain the maximum quality of the procedure.

Mechanism of [18F]FDG Uptake

The chemical structure of [18F]FDG is similar to natural glucose, differing in a carbon-2 atom labelled with [18F] (Ido et al. 1978), a radioisotope with a half-life of 109.8 min and a positron emission decay. Cancer tissue presents accelerated glucose metabolism even in the presence of oxygen, with an associated increase in lactate production (Potter et al. 2016). This phenomenon was firstly described by Warburg in 1920 and named "Warburg effect" (Warburg and Negelein 1924). On the basis of the increased lactate production even in the presence of oxygen, he hypothesized a mitochondrial dysfunction that was not supported by further research. Aerobic glycolysis, in fact, is a favorable metabolic pathway for tumoral cell because, despite generally leading to a lower production of ATP molecules compared to mitochondrial oxidative phosphorylation, on the other hand it is much faster and in the same amount of time, produces a higher number of ATP molecules (Chen et al. 2017).

Intracellular Pathways of Glucose and Labelled Glucose

As normal glucose, [18F]FDG is transported by membrane specific glucose transporters (GLUT) into the cell cytosol, and phosphorylated by hexokinase to [18F]FDG 6-phosphate that, differently to glucose 6-phosphate, is not a good substrate for further enzyme action through the glycolytic chain, and it is trapped into the cell and not metabolized to carbon dioxide and water (Larson 2006).

Five different glucose transporters (GLUT) are responsible for [18F]FDG transport across cell membrane: GLUT-1 is ubiquitously expressed in the cell membrane of various tissues and it is up-regulated by several growth factors (Pauwels et al. 2000); GLUT-2 expression is regulated by glucose concentration and it is mainly expressed by intestine, kidney, liver, pancreatic islets, and brain (Theorens et al. 1988); GLUT-3 is expressed in neurons and ensures a glucose supply in the brain even in hypoglycemic conditions (Maher 1995); GLUT-4 is stimulated by insulin and it is expressed in skeletal and cardiac muscle, and in brown and white adipose tissue (Rea and James 1997); GLUT-5 is expressed in the small intestine and is responsible for fructose transport (Kayano et al. 1990).

In euglycemic status, several organs present a physiologic biodistribution of [18F]FDG that reflects GLUTs expression (Fig. 47.1). It is very intense in brain, moderate in liver, and weak in skeletal muscle; furthermore it is variable in the cardiac muscle because myocardial cells primarily use the beta oxidation pathway of fatty acids,

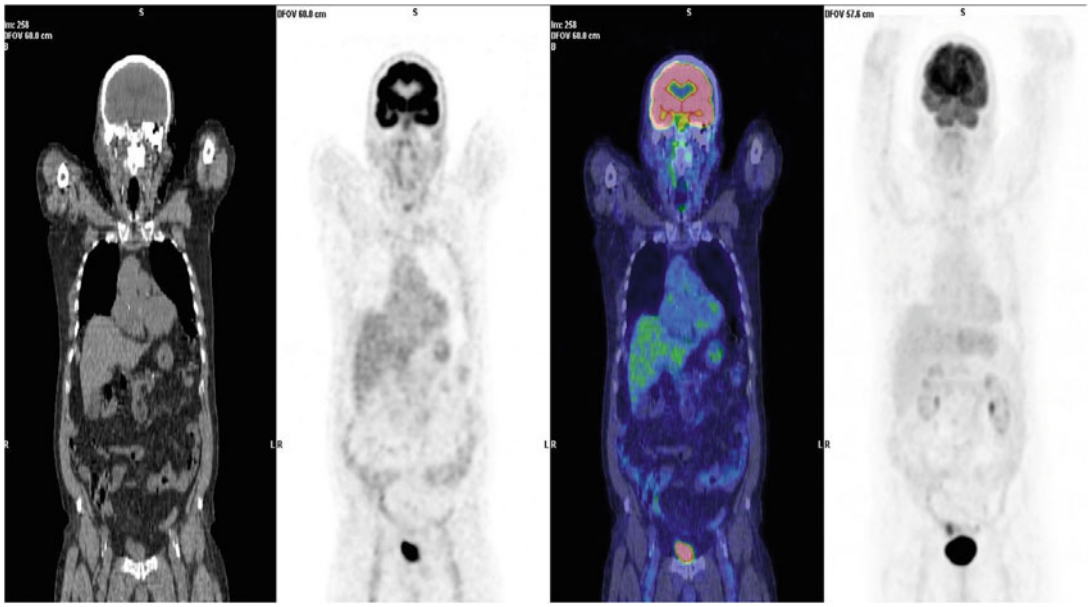

Fig. 47.1 Physiologic biodistribution of [18F]FDG. In fasting and euglycemic conditions [18F]FDG uptake reflects GLUTs expression: [18F]FDG uptake is intense in brain, because of GLUT-3 expression that ensures correct glucose levels even in hypoglycemic conditions, weak in skeletal muscle for GLUT-4 expression stimulated by insulin, variable in cardiac muscle that primarily uses free fatty acids, but may present a metabolic shift to glucose metabolism after glucose load; intense in the urinary system because of [18F]FDG physiological urinary excretion

but following a glucose load may present a metabolic shift toward glucose metabolism; moreover, myocardial cells protect themselves from hypoxic state by means of the "glucose-fatty acid cycle" (Randle et al. 1963).

Finally, urinary system presents high [18F]FDG concentration due to it physiological urinary tracer excretion. Despite the absence of glycosuria in physiological and euglycemic status, renal tubular cells, in addition to GLUTs, also present a sodium-dependent glucose transporter (SGLT) that is responsible for re-uptake of glucose from the filtrate in the proximal tubules, promoting glucose transport against its concentration gradient (Szabo et al. 2006). SGLT presents a lower affinity for [18F]-FDG compared to glucose, due to the replacement of a hydroxy group in D-glucose with a [18F] atom (Moran et al. 1999), and for this reason [18F]-FDG cannot be reabsorbed in the proximal tubules of the kidney and it is accumulated in the urine (Qiao et al. 2007).

Cancer Cell Pathways

Cancer cells [18F]FDG uptake can vary substantially depending on glycolysis levels at one site and it is associated with both increased GLUT and intracellular hexokinase expression (Brown and Wahl 1993); moreover, in cancer cells, glucose 6-phosphatase is markedly downregulated, so its levels are insufficient to break down [18F]FDG 6-phosphate (Larson 2006).

Generally, aggressive and proliferating tumors present a high expression of GLUT and hexokinases, so in these case [18F]FDG uptake is generally very high, but FDG avidity can differ among different histological subtype: Hodgkin Lymphoma, Diffuse Large B Cell Non-Hodgkin Lymphoma (DLBCL) or Follicular Lymphoma

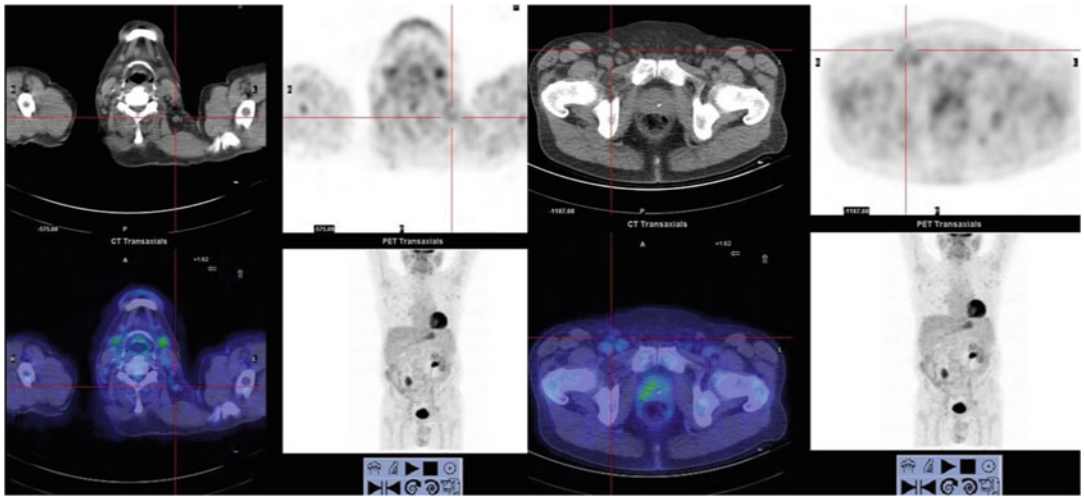

Fig. 47.2 [18F]FDG PET/CT in a patient with marginal zone lymphoma: laterocervical and inguinal lymphnodes that present very low [18F]FDG avidity

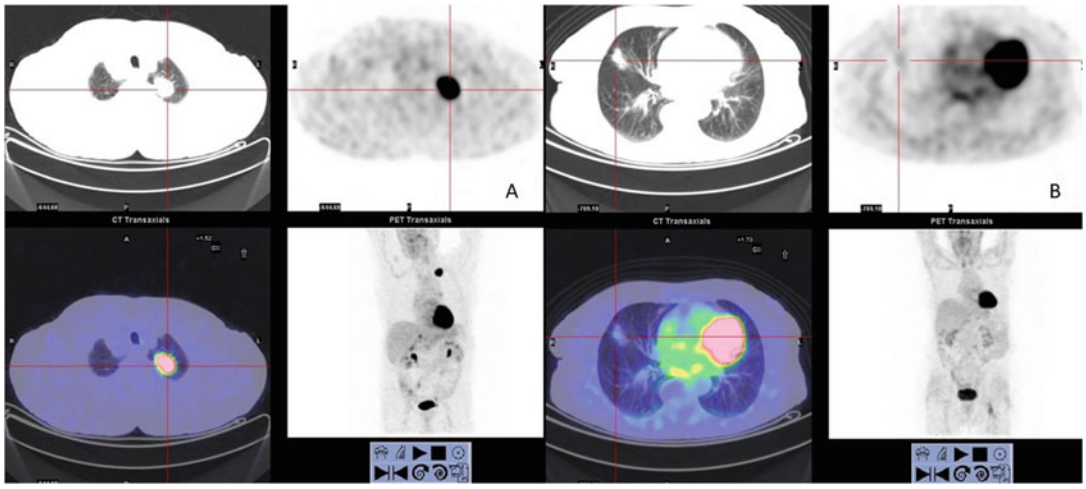

Fig. 47.3 [18F]FDG PET/CT scan in two patients with recent diagnosis of pulmonary nodule prior to histological diagnosis: left apical node of patient A presents very high [18F]FDG uptake compared to medium lobe node of patient B. Subsequent histological diagnosis revealed in case A a NSCLC instead in case B a typical lung carcinoid

presents high [18F]FDG uptake, while other hematologic malignancies, such as Marginal Zone Lymphoma (ML), for example, demonstrate low [18F]FDG uptake (Fig. 47.2). Also solid tumors may have different [18F]FDG avidity. In the case of lung cancer, in fact, Non-Small Cell Lung Carcinoma (NSCLC) presents high [18F] FDG uptake, while tumors with neuroendocrine differentiation (typical carcinoid) present low/absent [18F]FDG uptake (Fig. 47.3). Other well-differentiated tumors that use different metabolic pathway, for example, membrane phospholipids turnover in cell membrane instead of glycolysis, such as Prostatic Carcinoma or Hepatocellular Carcinoma (HCC), present a very low [18F]FDG avidity and should be studied specifically with other PET tracers.

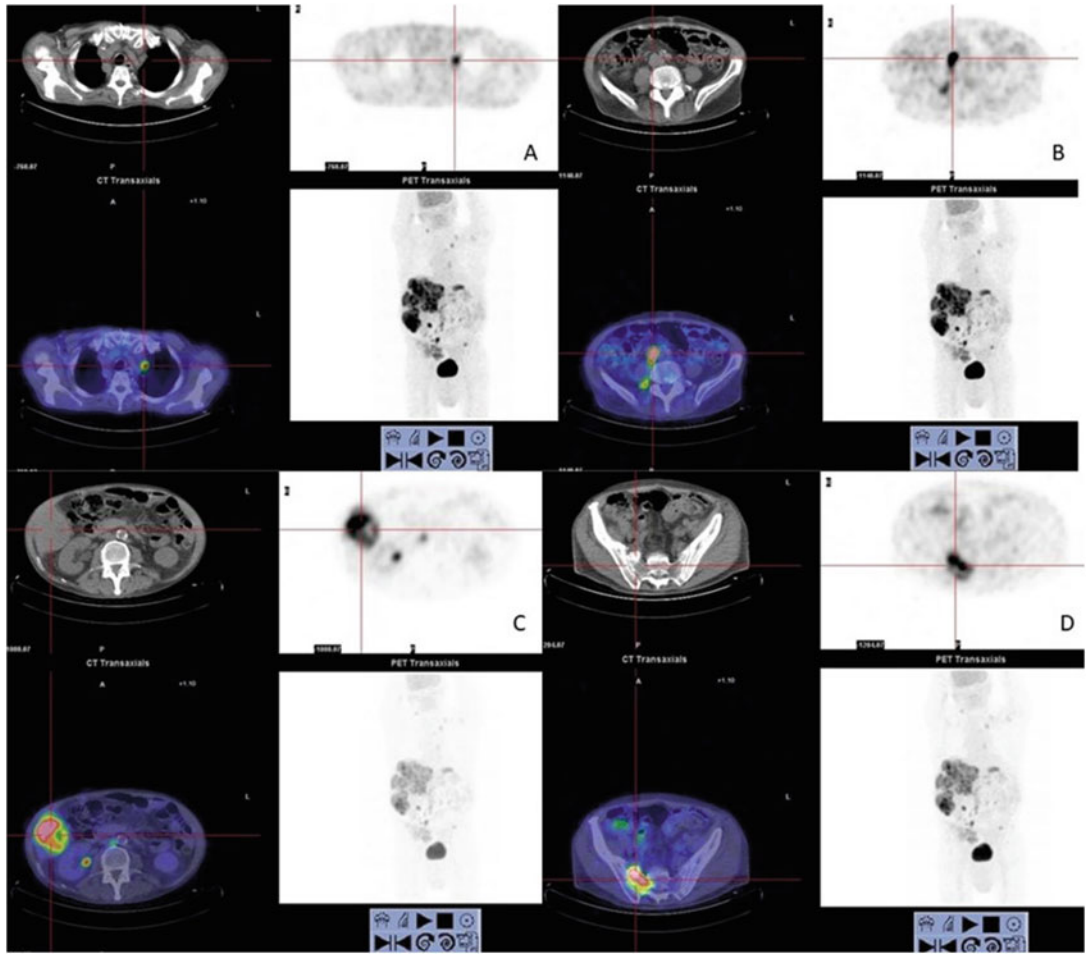

Fig. 47.4 Different [18F]FDG uptake in a patient with DLBCL. (**a**) prevascular lymphnode; (**b**) iliac lymphnode; (**c**) heterogeneous hepatic localization of lymphoma with central necrotic component that reduce [18F]FDG uptake; (**d**) bone localization of lymphoma

[18F]FDG uptake may be influenced not only by tumoral histological characteristics, but also by intra-tumoral heterogeneity in the case of intra-tumoral necrosis, that is responsible for low and heterogeneous uptake (Fig. 47.4) and cell dedifferentiation (undifferentiated neuroendocrine tumors, for example, may present high [18F]FDG uptake). Also different therapies effects may modify [18F]FDG uptake: cytotoxic therapies such as chemotherapy or external radiotherapy may reduce [18F]FDG uptake, but may also cause flogistic reaction with increased [18F]FDG uptake at that site. For these reason an interval of at least three weeks from the last cycle of chemotherapy and three months from the end of radiotherapy is often required, especially in hematologic malignancies, before performing [18F]FDG PET/CT scan to avoid false positive findings.

Effects of Hyperglycemia on [18F]FDG Distribution and PET/CT Scan Interpretation

Several clinical conditions may affect [18F]FDG uptake. Several published studies described the effects of hyperglycemia and hyperinsulinemia

on [18F]FDG biodistribution. Hyperglycemia is the leading cause of altered biodistribution because, both in normal and in cancer cells, it leads to a direct competition between plasmatic glucose and [18F]FDG uptake (Di et al. 2018), reducing the binding site of [18F]FDG (Wahl et al. 1992). Reactive hyperinsulinemia to hyperglycemia results in a higher skeletal and myocardial muscle [18F]FDG uptake (Diederichs et al. 1998) for GLUT-4 up-regulation with lower uptake in cancer cells compared to physiological tissue leading to the risk of false negative findings. Also the standardized uptake value (SUV), a semiquantitative parameter expressing FDG concentration in tissues (Juweid and Cheson 2006), may be affected by blood glucose levels. SUV is the a-dimensional semiquantitative expression of the tracer uptake in a region of interest (ROI), for example, tumoral lesion, normalized by total amount of activity administered and body weight (Body weighted SUV—SUV_{bw}) or body surface area (SUV_{bsa}); it is used as SUVmax or mean or peak to compare [18F]FDG uptake on pre and post-therapy scan and to define response to therapy (Wahl et al. 2009). Furthermore, SUVs of healthy tissues, such as liver and mediastinal blood pool, are used as references in international criteria to define disease uptake and to assess response to therapy in lymphoproliferative disease (Barrington and Kluge 2017).

In 2013 Büsing et al. (2013) enrolled 90 patients with Blood Glucose Levels (BGL) ranging from 50 to 372 mg/dl to assess the impact of chronically elevated BGL on [18F]FDG tumor uptake and biodistribution in healthy organs. The authors found a significant association between BGL increase and both cerebral uptake reduction ($p < 0.001$) and muscle uptake increase ($p < 0.001$) and weak associations between BGL and liver uptake ($p = 0.06$), tumoral ($p = 0.133$), fat, lung, and spleen uptake expressed as SUVmax ($p = 0.136$–0.157).

Sprinz et al. in 2018 investigated the effects of glycemia on [18F]FDG uptake in healthy liver, brain, and lungs in 5623 patients that underwent PET/CT, stratified into four groups by serum glucose levels. All organs showed significant differences in mean SUVmax according to different groups ($p < 0.001$) in univariate analysis, while multivariate analysis adjusted for sex, age, and BMI, confirmed significant differences only for brain and liver and not for lung uptake.

The effect of BGL on SUVmax and SUV mean of [18F]FDG uptake was assessed in 8380 patients collected in a recent meta-analysis published in 2019 (Eskian et al. 2019). Patients were divided into 5 groups by BGL, and SUVmax and SUVmean values of tumor, brain, muscle, liver, and blood pool were recorded. Significant inverse correlations ($p < 0.001$) were found between BGL and SUVmax and SUVmean both in brain and in muscle, while positive correlations were found between BGL and SUVmax and SUVmean in liver ($p = 0.001$, $p = 0004$) and blood pool ($p = 0.008$, $p < 0.001$). No significant correlation was found between BGL and SUVmax or SUVmean in tumors.

All hyperglycemic groups compared to the euglycemic group presented significantly lower brain and muscle SUVs ($p < 0.001$ for both), while higher SUVmax and SUVmean in liver ($p = 0.001$, $p = 0004$) and blood pool ($p = 0.008$, $p < 0.001$) were reported. On the contrary, tumoral tissue presented significantly lower SUVmax only in the case of BGL >200 mg/dl. The explanation could be that in tumoral tissue GLUT could be not saturated even in the case of high BGL because tumoral cells overexpress GLUT in order to respond to the hypoxic condition subsequent to induced angiogenesis (Eskian et al. 2019; Yang et al. 2017) demonstrated in various cancer types (Macheda et al. 2005; Carvalho et al. 2011).

Diagnostic Strategies in Normal and Disglycemic Patients

In order to avoid hyperglycemic status guidelines to manage correct patient preparation for [18F]FDG PET/CT scan have been proposed by international societies such as the European Association of Nuclear Medicine (EANM) (Boellaard

et al. 2014), the Society of Nuclear Medicine and Molecular Imaging (SNMMI) (Delbeke et al. 2006), the American College of Radiology (ACR) (American College of Radiology 2007), and the National Cancer Institute (NCI) (Shankar et al. 2006).

Non-diabetic patients should fast for at least 4–6 h and parenteral nutrition and intravenous fluids containing glucose should be discontinued for the same time before [18F]FDG injection to prevent high insulinemia. BGL must be measured by a glucometer prior [18F]FDG administration (Boellaard et al. 2014; Delbeke et al. 2006; American College of Radiology 2007; Shankar et al. 2006); for clinical routine the accepted upper BGL threshold is 200 mg/dL, while for research trials ranges between 126 and 150 mg/dL are recommended (Boellaard et al. 2014). In the case of hyperglycemia, it is possible to decrease BGL in patients by hydration until an acceptable level is achieved (Boellaard et al. 2014). The management of diabetic patient is more challenging providing specific recommendations in this setting (Boellaard et al. 2014) for diabetic patients treated by oral medication or insulin.

For diabetic patients treated with oral medication such as metformin, fasting for at least 4–6 h before [18F]-FDG injection in association with adequate hydration is recommended, without oral medication withdrawal to allow for a controlled blood sugar level. PET/CT scan should preferably be performed in the late morning. Metformin decreases BGL by lowering gluconeogenesis, increasing insulin sensitivity and enhancing glucose consumption by enterocytes (Rena et al. 2017). Its known action on the bowel assumes a critical role in [18F]FDG physiological distribution: metformin significantly increases [18F]FDG accumulation in the bowel, in particular in the colon (Martin and Saleem 2014) (Fig. 47.5a and b).

Massolo et al. (2013) in 2013 verified this phenomenon in fifty-three mice that performed dynamic acquisitions for [18F]FDG kinetic evaluation under fasting conditions over a 4-month study period. Mice were divided into 4 groups: untreated mice (group 1), mice exposed to metformin treatment for 48 h before each PET scan (group 2), mice treated for the whole study period (group 3), and mice in which treatment was interrupted 48 h before PET scan (group 4). They found that prolonged drug administration significantly increased bowel [18F]FDG uptake after a relatively long period of treatment and persisted after drug washout.

This increased [18F]FDG uptake has been also demonstrated in clinical practice.

A prospective study published by Gontier at al. (2008) demonstrated an intense, diffuse, and continuous pattern distribution of [18F]FDG along the bowel, strongly predominant in the colon, in patients treated with metformin. They enrolled fifty-five patients under oral medication for diabetes mellitus divided in two groups on the basis of anti-diabetic treatment (group 1a treated with metformin and group 1b in anti-diabetic treatment excluding metformin) and compared to control group (group 2, patients without diabetes mellitus). Patients treated with oral medication presented significantly increased [18F]FDG bowel uptake compared to controls ($p < 0.001$); [18F]FDG bowel uptake was significantly higher in group 1a compared to group 1b ($p < 0.01$).

The effect of metformin on [18F]FDG bowel uptake must kept in mind in the case of PET/CT scan performed for abdominal evaluation, in particular in the case of suspected peritoneal carcinomatosis, colo-rectal or gynecological neoplasm in which increased [18F]FDG bowel uptake could hide pathological uptake and induce false negative results (Gontier et al. 2008). No guideline consensus is available on the oral anti-diabetic treatment management in the case of abdominal evaluation, but several published studies on the timing of metformin discontinuation are available.

A retrospective study published in 2016 (Lee et al. 2016) aimed to assess the impact of metformin discontinuation up to 72 h in [18F]FDG bowel uptake. Two hundred and forty diabetic patients were divided into four groups on the

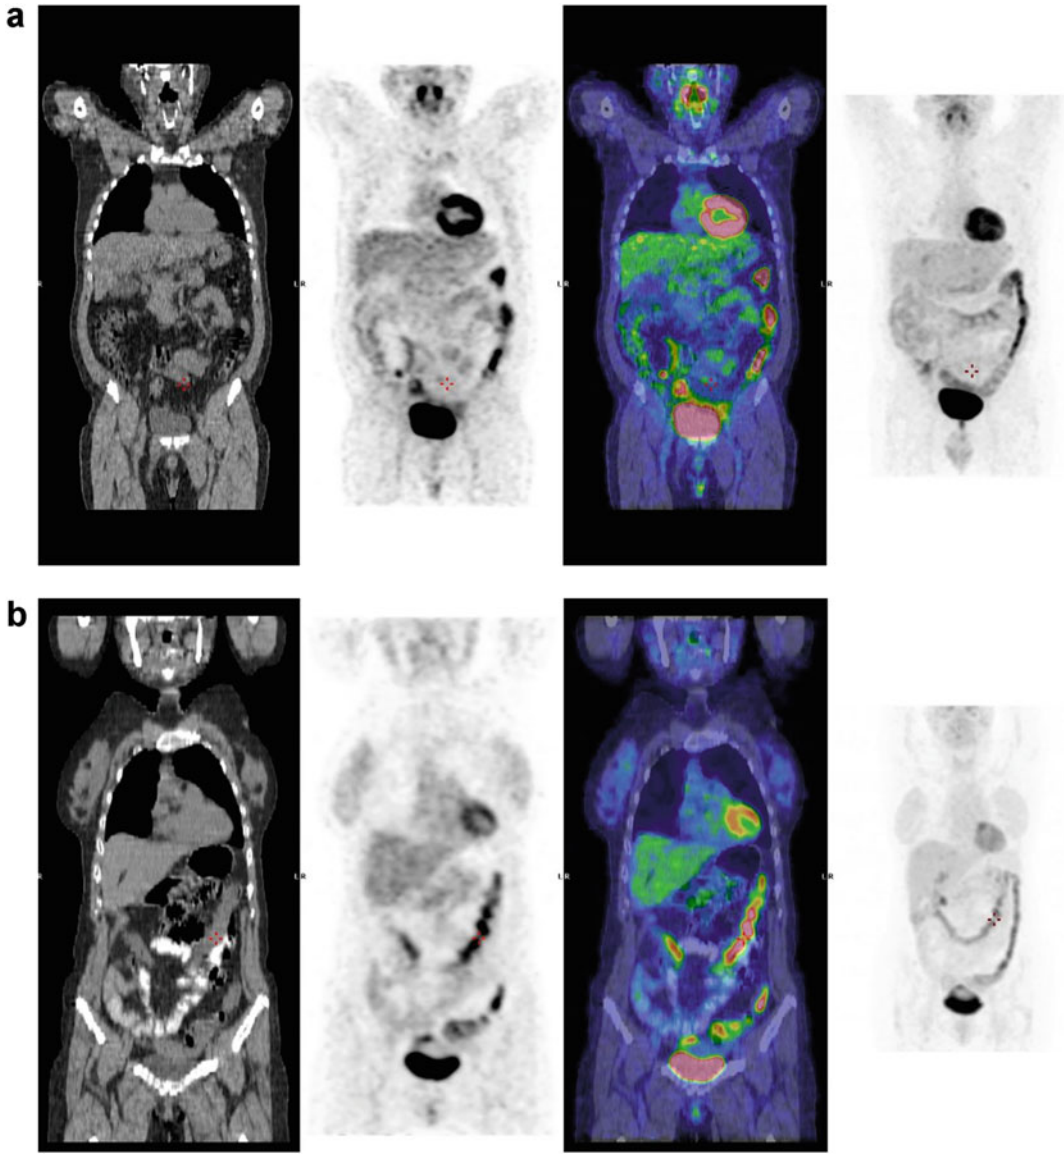

Fig. 47.5 (**a**) [18F]FDG PET/CT scan performed for characterization of a hepatic lesion in a 41 year old diabetic patient treated with metformin. High intestinal uptake is visible in particular in descending colon. (**b**) [18F]FDG PET/CT scan performed for suspected occult lesion in a 51 year old diabetic patient treated with metformin and hepatic lesions suspected for metastases. High intestinal uptake is visible in particular in transverse and sigmoid colon

basis of metformin discontinuation: <24 h (group A), 24–48 h (group B), 48–72 h (group C), and no metformin at all (control group). Compared with the control group, [18F]FDG uptake increased significantly from the ileum to the rectosigmoid colon in group A ($p < 0.001$), from the transverse to the rectosigmoid colon in group B ($p < 0.001$) and from the descending colon to the rectosigmoid colon in group C ($p < 0.001$), highlighting a suboptimal metformin discontinuation <72 h for images interpretation, in particular for the distal colon segments

Conversely, a prospective study published in 2010 (Oh et al. 2010) concluded that discontinuation of metformin for 2 days is feasible to reduce high [18F]FDG bowel uptake. One hundred thirty-eight diabetic patients were divided into two groups: group A treated with metformin and group B in which the regimen did not include metformin and they were compared to patients without diabetes mellitus (control group). Group A was divided into two subgroups on the basis of metformin discontinuation (group A1 continued metformin; group A2 stopped metformin treatment 2 days before PET/CT scan). Ten diabetic patients underwent two consecutive PET/CT scans before and after the discontinuation of metformin. Group A1 compared to group A2 and group B presented a significantly higher ($p < 0.001$) [18F]FDG bowel uptake. In 10 patients who underwent serial PET/CT scans, [18F]FDG bowel uptake decreased by 64% and hidden colorectal malignancies were revealed in two patients after the discontinuation of the drug.

Despite no consensus being available on the timing metformin discontinuation, in the case of [18F]FDG PET/CT scan for abdominal malignancies, a careful evaluation of patient's drug treatment must be conducted, to ensure the optimal patient preparation in order to avoid false negative result preventing the rise of BGL.

In the case of treatment with insulin, European guidelines (Boellaard et al. 2014) suggest different options for scheduling [18F]FDG PET/CT scan on the basis of treatment protocol. Commonly, insulin-dependent patients can be scheduled for PET/CT scan in late morning or midday, [18F]FDG should be injected no sooner than 4 h or 6 h after subcutaneous injection of rapid-acting and short-acting insulin respectively after breakfast in the early morning and subsequent fasting. For patients treated with intermediate-acting and/or long-acting insulin, [18F]FDG injection is not recommended on the same day of insulin administration and PET/CT scan should be scheduled in the early morning after insulin injection the evening before and after night fasting. Particular attention needs long-acting insulin management that could interfere with FDG uptake; thus, intermediate-acting replacement is mostly recommended. In the case of continuous insulin infusion, patients should be scheduled in the early morning and the insulin pump stopped for at least 4 h prior [18F]FDG injection.

The basis of this careful attention on insulin administration is the insulin's affinity for GLUT-4, expressed in the skeletal and cardiac muscle, and in brown and yellow adipose cells (Rea and James 1997): insulin causes the shift of GLUT-4 from intracellular location to the plasma membrane (Huang and Czech 2007; Bryant et al. 2002), promoting both normal glucose and [18F]FDG intracellular uptake and resulting in altered radiotracer biodistribution and suboptimal image quality (Martin and Saleem 2014; Surasi et al. 2014). The aforementioned study by Büsing et al. (2013) also found out that diabetic and insulin treated patients compared to nondiabetics and noninsulin patients presented significant lower mean cerebral SUVmax ($p < 0.001$) and higher mean muscular SUVmax ($p < 0.001$).

An increase up to 50% was also observed in average fat tissue SUVmax and myocardial uptake in diabetic patients and insulin patients, respectively.

Despite this known effect of both endogenous and exogenous insulin on [18F]FDG biodistribution, several studies investigated the impact on image quality of insulin administration before [18F]FDG injection to correct hyperglycemia (Fig. 47.6).

In 2006 Turcotte et al. (2006) assessed the impact of intravenous insulin 60 min before [18F]FDG injection on muscular, liver, or lung [18F]FDG uptake. They compared 53 diabetic patients with BGL >7.0 mmol/l vs 53 euglycemic nondiabetic patients and found no significant difference for the SUV calculated on the lung, liver, heart, and skeletal muscles.

A study published in 2009 (Roy et al. 2009) aimed to assess the clinical impact of intravenous administration of short-acting insulin in 63 patients with glycemia greater than 10 mmol/L according to standardized protocol: 2 units for glycemia of 10.0–12.0 mmol/L, 3 units for glycemia of 12.1–14.0 mmol/L, and 4–6 units for glycemia of 14.1 mmol/L and above to reach a glycemia lower than 10.0 mmol/L. In the case of

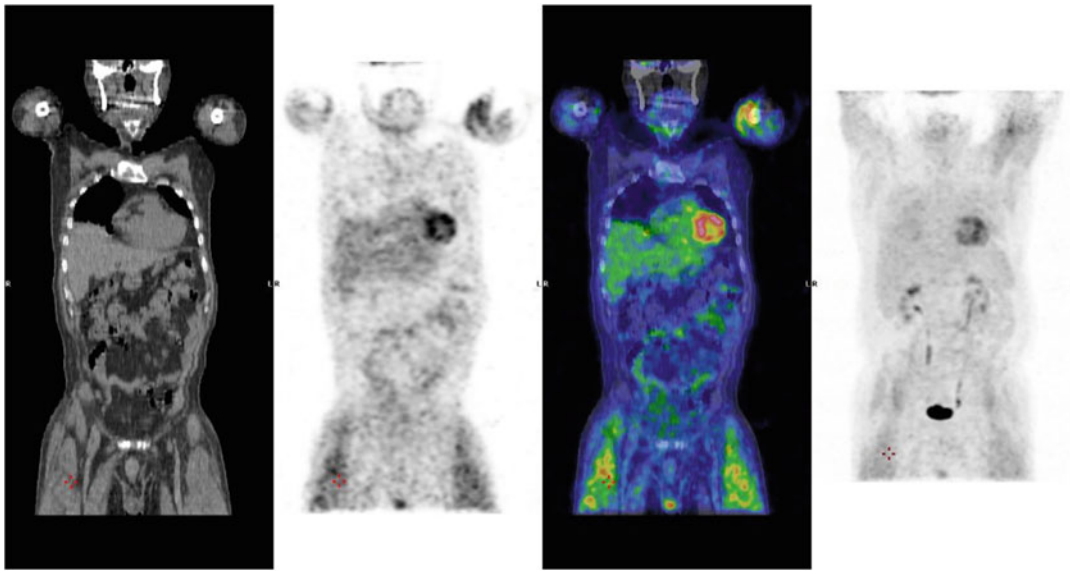

Fig. 47.6 [18F]FDG PET/CT scan performed for restaging of Hodgkin lymphoma after 6 cycles of chemotherapy in a 65 years old diabetic patient treated with short acting insulin. High muscular [18F]FDG uptake is visible in particular in quadriceps muscle

glycemia above 10.0 mmol/L after 30 min, a second insulin dose was given. [18F]FDG was administered at least 60 min after the last insulin administration. After PET/CT scan patients were divided in two groups on the basis of [18F]FDG visual distribution: group A with adequate biodistribution (normal biodistribution, mild muscular uptake or muscular uptake involving more than one muscle group) and group B with altered biodistribution (diffuse muscular uptake of moderate intensity or diffuse, intense muscular uptake resulting in a nondiagnostic examination). [18F]FDG distribution was also semi-quantitatively assessed by SUV *mean* of liver, gluteal muscles, and myocardium. Group A compared to group B presented a significantly longer delay between insulin and [18F]FDG injections ($p < 0.01$), higher glycemia reduction after insulin injection ($p < 0.01$), higher hepatic mean SUV ($p < 0.01$) and lower gluteal muscular mean SUV ($p < 0.01$). This study concluded that an interval of at least 90 min between insulin and [18F]FDG administration should be considered and that hepatic and muscular SUVs could be useful tools to define adequate biodistribution of [18F]FDG.

In 2013 Caobelli et al. (2013) evaluated the usefulness and impact on muscular [18F]FDG uptake of a protocol of intravenous insulin administration before [18F]FDG PET/CT scan in 130 diabetic patients. In 20 patients with BGL >180 mg/dl intravenous insulin was administered 30 min before 18F-FDG injection (group 1); in ten patients with BGL >160 mg/dl and <200 mg/dl, no insulin was injected (group 2); 100 euglycemic patients were used as control group. Biodistribution was adequate in group 2, control group, and in 95% of patients in group 1. No significant differences in gluteal muscle SUVmax were found between groups (p = 0.20) and no false negative result was recorded at 6-month follow-up evaluation. In 2013 Song et al. (2013) assessed the impact of intravenous ultra-short insulin administration 60 min before [18F]FDG injection in 105 diabetic patients: 52 patients with BGL >190 mg/dl received 3–5 IU of insulin were compared to the remaining 53 with BGL <190 mg/dl who did not receive insulin and no significant differences in image quality (p = 0.47),

hepatic SUVmean ($p = 0.13$), gluteal muscle, and brain uptake ($p = 0.71$ and $p = 0.16$, respectively) were found.

A study conducted by Garcia et al. in 2014 concluded that the quality of [18F]FDG PET/CT scan is not affected by subcutaneous administration of rapid-acting insulin if radiotracer is injected at least 4 h later. They enrolled 120 patients divided in 4 groups on the basis of insulin administration and delay to [18F]FDG injection: 30 diabetic patients with BGL<160 mg/dl without further insulin administration (group 1), 30 diabetic patients with BGL ranging from 168 to 260 mg/dl in which subcutaneous rapid-acting insulin was administered and [18F]FDG injection after a delay of 30–115 min with BGL below 160 mg/dl (group 2), 30 diabetic patients with BGL ranging from 192 to 324 mg/dl in which 18F-FDG was injected 4 h after subcutaneous rapid-acting insulin (group 3), and 30 nondiabetic patients with normal BGL (72–104 mg/dl) (control group). For each patient SUVmax of rectus femoris muscle was calculated: in group 2 SUVmax deviated without relation between BGL and [18F]FDG muscle uptake and the quality of PET-CT scan was suboptimal in 60% of patients in group 2, in 13% of patients in group 1, while it was optimal in all patients of group 3.

Despite several studies investigating protocols of intravenous administration of insulin before [18F]FDG administration in order to reduce BGLs, none has yet been validated. EANM and SNMMI guidelines (Boellaard et al. 2014; Delbeke et al. 2006) recommend, in the case of necessity of insulin to correct hyperglycemia, an appropriate delay between [18F]FDG and insulin administration depending on the type and insulin way of administration. Furthermore EANM guidelines (Boellaard et al. 2014) suggest avoiding insulin administration unless this interval is less than 4 h and preferring rapid-acting insulin subcutaneous injection (effective life 2–4 h), while short-acting, intermediate-acting, or long-acting insulin is not recommended for their longer effective life (3–6 h, 12–18 h and 24 h, respectively).

Conclusions

The management of hyperglycemia in both diabetic and non-diabetic patients represents an issue in PET/CT practice, extensively described by the studies mentioned above. Both hyperglycemia and oral and insulin medications showed advantages and disadvantages on PET/CT scan accuracy: the respect of simple rules guarantees a good quality [18F]FDG PET/CT in staging cancer, and it assumes a pivotal role in patient clinical management.

Abstract

The medical and social burden of T1DM places large constraints on both patients and their families. Transplantation of pancreatic beta cells can be a viable therapeutic alternative. Current challenges are the shortage of donors and the toxicity of immunosuppression. Xenotransplantation and biomaterial protection are currently the most promising technology. Immunoisolation is necessary to protect the recipient from foreign antigens. In turn, shortage of donors ceases to be a barrier. Improvements in certain areas of immunoprotection and graft site neovascularization are the focus of current clinical efforts.

Keywords

Islet engraftment · Autologous pancreatic islet · Xenogeneic pancreatic islet · Immunosuppression pancreatic transplantation · Pancreatic islet protection · Islet site neovascularization

Cost and Prevalence of Diabetes

In 2015 diabetes affected over 9.4% of the US population (5–10% type 1 diabetes), with 1.5 million new cases every year, and many more cases (33.9% of the population) suffered from prediabetes. Worldwide as many as 642 million diabetics will be seen by 2040 (Control 2017; Cho et al. 2018). The world financial burden reaches US$1.31 trillion (Bommer et al. 2017), with the highest expenses corresponding to the United States. They reached $327 billion (1.69% of the 2017 US GDP (Group TWB 2019)), or 26% more than 5 years earlier (2012) (Association AD 2018).

Diabetes Pathophysiology

Pancreatic β-cells sense glucose by means of GLUT2 (Thorens 2015) and other pathways, monitoring shifts such as elevations in the post absorptive state (Leibiger et al. 2008). They allow glucose entry in multiple cells enabling glycolysis, glycogenesis, and lipogenesis (Leibiger et al. 2008). Impairment of glucose-stimulated insulin secretion, or GSIS, is one of the central derangements of diabetes (Boland et al. 2017). Insulin resistance and β-cell dysfunction predominate in type 2 diabetes (T2DM) (Petersen and Shulman 2018), differently from type 1 or insulin-dependent diabetes mellitus (T1DM, IDDM), in which autoimmune destruction of pancreatic β-cells is the hallmark.

A Type IV hypersensitivity reaction is described in T1DM (McLaughlin et al. 2016), leading to β-cell destruction (Lampasona et al. 2010; Rewers and Ludvigsson 2016; Pociot and Lernmark 2016). When 90% of β-cell mass is damaged, insulin dependence becomes inevitable (Atkinson et al. 2014). Highly dangerous diabetic ketoacidosis and/or hyperosmolar hyperglycemia are some of the possible consequences of ensuing glucose elevation (Umpierrez and Korytkowski 2016).

Chronically macroangiopathy and particularly microangiopathy can be followed by microvascular and neural troubles, including retinopathy and neuropathy (Madonna et al. 2017). Cardiovascular events and peripheral arterial obstruction are other possibilities, with risk of appendage/limb amputation (Chillarón et al. 2014).

Exogenous Insulin Treatment

Since 1922 (Best 1956), insulin, along with self-monitoring of blood glucose (SMBG), has been introduced in clinical routine (Association AD 2019). In the Diabetes Control and Complication Trial (DCCT), intensive insulin therapy diminished the advent of major complications (Control and Group CTR 1993). Among cases of non-insulin-dependent diabetes mellitus (NIDDM) and T2DM patients in the UK Prospective Diabetes Study (UKPDS), restoration of glucose homeostasis was equally beneficial (Group UPDS 1998; Ohkubo et al. 1995).

Even careful exogenous insulin confers less protection against long-term organ damage than

physiological release. Moreover, intensive therapy entails a higher risk of hypoglycemia (McCall 2012). Two hypoglycemic episodes (BG < 50 mg/dL = 2.8 mmol/L) per week have been documented during intensive insulin therapy, with at least one of these potentially disabling (Arabi et al. 2009; MacLeod et al. 1993).

Islet Transplantation

In 1893, Minkowski and von Mering, in Strasbourg, France, performed a subcutaneous partial auto-transplantation of the pancreas in a dog, which marginally improved physiology after subsequent pancreatectomy (Minkowski 1893). Williams subsequently attempted sheep pancreas transplantation in an IDDM adolescent (Williams 1894). The endocrine tissue eventually emerged as the relevant fraction (1–2% of total mass), with acinar tissue potentially precipitating inflammation, necrosis, and graft failure (Fichera 1928; Heuser et al. 2000; Gray 1989).

The Edmonton Protocol clinical trials (NCT00014911) introduced sirolimus (0.2 mg/kg; 0.1 mg/kg/day), low-dose tacrolimus (3–6 ng/ml), and daclizumab (5 × 1 mg/14 days) for immune suppression. (Shapiro et al. 2000; Ryan et al. 2001) A trial adopting the Edmonton protocol achieved 31% insulin independence for over 2 years (Shapiro et al. 2006). Over 50% insulin independence for 5 years was subsequently accomplished (Tekin et al. 2016).

Intrahepatic Duct Site

The intrahepatic duct was selected for some time; however, instant blood-mediated inflammatory reaction (IBMIR), hypoxic apoptosis, and supraphysiological levels of drugs and nutrients resulted in frequent failures (Johansson et al. 2005; Shapiro et al. 2005). Portal hypertension and thrombosis were additional risks, besides the inconveniences of the invasive operation and prolonged immunosuppression (Bottino et al. 2018; Ryan et al. 2005).

Clinical Autologous Islet Engraftment

Over 827 infusions in 819 recipients are available at the Clinical Islet Transplant Registry (CITR) since 1999 (Registry 2017a). Indications mainly address severe and refractory pancreatitis requiring pancreatectomy (Bellin et al. 2017). Total pancreatectomy with islet transplantation (TPIAT) is similar to islet allotransplantation; however, it is free from rejection.

Approximately 90% of TPIAT patients have islet graft function; however, only one-third become insulin independent. Islet autograft attrition may also occur especially in cases >35 years, resulting in low insulin retention after 5 years. In turn when doses of ≥275,000 islet equivalents (IEQs) are administered to those in a lower age bracket (18–35 years), over 70% insulin independence is demonstrated (Registry 2017a). C-peptide responds in all age groups, however not HbA1c (baseline < 7.0%), with favorable outcome only for age groups 12–18 and 18–35 years old. Differently from exogenous insulin prescriptions, hypoglycemia practically never occurs (Registry 2017a).

Clinical Islet Allogenic Engraftment

Allotransplantation uses cadaveric islets, collected from digested pancreatic tissue. As occurs with all allotransplantations, a long waiting list for suitable donors and strict matching criteria mean very substantial delays till treatment. Moreover immunosuppression is necessary and entails an array of potential complications (Shapiro et al. 2017; Registry 2017b).

Post-procurement islet culturing before allotransplantation is currently a routine, from just 35% from 1999 to 2002 to 100% from 2015 to 2018. Culturing time is now longer, consistent with the benefits of stabilizing the donor islets. Total islet graft volume is diminishing, without affecting the IEQs and IEQ/kg ratio, thus rendering the transplant less invasive. Total β-cells and β-cells/kg recipient ratio are higher, with less endotoxin content.

Islet Graft Assessment

Approximately 10,000 IE/kg of body weight is recommended. Multiple donors may be required to this aim. In 2015 the CITR Registry included data on 1086 allogeneic islet transplant recipients (877 islet transplant alone "ITA," 183 islet after kidney "IAK," 24 simultaneous islet kidney "SIK," and 2 kidney after islet "KAI") (Registry 2017b). Insulin independence was 70% and 55% respectively, after one and 5 years, with C-peptide of 90% and 70% after identical follow-up periods.

Blood glucose of 60–140 mg/dL for 5 years was achieved in the majority (80%), without severe hypoglycemic episodes. Re-infusion was often necessary (73%); nevertheless, the procedures were less invasive and with considerably milder post-operative complications than whole pancreas transplantation.

Clinical Islet Xenogeneic Engraftment

Massive demand and limited cadaver donors are a significant barrier for allogenic transplants (Peloso et al. 2015; Ris et al. 2004). Furthermore whole pancreas transplantations are preferred, because of a rather well-established experience. Islet xenotransplantation is a very promising route (Markmann et al. 2016; Cozzi et al. 2009; Van Der Windt et al. 2012). particularly porcine pig islets (Lanza et al. 1991; Bottino et al. 2014).

Human and porcine insulin differ by only one amino acid (Richter and Neises 2003; Han and Tuch 2001). Pure transgenic, pathogen-free donors, available in unlimited numbers and devoid of ethical constraints, are other important points. For ideal islet size, yield, and functionality juvenile porcine islet sources (JPIs) seem the best (Kim et al. 2009; Bottino et al. 2007; Smith et al. 2018; Nagaraju et al. 2015). They are also more resistant to hypoxia (Nagaraju et al. 2015).

While adult porcine islet (API) donors yield large amounts of mature islets (Fig. 48.1), the isolation and digestive process is more extensive and costly than with JPI, even though these are not fully mature and require culturing in nutrient-rich media (Lau et al. 2019; Lau et al. 2018). Porcine islets can maintain viability in vivo, (O'Shea and Sun 1986) with insulin secretion in vivo for up to 174 days (Omer et al. 2003). Also in T1DM patients, encapsulated porcine islets remained active for 9.5 years (O'Shea and Sun 1986).

Long-term Challenges

In keeping with endogenous defense against non-self-antigens in general, hemagglutinating and lympho-cytotoxic antibodies against pig tissue occur in humans, (McKenzie et al. 1968) including α-(1,3)-galactose, incriminated in acute host immune rejection (Omori et al. 2006; Sandrin and Mckenzie 1994), potentially requiring immune suppression. Porcine endogenous retroviruses (PERVs) and other microorganisms could be another source of concern. (Sandrin and Mckenzie 1994) Biocompatible polymers to encapsulate xenogeneic tissues could avoid most of these obstacles. Yet xenografts in the United States are strictly regulated; therefore, most studies proceed in animal models (Cooper et al. 2017).

Regulatory Issues

Some protocols prefer other countries, in order to avoid rigorous FDA scrutiny. In Mexico, two cohorts underwent xenograft implantation of a collagen-covered pre-vascularized scaffold (250,000 islets, 30,000–100,000 Sertoli cells). HbA1c, insulin requirements, and C-peptide responded for up to 4 years; no pig-related microorganisms were detected in these populations (Valdés-González et al. 2005; Valdes-Gonzalez et al. 2010).

DIABECELL microencapsulated islet scaffold (Living Cell Technologies/LCT, Melbourne, Australia) has been intraperitoneally injected for unstable type 1 diabetes. This microencapsulated graft is delivered via laparoscopy into the

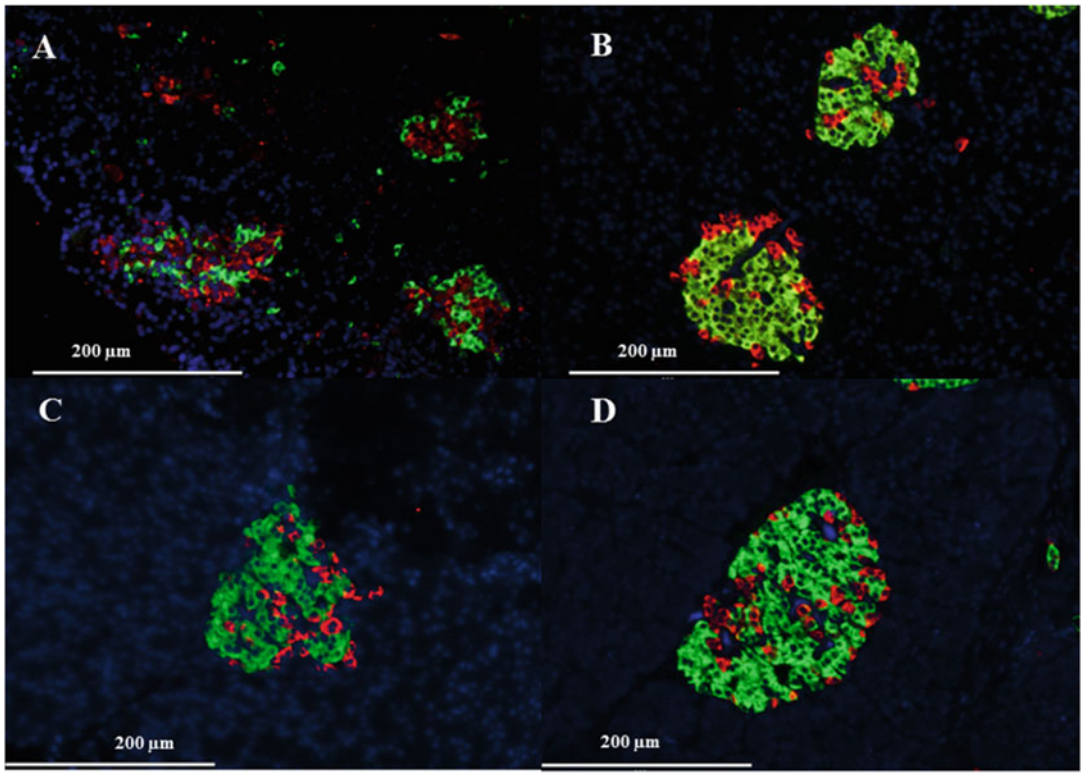

Fig. 48.1 Characterization of Porcine Islet Endocrine Composition. Characterization of porcine pancreatic islet cellular composition using fluorescence immunohistochemistry. Neonatal porcine islets (**a**) demonstrate a lower incidence of insulin positive cells (green) compared to juvenile (**b, c**) and adult pigs (**d**) and are significantly smaller in size ($p = 0.001$). Juvenile porcine islets (weaned (**b**) and pre weaned (**c**)) are significantly smaller ($p = 0.03$, pre weaned; $p = 0.04$, weaned) but do not demonstrate significant differences in insulin content ($p = 0.4$, pre weaned; $p = 0.1$, weaned). Glucagon positive cells stain red. A blue counterstain (DAPI) is used to stain the nuclei

intraperitoneal (IP) cavity, and has been approved in Russia, New Zealand, and Argentina. In the Russian pilot protocol all eight patients partially responded, and two became insulin independent for 4 weeks post-operation (Schuurman 2011). Somewhat analogously in New Zealand, 14 IDDM patients (5000–20,000 IE/kg, wild-type pre-weaned JPI) were followed with no immunosuppression for 52 weeks, with partial response in 57% (8/14) (Matsumoto et al. 2016). As many as 10 bacteria, 15 viruses including porcine endogenous retroviruses, and one protozoan were systematically screened with no transmission observed (Wynyard et al. 2014; Morozov et al. 2017).

Acceptance by Hospital Personnel

Past graft failures have generated negative attitudes against xenotransplantations; however, this could be overcome with better results and more transparent information (Abalovich et al. 2017).

Advances in Immunosuppression Regimes

Robust immune suppressors, such as those adopted in the Edmonton protocol, are compatible with prolonged function, of up to 10–12 years

(Ryan et al. 2005; Brennan et al. 2016). Less positive outcomes are also noticed (Shapiro et al. 2006), with insulin independence after one and 2 years of 44% and 31% respectively. Tacrolimus has recently been the most adopted drug, with a substantial reduction of sirolimus and other mammalian targets of rapamycin (mTORs) (Berney et al. 2018).

Nevertheless calcineurin inhibitors (CI), encompassing tacrolimus, can have diabetogenic effects and β-cell toxicity (Rangel 2014). CI-free immunosuppressant belatacept and the anti-leukocyte antigen-1 antibody efalizumab could be an option (Posselt et al. 2010). Janus kinase inhibitor tofacitinib is also being investigated (Kim et al. 2018).

Advances in Immunomodulatory Drugs

Various modalities of rejection can be inhibited through modulation of immune cells by cytokines, interleukins, and chemokines (Tian et al. 1996; Kovarik 2013). One such cocktail utilized in conjunction with islet allograft adopted T-cell mediator thymoglobulin, an interleukin-1β (Il-1β) blocker called anakinra, and tumor necrosis factor-α (TNF-α) blocker etanercept, with extended survival of the graft (Naziruddin et al. 2018; Matsumoto et al. 2011).

Enhancing Immunoisolation Technology

The use of fibrin has extended islet survival and functionality as well as diminished the marginal islet mass up to 90% (Pappalardo 2019; Riopel et al. 2015).

Microencapsulation of Islet Graft

Alginate and other biocompatible materials have been used to create a semi-permeable capsule, for immunoisolation without impairing glucose sensitization and insulin release (de Vos and Marchetti 2002; Pawar and Edgar 2012; Food and Drug Administration 2019; Sondermeijer et al. 2016; De Vos et al. 1997a; Paques et al. 2014; Goosen et al. 1987). Viscous alginate can be polymerized into a rigid hydrogel capsule, (Paques et al. 2014; Goosen et al. 1987) and further polycations (e.g., poly-l-lysine) (Thu et al. 1996) can be added to increase both the integrity and immunoprotection (De Vos et al. 1997b; Fritschy et al. 1991) (Fig. 48.2).

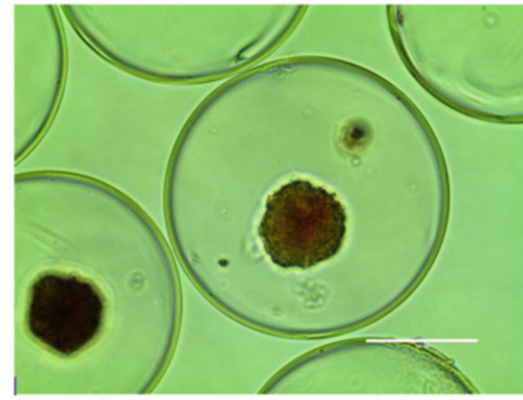

Fig. 48.2 Alginate Encapsulated Porcine Islet with poly-l-lysine (PLL) coating. Image taken by research associates of the Lakey lab at UC Irvine. Porcine Islets stained with dithizone for 15 min. Image taken with inverted-light microscopy (EVOS Microscope system, Thermo Fisher) at 4/10PH lens at 20× magnification. Scale bar = 200 μm

All these advances notwithstanding results in non-human primates (Bottino et al. 2014; Safley et al. 2018) and humans (Matsumoto et al. 2016) are not as favorable as in other species. Lack of metabolite supply to the intraperitoneal transplantation site, spherical aggregation, and pericapsular fibrotic growth (PFO) are significant problems (Krishnan et al. 2017). Capsules often clump together in the Douglas space (recto-uterine pouch). Incidentally the whole peritoneal cavity has been described as a low-oxygen environment, which prevents adequate functioning of the encapsulated graft.

Macroencapsulation

Retrievable macroencapsulation devices have room for large amounts of islets within a biocompatible shell, potentially made with alginate

(de Vos et al. 2002; Dufrane et al. 2010; Evron et al. 2018), collagen (Harrington et al. 2017), polycaprolactone (Smink et al. 2017, 2018; Marchioli et al. 2016), polyurethane (Zondervan et al. 1992), and polytetrafluoroethylene (Boettler et al. 2016). The subcutaneous space (SC) has been the suggested site (Bottino et al. 2018). In order to overcome the scarcity of oxygen, one polyurethane shell with inner chamber islet-containing alginate matrix was designed to receive external oxygen infusion (β-Air, Beta-O_2 Technologies. Rosh-Haayin, Israel). Preliminary results indicated no immunization or rejection for 6 months, even though viability was insufficient (Rotem and Avni 2017; Carlsson et al. 2018).

Pre-vascularization of engraftment site, with the help of such agents as vascular endothelial growth factor (VEGF), was attempted to solve hypoxia-induced graft loss with the macroencapsulation technique (Sakata et al. 2014). Good vascularization and islet structure preservation were noticed with the two-step Sernova Cell Pouch procedure (Sernova Corp, London, Ontario, Canada); however, functional end points were not successful (Gala-Lopez et al. 2016).

Pancreatic Transplantation in Diabetes: Indications, Contraindications and Perspectives

49

Vinicius Rocha-Santos and Carlos Andres Pantanali

Contents

Abstract

Pancreas transplantation (PT) is the only currently available therapeutic modality capable of definitely treating type I diabetes mellitus (T1DM). The patient can recover endogenous pancreatic function avoiding continuous use of exogenous insulin. Furthermore, stable blood glucose allows avoiding severe complications associated with diabetes. Simultaneous pancreas-kidney transplantation presents better results than isolated pancreas or kidney transplants, being followed by lower incidence of perioperative morbidity such as graft thrombosis and lower immune rejection. These and other modalities, including robotic surgery, stem (beta) cell implants and bioprinting/organoid techniques, are discussed in the chapter.

transplantation · Pancreatic thrombosis · Type 1 diabetes · Type 2 diabetes

Introduction

The first pancreatic transplantation (PT) (Redfield et al. 2015a) was performed by William Kelly and Richard Lilley at the Minnesota University in 1966 (Kelly et al. 1967). The patient was a young female with T1DM in association with end-stage renal failure. She died a couple of days following transplantation. The 1970s were called "the partial graft period" in the United States and Europe due to the implantation of a partial body and tail pancreas graft in the iliac vessels of the recipient (Gliedman et al. 1973; Dubernard et al. 1978; Sollinger et al. 1983). Only in the middle of the 1980s with the introduction of cyclosporine and the creation of the International Pancreas Transplantation Association (IPTA) did PT treatment for T1DM increase patient and graft survival, becoming an efficient treatment (Starzl et al. 1981; Wadstrom et al. 1995; Brayman et al. 1994; Cantarovich et al. 1997; Stratta et al. 1994, 1996; Knechtle et al. 1991).

T1DM causes renal failure in around 9% of the patients, who should undergo replacement renal therapy such as dialysis or kidney transplant (Mogensen et al. 1983a; de Boer et al. 2007). T1DM patients who are in hemodialysis and have no medical contraindication should be submitted to kidney and pancreas transplant, for better survival. It can be done with a living kidney donor first, followed by cadaver PT alone. Or the simultaneous transplantation of both organs can be performed from the same deceased donor (Gruessner and Gruessner 2018).

In early times PT was associated with a high number of postoperative complications that caused pancreas graft loss in 8–30% of the recipients. In the last two decades advances in surgical techniques, improvement in the immunosuppressor field and better management of postoperative complications contributed to pancreas graft survival comparable to kidney and liver transplants (Redfield et al. 2015b; Lindahl et al. 2013, 2014; Sollinger et al. 2009).

Indication

There are advantages for PT when compared with other therapies in patients with T1DM and end-stage renal disease (Dean et al. 2017; Dunn 2014). It is well recognized that PT is the gold standard treatment to achieve exogenous insulin independence. PT recipients present adequate glucose control, avoiding secondary diabetic complications encompassing retinopathy, nephropathy, and neuropathy (Redfield et al. 2015a; Boggi et al. 2013; Lombardo et al. 2017).

Type 1 Diabetes

Around 425 million of adults present different types of diabetes worldwide. One million children and adolescents have T1DM with a higher incidence in children under 15 years. Geographical variation occurs, with 38.4 cases per 100,000 individuals in Finland, 7.6 in Brazil, and just 0.5 in Korea (International Diabetes Federation 2018).

Microvascular complications such as retinopathy, neuropathy, and nephropathy occur in patients with worse glycemic controls suggesting that glycated hemoglobin has a direct relationship with morbidity (Groop et al. 2009). According to Morgensen et al., in a large number of patients (30–50%) renal function deteriorates (Mogensen et al. 1983b). The author classified kidney injury in five phases: the first one presents proteinuria only whereas the last phase, occurring in 9% of the patients, is considered end-stage renal failure. At this time, only replacement therapy by means of dialysis or kidney transplant can be a lifesaving option.

Type 2 Diabetes (T2DM)

Type 2 diabetes accounts for around 90% of the cases of diabetes, being the cause of renal failure in 30% of the kidney transplant waiting lists (Stumvoll et al. 2005). Pancreas transplant has

been performed in nearly 10%, representing 90% of the total of PT (Gruessner and Gruessner 2016). The most import issue in T2DM with end-stage renal disease is a refined selection of these patients. Currently, even in insulin-dependent patients with measurable C-peptide, criteria similar to T1DM cases selected for PT have been applied. Comorbidities, body mass index (BMI), and age are some of the benchmark variables utilized for these selections (Light and Tucker 2013; Light and Barhyte 2005; Stratta et al. 2015).

In the United States, the United Network for Organ Sharing (UNOS) helped the pancreas transplantation society to regulate T2DM patients that should be selected for PT. The criteria are insulin-dependence with positive C-peptide (at least 2 ng/ml), and maximum BMI of 30 kg/m^2, depending of the percentage of the T2DM patients in waiting list. BMI and C-peptide limits in T2DM candidates are still controversial, and debates go on.

The International Pancreas Transplant Registry (IPTR) evaluated the results in T2DM recipients (Gruessner et al. 2017). The data was divided over three eras: 1995–2001, 2002–2008, and 2009–2015. PT in T2DM was performed in 1514 patients. The vast majority of the recipients (97%) were submitted to pancreas transplantation in association with kidney transplant, either simultaneously or pancreas transplant after kidney transplant. The pancreas graft survival improved significantly after 1 and 3 years from 80.2% and 70.5% in era 1–89.0% and 83.3% in era 2 (Al-Qaoud et al. 2018).

Simultaneous Pancreas Kidney (SPK)

The International Registry of Pancreas Transplantation reported more than 50,000 pancreas transplants described by the end of 2016. According to Gruessner et al., from 2011 to 2016, 84% of total PTs were SPKs (Gruessner and Gruessner 2018). In the study from Indiana University, SPKs made up 63% of PT modalities, for those aged 30–39 (Shah et al. 2013). In fact, SPK is well accepted as the main therapy in type 1 diabetes patients with end-stage renal disease, on dialysis or pre-dialysis with glomerular filtration rate (GFR) <20 mL/min/1.73 m^2 (Gruessner and Gruessner 2018). These patients should undergo kidney transplant simultaneously from the same deceased donor. The kidney graft presents better survival when performed with simultaneous PT due to diabetes control, in comparison with cadaveric kidney alone (Gruessner and Sutherland 2005). SPK is particularly recommended in T1DM candidates who lack an available living donor for isolated kidney transplantation first.

Perioperative morbidity such as graft thrombosis and immune rejection during a 3-year period are lower (Gruessner and Sutherland 2005). We can speculate that grafts (pancreas and kidney) from the same donor can reduce exposure to different antigens decreasing the risk of immunological rejection. The anticoagulant effects of uremia could also explain the lower risk of vascular thrombosis in this scenario.

At the Liver and Gastrointestinal Transplant Division, Department of Gastroenterology, University of Sao Paulo Medical School, 89.7% of the pancreas recipients were simultaneous pancreas kidney transplants. In a cohort study, there were no differences between the three transplant modalities concerning graft loss due to thrombosis. However, we notice that global graft failure seems to be higher in the pancreas after kidney modality (Rocha-Santos 2018).

Pancreas After Kidney (PAK)

PAK is the second main modality of PT. It is considered for T1DM patients who have already undergone kidney transplant. These kidney recipients are already under immunosuppression, and can be evaluated for PAK in order to obtain the potential benefits of sustained euglycemia. The selection criteria of patients for PAK include normal renal graft function and it can be performed 4–6 months after the kidney transplant.

In Brazil, the waiting list for a pancreas graft follows chronological criteria including blood type. At Sao Paulo city, the waiting time for SPK transplantation can be greater than 2 years, extending dialysis therapy and increasing risk of death. In this context when there are living kidney donors, kidney transplantation should be

conducted first, and then a cadaveric PT. PAK presents slightly worse results when compared with SPK, concerning graft thrombosis and immunological rejection (Gruessner and Gruessner 2018).

Pancreas Transplantation Alone (PTA)

PTA is the minor modality of PT. It is considered for patients with labile T1DM usually characterized by an endocrinologist, including acute and severe metabolic complications such as hypoglycemia, hyperglycemia, or ketoacidosis requiring medical attention; clinical and emotional issues due to exogenous insulin therapy, that are so severe as to be incapacitating; and consistent failure of insulin-based management to prevent acute complications. GFR>60 mL/min/1.73 m^2 is required, since nephrotoxicity caused by calcineurin inhibitors can be associated with progressive nephropathy, accelerating the advent of end-stage renal failure. In such circumstances, subsequent need for a kidney transplant can be complicated by the patient's hypersensitization due to previous PTA. Thus a solitary transplant should be considered early on, before the patient develops end-stage renal disease (Niederhaus 2015; Gruessner and Gruessner 2013).

The number of patients submitted to PTA remains relatively stable, and survival was the highest compared with other categories. Such outcome notwithstanding, there is still hesitancy to consider PTA without severe diabetic secondary complications, given the postoperative surgical and immunosuppression risks.

Contraindications

As pancreas transplant presents a high level of perioperative complications, even in young patients, preoperative evaluation is very important to select the best recipient (Stockland et al. 2009; Fridell et al. 2011; Gilabert et al. 2002). Patients able to tolerate medical or surgical complications should be preferred. Reoperations can be needed, and some candidates suffer from hemodynamic lability due to long periods of diabetes, needing high doses of vasopressors. On the other hand, the waiting list mortality for PT candidates submitted to dialysis has been described as 6.6% at one year and 54% at 5 years (Gruessner et al. 2004). A multidisciplinary transplantation team is essential to critically compare mortality risk in the waiting list versus morbidity and mortality in the postoperative period.

Malignancies, chronic and acute infections, and severe cardiovascular morbidity are contraindications for PT. Older recipients above 50–55 years of age should be avoided due to the long period of diabetes. On the other hand when PT is pondered, biological age could be more relevant than chronological age (Siskind et al. 2014a). Obese patients also present worse post-transplant results.

Cardiac and Pelvic Vascular Assessment

Preoperative cardiovascular evaluation should include cardiac stress testing and cardiac catheterization. T1DM patients, due to the long period of diabetes, often suffer from severe atherosclerosis, and cardiovascular complications are the main cause of death after pancreas transplantation (Samoylova et al. 2019). In the preoperative evaluation, we routinely perform Doppler ultrasonography of the iliac vessels. Upon any alteration of the flow or caliber of the vessel, a noncontrast computed tomography scanning of the pelvis is requested to evaluate the extent of calcification of the iliac vessels. This strategy permits the choice of the best preoperative strategy for PT implantation or even, in case of severe stenosis, to rule out PT.

Psychosocial status should also be evaluated, as these candidates will require permanent treatment after hospital discharge.

Surgical Complications

Pancreas graft failure is higher during the first year of PT. Among the complications of the first 60 days pancreatitis occurs in 3–12%, wound

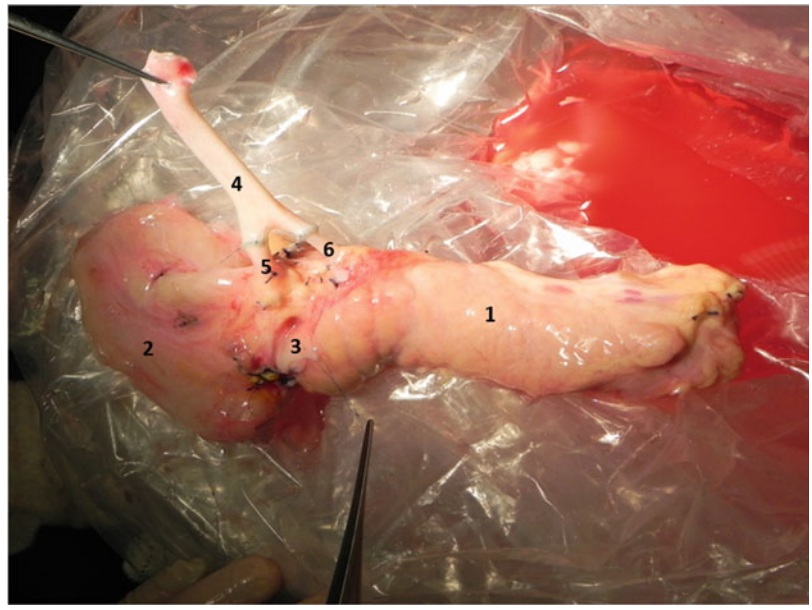

Fig. 49.1 Pancreas graft: (1) body of the pancreas, (2) duodenum, (3) portal vein, (4) y-graft, (5) superior mesenteric artery and (Starzl et al. 1981) splenic artery

infection or abscess in 1–5%, and focal or diffuse pancreas graft necrosis in 12% of the recipients (Grochowiecki et al. 2014).

Major complications, including graft thrombosis, have been demonstrated in 6–17% of PT, duodenal fistula in 0.5–2%, and intra-abdominal hemorrhage in 0.5% of the patients (Grochowiecki et al. 2014; Sansalone et al. 2005; Michalak et al. 2005; Gruessner et al. 2010; Malaise et al. 2005). Reoperations, abdominal wall dehiscence, infection, malnutrition, and graft failure with renal dysfunction and death are also listed. Thrombosis is the most important cause of pancreas graft loss.

Cohort Study

In our Service, the standard surgical technique for pancreas transplantation was adopted (Fig. 49.1), and risk factors that lead to early pancreas graft loss due to thrombosis were the aim (Fig. 49.2). We evaluated the records of 137 individuals in a retrospective design, from March 2000 to May 2017 (Table 49.1).

Fig. 49.2 Pancreatic thrombosis

Thirty-five transplants (25.5%) had cold ischemia time over 14 h; in 44 recipients (32.1%) it was less than 10 h, and in the other 58 patients (42.3%) the range was 10–12 h. Fourteen patients (10.2%) underwent isolated transplants, with 13 pancreas transplants after kidney and one PTA (Rocha-Santos 2018). In all univariate analyses, the experience of the harvest team ($p = 0.04$) was the only feature that achieved significance. With multiple logistic regression in addition to the team ($p = 0.021$), age of the recipient less than 30 years, donor intensive care

unit time ($p = 0.033$) and donor blood glucose ($p = 0.023$) were significant (Table 49.2). Pancreas graft survival was 86.7%, 85.7%, and 85.7% after 1, 5, and 10 years respectively. Patient survival at 1, 5, and 10 years was 88.0%, 82.5%, and 78.5%, respectively.

In the late postoperative period, patients can stay euglycemic for a period superior to 10 years. Even when late failure occurs due to so-called "immunological graft loss," there is little invasive surgery risk. Only rarely will the transplanted patient need to undergo a new laparotomy (Sansalone et al. 2005; Michalak et al. 2005; Gruessner et al. 2010).

Age

Most centers worldwide limit PT for patients younger than 50 years (Shah et al. 2013; Sener et al. 2010). According to IPTR, only 2% were performed in those older than 60 years (Fourtounas 2014). Some studies recommend that pancreas transplantation should be performed in patients younger than 45 years, in order to decrease postoperative morbidity and mortality (Freise et al. 1998). On the other hand, the chronological age cannot express the real health condition of the patients. In fact, the upper age cutoff point has been questioned (Heldal et al. 2010; Schmitt et al. 2009).

At the University of Indiana, recipients older than 60 years with simultaneous pancreas kidney transplantation presented no statistical difference concerning postoperative morbidity and cardiovascular events (Shah et al. 2013). In contrast, in the experience of Strata et al. older recipients presented higher graft loss. They seem to die more often due to cardiac events in contrast to younger recipients, who in turn suffer higher immunological graft loss (Tullius et al. 2010).

The higher risk of death due to preoperative morbidity, compared to the risk of immunological pancreas graft loss in young patients, should be balanced. If more aged patients survive the postoperative period with no cardiac events, graft function can increase patient survival for a long period of time.

Outcomes by age using the UNOS database indicated that out of 280 patients over 60 years old who underwent pancreas transplantation, 154 (55%) were submitted to SPK. Survival was shorter in older patients, however, with minimal differences between the various age groups. No difference in one-year graft survival was observed for any age group. Those with 40–49 years achieved 67.8% 5-year graft survival, among those with 50–59 years survival was 59.9%, and for the 18- to 29-year bracket it was not better than 56.8% (Siskind et al. 2014b).

In our series age was mostly 25–40 years and BMI 18–25 kg/m^2. This is a safe range for both age and BMI. Only 5 individuals (3.6%) were older than 50 years. Surprisingly, in the multiple logistic regression model, those under age of 30 had a greater possibility of graft loss. We speculate that although the arteries for the implant are healthier in younger patients, coagulation cascade could be more active. The intrinsic thrombophilia of the diabetic could be the main risk factor, without technical interference (Rocha-Santos 2018).

Obesity

The ONUS database evaluated simultaneous pancreas kidney transplants as related to obesity (Zalewska and Ploeg 2014). Among 5725 patients BMI <25 corresponded to 56%, 33% were overweight (BMI 25–29.9), and 11% obese (BMI 30–40). Postoperative transplant complications, including delayed kidney graft function, pancreas graft thrombosis, and mortality, were higher in the obese group.

The growing prevalence of obesity in the general population accelerates insulin resistance in the T1DM population. In most studies, obesity of the recipient is a risk factor for graft loss (Bumgardner et al. 1995). A few authors have published good results in low-grade obesity (Laurence et al. 2015). In our experience with 23 patients (16.8%) exhibiting BMI above 25, no increased risk for graft thrombosis emerged. In contrast, 16 patients (11.6%) had a BMI below 18. The effects of malnutrition on graft thrombosis are poorly studied.

Donors

There is a consensus that donor advanced age, obesity, certain causes of brain death, and presence of shock are risk factors for thrombosis of the pancreas graft (Fridell et al. 2011). In a multivariate analysis, Troppman et al. concluded that donor age and cardiovascular cause of brain death increase the risk of vascular thrombosis of the pancreas (Troppmann et al. 1996).

These variables are so important that scales assessing the risk of graft loss according to donor features were published. Axelrod et al. analyzed data from 9401 transplants and calculated a donor risk index for graft one-year survival. Variables were age, BMI, height, serum creatinine, gender, ethnicity (African-American, Asian, Caucasian), stroke, donation after cardiac death, transplantation modality. and cold ischemia time. The reference donor was male, 28 years old, white, with a BMI of 24, height of 173 cm, absence of stroke, serum creatinine less than 2.5 mg/dl, pancreas not donated after cardiac death or pancreatitis, with up to 12 h of cold ischemia (Axelrod et al. 2010).

The Eurotransplant Group pre-acquisition pancreas adequacy score (P-PASS considers donor age, body mass index, admission to the intensive

care unit (ICU), cardiac arrest, serum sodium, serum amylase, serum lipase, and use of catecholamines. The study concludes that high-score P-PASS donor grafts reduced the risk of organ loss by up to 3 times. However, several studies have shown that these risk scores are not necessarily appropriate for other populations (Schenker et al. 2010; Blok et al. 2016; Woeste et al. 2010).

Perspectives

Robotic Pancreas Transplantation

The first robotic pancreas transplant was performed in 2012 by Boggi et al. (2012). Although they reported only two patients, they proved that it was feasible despite technical challenges, with lower surgical morbidity. On the other hand, ischemia time was higher. Large series are now available (Spaggiari et al. 2013). Robotic transplant surgery is standard at a small number of pioneering centers, (Stiegler and Schemmer 2018) not being routinely adopted.

β Cell Replacement

PT for T1DM includes the exocrine pancreas, which can precipitate pancreatitis and duodenal and pancreatic fistula. New perspectives aim to bypass the exocrine portion of the pancreas.

Pancreas Islet Transplantation

From 1990 to 1999, the International Islet Transplant Registry informed a one-year islet survival of 41%, with 11% insulin free (Brendel et al. 2001). The Edmonton immunosuppression protocol in 2000 improved the outlook. It included corticosteroid-free immunosuppression and islet infusion from different donors (Shapiro et al. 2000). Seven patients became insulin free (1 year), which to some extent continued thereafter (5 years) (Shapiro et al. 2000; Ryan et al. 2005). The technique is accepted as a valid option for beta cell replenishment (Rheinheimer et al. 2015).

A transhepatic catheter inoculates islets into the portal vein. Surgical catheterization of the mesenteric vein is also possible (Mallett and Korbutt 2009). A receptive vascular bed with little rejection and long-term graft function would be ideal; (Rajab 2010) however, few locations fulfill such requirements.

The stomach submucosa, chosen for our experimental study, has already shown a reduced inflammatory response (Echeverri et al. 2009). It is a well-vascularized region with easy approach for the graft and subsequent analysis, which in larger organisms could be done by endoscopy (Echeverri et al. 2009; Wszola et al. 2009). Adequate glycemic control and reduced immunological response are also expected (Xinnong et al. 2014). In our experience, five rats were inoculated in the gastric body submucosa, and four in the fundus submucosa. No immunosuppression was used. The gastric body location was associated with better glycemic control (de Mesquita et al. 2018).

The omentum also enjoys convenient vascularization, and blood flow straight to the portal vein. An in situ adherent, resorbable plasma-thrombin biological scaffold has already been tested in rats. The subcutaneous area could not be overlooked as a potential inoculation region either, as it is convenient, safe, and compatible with easy graft removal, if necessary. Unfortunately blood supply is insufficient (Berman et al. 2016).

Stem Cell–Derived Beta Cells

The B cell replacement from whole organ transplantation continues to be the gold standard therapy for T1DM with end-stage kidney failure. Although this invasive therapy can provide insulin-free independence, it is well recognized the great number of postoperative complication leading a high number of morbidity and mortality. On the other hand, the B cell replacement from islet transplantation presents a higher benign postoperative course, although the insulin-free independence is poor and patients

present the morbidity associated with the immunosuppression.

The results displayed above open the doors for others options for B cell replacement. The International Pancreas and Islet Transplant Association, in collaboration with the Harvard Stem Cell Institute, the Juvenile Diabetes Research Foundation (JDRF), and the Helmsley Foundation, held a 2-day Key Opinion Leaders Meeting in Boston in 2016 (Odorico et al. 2018).

Advances concerning the successful transplantation of stem cell–derived beta cells for diabetic patients have been remarkable. The steady generation of pure populations of fully functional beta cells remains obscure and according to this meeting, the question persists as to whether pure or mix of beta cells with other islet endocrine cells can provide superior presentation. Maybe it will be necessary to create an immunoisolation strategy that offers a hospitable environment while preventing immune-mediated injury and to define an ideal local for its location. Despite these challenge, development has been done since several teams working together in early phase trials. Moreover, the growth in the field of genome can help this issue in the future by creating better disease models and producing safer and more effective health cell mass. The meeting concluded that "It seems inevitable that stem cell–derived beta cells will play an important role in the care of diabetic patients within the next decade." (Odorico et al. 2018).

3D Bioprinting

The 3D bioprinting method employs degradable biopolymer scaffolds mimicking the islet architecture (Wang and Rosenberg 1999). Hydrogel capsules provide a semi-permeable membrane with favorable oxygen and nutrient supply (Gibly et al. 2011). Despite some scaffold loss, extracellular matrix proteins are deposited, enhancing islet survival (Berman et al. 2009).

Loss of extracellular matrix interactions is deleterious for beta cell survival. In another protocol in our laboratory, extracellular protein laminin (LN) was combined with a biodritin (alginate) microencapsulation procedure. Satisfactory stability and biocompatibility were achieved in a mouse transplantation model, with long-term islet survival (Campanha-Rodrigues et al. 2015).

Contents

Abstract

Type 2 diabetes mellitus (T2DM) is the most common form of diabetes, distinguished by insulin resistance and beta-cell dysfunction. Increased body mass index and central adiposity are in a strong relationship with insulin resistance, and are believed to be among the key factors involved in the incidence of T2DM. The prevalence of T2DM is exponentially expanding, and has paralleled that of obesity. The objective of this review is to encapsulate the pharmacology of major antidiabetic drug families along with efficacy, effect on body weight, dose, contraindications, and associated adverse effects. It also focuses on recent pharmacological approaches and drugs under clinical trial, for the successful therapy of T2DM and diabesity in the future.

Type 2 diabetes · Obesity · Antidiabetic drugs · Pharmacotherapy

Introduction

Type 2 diabetes mellitus (T2DM) can be characterized by insulin resistance and variable insulin secretion that is associated with increased blood glucose levels and glucotoxicity. The number of diabetics globally is expected to reach 642 million by 2040 (Upadhyay et al. 2018). Increased BMI or obesity is found to be in strong association with many pathophysiological conditions, notably T2DM, as both share insulin resistance. Obese individuals can be up to 80 times more likely to develop T2DM in comparison to individuals with BMI < 22 (Al-Goblan et al. 2014; Diabetes.co.uk 2019a). Therapeutic targets include tight control of glycosylated hemoglobin (HbA1c $\leq 7.0\%$) levels, to prevent long-term complications and mortality (Upadhyay et al. 2018). In the case of obesity (BMI ≥ 27 for Asian countries, or BMI ≥ 30 in the Western world), medications are recommended, and it is a prerequisite to review the weight gain or weight loss effect of antidiabetic medications before prescribing.

A minimum 5% weight loss in obese T2DM patients is desired, and if the goal is not attained, alternative medication with good efficacy and reduced risk of hypoglycemia should be considered (American Association of Diabetes Educators 2016). Weight reduction in overweight and obese individuals could help in improving insulin sensitivity, as well as attenuating the risk of metabolic and cardiovascular complications (Diabetes.co.uk 2019a).

Major Antidiabetic Drug Families

Sulfonylureas

Sulfonylureas (SUs) were the first oral antidiabetic agents approved by FDA, starting in 1958. Their origin is traced to the observation in 1942 that some sulfonamide antibacterial products triggered critical hypoglycemia in typhoid patients (Upadhyay et al. 2018). These are produced from substitution at a para position on the benzene ring, and at one nitrogen residue of urea moiety (Brunton et al. 2013). First-generation SUs are rarely used, as they carry a great risk of hypoglycemia in contrast to modern SUs.

Mechanism of Action

SUs act as insulin secretagogues by modulating ATP sensitive potassium ion channels (K_{ATP} channel), via sulfonylurea receptor present on the pancreatic beta-cell membrane. SUs bind with K_{ATP} channel and cause its inhibition, which leads to an increase in the concentration of K^+ ions in the cytoplasm of beta-cells, and depolarizes calcium ion channels. This leads to the increased influx of calcium ions into the beta-cell that provokes exocytosis of insulin granules and stimulates insulin release. To some extent, SUs also bind and activate Epac2 (guanine nucleotide exchange factor), which further works together with Rap1 protein to increase the approachability of insulin vesicles, to meld with the plasma membrane of the beta cell (Thulé and Umpierrez 2014).

Extra-Pancreatic Actions

Increased expression of glucose transporter GLUT-4 in the periphery and reduced peripheral insulin resistance are recognized. Suppression of sarcolemma and mitochondrial ATP channels on cardiac cells, and K_{ATP} channels on smooth muscle cells, by binding with sulfonylurea receptor SUR2A which causes cardiovascular complications, is also mentioned. Gliclazide causes reduced hepatic glucose output, with anti-oxidant and antiplatelet effect. Glyburide, in turn, aggravates blood pressure due to sympathetic activation (Kalra et al. 2015).

Efficacy

All SUs are equally efficacious at equipotent doses. Therapy is initiated from a lower dose range, on the basis of glycemic control. Longer-

acting SUs are administered as a single dose daily and rest is available in extended-release dosage forms (glipizide) or micronized tablets (glyburide), to prolong the duration of action and the dose is kept lower. SUs reduce glycated hemoglobin by 1.5%–2%, with a fasting plasma glucose (FPG) decrease of up to 60–70 mg/dl.

Usually, the primary failure of SU monotherapy is seen in patients with low C-peptide levels and high FPG levels (>250 mg/dl). In such patients, SUs cause less than 30 mg/dl decrease in FPG levels. Almost 75% of the patients come under secondary failure on SU monotherapy, initially responding well (>30 mg/dl reduction in FPG), however failing to reach acceptable glucose control (Brunton et al. 2013; Dipiro et al. 2005).

Effect on Body Weight

Older SU drugs (glimepiride, glyburide, glipizide, gliclazide) are reported to induce weight gain of 1.8–2.6 kg in previous studies (Pappachan et al. 2019). Modern SUs (glimepiride, gliclazide) are widely preferred over SUs due to less risk of hypoglycemia, weight gain, and cardiovascular complications. The Scottish Intercollegiate Guidelines Network (SIGN), International Diabetes Federation (IDF), and National Institute for Health and Care Excellence (NICE) recommend SUs use in patients who are not obese. Weight neutrality is reported with glimepiride ER and gliclazide MR during the period of 1 year. Regular consumption of glimepiride produces weight neutrality for about 1.5 years (Kalra et al. 2015).

Contraindications

SUs are not used in patients with cardiovascular diseases, liver, and renal dysfunction, as well as those exhibiting hypersensitivity to the drug.

Adverse Effects

Due to the narrow therapeutic index, SUs even in small doses can induce hypoglycemia in pediatrics and geriatrics. High doses can cause chronic hypoglycemia (less than 60 mg/dl), rarely leading to death due to neuroglycopenia and cardiotoxicity (Klein-Schwartz et al. 2016).

Glinides (Meglitinides/D-Phenylalanine Analogs)

This class of anti-diabetic drugs includes repaglinide and nateglinide, which act as ATP-sensitive potassium channel blockers. They are also insulin secretagogues, and are sometimes named prandial glucose regulators. They have a similar mechanism of action (MOA) as SUs but are structurally unrelated. The first agent of this class, repaglinide, was approved by FDA in 1997, and nateglinide in 2000. They are rapidly absorbed and have a short duration of action, in contrast to second-generation Sus; thus, flexible dosage can be designed (White 2010).

Mechanism of Action

Both meglitinides, analogously to SUs, block ATP-dependent potassium ion channels, causing insulin release from pancreatic beta-cells. Repaglinide is derived from benzoic acid, while nateglinide is derived from d-phenylalanine (Brunton et al. 2013). Meglitinides bind to sulfonylurea receptor SUR1, and are also reported to bind at a separate site on beta-cells. Nateglinide shows larger selectivity for SUR1 over SUR2, in contrast to repaglinide and SUs. Nateglinide remains bonded to the receptor for a very limited period of about 2 s, contrasting with repaglinide which stays for 3 min, whereas the dissociation from the receptor is 90 times greater than repaglinide. Therefore nateglinide has a very limited on-off impact on insulin discharge (Guardado-Mendoza et al. 2013).

Efficacy

These agents are reported to treat long-term hyperglycemic stages in patients with T2DM. In a 3.6 months clinical trial, repaglinide (0.5–4 mg/meal) reduced glycated hemoglobin level by 1.57%, while nateglinide (60–120 mg/meal) achieved 1.04% decrease. Repaglinide reduced

pre-prandial glucose values by 57 mg/dl, while nateglinide by 18 mg/dl, in a period of 16 weeks (Rosenstock et al. 2004).

Effect on Body Weight

Patients on repaglinide suffer a weight gain of 1.8 kg and with nateglinide 0.7 kg, after 3.6 months of therapy (Rosenstock et al. 2004). Meglitinides are indeed associated with minor to moderate weight gain, as per a report by the American Association of Diabetes Educators 2016 (American Association of Diabetes Educators 2016).

Contraindications

They are contraindicated in diabetic ketoacidosis, hypersensitivity, and renal and liver diseases. Repaglinide is contraindicated in patients on lipid-lowering gemfibrozil, as it can increase repaglinide blood levels by 28.6 fold (Grant and Graven 2016).

Adverse Effects

Meglitinides are associated with hypoglycemia (16–31%) and weight gain, however less remarkably than Sus (Hinnen 2015; Hossain and Pervin 2018).

Biguanides

Guanidine is the active ingredient in *Galega officinalis*, a small tree found in Europe and Western Asia, which was prescribed in primitive times for diabetic patients. However, guanidine and derivatives showed toxicity. First-generation biguanides (phenformin and buformin) were introduced for diabetes pharmacotherapy in 1950. In 1970 phenformin was withdrawn due to cardiac mortality and lactic acidosis. Metformin appeared as a safer alternative and was approved in the United States in 1995. Now it is one of the most widely prescribed antidiabetic agents (Hundal and Inzucchi 2003).

Mechanism of Action

Metformin is an AMPK (AMP-dependent protein kinase) activator. When cellular energy stores are reduced, AMPK is stimulated by phosphorylation. Stimulated AMPK initiates the process of fatty acid oxidation and glucose uptake, reducing lipid production and gluconeogenesis. The net outcome of such actions is decreased hepatic glucose output, enhanced insulin sensitivity in fat cells and muscles, enhanced storage of glycogen in skeletal muscles, and reduced blood glucose levels. The exact mechanism by which metformin stimulates AMPK is unknown. Metformin has shown reduced cellular respiration by selectively affecting mitochondrial complex I. It does not disturb the discharge of any islet hormones, and hardly causes hypoglycemia (Brunton et al. 2013).

Efficacy

Metformin decreases glycated Hb level by 1.5%–2%, with fasting glucose reduction by 60–80 mg/dl. It is acceptable even in cases of extremely high postprandial glucose (PPG) (>300 mg/dl), and is also able to reduce triglycerides and LDL-C by 8%–15%, with a slight increase in HDL-C by 2%. It stimulates PAI-1 (plasminogen activator inhibitor-1), and induces a decrease in weight by 2–3 kg (Dipiro et al. 2005).

Effect on Body Weight

Metformin is recommended for diabesity patients on account of suppression of hepatic gluconeogenesis, increased insulin sensitivity in peripheral tissue, and some degree of anorexia. Approximately 31% reduction in episodes of T2DM in highly obese patients has been achieved by metformin as stated by Diabetes Prevention Program (DPP) clinical trial (The Diabetes Prevention Program Research Group 2002). A combination of metformin with lifestyle modification has shown improvement in gestational diabetes (Pappachan et al. 2019).

Contraindications

Caution is advised for patients liable to display metabolic acidosis including renal insufficiency, hepatic failure, alcoholism, congestive heart failure (CHF), sepsis, and surgery. Certain studies reported the safety of metformin with stable CHF,

resulting in reduced mortality rates (Upadhyay et al. 2018).

Adverse Effects

Gastrointestinal symptoms (10–25%) can include dyspepsia, diarrhea, nausea, and intestinal muscle spasm. Dosage tapering or an intake with a meal can be helpful. Reduced levels of cobalamin (20–30%) in malabsorption is a possibility. Overdose, or regular use of metformin for years, can rarely precipitate metabolic acidosis (3–6/100,000 patients) (Brunton et al. 2013).

Thiazolidinediones (TZDs)

TZDs (insulin sensitizers) were approved for clinical use by FDA in 1997, though controversies surrounded the first agent of this class, troglitazone. Troglitazone was withdrawn from the market due to liver toxicity (Yki-Jarvinen 2004). Pioglitazone is the only widely used TZD, as rosiglitazone was also withdrawn in some countries in terms of cardiovascular safety (Pappachan et al. 2019).

Mechanism of Action

TZDs or glitazones are the selective synthetic ligands of nuclear peroxisome-proliferator–activated receptor gamma (PPARγ) (Yki-Jarvinen 2004). Such types of receptors are a subfamily of 48-member nuclear–receptors, and regulate transcription of genes linked to glucose and lipid metabolism (Brunton et al. 2013; Yki-Jarvinen 2004). PPARγ is mainly expressed in adipocytes, with minor findings on skeletal, cardiac, smooth muscle cells, pancreatic β-cells, macrophages, and vascular endothelial cells (Brunton et al. 2013). Hence adipose tissue is the main target of PPARγ agonists. However, there is no evidence whether TZDs reduce insulin resistance by directly acting on to the target tissues, or indirectly through the release of secreted products by adipocytes such as adiponectin, that increases insulin sensitivity. TZDs binding with PPARγ receptor induce a conformational change, and form a heterodimer with another nuclear receptor (retinoid X receptor), which then further binds with peroxisome proliferator response element. Such activation causes adipocyte differentiation, increases subcutaneous fat cells, FFA oxidation, FFA uptake into adipocytes, and storage from extra-adipose tissues to adipose tissues. Such effects enhance insulin sensitivity in fat cells, muscles, and liver (Brunton et al. 2013; Dipiro et al. 2005; Yki-Jarvinen 2004).

Efficacy

Pioglitazone or rosiglitazone therapy for 6 months decreases glycated hemoglobin by 1.5%, and PPG level by 60–70 mg/dl at a higher dose. TZDs slowly reduce blood glucose levels for about 3–4 months, after which the highest glucose response is seen. Patients must be counseled regarding such point, so that they continue therapy without any drop-out (Brunton et al. 2013; Dipiro et al. 2005).

Effect on Body Weight

A weight gain of 3.6 kg after 35 months has been registered in a large trial (Dormandy et al. 2005). TZDs lead to weight gain of up to 3–4 kg in 6 months and 5 kg in 3–5 years as per UKPDS (Ko et al. 2017). Weight gain varies on the basis of dose regimen used (Wilding 2006). These agents also affect lipid parameters such as TGs, LDL-C, and HDL-C. Pioglitazone reduces triglyceride levels by 10–20% while rosiglitazone has a neutral effect. Rosiglitazone increases LDL-C up to 5–15%, whereas pioglitazone is devoid of such effect. Both are able to alter minor, dense LDL-C particles to bulky soft particles, which are less dense and less atherogenic, and also increase HDL-C up to 3–9 mg/dl (Dipiro et al. 2005).

Contraindications

In patients with New York Heart Association (NYHA) class III and IV cardiac failure, and even in class I and II patients, caution is advised (Dipiro et al. 2005).

Adverse Effects

TZDs as single oral anti-diabetic agents do not produce hypoglycemia, whereas in combination

with SUs can slightly increase the risk (Elte and Blicklé 2007). Other adverse effects include edema (2–4%) due to sodium/water retention and enhanced vascular permeability, cardiac failure, and weight gain. The severity of edema (approx. 15%) increases in combination with insulin. Edema is dose-dependent, so by dropping the dose and using diuretics, alleviation could follow, especially if edema is not severe (Dipiro et al. 2005).

GLP-1 Receptor Agonists (Injectable Drugs)

These are also called incretin mimetics. Incretins are hormones produced by epithelial intestinal L-cells, in response to food ingested: GIP (glucose-dependent insulinotropic polypeptide) and GLP-1 (glucagon-like peptide 1). GLP-1 administration reduces blood glucose levels by mediating insulin release, and also inhibits it when the glucose level is normal, while GIP is not clinically effective in T2DM patients (Brunton et al. 2013; Hinnen 2017; Yammine et al. 2019).

Pancreatic alpha-cells produce and split proglucagon into glucagon and a large peptide (C-terminal) comprising GLPs (GLP-1 and GLP-2), whereas intestinal L-cells transform proglucagon into a large peptide (N-terminal) comprising glucagon or GLPs. GLP-2 is of little importance for diabetes management. It mainly influences epithelial cell proliferation in the digestive tract; hence, it has been approved as an orphan drug (teduglutide; GLP-2 agonist) for the treatment of short bowel syndrome, by both the FDA and the European Medicine Agency (Brunton et al. 2013).

Mechanism of Action

There are two GLP-1 receptor agonists (exenatide and liraglutide) prescribed intravenously for type 2 diabetic subjects. These agents increase insulin secretion which is glucose-dependent, inhibit glucagon, slow gastric emptying, reduce appetite and body weight, and normalize pre-prandial and postprandial glucose levels, by stimulating GLP-1 receptor (Brunton et al. 2013; Meloni et al. 2013). These receptors are G-protein coupled receptors (GPCR) expressed in pancreatic alpha-cells, beta-cells, specific neurons in hindbrain, intestinal cells, and other structures.

Beta-cell functioning is required for incretin-based therapy; else, it could lead to failure (Tripathi 2013). GLP-1 as such has limited therapeutic potential, due to rapid degradation by dipeptidyl peptidase 4 enzyme (DPP-4); consequently, half-life is just 2–3 min. The enzyme is mainly expressed in luminal capillary endothelial cells, kidney, gastrointestinal mucosa, and immune cells. To increase the half-life, DPP-4-resistant GLP-1 agonists have been produced. The use of DPP-4 inhibitors potentiates the pharmacological action of incretin-based therapy (Brunton et al. 2013; Tripathi 2013).

Exenatide: It is a synthetic exendin-4, potent, DPP-4-resistant GLP-1 agonist which is short-acting. It is injected subcutaneously twice daily, with a plasma half-life of 3 hours, and acts for about 6–10 h. It can be used as monotherapy or in combination with metformin, SUs, or TZDs if required. It reduces glycated hemoglobin by 1% in patients with T2DM, after 6.9–18.8 months (Brunton et al. 2013; Tripathi 2013; Soni 2016).

Liraglutide: It is rigidly bound to a plasma protein that accounts for increased plasma half-life of >12 h, and thus acts for >24 h. Due to its prolonged plasma half-life, it is given subcutaneously once daily. It reduces glycated hemoglobin by 30%, which is greater than exenatide. It can be used as monotherapy, or in combination with metformin, SUs, or TZDs (Brunton et al. 2013; Tripathi 2013; Soni 2016).

Effect on Weight

Patients on exenatide show a weight reduction of 2.5–4 kg within 30–82 weeks of therapy, whereas liraglutide can be followed by a weight reduction of 5.6 kg, in obese non-diabetic or diabetic patients. Therefore it can also be used as an anti-obesity drug (Brunton et al. 2013; Tripathi 2013; Soni 2016).

Contraindications

Patients with a family history of medullary carcinoma of the thyroid, and patients with multiple endocrine neoplasias, should avoid such therapy. Caution is advised due to the presence of gastroesophageal reflux (Hinnen 2017).

Adverse Effects

Nausea, vomiting, and diarrhea are common (40–50%) and dose-related. Hypoglycemia is rarely reported with GLP analogs, except when used in combination with Sus (Brunton et al. 2013; Tripathi 2013).

DPP-4 Inhibitors

DPP-4 belongs to the family of prolyl oligopeptidases. It is a serine protease highly expressed on intestinal epithelial cells, brush-border renal cells, pancreatic cells, hepatic cells, endothelial cells, glandular epithelium, and T-cells. It is also called as T-cell differentiation antigen (CD26). DPP-4 protein consists of an extracellular domain, with the catalytic site in the C-terminal attached to the transmembrane protein, and an intracellular tail at the N-terminal. When it is cleaved it discharges the extracellular domain in the blood, in the form of soluble DPP-4, and also circulates in body fluids (seminal and cerebrospinal fluids).

The extracellular domain of the protein also contains glycosylation and cysteine-rich sites that contribute to non-enzymatic actions of DPP-4. Such sites are believed to interact with adenosine deaminase, streptokinase, and plasminogen, and are also a binding site for chemokines. The antidiabetic effect of DPP-4 inhibitors was evaluated after the investigations about inactivation of incretin hormones by DPP-4 (Deacon 2019). DPP-4 inhibitors are identified to enhance plasma half-life of incretin-based therapy. The first DPP-4 inhibitor sitagliptin was approved by FDA in 2006. After this saxagliptin was approved in the United States and vildagliptin in Europe and America, as monotherapy or combination therapy with other anti-diabetics. DPP-4 inhibitors linagliptin and alogliptin are also available (Dicker 2011).

Mechanism of Action

Due to the essential role of DPP-4 enzyme in inactivation of incretin hormones, orally active inhibitor drugs of this enzyme have been produced. These are indirectly acting insulin-secreting agents and are mostly used in combination therapy (Brunton et al. 2013; Tripathi 2013). DPP-4 inhibitors such as sitagliptin, vildagliptin, and saxagliptin are selective competitive inhibitors of DPP-4, with high affinity for the enzyme. The concentration of physiologically produced GLP-1 and GIP after food intake was doubled with DPP-4 inhibitors. Such selective inhibition of enzyme provides an extended safety profile and allows prolonged treatment with DPP-4 inhibitors.

It indirectly increases insulin secretion and inhibition of glucagon in patients with T2DM. DPP-4 inhibitors are also reported to counter-regulate glucagon release by pancreatic alpha-cells under hypoglycemia. Thus, these agents do not cause alpha-cell dysfunction, and improve alpha-cell sensitivity to glucose without affecting appetite. Experimental beta-cell neogenesis was demonstrated, and genetically DPP-4-deficient rats showed resistance to streptozotocin (STZ)-induced beta-cell destruction. These drugs also improve TGs and FFA levels (Brunton et al. 2013; Thornberry and Gallwitz 2009).

Efficacy

Sitagliptin has been shown to reduce glycated hemoglobin by 0.65–1.0% within 2–7 months, and 0.67% upon 12 months of therapy. Saxagliptin reduces glycated hemoglobin by 0.43–1.17%, while vildagliptin reduces by 1.4% in 24 weeks of therapy. In terms of anti-hyperglycemic effect, DPP-4 inhibitors were found to be slightly less effective than SUs, and equivalent to metformin and TZDs (Dicker 2011; Amori et al. 2007).

Effect on Weight

Sitagliptin during 12 months triggered weight reduction of 1.5 kg, up to weight gain of 1.8 kg.

Vildagliptin and saxagliptin were not much different: weight shifts of −1.8 kg to +1.3 kg, and −1.8 kg to +0.7 kg, respectively, after 5 months. In a meta-analysis of 13 studies they were considered to be weight-neutral (Dicker 2011).

Contraindications

Hypersensitive persons and those with chronic pancreatitis and renal diseases are not safe candidates for such therapy (Pathak and Bridgeman 2010).

Adverse Effects

A slight effect on in-vitro immune cell functions has been seen with DPP-4 inhibitors, and allergic reactions such as anaphylaxis, angioedema, Stevens-Johnson syndrome, flu-like symptoms, and skin reactions are reported. Hypoglycemia is observed during combination therapy of DPP-4 inhibitors with SUs and insulin (Brunton et al. 2013; Dicker 2011; Diabetes.co.uk 2019b).

Alpha-Glucosidase Inhibitors

The alpha-glucosidase enzyme is released by the chorionic epithelium of enterocytes, with the function of digestion of carbohydrates and glucose production. Due to its important role in glucose production, various alpha-glucosidase inhibitors were produced as a new class of oral hypoglycemic agents in the 1980s. They are obtained from natural sources, including plants and micro-organisms. The alpha-glucosidase enzymes from rodent intestine and yeast are employed for pharmacological purposes. They include acarbose, miglitol and voglibose (Yin et al. 2014).

Mechanism of Action

Alpha-glucosidase inhibitors retard intestinal absorption of carbohydrates by preventing alpha-glucosidase action in enterocytes of the brush border of the mucosa. Mouth to cecum transit time is reduced and leads to larger evacuation of carbohydrates via stools. Acarbose, produced by actinobacteria *Actinoplanes utahensis,* as well as voglibose, is a reversible inhibitor. These agents also cause the release of GLP-1 in systemic circulation which adds on to the therapeutic action, while miglitol is a powerful inhibitor of the enzyme sucrase (Brunton et al. 2013; Tripathi 2013). Acarbose also inhibits glucoamylase and alpha-amylase enzymes, thus impairing carbohydrate digestion and absorption (Derosa and Maffioli 2012).

Efficacy of Alpha-Glucosidase Inhibitor

Post prandial glucose concentration diminishes by 1–3 millimole/liter and pre-prandial glucose concentration by 1 millimole/l. Also glycated hemoglobin can be lowered by 0.5–0.8%, and even can exceed 1% at higher doses; however, proper maintenance of diet is a must. Body weight and lipid parameters remain unchanged. Long-term administration of these agents in prediabetics can prevent the onset of T2DM and heart disease. Both monotherapy and combination protocols are available (Brunton et al. 2013; Krentz 2018).

Contraindications

Diabetic ketoacidosis, inflammatory bowel disease, other gastrointestinal conditions, and hypersensitivity are contraindications (Access.fda.gov. PRECOSE (acarbose tablets) 2019).

Adverse Effects

Flatulence (78%) and loose stools (14%) are dose-related. In certain cases hepatitis is reported, which reverts when therapy is stopped (Derosa and Maffioli 2012).

Sodium-Glucose Co-transporter-2 Inhibitors/Gliflozins (SGLT-2 Inhibitors)

This is the FDA-approved latest class of antidiabetics. Primarily introduced in 2013, SGLT-2 inhibitors consist of canagliflozin, dapagliflozin, ertugliflozin, and empagliflozin, which can be used as monotherapy, or in combination with metformin and linagliptin. These agents are reported to reduce the incidence of mortality due to cardiac diseases in patients with T2DM (Fda.gov 2019a, b; Hsia et al. 2017).

Mechanism of Action

The glomerulus of the kidney filters all the circulating glucose, which is reabsorbed into the blood via SGLT-2 of the proximal convoluted tubule. These transporters cause 90% reabsorption of filtered glucose, so these are an interesting target for T2DM. Inhibition of this co-transporter promotes glucouresis, and lowers blood glucose levels along with weight reduction (Tripathi 2013; Hsia et al. 2017). Empagliflozin has maximum specificity for SGLT-2, while canagliflozin is the least specific. These drugs can also be used in obese individuals, due to their weight reduction effect (Hsia et al. 2017).

Efficacy of SGLT-2 Inhibitors

They are useful in all the stages of T2DM because the mechanism of action is independent of beta-cell function. Hypoglycemia can occur if these agents are used in combination with an insulin secretagogue (Zurek et al. 2017). SGLT-2-inhibitors showed a 9.1% reduction of glycated hemoglobin at baseline, 0.9% in 1 month, and 0.8% in 6 months of therapy (Schork et al. 2019).

Effect on Body Weight

Weight loss of 2.6 kg in 6 months of therapy is documented, due to glucouresis and loss of adipose mass. Apart from body fat these agents also reduce epicardial fat. Extracellular fluid diminishes after 28 days, and returns to baseline after 3–6 months of therapy (Schork et al. 2019). Therefore SGLT-2 therapy is associated with conspicuous weight loss.

Contraindications

These are contraindicated in patients with kidney diseases or nephropathy (GFR $<$ 45 mL/min/1.73 m (Al-Goblan et al. 2014; Hsia et al. 2017).

Adverse Effects

They can increase the risk of serious genital anaerobic infections (Fournier's gangrene), and urinary tract infections in diabetic patients (Fda.gov 2019b; Hsia et al. 2017).

Oral/Nasal Insulin

Insulin therapy can be used in all modalities of diabetes, including T1DM, T2DM, and gestational diabetes. It can be taken subcutaneously, intravenously, intramuscularly, and more recently also orally. The subcutaneous route is classic for long-term management of glycemic control, notably in patients with T1DM (Brunton et al. 2013). Oral insulin is a long-acting, basal insulin analog. When target with combination therapy of oral hypoglycemic agents is not achieved, oral insulin therapy is instigated to control glycosylated hemoglobin levels (A1C) $>$ 7% in type 2 diabetic patients (Box 50.1).

Box 50.1 Pharmacotherapical Recommendations for Type 2 Diabetes (Modified from American Diabetes Association) (American Diabetes Association 2019)

(A) Initial therapy in all cases: Metformin (Goal HbA1c $\leq$ 7.0%.

(B) Patients without atherosclerosis or heart/renal failure.
   1. With obesity: GLP-1 receptor agonists (liraglutide, semaglutide, exenatide) or SGLT-2 inhibitors (empaglifozin, canaglifozin); if necessary, the two can be combined, or DPP-4 inhibitors (in the absence of GLP-1 receptor agonists), SUs, TZDs, and basal insulin can be included.
   2. Weight loss not required: DPP-4 inhibitors, GLP-1 receptor agonists, SUs and TZDs are the first options; in case of insufficient response, two of these can be combined, eventually including SGLT-2 inhibitors; as a third line of therapy, SUs or basal insulin can be added.

(C) Cardiovascular atherosclerosis.
   1. GLP-1 receptor agonists or SGLT-2 inhibitors.

(continued)

Box 50.1 (continued)

2. If necessary, the following adjuvants can be introduced: Basal insulin, TZDs, SUs, and also DPP-4 inhibitors (however these are incompatible with GLP receptor agonists).

(D) Heart or renal failure.

1. SGLT-2 inhibitors are the first option, however GLP receptor agonists can be added.
2. Should compensation not be adequate, GLP-1 receptor agonists), SGLT-2 inhibitors, DPP-4 inhibitors (however these are incompatible with GLP receptor agonists), and basal insulin can be used.

Oral insulin at high dose, in insulin-naive patients with T2DM, seems to be effective in controlling FPG (7.1 mmol/L) levels after 8 weeks, comparable to subcutaneous insulin glargine (6.8 mmol/L), with the absence of any serious adverse effects or hypoglycemia (Halberg et al. 2019). Only nasal insulin (Afrezza), for both type 1 and type 2 diabetic patients, is already FDA approved. Afrezza is rapid-acting inhaled insulin and is not a substitute for long-acting insulin. It is taken before a meal or within 20 minutes of starting a meal and can be used along with long-acting insulin in patients with T1DM (Medscape.com 2014). The FDA has also approved the first glucagon therapy (Baqsimi nasal powder) for the emergency management of severe hypoglycemia (Fda.gov 2019c).

Pharmacological Approaches of the American Diabetes Association (ADA)

Metformin is recommended as the first-line agent for the treatment of T2DM. Metformin therapy should be continued till it is tolerated and not contraindicated and in the long run causes vitamin B12 deficiency especially in patients with anemia or peripheral neuropathy. Therefore, vitamin B12 levels should be monitored during metformin therapy. Initially, insulin can be added with anti-diabetic drugs in case of weight loss, hypertriglyceridemia, ketosis, and hyperglycemia ($\geq$300 mg/dl) or glycated hemoglobin (>10%). ADA recommends a patient-oriented approach for selecting an appropriate pharmacotherapy to control blood glucose levels, including the efficacy of the drug and patient-related factors as important considerations. Along with active pharmacological agents, lifestyle modification should be considered to improve health. For T2DM patients having atherosclerotic cardiovascular disease, SGLT-2 inhibitors and GLP-1 receptor agonists are recommended as part of an anti-diabetic regimen with its well-known cardiovascular profits. For patients having atherosclerotic cardiovascular disease at risk of cardiac failure or if cardiac failure co-exists SGLT-2 inhibitors are ideal. T2DM patients with chronic renal diseases should be recommended SGLT-2 inhibitors and GLP-1 receptor agonists to prevent the progression of kidney diseases or cardiovascular diseases or both. Among the parenteral drugs to achieve extreme blood glucose reduction, GLP-1 receptor agonists are considered over insulin. After every 3–6 months, anti-diabetic drug regimen should be assessed and adjusted based on the patient's factor. The combination of new anti-diabetic agents with initial therapy should be recommended to reduce glycated hemoglobin level by 0.7–1%. If glycated hemoglobin levels are not controlled in 3 months without atherosclerotic cardiovascular disease or chronic kidney disease, SUs, TZDs, SGLT-2 inhibitors, GLP-1 agonists, DPP-4 inhibitors, and basal insulin can be combined with metformin with special emphases on patient factor and treatment selective effects (American Diabetes Association 2019). For the treatment of T2DM in obese patients, selection of anti-diabetic drug should be based on their effect on body weight. Initially, diet modification should be recommended and can be further combined with exercise and anti-obesity agents (BMI $\geq 27\ kg/m^2$) in T2DM patients. For patients receiving anti-obesity agents with weight loss <5% in 3 months or any safety and tolerability issues during the

Table 50.1 Properties of anti-diabetic agents used in the treatment of T2DM

Class	Drugs	Dosage range	HbA1c reduction (%)	Weight change	Hypoglycemia	Duration of action
Oral						
Biguanide	Metformin	500–3000 mg (Waring 2016)	1–2% (Brunton et al. 2013)	Neutral (American Diabetes Association 2019)	No (American Diabetes Association 2019)	24 h (Dipiro et al. 2005)

course of therapy the drugs should be discontinued and alternative pharmacological approaches should be taken into account. Antidiabetic agents having an influence on body weight include metformin, alpha-glucosidase inhibitors, SGLT-2 inhibitors, GLP-1 receptor agonists, and amylin mimetics. Dipeptidyl peptidase 4 inhibitors are weight-neutral while insulin

Table 50.2 Drug therapy under investigation for the treatment of diabesity and T2DM

Drug	Sponsor	Phase	Status	Study title/ objective	Completion date	References
Trodusquemine (MSI-1436)	Genaera corporation	I	Completed	Single dose, tolerance, and pharmacokinetic study in obese T2DM patients	April 2009	Clinicaltrial.gov (2019a)
SAR425899	Sanofi	I	Completed	Safety and tolerability in overweight to obese and T2DM patients	Oct 2018	Clinicaltrial.gov (2019b)
KRP-104 (novel DPP-4 inhibitor)	ActivX biosciences, Inc.	II	Completed	Randomized, double-blind, placebo-controlled trial to assess safety and effectiveness in T2DM patients	Aug 2008	Clinicaltrial.gov (2019c)
Oral ORMD-0801 (oral insulin)	Oramed, ltd.	II	Completed	Randomized, double-blind, placebo-controlled, parallel-group trial to evaluate safety and efficacy.	April 2016	Clinicaltrial.gov (2019d)
LX4211	Lexicon pharmaceuticals	II	Completed	Assessment of safety, efficacy, and tolerability in T2DM patients	Dec 2009	Zambrowicz et al. (2012); Clinicaltrial.gov (2019e)
HOE901-U300 (new formulation of insulin glargine)	Sanofi	III	Completed	Consideration of efficacy between HOE901-U300 and lantus in T2DM patients	March 2014	Bolli et al. (2015); Clinicaltrial.gov (2019f)
Rimonabant (SR141716)	Sanofi	III	Completed	Assessment of weight reduction and persistence in 12 months with a diabetic diet in obese T2DM patients	May 2004	Clinicaltrial.gov (2019g)
Sitagliptin and metformin therapy	The University of Texas Health Science Center at san Antonio	IV	Completed	Assessment of sitagliptin and metformin effects alone and in combination contrast to placebo on liver gluconeogenesis.	Oct 2012	Solis-Herrera et al. (2013); Clinicaltrial.gov (2019h)

secretagogues, thiazolidinediones, and insulin induce weight gain. For short-term and long-term management of obesity (BMI $\geq$ 27 kg/m^2), all FDA approved agents for weight loss are found to be associated with glycemic control in T2DM patients or patients at risk of T2DM. Five weight-reducing drugs (combination drugs)—orlistat, lorcaserin, phentermine/topiramate (ER), naltrexone/bupropion ER, and liraglutide—have been approved by FDA for long-term use in patients with obesity-associated T2DM, dyslipidemia, and high BP who want to lose weight (Care and Suppl 2019).

General Features of Available and Pipeline Drugs

Table 50.1 summarizes the prescription characteristics of common antidiabetic drugs, whereas Table 50.2 highlights coming products or combinations, for diabetes with or without obesity.

Contents

Abstract

Type 2 diabetes mellitus (T2DM) increases the risk of cardiovascular disease (CVD) and frequently presents a phenotype related to other comorbidities, such as obesity, nephropathy, hepatic steatosis, and increased risk of type 3 diabetes, i.e., neurodegenerative diseases associated with metabolic dysfunction. Although previous large clinical trials reported inconsistent reduction in all-cause mortality and CVD after glycemic control, the new pharmacologic classes of sodium-glucose co-transporter 2 inhibitors (SGLT2-i) and glucagon-like peptide-1 receptor agonists (GLP-1RAs) were associated with a reduction of major cardiovascular events (MACE), changing the paradigm of T2DM treatment. These classes of drugs are able to act concomitantly in distinct pathways of the metabolic syndrome. This chapter aims to review: (i) T2DM and obesity as CVD risk factors; (ii) previous clinical trials with neutral, deleterious, or beneficial results; (iii) why GLP-1RAs are an interesting class of drugs in the context of the metabolic syndrome; (iv) up-to-date information about GLP-1RAs in clinical trials; and (v) future perspectives.

GLP-1-RA · Cardiovascular risk · Diabetes · Obesity · Metabolic syndrome

Cardiovascular Risk of Obesity and Diabetes

A cohort study including 190,672 participants free of clinical cardiovascular disease (CVD) found that higher BMI increased the CVD risk for men and women by 21% and 32% in overweight, 67% and 85% in obese, and 314% and 253% in morbidly obese participants (Khan et al. 2018). In a meta-analysis of Mendelian randomized studies that grouped 881,692 participants, each standard deviation (SD) increase in BMI elevated the odds ratio of type 2 diabetes mellitus (T2DM) by 67%, and of coronary artery disease (CAD) by 20% (Riaz et al. 2018).

Visceral obesity is related to epicardial and pericardial fat accumulation, worsening the coronary lesions (Ding et al. 2009) by a pro-inflammatory environment mediated through endoplasmic reticulum (ER) stress, cell death, and production of pro-inflammatory cytokines (Rocha and Libby 2009). Moreover, obesity increases insulin resistance, which is a well-established risk factor for CAD, heart failure (HF), and sudden death. As a result, T2DM patients present a similar or higher risk of CVD events when compared to patients with previous myocardial infarction (Juutilainen et al. 2005).

Contrary to expectations, for many years consecutive clinical trials demonstrated that glycemic control was not a robust means of reducing cardiovascular events (Turner 1998; Patel et al. 2008; Hayward et al. 2015). Therefore, new anti-diabetic treatments that concomitantly reduce mortality or cardiovascular events are highly desired, even more so if they are able to reduce metabolic syndrome compounds, such as obesity, insulin resistance, and elevated blood pressure, while offering a good security profile (Sposito et al. 2018).

GLP-1RA Drugs

The incretin effect was first described in the 1960s (Elrick et al. 1964). It was characterized as a greater insulin release after oral meal intake, compared with intravenous glucose. Later, gastric inhibitory polypeptide (GIP) (1970s) (Brown et al. 1975) and GLP-1 (1980s) (Mojsov et al. 1987) were described as incretin mimetic hormones. In native conditions GLP-1 is released by L-cells presents in the distal ileum and colon, which are stimulated mainly by ingested fat and carbohydrates. The action of GLP-1 happens through its receptor, a G-protein present in the pancreas, gastrointestinal tract, lungs, kidney, brain, arteries, and heart. In natural conditions, the hormone is degraded in 1–2 min by the enzymes dipeptidyl peptidase-4 (DPP-4) and neutral endopeptidase (Mojsov et al. 1987). For this reason, molecular modifications were made in an effort to reduce this quick degradation, allowing GLP-1 to be used medically.

After molecular changes, two distinct groups were produced: (i) Exendin-4 derivatives, synthesized from the saliva of the lizard *Heloderma suspectum*, which have approximately 50% homology with native GLP-1; and (ii) human GLP-1 analogues, with greater than 90% of homology (Sposito et al. 2018; Røder 2018). Subsequently, these groups underwent differentiations in molecular characteristics, which account for the difference in half-life between the first generation (hours) and the second generation (days) (Table 51.1).

General Effects

Although the apparent major effect of GLP-1 is to improve insulin release in a glycemic-dependent manner, many other pleiotropic effects in organs/systems have been reported

Table 51.1 General characteristics of GLP-1RAs

Drugs	Structure	Molecular Weight	Half-life
Exenatide	Exendin-4	4.2 KDa	2–4 h
Lixisenatide	Exendin-4	4.9 KDa	3.0 h
Exenatide ER	Exendin-4	4.2 KDa	7–14 days
Liraglutide	GLP-1 analogue	3.8 KDa	12 h
Dulaglutide	GLP-1 analogue	59.7 KDa	~4 days
Albiglutide	GLP-1 analogue	73 KDa	~5 days
Semaglutide	GLP-1 analogue	4.1 KDa	~7 days

Adapted from Sposito et al. (Sposito et al. 2018)

Pancreas

Activation of GLP-1 receptor leads to AMPc stimulation, which culminates in insulin release (Baggio and Drucker 2007) in a glycemic-dependent manner. Moreover, GLP-1RA reduces endoplasmic reticulum (ER) stress, a process present in diabetes that leads to reduced activity and apoptosis of β-cells (Rowlands et al. 2018). Many experiments have already demonstrated that GLP-1RAs are able to reduce ER stress and therefore protect against β-cell death. In Wolfram syndrome, a rare disease considered a pure model of ER stress, GLP-1 improved β-cell responsiveness inhibiting ER stress (Kondo et al. 2018).

Glucagon secretion in α-cells is also modulated, through both a direct and an indirect mechanism. The indirect action may happen due to insulin release, which exerts a negative feedback on glucagon secretion. The direct mechanism is related to an ability to inhibit glucagon secretion during hyperglycemia and increase glucagon secretion during hypoglycemia. This direct action may explain, at least in part, why patients with type 1 diabetes and no residual β-cells responded to GLP-1RA reducing glucagonemia and fasting glycaemia (Creutzfeldt et al. 1996), and why hypoglycemia is an uncommon adverse event in patients with T2DM using GLP-1RA therapies (Zhang et al. 2019).

Gastrointestinal Tract

GLP-1RAs inhibit gastric emptying through vagal stimulation (Abbott et al. 2005). The slowed gastric emptying explains the indirect reduced post-prandial glycemia, insulinemia, and triglyceridemia. Even in patients with type 1 diabetes, in whom GLP-1 is not able to induce insulin secretion, a reduced glycemic excursion secondary to the lower gastric emptying has been described (Baggio and Drucker 2007; Dupre et al. 1995).

Renal

The LEADER (liraglutide) and SUSTAIN-6 (semaglutide) clinical trials reported approximately 36% reduction of nephropathy events after GLP-1RA treatment (Verma et al. 2019). Recently, a post hoc analysis of REWIND also demonstrated renal protection by dulaglutide, like liraglutide and semaglutide, mainly by reduced albuminuria (Gerstein et al. 2019). Renal protection could happen through both indirect and direct mechanisms. The indirect are: (i) increased urinary sodium excretion, (ii) decreased systemic tumor necrosis factor (TNF)-α, interleukin (IL)-6, and IL-1, (iii) decreased oxidative stress, (iv) decreased protein intake, and (v) reduced blood pressure (DeFronzo 2017). The direct protection of the kidneys by GLP-1RAs was demonstrated by an experiment where podocytes were co-cultured with palmitic acid and GLP-1RA, presenting lower rates of apoptosis and improving the levels of autophagy inhibitor markers, such as nephrin and podocin (Guo et al. 2017).

Liver

GLP-1RAs may improve non-alcoholic fatty liver disease (NAFLD) by direct and indirect mechanisms. The direct are related to AMP-activated protein kinase (AMPK), an

enzyme that senses energy expenditure fluctuations, switching the metabolism from lipogenesis to lipid oxidation, targeting ATP formation. When there is triglyceride accumulation the phosphorylation of AMPK is inhibited, worsening insulin resistance, local inflammation, and oxidative stress (Madiraju et al. 2016). Liraglutide, a GLP-1RA, improves AMPK phosphorylation, restoring lipid and glucose metabolism (Yu et al. 2019). Indirect effects are linked to weight loss, triglycerides reduction, and glycemic improvement. Clinical trials have already demonstrated that liraglutide reduces hepatic fat content (Petit et al. 2017; Feng et al. 2017; Armstrong et al. 2013).

Adipose Tissue and Energetic Control

GLP-1 receptors are expressed in the nuclei related to brown adipose tissue (BAT) control, in the brain. Therefore, it seems reasonable that GLP-1RAs could interfere with body temperature. In preclinical studies GLP-1 activated BAT with browning of white adipose tissue (WAT) after intra-cerebral injection. This may happen through AMPK activation and/or by sympathetic stimulation. However when the medicine is injected peripherally results are not so consistent, leading to the hypothesis that peripheral vagal stimulation could interfere with this pathway. In clinical studies the results are also not conclusive, varying from neutral to stimulating effects of BAT and browning of WAT (Beiroa et al. 2014; López et al. 2015).

Neurodegenerative Diseases

At least two clinical trials demonstrated some protective effects of GLP-1RAs on the central nervous system. Exenatide extended-release was tested on patients with Parkinson's disease, resulting in a significant improvement on the Movement Disorder Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS) part III (motor) scale (Athauda et al. 2017). In another trial with Alzheimer's disease, liraglutide prevented the decline of glucose consumed by the brain, although no effect on cognition was reported (Gejl et al. 2016). Preclinical studies have demonstrated that GLP-1RAs inhibit inflammation, promote mitochondrial biogenesis, stimulate neurogenesis, and restore neuronal insulin signaling inhibiting ER neuronal stress and apoptosis (Panagaki et al. 2017). In a rat model of Wolfram syndrome, 6 months of liraglutide treatment reduced neuroinflammation, ER stress, and the death of retinal ganglion cells (Seppa et al. 2019).

Cardiovascular: Arteries

GLP-1 receptors are present in the microvascular endothelium and smooth muscle cells (Bangshaab et al. 2019), showing direct effects on the artery wall, as demonstrated in cultured cells, animal models, and clinical trials. GLP-1-RAs activate protein kinase A (PKA)/ERK pathways, stimulating nitric oxide synthesis and thereby improving endothelial vasomotor function (Wei et al. 2016). GLP-1RAs also reduce vascular inflammation and oxidative stress, inhibiting the pro-atherogenic environment in vessels, thus stabilizing the plaques against rupture (Balestrieri et al. 2015). In clinical trials, GLP-1RAs consistently reduced carotid pulse wave velocity (PWV), what also suggests improvement in arterial stiffness.

On the other hand, a meta-analysis grouping five studies demonstrated that GLP-1RAs had a neutral effect on vasodilation, as evaluated by Flow-Mediated Dilatation (FMD). It is important to note that these studies had high heterogeneity and small numbers of enrolled patients, and did not perform FMD using a modern method, including a continuous evaluation and the use of stereotaxic probe stabilizer (Batzias et al. 2018; Thijssen et al. 2019).

Myocardium

GLP-1-receptors were found in the myocardium, explaining in part the pleiotropic effects on the cardiovascular system. (i) In isolated hearts of mice, GLP-1RAs led to enhancement of glucose update and coronary flow (Ban et al. 2008). (ii) Intravenous GLP-1RAs infusion improved

regional and global left ventricular function in patients with severe systolic dysfunction after coronary angioplasty (Nikolaidis et al. 2004). (iii) Exenatide administered over a 6-month period to patients diagnosed with ST-segment elevation after myocardial infarction resulted in lower creatine kinase myocardial band (CK-MB) and troponin I levels, and improved the global longitudinal strain (Woo et al. 2013). (iv) Treatment-naïve patients diagnosed with T2DM receiving GLP-1-RA showed improved left ventricular strain, left ventricular twisting, and reduced N-terminal-pro hormone brain natriuretic peptide (NT-proBNP) (Lambadiari et al. 2018).

However, in a placebo-controlled crossover protocol of 41 patients diagnosed with T2DM and stable coronary disease, liraglutide did not improved left ventricular ejection, global longitudinal strain, or strain rate (Kumarathurai et al. 2016). Also, the FIGHT trial enrolled a total of 300 recently hospitalized patients diagnosed with established HF and reduced left ventricular failure, and no reduction in deaths, re-hospitalization for HF, or any echocardiographic parameters emerged, when comparing liraglutide to placebo (Margulies et al. 2016). Taking these data together, there is no consensus about GLP-1RA improving HF.

Blood Pressure and Heart Rate

GLP-1RAs have an anti-hypertensive effect that seems to be independent of the improvement of HbA1c or weight reduction, and is additive to anti-hypertensive drugs. A large meta-analysis involving 33 trials demonstrated a reduction of approximately 2.2 mmHg after long-term use of GLP-1RA (Katout et al. 2014). Another meta-analysis grouping 31 trials demonstrated a reduction in systolic blood pressure of approximately 2.4 mmHg (Robinson et al. 2013).

Higher heart rate (HR) is associated with all-cause mortality (Jensen et al. 2013). GLP-1 receptors are also found on the sinoatrial node, stimulating HR. In fact, both short- and long-term administration of GLP-1 leads to higher HR and reduced HR variability (HRV), even after metabolic improvement and weight reduction (Smits et al. 2017; Kumarathurai et al. 2017). However, the exact mechanisms in humans are still unclear and were not associated with a worse cardiovascular outcome (Fig. 51.1).

Cardiovascular Impact of GLP-1RA Drugs

Early clinical trials regarding CVD in diabetes, such as UKPDS (United Kingdom Prospective Diabetes Study) (Holman et al. 2008), ACCORD (Action to Control Cardiovascular Risk in Diabetes) (Gerstein et al. 2008), ADVANCE (Action in Diabetes and Vascular Disease: Preterax and Diamicron-MR Controlled Evaluation) (Patel et al. 2008), and VADT (Veterans Affairs Diabetes Trial) (Hayward et al. 2015), did not find a consistent reduced risk of mortality or cardiovascular events after intensive glycemic control (Eckel et al. 2019).

Thiazolidinediones

In 1999, a meta-analysis grouping 42 clinical trials with rosiglitazone, a thiazolidinedione, found a significantly higher risk of myocardial infarction and a borderline risk of death from cardiovascular causes (Nissen and Wolski 2007). Studies on dipeptidyl peptidase-4 inhibitors (DPP4-i) mainly reported a neutral effect on CVD. A meta-analysis involving 40,781 participants included in DPP4-i trials reinforced that this class of drugs was related to higher or lower all-cause mortality and cardiovascular mortality (Zheng et al. 2018). Saxagliptin, a member of this class, was the only one associated with significantly higher incidence of hospitalization for HF (Scirica et al. 2014).

Sodium Glucose Co-transporter 2

EMPA-REG (empagliflozin) (Steiner 2016), CANVAS (canagliflozin) (Guthrie 2018), and

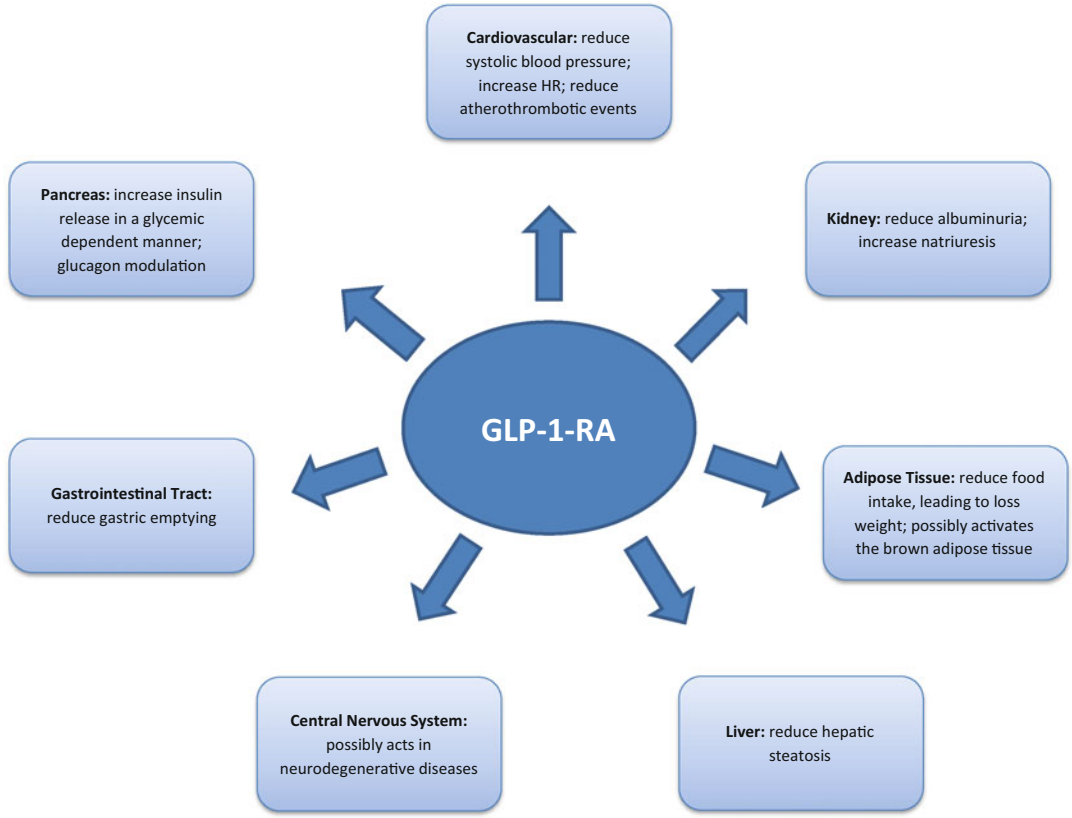

Fig. 51.1 Metabolic effects of GLP-1RAs

DECLARE (dapagliflozin) (Wiviott et al. 2018) studies reported a benefit in CV outcomes, reducing the incidence of HF hospitalization and CV deaths. A meta-analysis including these three randomized controlled trials also found a relative risk reduction for 3-point major adverse cardiovascular events (MACE) in individuals on secondary prevention (Zelniker et al. 2019), suggesting a smaller but significant effect of SGLT2-i on atherothrombotic events.

GLP-1RA

The EXSCEL trial studied exendin-4 derivatives, represented by exenatide, in 14,752 patients, while the ELIXA trial studied lixisenatide in 6068 patients. These drugs reached statistical significance regarding non-inferiority ($p < 0.001$), but not for superiority to placebo ($p = 0.06$ and 0.81, respectively). Among GLP-1 analogues, liraglutide (LEADER trial), subcutaneous semaglutide (SUSTAIN-6 trial), and dulaglutide (REWIND trial) showed significance for both inferiority and superiority, in contrast to oral semaglutide (PIONEER 6). In a meta-analysis of oral semaglutide grouping a total of 9890 patients, no superiority was found in cardiovascular protection compared with active control by liraglutide, empagliflozin, or sitagliptin (Avgerinos et al. 2019).

Another recent meta-analysis combined a total of 56,004 participants and included ELIXA (lixisenatide), EXSCEL (exenatide), LEADER (liraglutide), SUSTAIN-6 (subcutaneous semaglutide), Harmony Outcomes (albiglutide), REWIND (dulaglutide), and PIONEER 6 (oral semaglutide) (Kristensen et al. 2019), concluding that GLP-1RAs improved all the endpoints: MACE, by 12%; death from cardiovascular

causes, by 12%; deaths by fatal and non-fatal stroke, by 9%; and all-cause mortality, by 12%. Interestingly, for the first time GLP-1-RAs were demonstrated to reduce in 9% the risk of admission by HF, hypothetically secondary to myocardial infarction reduction.

In addition, our group previously published a meta-analysis (Sposito et al. 2018) comparing the efficacy related to pharmacological composition between the clinical trials of exendin-4-based therapy, ELIXA (lixenatide) and EXSCEL (exenatide), versus GLP-1 analogues LEADER (liraglutide), SUSTAIN-6 (semaglutide), and Harmony (Albiglutide). When evaluating cardiovascular death, non-fatal myocardial infarction, non-fatal stroke, and hospitalization for unstable angina and HF, GLP-1-analogs were superior to placebo, unlike the exendin-4 derivatives (risk ratio 0.96 vs 0.85; 1.00 vs 0.82; 0.92 vs 0.86).

International Endorsements

The European Society of Cardiology indicated that GLP-1RAs or SGLT2-i should be the first line therapy for high cardiovascular risk patients (Kristensen et al. 2019), while the European Association for the Study of Diabetes (EASD)-American Diabetes Association (ADA) consensus suggested the prescription of GLP-1RA in high-risk patients with T2DM (Cosentino et al. 2019; Davies et al. 2018). Featuring a good safety profile, acting on diverse components of the metabolic syndrome puzzle, and improving cardiovascular outcomes, GLP-1RAs seem to be a very promising class of drugs to be offered in clinical practice.

Future Perspective

SUSTAIN-9 (Zinman et al. 2019), AWARD-10 (Ludvik et al. 2018), and DURATION-8 (Frías et al. 2016) reported additive metabolic and glycemic control when GLP-1RAs were prescribed together with SGLT2-i therapies. Although this is provocative, there have been no studies of the concomitant use of both regarding hard cardiovascular outcomes.

Type 1 diabetes seems to be another possible target of GLP-1 use. When liraglutide was added to insulin pump therapy, patients presented a significant reduction in both HbA1c and weight, and improvement in the time in range of glycemia target, without increased hypoglycemic events (Dejgaard et al. 2019).

Finally, phase II trials of two co-agonists GLP-1/GIP and GLP-1/glucagon and three co-agonists (GLP/GIP/glucagon) showed good results regarding glycemic control, glycemic excursions, and weight loss, with promising implications for clinical practice (Petersen et al. 2019).

Abstract

The diabetes pandemic demands solutions for proper glycemic control and prevention of future chronic complications that could result in organ failure or comorbidities. In this regard, we now know that patients diagnosed with diabetes require individual management plans. Thus, new treatment management strategies have been designed to allow clinicians to tailor the most appropriate therapy for diabetes patients individually. These treatment management plans extend beyond defining the appropriate medications for patients; they provide a directive toward some acute and chronic complications that should be screened for, as they are historically known to occur with diabetes. Observing any of the complications or comorbidities requires the patient medication regimen to be adapted accordingly. This chapter describes such modern treatment plans for the two primary forms of diabetes, type 1 and type 2, based on both basic and clinical studies, later incorporated in various diabetes management guidelines and outlines expected future trends.

Diabetes · Delivery of insulin · Islet transplantation · Stem cells therapy · Hyperbaric oxygen therapy · Pharmacotherapy of diabetes

Introduction

Diabetes mellitus (DM) is an endocrine disease, characterized by hyperglycemia and multiple metabolic disorders that cause serious local and systemic effects (Nair 2007; Forbes and Cooper 2013; Katsarou et al. 2017). Nowadays, DM is one of the biggest health problems and has reached pandemic proportions (Forouhi and Wareham 2014). According to the International Diabetes Federation, 425 million people worldwide have DM, with a tendency to be 629 million in 2045 (Cho et al. 2018). There are at least five types of DM, while the two primary forms are DM type 1 (DMT1) and DM type 2 (DMT2) (ADA 2010; Katsarou et al. 2017; Cho et al. 2018). Autoimmunity is a significant factor in the development of DMT1, while genetic predisposition and obesity are leading risk factors for the development of DMT2 (Al-Goblan et al. 2014; Nair 2007).

Long-term anti-diabetic pharmacotherapy and lifestyle adaptations are necessary to achieve glycemic control and decline multisystem disorders in DM patients (Rai et al. 2016; Katsarou et al. 2017).

History

Nearly one century ago, exogenous insulin became available (Banting and Best 1990; Maclean 1926). In the meantime, plenty of oral hypoglycemics were designed, and they achieve desirable results in patients with DMT2 (Butterfield et al. 1957; Krall et al. 1958). However, exogenous insulin is irreplaceable in the treatment of people with DMT1, being required in abundant cases of DMT2 as well (Handelsman et al. 2015). Despite constant progress in terms of the new therapeutic approaches, a comprehensive and efficacious cure for DM is still not accomplished. Current therapies for patients with DM have several shortfalls, including efficacy, timings, and glycemic control (Shah et al. 2016; Castle et al. 2017; Evans et al. 2011; Pathak et al.

2019). Also, these therapies produce numerous side effects like gastric irritation, injection phobia, diarrhea, and loss of appetite (Pathak et al. 2019; Rai et al. 2016; Zaric et al. 2019).

Etiology and Pathophysiology of DMT1 and DMT2

Diabetes mellitus (DM) is a metabolic disorder characterized by alterations and impairment in insulin and glucagon secretion and/or action that lead to hyperglycemia (ADA 2009; Girard 2017). Besides the increased blood glucose level, DM is also characterized by other biochemical disorders arising as a consequence of inadequate regulation of insulin synthesis/actions, in association with long-term injury, dysfunction, and failure of different organs, especially blood vessels and heart (Jovanovic et al. 2017; Obradovic et al. 2017; Sudar-Milovanovic et al. 2015, 2017; Obradovic et al. 2015; Soskic et al. 2011), however also nerves, kidneys, and eyes (ADA 2009).

The overall prevalence of DM among adults over 18 years of age is steadily growing, and it has been increasing more rapidly in countries with low- and middle-income economies. The growth in DM prevalence reflects the rise in overweight and obesity, which are a consequence of physical inactivity and unhealthy diets (Roglic 2016). The World Health Organization (WHO) shows DM prevalence grew from 4.7% (1980) to 8.5% (2014), being the seventh leading cause of death worldwide in 2016 (WHO 2018). Furthermore, it is one of the leading causes of stroke, heart and kidney failure, blindness, as well as lower limb amputation.

Type 1 Diabetes

DMT1 is a multifactorial autoimmune disease that develops under the influence of environmental or/and genetic factors (Atkinson et al. 2014; Ikegami et al. 2011). DMT1 mostly develops in patients at a young age, before the age of 30. The main characteristic of DMT1 is lack of insulin production, and DMT1 patients are dependent on exogenous insulin application.

DMT1 is an immune-mediated type of DM, and typically an autoimmune demolition of the insulin-secreting beta cells is based on DMT1 development. Factors involved in its pathogenesis trigger lymphocyte infiltration in pancreatic beta cells, and the consequent production of different proinflammatory cytokines responsible for the pancreatic beta cells destruction (Fatima et al. 2016).

Increased risk for DMT1 is generally recognized in patients by serological confirmation of an autoimmune process occurring in pancreatic islets/beta cells, considering that this is one of the first pathological alterations, and additionally by genetic marker determination (ADA 2009). Some patients with DMT1 can exhibit detectable insulin secretion, indicating some surviving beta cells, or an ongoing cycle of destruction and regeneration of such cells (Meier et al. 2005).

Type 2 Diabetes

It represents the vast majority (85–90%) of DM cases. DMT2 is a heterogeneous, progressive metabolic and endocrine illness, and it occurs as an interplay of various genetic as well as environmental factors. The underlying origins are insulin resistance in combination with deficient compensatory beta-cell reaction and adequate insulin secretion (ADA 2009). The impairment of insulin-secreting pancreatic beta cells shows progression over time.

When DMT2 patients with normal fasting plasma glucose, however with postprandial hyperglycemia, exhibit impaired insulin action, usually it is caused by a reduction of total insulin receptor numbers (Belfiore et al. 2009; Obradovic et al. 2019).

Delivery of Insulin, Islet Transplantation, and Stem Cells

The management of DM aims to recover glycemic control and reduced micro- and

macro-vascular complications, by administrating pharmacological therapy and modifications of lifestyle. Insulin replacement represents the first-line option for insulin-dependent DM patients (Pathak et al. 2019). One of the significant challenges in the treatment of patients with DM is the efficacy of exogenous insulin in achieving long-term normal ranging glycemia (Yeh et al. 2012). One alternative is the use of continuous insulin infusion pumps (Yeh et al. 2012; Heller et al. 2017). Also, the creation of insulin analogs with different times of action, from rapid and short-acting to ultra-long acting, contributed to improvements in therapy (Shah et al. 2016; Pathak et al. 2019). Implementation of these technological advances does not prevent long-term insulin dependence, and adverse effects like invasiveness (Shah et al. 2016).

Noninvasive Insulin Administration

To avoid such complications, researchers proposed new routes for insulin administration beyond the standard subcutaneous route (Rys et al. 2018; Atkinson et al. 2014), such as nasal (Kullmann et al. 2018; Schmid et al. 2018), oral (Fonte et al. 2013), pulmonary (Mastrandrea 2010; Ledet et al. 2015), and transdermal delivery systems (Zaric et al. 2019).

Drug delivery carrier systems protect antidiabetic drugs from enzymatic degradation at the absorption site, and ensure delivery at the optimal and effective concentration for a more extended period at the target site (Rai et al. 2016). The encapsulation of insulin in particles increases its potential and allows its appropriate transport to the specific site to better control of DM (Rai et al. 2016; Zaric et al. 2019). These particles are usually microsized or nanosized. The microparticle system adjusts the pattern of drug release and improves the hypoglycemic effect of oral delivery of insulin (Wong et al. 2018). The main limiting factors of microparticle systems are the size of particles and their hydrophilic/hydrophobic nature that makes difficult their transport through biological membranes (Wong et al. 2018).

The use of nanocarriers reduces these obstacles (Bahman et al. 2019). The small size and structural diversity of nanoparticles increase the potential of insulin through better absorption and distribution, site specificity, and protection from enzymatic degradation (Bahman et al. 2019). Also, this form of application extends the release pattern of insulin and decreases the frequency of dosage, facilitating normoglycemia for a more extended period, up to 22 days (Peng et al. 2012). Other approaches considered for delivery of insulin and antidiabetics include encapsulation in liposomes, vesicular systems, and other nanoparticles (Souto et al. 2019).

The Artificial Pancreas

The use of continuous insulin infusion pumps and glucose monitoring has enabled a constant movement toward artificial pancreas development (Boughton and Hovorka 2019). Pancreas or islet transplantation seems to be the best choice to prevent dependence on insulin; however, donor shortages limit this option. Although islet transplantation was substantially enhanced in the past 2 decades, there are still limitations like instant blood-mediated inflammatory reaction, ischemia-induced loss of islet, harmful effects of immunosuppressive drugs, and apoptosis of transplanted cells (Bottino et al. 2018).

Stem cells generating new beta cells represent a promising approach for long-term treatment of DM (Stanekzai et al. 2012; Cierpka-Kmiec et al. 2019; Aguayo-Mazzucato and Bonner-Weir 2010). Many studies show that human embryonic stem cells can be used for beta cell generation and transplantation in patients with DMT1 (Cierpka-Kmiec et al. 2019; Kalra et al. 2018). Challenges are generation of genetically stable cells, survival rate of the cell, potential of transplanted cells, and ethical issues considering utilization of embryo-derived stem cells (Kalra et al. 2018). Some of these issues are overcome using induced pluripotent stem cells generated from somatic cells of patients with DMT1 to produced functional beta cells (Kalra et al. 2018; Kunisada et al. 2012).

Transplantation of insulin-producing human embryonic stem cells into streptozotocin-induced diabetic mice resulted in long-term normalization of blood glucose levels (Vegas et al. 2016). Yet loss of novel beta cells immediately after portal vein transplantation is in the range of 5–47% (Potter et al. 2014; Naziruddin et al. 2014). A current suggestion is co-transplantation of islets with different cell types, such as mesenchymal stem cells (MSC), bone marrow-derived MSC, endothelial colony-forming cells, and others (Kerby et al. 2013; de Souza et al. 2017; Borg et al. 2014; Corradi-Perini et al. 2017; Jung et al. 2014), to reduce losses of beta cells and increase their potential. This approach was shown to increase islet survival and function, and promote angiogenesis and better glycemic control due to the anti-apoptotic and pro-angiogenic effects of MSC (de Souza et al. 2017; Pathak et al. 2019).

Drugs

Non-insulin agents or those who sensitize insulin action enable the opening of new chapters in diabetes management (Grant and Kirkman 2015; Rowley et al. 2017; Leon and Maddox 2015). Some of the innovations also concern insulin treatment, namely insulin analogs with improved control of glycemia and lowered hypoglycemia risk, as well as the development of non-parenteral route/s of insulin administration (Biester et al. 2017; Fink et al. 2018). Such innovations are placed into clinical practice through precisely defined recommendations, such as those of the American Diabetes Association (ADA) (ADA 2018), American Association of Clinical Endocrinologists (AACE) (Garber et al. 2019), European Association for the Study of Diabetes (EASD) (Davies et al. 2018), and the National Institute for Health and Care Excellence (NICE) (McGuire et al. 2016). Even though these recommendations have subtle differences, they are oriented toward a patient-centered approach, and direct clinicians toward better and more uniform management of the patients (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016). Well-controlled diabetes apparently slows down the atherosclerotic process, which is the base of associated micro- and macrovascular diabetes complications and major cardiovascular events, including ones with fatal outcomes (Zoungas et al. 2014).

Pharmacotherapy of DMT1

Current recommendations are focused on individually tailored management of DMT1, consisting of appropriate dietary habits and physical activities, along with administration of insulin. It is strongly advised to adapt insulin treatment to carbohydrate intake, pre-prandial glycaemia, and anticipated physical activity (ADA 2018; Handelsman et al. 2015; National Clinical Guideline Centre 2015).

The mainstay of DMT1 management is insulin, administered by pen device or continuous subcutaneous insulin infusion (CSII). The amount and number of divided insulin doses in children or adults immediately after DMT1 diagnosis are often small (1–2 divided doses), however often increases in time (Biester et al. 2017; Fink et al. 2018; Pickup 2019). In the last decades, there was a tendency to opt for insulin analogs with improved pharmacokinetics, pharmacodynamics, and safety compared to human insulin (Biester et al. 2017; Fink et al. 2018; Heinemann et al. 2017).

Rapid insulin analogs are active immediately after administration, with short-lived effects. Basal analogs have more prolonged effects than classic neutral protamine Hagedorn (NPH) human insulin regarding glycemia control, with lower hypoglycemic risk. The usual dose is 0.5 IU/kg of body weight. During puberty and in exceptional circumstances, insulin requirements are higher. Overall, CSII is widely recommended, and it can be used in patients older than 65 years (ADA 2018; Handelsman et al. 2015; National Clinical Guideline Centre 2015; REPOSE Study Group 2017; Beck et al. 2017).

In addition, pre-prandial inhaled insulin has been shown to be efficient in the form of rapid insulin analogs (B28 aspart-insulin); however, its use in DMT1 patients is not widespread as it was

expected (ADA 2018; Heinemann and Parkin 2018).

Non-insulin Pharmacological Agents

Metformin, dipeptidyl peptidase 4 inhibitors (DPP-4i), glucagon-like peptide 1 receptor agonists (GLP-1 RA), and sodium-glucose cotransporter-2 inhibitors (SGLT-2i) are not Food and Drug Administration (FDA)-approved, despite showing beneficial effects in obese DMT1 patients (ADA 2018; Handelsman et al. 2015; Livingstone et al. 2017).

Pramlintide, an analog of the hormone amylin also secreted by pancreatic beta cells, is approved for use of DMT1 adults; however, it exhibits higher risk for hypoglycemia and obliged reduction of prandial insulin (Hieronymus and Griffin 2015). For patients with ineffective glycemic regulation or diabetics referred to renal transplantation, pancreas and islet transplantation could be the better treatment option (Gruessner 2011; Nakamura et al. 2019).

Pharmacotherapy of DMT2

Non-pharmacological measures are usually the preferred initial treatment for DMT2 patients. Apart from lifestyle changes (nutrition and physical activity) and eventual pharmacotherapy, an integral part of DMT2 management is the screening for cardiovascular disease (CVD) risk factors as well as the detection of chronic micro- and macro-vascular complications (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016).

DMT2 management aims to achieve clinical and biochemical goals (actual profile and retrograde glycemic regulation), avoiding hypoglycemic episodes and gain in body weight in obese patients, as well as controlling the risk of atherosclerotic CVD (ASCVD) (ADA 2018).

Therapeutic Aims

HbA1c, morning glycemia, and 5-point daily glycemic profile should be adjusted to age, duration of DM, risk of hypoglycemia, and the presence of comorbidities and chronic vascular complications. The level of HbA1c is an essential marker for the assessment of retrograde glycemic control. In DM patients with no comorbidities and low hypoglycemia risk, HbA1c level $\leq$7% (ADA 2018) indicates reasonable retrograde DM control for the previous 90–120 days. On the other hand, in DM patients with severe comorbidities and considerable risk of hypoglycemia, the acceptable level of HbA1c is $<$8% (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016). A more stringent HbA1c goal of $<$6.5% is set in some special populations of individuals suffering from DM (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016).

Pharmacotherapy of DMT2 is conducted as mono- or combination-therapy. The therapy chosen depends on biochemical and clinical factors, existing comorbidities, as well as side effects of administered drugs.

Monotherapy of DMT2

For patients with newly diagnosed DMT2 and HbA1c $<$9% (6) or $>$6.5% (9), metformin is the initial therapy, with a daily dose of 1.5–2.0 g. Metformin contributes to decrease in body weight, and reduces the risk of hypoglycemia. Gastrointestinal side effects are often transitional and dose-dependent. It is contraindicated if glomerular filtration rate (eGFR) is $<$30 ml/min. (Livingstone et al. 2017; Sanchez-Rangel and Inzucchi 2017).

In metformin-intolerant patients, acceptable alternatives are GLP1-RA, DPP-4i, alpha glucosidase inhibitors (AGi), and SGLT-2i. With the administration of such agents, the risk of

hypoglycemia is lower, and there is no weight gain. Other alternatives are thiazolidinediones (TZD) and sulphonylureas (SFU) or glinides, however with more risk of hypoglycemia and weight gain (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016).

Combination Therapy for DMT2

In DMT2 patients with HbA1c >9% (ADA 2018) or ≥7.5% (Garber et al. 2019; McGuire et al. 2016), as well as in those for whom metformin is not enough to achieve adequate glycemic regulation, another agent is added to the treatment regime (management intensification). Metformin-intolerant patients are administered two or more agents, with a complementary mechanism of action. There are fixed combinations that include metformin + DPP-4i/TZD/SFU on the market. Additionally, metformin with modified-release could be a suitable alternative for some of the metformin-intolerant. The acceptable level of HBA1c after management intensification should be <7%.

Insulin Introduction

If despite the use of non-pharmacological measures and dual pharmacotherapy, HbA1c is ≥7.5%, basal insulinization should be the solution. Insulin treatment starts with a plan of its administration, and continued use of metformin is recommended in suitable and tolerant patients (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016).

Dose tapering or need for administration of other non-insulin glucose-lowering agents are relevant concerns (McGuire et al. 2016). If HbA1c >9%, indicating poor control, the patient should be conducted to dual oral treatment. Furthermore, if the patient initially presented with HbA1c ≥10% or with glycemia >16.7 mmol/L or is clinically symptomatic, combined treatment of insulin and oral antihyperglycemic therapy, or even multiple insulin injections, should be considered (ADA 2018). If an insulinization process of basal insulin introduction along with metformin and/or other non-insulin glucose-lowering agents fails to control DMT2, the addition of one or more doses of rapid-acting insulin or GLP-1RA is a possible alternative (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016). Also, if a DMT2 patient is suffering from ASCVD, the addition of a CVD-beneficial agent such as empagliflozin, canagliflozin, dapagliflozin, or liraglutide is worth considering (Arnett et al. 2019; Zelniker et al. 2019; Wiviott et al. 2019; Furtado et al. 2019).

Exenatide, Liraglutide, Lixisenatide and Semaglutide

These are GLP-1RA peptides, structurally homologous to the natural incretin glucagon-like peptide-1 (GLP-1), and currently available for subcutaneous administration. Semaglutide has been approved by FDA in 2019 for oral use. GLP-1RA stimulate glucose-dependent pancreatic insulin secretion as well as reduce glucagon secretion, slowing down gastric emptying. They also significantly reduce body weight and lower HbA1c levels. They are devoid of negative effects on bone metabolism, the appearance of diabetic ketoacidosis (DKA), and congestive heart failure (CHF) deterioration. Some gastrointestinal side effects could be encountered (nausea, vomiting, bloating, gastroesophageal reflux disease, and gastroparesis); however, they often improve with time. The risk of hypoglycemia is low.

In studies on rodents, exenatide intake lead to hyperplasia of C cells and medullary thyroid cancer, while all GLP-1RA were associated with pancreatitis. Exenatide is not indicated in patients with eGFR < 30 ml/min. (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016; Deacon 2019).

Sitagliptin, Vildagliptin, Saxagliptin, Linagliptin, and Alogliptin

These represent the family of DPP-4i, blocking the DPP4 enzyme involved in the degradation of incretins such as GLP-1 and gastric inhibitory peptide (GIP). As a result, more elevated incretin levels act on a simultaneous increase in glucose-dependent insulin secretion, and decrease in glucagon secretion. There is no convincing evidence regarding the higher risk of pancreatitis or pancreatic cancer with the use of DPP-4i. DPP-4i exhibit neutral effects regarding hypoglycemia risk and body weight change, and gastrointestinal side effects are not frequent. DPP-4i effectively reduce albuminuria and do not have negative effects on the bones and the appearance of DKA. Saxagliptin is not recommended for CHF patients. Also, renal dose adjustment is required when using all DPP-4i except for linagliptin (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016; Deacon 2019; McGuire et al. 2019; Scirica et al. 2013).

Acarbose, Miglitol, and Voglibose

These AGi block the alpha-glucosidase enzyme involved in carbohydrate reabsorption in the gastrointestinal system. Digestive side effects can be frequent, including bloating, diarrhea, abdominal cramps, and mild elevation of liver enzymes. They are neutral regarding hypoglycemia risk, body weight change, bone disease, CHF deterioration, and the appearance of DKA. Renal dose adjustment is not required (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016; Liu and Ma 2017).

Pioglitazone

This TZD activates the PPARγ receptors and, through determined signal pathways, decreases insulin resistance in various tissues, predominantly in skeletal muscles (Yki-Jarvinen 2004). The clinicians are under pressure to precisely select the patients for their use because of some associated side effects, such as body weight gain, fluid retention, higher risk of bone fractures, and bladder cancer (Wang et al. 2017; Mehtala et al. 2019). Hypoglycemia risk and body weight change are not common with moderate doses, and there are no associated gastrointestinal side effects. They occasionally exhibit mild negative effects on the bones, CHF deterioration, and the appearance of DKA. Renal dose adjustment is not required; however, TZDs are generally not recommended in any stage of renal failure due to fluid retention (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016; Yki-Jarvinen 2004; Wang et al. 2017; Mehtala et al. 2019).

Sulphonylureas and Glinides (Gliclazide, Glipizide, Glimepiride, Repaglinide)

Such drugs mediate insulin secretion after binding to SUR Ki6.2 receptor, the sodium channel (Kalra and Gupta 2015). Significant effects are to be expected regarding hypoglycemia and weight gain. Mild negative effects on CHF deterioration are likely, however not on bones and DKA. Renal dose adjustment is required (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016; Wang et al. 2018; Harsch et al. 2018).

Dapagliflozin, Canagliflozin, and Empagliflozin

SGLT-2i reduce proximal tubule glucose reabsorption by binding to the SGLT-2 receptors. Ascending urinary infections, chronic and treatment-resistant urinary and vaginal candidiasis, elevation of LDL-cholesterol, dehydration, and hypotension, as well as DKA have been registered (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016; Wanner and Marx 2018; Lupsa and Inzucchi 2018). They are usually safe regarding hypoglycemia risk and contribute to bodyweight reduction. There are no associated gastrointestinal side effects.

SGLT-2i use is not indicated in patients with eGFR < 45 (60) ml/min. Empagliflozin use requires special attention regarding potential negative effects on the bones, as well as the use of all SGLT-2i regarding DKA appearance (ADA 2018; Garber et al. 2019; Davies et al. 2018; McGuire et al. 2016; Singh and Kumar 2018). Some studies point out to positive effects of empagliflozin and dapagliflozin in cases with the occurrence of major CVD, ASCVD, and CHF deterioration (Arnett et al. 2019; Zelniker et al. 2019; Wiviott et al. 2019; Furtado et al. 2019).

In exceptional circumstances, when it is impossible to control DMT2 with the usual mono/dual/combined therapy, colesevelam (Ooi and Loke 2014) and quick-release bromocriptine (Lopez Vicchi et al. 2016) could be used. Their mechanism in blood sugar lowering is not known; however, the risk of hypoglycemia is low.

Acknowledgments This work is part of the collaboration between the Laboratory of Radiobiology and Molecular Genetics, Vinca Institute of Nuclear Sciences, University of Belgrade, Belgrade, Serbia, Department of Endocrinology and Diabetes, Zemun Clinical Hospital, School of Medicine, University of Belgrade, Belgrade, Serbia, and, Computational Bioscience Research Center (CBRC) at King Abdullah University of Science and Technology (KAUST). Abstract

Accelerated atherosclerosis is a well-known complication of diabetes, and recently the importance of heart failure independent of coronary artery disease has become a focus of research and innovation. A number of recent cardiovascular outcome trials have demonstrated cardiovascular and renal benefits with two novel classes of glucose-lowering drugs: SGLT2 inhibitors and GLP-1 agonists. Work is ongoing to define the underlying mechanisms of these benefits. Interest in demonstrating the cardiovascular safety of older glucose-lowering drugs has also been rekindled. In addition, in the very near future, it is likely that SGLT2 inhibitors will be administered to new patient populations, including those with type 1 diabetes or without diabetes altogether. Efforts in lifestyle management and preventive health continue to be well spent, due to their potential effectiveness and the growing global burden of disease.

Keywords

Heart failure · Diabetes · Cardiovascular outcome trial · SGLT2 inhibitor · GLP-1 agonist

Introduction

Type 1 and 2 diabetes mellitus, referred to hereafter as simply "diabetes," is a major worldwide health issue (Williams 2019). Cardiovascular disease is a well-documented complication and a leading cause of death in these patients (Williams 2019; Grant and Cosentino 2019; Brochu and Chan 2019). Historically, efforts to reduce adverse cardiovascular endpoints have focused on atherosclerotic outcomes, such as myocardial infarction, stroke, and peripheral vascular disease. It is important to recognize that heart failure represents a large burden of disease in patients with diabetes, and is frequently a presenting diagnosis (Shah et al. 2015). The clinical courses of diabetes and heart failure are intertwined: diabetes is known to cause heart failure through a number of mechanisms; however, heart failure can also be a risk factor for the development of type 2 diabetes (Grant and Cosentino 2019).

Diabetes is recognized as a heterogenous disease, and approximately 90% of the patients have type 2 diabetes (Grant and Cosentino 2019). Patients with type 1 diabetes have an absolute deficiency of insulin, and at least early in their disease experience are less subject to the complications of insulin resistance. These patients tend to be younger and are often more motivated: they readily adopt new technology such as insulin pumps and continuous blood glucose monitors (American Diabetes Association 2019a). Glycemic control is of the utmost importance for the prevention of microvascular complications, as patients with type 1 diabetes are faced with a disease experience that is often two to three decades longer than their counterparts with type 2 diabetes.

Adverse cardiovascular outcomes are related to glycemic control and length of diabetes diagnosis (Grant and Cosentino 2019). Patients with type 2 diabetes have a disease course which is dominated by insulin resistance and its subsequent complications. There are frequently comorbid conditions that must be considered when developing appropriate prevention and treatment strategies. Regardless, all patients with diabetes mellitus should benefit from dedicated preventative efforts to reduce the risk of developing or worsening cardiovascular disease.

Over the last 30 years, the target glycated hemoglobin (HbA1c) and the glucose-lowering drugs (GLDs) available for clinical use have changed considerably. The curve of cardiovascular events and glycemic control has been defined as U-shaped by several studies that demonstrated worse outcomes with very aggressive HbA1c targets (The Action to Control Cardiovascular Risk in Diabetes Study Group 2008; Duckworth et al. 2009). Several agents have also been

independently associated with adverse cardiovascular events, leading regulatory bodies to impose safety restrictions on the approval of new GLDs (Gerstein et al. 2006; Home et al. 2009; Nissen and Wolski 2007). This requirement has led to the publication of a number of cardiovascular outcome trials (CVOTs) in the last 5 years, including several landmark publications that unexpectedly showed significant benefit with novel GLDs (Zinman et al. 2015; Marso et al. 2016a; Neal et al. 2017; Wiviott et al. 2019). For this reason, the landscape of diabetes and heart failure is rapidly changing.

Cardiovascular Disease Profiles

Heart failure is also a heterogenous disease with at least two well-recognized phenotypes. Heart failure with reduced ejection fraction (HFrEF) is the most intuitive, and is defined by left ventricular systolic dysfunction with a left ventricular ejection fraction (LVEF) of less than 40% (Grant and Cosentino 2019). Ischemic heart disease is felt to be the commonest etiology of HFrEF in patients with diabetes due to accelerated, diffuse and often silent coronary artery disease (Grant and Cosentino 2019). Heart failure with preserved ejection fraction (HFpEF) is defined by symptoms of heart failure with LVEF greater than 50% (Grant and Cosentino 2019). Some guidelines advocate for additional parameters, such as left atrial enlargement or evidence of diastolic dysfunction on echocardiography (Grant and Cosentino 2019). Though there remains debate regarding the precise definition, diabetic cardiomyopathy is an entity postulated to be responsible for these changes, through fibrosis and elevated left ventricular mass in the absence of hypertension or other conditions of increased afterload (Connelly et al. 2018; Dunlay et al. 2019; Verma and McMurray 2018). Some authors advocate for the use of the term "heart failure" with mid-range ejection fraction (HFmrEF) to define patients with symptoms of heart failure and a LVEF between 40 and 49%, though this has not yet been widely adopted (Grant and Cosentino 2019).

Guidelines for Primary and Secondary Prevention of Cardiovascular Disease in Diabetes

Accelerated atherosclerosis is a well-known complication of diabetes and recently the importance of heart failure independent of coronary artery disease has become a focus of research and innovation. Many complications seen with diabetes are irreversible owing to their involvement of micro- or macrovasculature; this highlights the importance of prevention in the management of complications of diabetes. Owing to the evolving landscape of diabetes management, many national and international organizations have published updated clinical practice guidelines (Grant and Cosentino 2019; Connelly et al. 2018; American Diabetes Association 2019b), not overlooking lifestyle measures (Grant and Cosentino 2019; American Diabetes Association 2019c; Sigal et al. 2018; Wharton et al. 2018).

Physical Activity

Physical activity is important in both primary and secondary prevention of cardiovascular disease in patients with diabetes. It has been shown to improve glycemic control, reduce insulin resistance, lower blood pressure, and contribute to weight loss (Grant and Cosentino 2019; American Diabetes Association 2019c; Sigal et al. 2018). Adults with diabetes should participate in a minimum of 150 min per week of moderate intensity activity (Grant and Cosentino 2019; American Diabetes Association 2019c; Sigal et al. 2018). Aerobic activity should be divided into sessions of at least 10 min duration, with the goal of amassing 30 min or more of activity on most days of the week (Grant and Cosentino 2019; American Diabetes Association 2019c; Sigal et al. 2018). Improvements in insulin resistance are best maintained if there are not more than 2 days between scheduled physical activity (American Diabetes Association 2019c). It has been suggested that prolonged periods of sedentary activity be briefly interrupted by standing or

performing a physical task approximately every 30 min; wearable fitness accessories may provide helpful reminders (American Diabetes Association 2019c). Patients with diabetes also benefit from resistance and flexibility training, and are encouraged to incorporate this into their planned activity two or three times per week (American Diabetes Association 2019c; Sigal et al. 2018). It is reasonable to suggest that patients considering resistance training obtain expert instruction to avoid injury (American Diabetes Association 2019c).

Weight Loss

Loss of 5% or more of total body weight will lead to a significant reduction in insulin resistance and an improvement in blood pressure control (Wharton et al. 2018).

Smoking Cessation

Smoking is an independent risk factor for cardiovascular disease. Smoking cessation should be encouraged, and assistance should be provided to all patients who use tobacco (Grant and Cosentino 2019; Stone et al. 2018).

Blood Pressure

Blood pressure screening and control are important for both primary and secondary prevention of cardiovascular disease in patients with diabetes (Grant and Cosentino 2019; American Diabetes Association 2019b; Tobe et al. 2018). With the heterogeneity of data available, there is some variation in the suggested blood pressure targets in various published guidelines (Grant and Cosentino 2019; American Diabetes Association 2019b; Tobe et al. 2018). A blood pressure target of $<$130/80 mmHg is generally recommended in patients with diabetes, provided it can be achieved safely and with few adverse effects (Grant and Cosentino 2019; Tobe et al. 2018). In patients over the age of 65, more conservative targets may be appropriate (Grant and Cosentino 2019). Some groups advocate for a blood pressure target of 140/90 mmHg in most patients with diabetes, reserving the blood pressure target of 130/80 mmHg for higher-risk individuals, including secondary prevention (American Diabetes Association 2019b). It is recommended that antihypertensive therapy be targeted to home or ambulatory blood pressure readings, as these are felt to be more representative of a patients' true blood pressure than office-based measurements (Grant and Cosentino 2019; American Diabetes Association 2019b; Tobe et al. 2018). For patients in whom lifestyle modifications are not sufficient to achieve the desired blood pressure, angiotensin receptor blockers (ARB), angiotensin converting enzyme inhibitors (ACEi), and non-dihydropyridine calcium channel blockers have evidence for reducing cardiovascular endpoints in patients with diabetes (Grant and Cosentino 2019; Tobe et al. 2018).

Antiplatelet Therapy

At the present time, there is insufficient evidence to recommend antiplatelet therapy for the primary prevention of cardiovascular disease in all patients with diabetes (Stone et al. 2018). Daily low-dose acetylsalicylic acid has not been shown to reduce the rates of key cardiovascular endpoints in diabetics who are deemed low risk, and has been demonstrated to significantly increase the rate of gastrointestinal bleeding (Stone et al. 2018). In patients with and without diabetes, guidelines continue to advocate for antiplatelet therapy for the secondary prevention of cardiovascular disease; however, this is largely on the basis of treatment of coronary artery disease (Stone et al. 2018).

Lipid-Lowering Therapy

Lipid-lowering therapy plays a key role in the prevention and treatment of cardiovascular disease in patients with diabetes (Grant and Cosentino 2019; American Diabetes Association

2019b; Stone et al. 2018). Of the agents available for clinical use, HMG-CoA reductase inhibitors (statins) have the largest body of evidence (Grant and Cosentino 2019; Stone et al. 2018). High-intensity statin therapy is generally recommended for primary prevention in patients with diabetes over the age of 40 (American Diabetes Association 2019b; Stone et al. 2018). In patients under 40, guidelines generally endorse the use of moderate- to high-intensity statin therapy in the presence of multiple additional risk factors, a long duration of diabetes, or signs of other end-organ damage attributable to diabetes (Stone et al. 2018). Statin therapy is strongly recommended for secondary prevention of atherosclerotic cardiovascular disease, in all patients with diabetes (American Diabetes Association 2019b; Stone et al. 2018).

In patients who do not achieve a target low-density lipoprotein cholesterol (LDL-C) of less than 1.8 mmol/L, addition of ezetimibe 10 mg daily is recommended (American Diabetes Association 2019b; Stone et al. 2018; Cannon et al. 2015). Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors are the newest and most potent lipid-lowering therapy available (evolocumab, alirocumab), though their role specifically in patients with diabetes remains to be defined (Grant and Cosentino 2019). PCSK9 inhibitors are currently indicated in patients who are unable to tolerate statins or achieve target LDL-C on combination therapy with a statin and ezetimibe (Stone et al. 2018). There is less evidence of a direct benefit of lipid-lowering on heart failure; however, prevention of epicardial and microvascular coronary disease is key in preventing development and progression of left ventricular dysfunction, and therefore felt by the authors to be important in the management of patients with diabetes.

Glucose-Lowering Drugs and Cardiovascular Disease

Insulin

Insulin has prothrombotic and inflammatory effects mediated by mitogen-activated protein kinase (MAPK), and antithrombotic effects mediated by phosphatidylinositol 3-kinase (PI3K) (Dongerkery et al. 2017). It has been demonstrated that PI3K-mediated effects are blunted in states of insulin resistance, theoretically causing excess insulin to induce a prothrombotic state (Dongerkery et al. 2017). In addition, it has been observed that the inflammatory vascular changes in diabetes and the metabolic syndrome, termed endothelial dysfunction, cannot be corrected by achieving tight glycemic control alone (Dongerkery et al. 2017). Therefore, in type 2 diabetes insulin use can be used as a surrogate marker for more significant insulin resistance and endothelial dysfunction; however, it has not been mechanistically linked to adverse outcomes from the metabolic syndrome (Dongerkery et al. 2017). This suggests that it is the underlying disease process, rather than exogenous insulin use, that is responsible for cardiovascular outcomes.

A longer duration of diabetes must be recognized as a confounder, as it has been associated with an increased likelihood of requiring insulin therapy and experiencing adverse cardiovascular outcomes (Dongerkery et al. 2017). To mitigate this effect, as well as other confounders associated with the metabolic syndrome, it is useful to consider patients with type 1 diabetes. In the landmark Diabetes Control and Complications Trial (DCCT), there were few cardiovascular events due to the young age of the patients studied and the relative paucity of comorbid medical conditions; however, a 10-year follow-up study was able to demonstrate a 42% reduction in a composite cardiovascular endpoint in those treated with intensive insulin therapy, compared with conventional twice-daily insulin (The Diabetes Control and Complications Trial Research Group 1993; The Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) Study Research Group 2005). The HbA1c was 0.5% higher in patients who experienced a cardiovascular endpoint, and this difference met statistical significance (The Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) Study Research Group 2005).

More recent data from the Outcome Reduction with the Initial Glargine Intervention (ORIGIN) trial suggests that the addition of low-dose insulin glargine does not increase the risk of composite major adverse cardiovascular endpoints (MACE), when compared with standard care. The very large ORIGIN randomized clinical trial reported that cardiovascular outcomes among those who received basal insulin glargine were no better than among patients who received standard care, including those with impaired fasting glucose, impaired glucose tolerance, or early type 2 diabetes (Gerstein et al. 2012). Further to this, ultra-long-acting insulin degludec was non-inferior to insulin glargine for MACE in an RCT of patients with established type 2 diabetes (Marso et al. 2017).

Prevention of Hypoglycemia

Patients who have concomitant medical comorbidities are at higher risk of serious hypoglycemia. Historically, insulin therapy has been felt to be the agent with the highest potential risk of hypoglycemia, and this effect is potentiated by more intensive regimens (The Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) Study Research Group 2005). Basal-only insulin is felt to confer the lowest risk of hypoglycemia, and recent studies of ultra-long acting insulin degludec demonstrate fewer symptomatic and blood glucose–confirmed hypoglycemic events than insulin glargine (Marso et al. 2017; Heller et al. 2019). In addition to the challenge of clinical management, major hypoglycemic events may be associated with as much as a two-fold increase in adverse cardiovascular outcomes, and should be avoided (Goto et al. 2013).

The authors prefer to use glucose-lowering drugs with proven cardiovascular benefit as first- and second-line choices, reserving insulin for those with difficult to manage hyperglycemia and with type 1 diabetes. In patients with type 2 diabetes who require insulin, we suggest long- or ultra-long acting basal insulin, and the involvement of a multidisciplinary team for comprehensive diabetes management.

Metformin

Metformin is a biguanide that has been used in the management of type 2 diabetes for decades (Rena et al. 2017). Despite its years of clinical use, researchers and clinicians have recently become more aware of the complex and incompletely understood mechanisms of action, including decreased hepatic gluconeogenesis, modulation of intestinal absorption, and reduced insulin resistance (Rena et al. 2017). Metformin is a preferred glucose-lowering drug due to its efficacy, weight neutrality, and low likelihood of inducing serious hypoglycemic events. Historically, there has been concern regarding the risk of lactic acidosis in patients receiving metformin which has limited its use in patients with multiple comorbidities, especially chronic kidney disease (Grant and Cosentino 2019). In a large, observational trial of patients hospitalized with heart failure, metformin has been shown to reduce the risk of all-cause mortality when compared to sulfonylurea or insulin monotherapy (Andersson et al. 2010).

In a recent retrospective cohort study of patients with type 2 diabetes and reduced renal function, metformin monotherapy was found to result in fewer adverse cardiovascular endpoints than sulfonylurea monotherapy (Roumie et al. 2019). Overall, metformin is a recommended glucose-lowering drug in patients with type 2 diabetes and an estimated glomerular filtration rate of greater than 30 mL/min. In patients with a new diagnosis of type 2 diabetes and at high cardiovascular risk, recent international guidelines have advocated that glucose-lowering drugs with demonstrated cardiovascular benefit, such as SGLT2i, be started preferentially over metformin, reserving metformin for patients who do not achieve target HbA1c on monotherapy (Grant and Cosentino 2019).

Sulfonylureas

Along with metformin and insulin, sulfonylureas are the oldest effective glucose-lowering drugs that remain on the market in North America.

These agents act by inhibiting K_{ATP} channels on the cell membrane of pancreatic beta cells, thereby stimulating insulin release (Wexler 2019). Owing to this mechanism of action, sulfonylureas are susceptible to causing hypoglycemic events and this is observed with relative frequency in clinical practice (Wexler 2019). An added consideration is that many sulfonylureas are renally excreted, increasing their potential to cause hypoglycemia in patients with concomitant renal dysfunction.

Early trials with the sulfonylurea tolbutamide showed a 2.5-fold increase in cardiovascular mortality and for this reason, sulfonylureas continue to display a special warning on increased risk of cardiovascular mortality mandated by regulatory bodies (Pfizer Inc 2009). Overall, historical data have been equivocal regarding the cardiovascular safety of other sulfonylureas. Recently, the long-acting sulfonylurea glimepiride was compared to linagliptin, a DPP-4 inhibitor which will be discussed later in this chapter, in an RCT (Rosenstock et al. 2019). Glimepiride was found to be non-inferior to linagliptin for MACE as well as the prespecified secondary outcome hospitalization for heart failure, though it was significantly less effective at meeting and maintaining HbA1c targets (Rosenstock et al. 2019).

It has been proposed that this data can be taken in concert with the findings of a second RCT which compared linagliptin to placebo, to suggest that glimepiride has effective non-inferiority to placebo for adverse cardiovascular outcomes (Wexler 2019; Rosenstock et al. 2019; Martin et al. 2019). While these data do imply the cardiovascular safety of the sulfonylurea glimepiride, the authors of this chapter are reluctant to accept that it is non-inferior to linagliptin based on the comparison of two separate study populations. Additionally, recent registry data suggest that adverse cardiovascular outcomes are more prevalent with sulfonylurea monotherapy as compared with metformin monotherapy (Roumie et al. 2019). With the advent of new glucose-lowering drugs with enhanced safety profiles and demonstrable cardiovascular benefit, sulfonylureas have fallen to third- and fourth-line agents (Grant and Cosentino 2019; Connelly et al. 2018). In the opinion of the authors, sulfonylureas should not be used without a compelling justification, such as extreme needle phobia or irremediable financial constraint.

Thiazolidinediones

Thiazolidinediones (TZDs) are potent glucose-lowering drugs that act by activating the gamma isoform of the peroxisome proliferator-activated receptor (PPARg) and modulating the transcription of several genes involved in glucose and lipid handling (Hauner 2002). They were quickly adopted into clinical practice due to their efficacy and modest patient-reported side effect profile. As the use of TZDs increased, a signal toward increased major adverse cardiovascular outcomes was noted (Nissen and Wolski 2007). An RCT of patients with impaired fasting glucose and/or impaired glucose tolerance demonstrated that while rosiglitazone did prevent progression to a diagnosis of diabetes, it was associated with a sevenfold increase in the risk of heart failure (Gerstein et al. 2006). A meta-analysis published in 2007 found a 43% increase in the risk of myocardial infarction in patients receiving rosiglitazone (Nissen and Wolski 2007).

The following year, an RCT of intensive glycemic control with a target HbA1c of <6.0% compared with standard care demonstrated an increase in the risk of death from any cause, death from a cardiovascular cause and non-fatal myocardial infarction; in this trial, 91.2% of participants in the intensive-therapy arm were prescribed rosiglitazone, compared with 57.5% in the standard therapy arm (The Action to Control Cardiovascular Risk in Diabetes Study Group 2008). Notably, there was also a numerical increase in fatal and non-fatal cases of decompensated heart failure in the intensive control group, though this did not reach statistical significance (The Action to Control Cardiovascular Risk in Diabetes Study Group 2008). Finally, in a randomized, open-label study of patients treated with metformin and a sulfonylurea, the addition of rosiglitazone was found to increase

the risk of hospitalization or death from heart failure more than twofold despite no increase in all-cause mortality (Home et al. 2009). The findings of these studies led regulatory bodies to place warnings and restrictions on the use of rosiglitazone. The authors of this chapter discourage the clinical use of TZDs.

Dipeptidyl Peptidase-4 Inhibitors

Dipeptidyl peptidase-4 (DPP-4) is an enzyme responsible for degradation of the endogenous incretins glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP) (Nauck et al. 2017). DPP-4 inhibitors selectively inhibit this enzyme, potentiating the effect of endogenous incretins and thus the effect of insulin secretion (Nauck et al. 2017). This class of medications had its cardiovascular safety examined by RCTs years after the first agent, sitagliptin, was approved for clinical use. The first of these trials in 2013 assessed saxagliptin in patients with type 2 diabetes, with or at high proximate risk for cardiovascular disease (Scirica et al. 2013). Saxagliptin was found to be non-inferior to placebo for MACE; however, there was a 1.27-fold increase in the rate of hospitalization for heart failure (HHF) (Scirica et al. 2013). Alogliptin was assessed in an RCT of patients post-myocardial infarction and found to be non-inferior for MACE; however, death or hospitalization from heart failure was not reported (White et al. 2013). For these reasons the authors do not recommended saxagliptin or alogliptin in patients with or at risk for heart failure.

Sitagliptin was found to be non-inferior to placebo for MACE in an RCT of patients with type 2 diabetes and established cardiovascular disease (Green et al. 2015). Importantly, there was no increase in the rate of HHF with sitagliptin therapy (Green et al. 2015). In a 2018 RCT, linagliptin was shown to be non-inferior to placebo for MACE and HHF in patients with type 2 diabetes and high cardiovascular risk (Martin et al. 2019). Sitagliptin and linagliptin appear to be neutral in their effect on MACE and HHF, and as such the authors recommend these agents when clinically indicated, as an adjunct to agents with proven cardiovascular benefit.

Sodium Glucose Cotransporter 2 (SGLT2) Inhibitors

Sodium glucose cotransporter 2 (SGLT2) is a member of a family of glucose-sodium cotransporters that relies on a sodium gradient established by the Na/K ATPase within the cell membrane (Kalra 2014). SGLT2 is concentrated in the proximal convoluted tubule of the nephron and is responsible for the majority of the reabsorption of renally-filtered glucose, approximately 350 mg/min (Kalra 2014). SGLT2 inhibitors act by selectively blocking this cotransporter, therefore promoting glycosuria and lowering plasma levels of glucose (Kalra 2014). Though modest in reduction of HbA1c, SGLT2 inhibitors are attractive due to a low risk of major hypoglycemia, and effective weight neutrality (Zinman et al. 2015; Neal et al. 2017; Wiviott et al. 2019).

The first Cardiovascular Outcome Trial (CVOT) to demonstrate superiority of a GLD over placebo was empagliflozin, cardiovascular outcomes and mortality in type 2 diabetes (EMPA-REG OUTCOME), published in 2015 (Zinman et al. 2015). Patients with established cardiovascular disease were randomized to receive empagliflozin or placebo (Zinman et al. 2015). Empagliflozin was found to be superior to placebo for MACE and key prespecified secondary endpoints, including HHF and all-cause mortality (Zinman et al. 2015). There was no increase in major adverse outcomes, although an increase in genital infections in both male and female patients was noted (Zinman et al. 2015). In the Canagliflozin and Cardiovascular and Renal Events (CANVAS) trial, an RCT of patients with type 2 diabetes with or at high risk for cardiovascular disease, canagliflozin was superior to placebo for MACE and HHF; however, it was non-inferior to placebo for cardiovascular death and all-cause mortality (Neal et al. 2017).

Lower Limb Amputation

In addition to increasing the risk of genital infections, treatment with canagliflozin was shown to increase the risk of amputation, and this has since been adopted as a safety parameter for trials of new glucose-lowering drugs (Neal et al. 2017). In the Dapagliflozin and Cardiovascular Outcomes (DECLARE–TIMI 58) trial, an RCT of patients with type 2 diabetes with or at high risk for cardiovascular disease, dapagliflozin was non-inferior to placebo for MACE and superior in the composite endpoint of prevention of cardiovascular death or HHF (Wiviott et al. 2019). An RCT assessing the cardiovascular outcomes with the use of ertugliflozin is underway at the time of writing. It has been postulated that the difference in cardiovascular outcomes observed in the three published CVOTs relates to the patient populations studied, with empagliflozin being assessed only in patients with established cardiovascular disease.

A recent meta-analysis of these trials demonstrated that the superiority for MACE was present only in patients with prior cardiovascular disease. However it confirmed that SGLT2 inhibitors reduced the risk of cardiovascular death or hospitalization for HHF, irrespective of previously diagnosed atherosclerotic cardiovascular disease (Zelniker et al. 2019a). While there was a numerical difference in the composite of HHF or cardiovascular death, it did not reach statistical significance in patients without established cardiovascular disease (Zelniker et al. 2019a).

Involved Pathways

There have been a number of postulated mechanisms for the improvement in cardiovascular outcomes observed with SGLT2 inhibitors. The most widely accepted and intuitive mechanism is an improvement in ventricular loading conditions, caused by the diuretic effects of these medications (Verma and McMurray 2018). Unlike classical diuretics, SGLT2 inhibitors cause glycosuria and osmotic diuresis in addition to natriuresis, assisting in the removal of extravascular fluid with less intravascular volume depletion and compensatory tachycardia; this may also optimize the abnormal pressure-volume relationship in the diabetic heart (Verma and McMurray 2018; Bertero et al. 2018). A second well-supported mechanism is based on an improvement in the bioenergetics of the diabetic heart. In patients with diabetes or heart failure, the heart is less able to utilize various energy sources, and comes to rely on the metabolism of free fatty acids (Verma and McMurray 2018; Bertero et al. 2018). In addition to being a less efficient source of ATP production, the accumulation of free fatty acid intermediates may contribute to diastolic dysfunction (Verma and McMurray 2018; Lopaschuk et al. 2010).

SGLT2 inhibitors induce a mild hyperketonemic state, similar to a period of fasting, increasing the production and myocardial uptake of the ketone b-hydroxybutyrate (Bertero et al. 2018). This ketone has similar energy efficiency to glucose and is not known to produce toxic intermediates or metabolites (Verma and McMurray 2018; Bertero et al. 2018). A third developing hypothesis is that SGLT2 inhibitors may slow the process of myocardial fibrosis through direct effects on cardiac fibroblast phenotype and function (Verma and McMurray 2018). In a recent RCT, empagliflozin was associated with a small reduction of left ventricular mass when compared with placebo, in patients with type 2 diabetes and coronary artery disease (Verma et al. 2019). Encouraging data exist in animal and in vitro models with human cardiac fibroblasts, and may help explain the cardiovascular benefits of SGLT2 inhibitors in patients without diabetes or hyperglycemia (Verma and McMurray 2018).

There are also a number of proposed mechanisms of cardiovascular benefit that are less well defined. SGLT2 inhibitors may modulate cytosolic and mitochondrial calcium concentrations in cardiac myocytes through inhibition of a Na^+/H^+ exchanger; however, the mechanism remains to be defined, as SGLT2 is not expressed in the human heart (Verma and McMurray 2018). SGLT2 inhibitors may also reduce inflammation and endothelial dysfunction through modulation of adipokines (Verma and McMurray 2018). Research is ongoing to determine if these mechanisms may be utilized in the

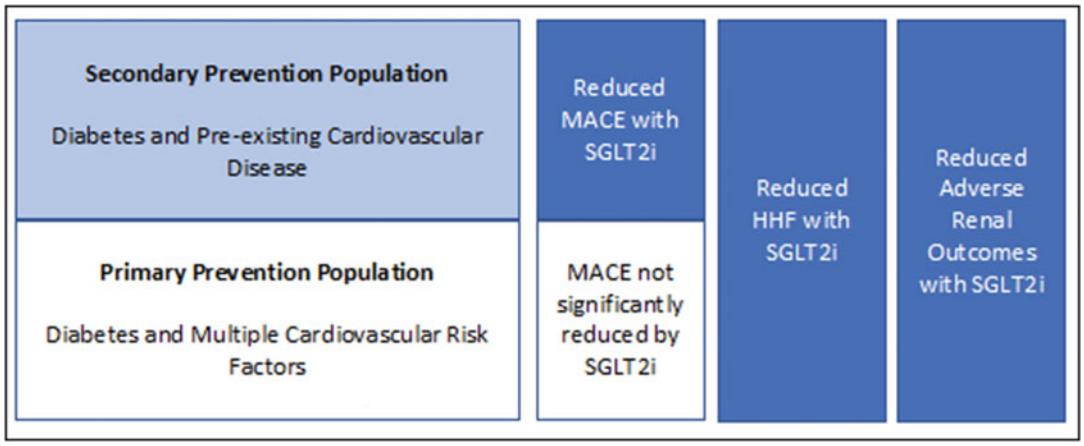

Fig. 53.1 The effect of SGLT2 inhibitors (SGLT2i) on major adverse cardiovascular outcomes (MACE), hospitalization for heart failure (HHF), and adverse renal outcomes, stratified by primary versus secondary prevention

development of novel pharmaceutical agents (Fig. 53.1).

The authors recommend the use of SGLT2 inhibitors in most patients with type 2 diabetes in the absence of contraindications.

GLP-1 Agonists

GLP-1 is an incretin which lowers plasma glucose by enhancing the secretion of endogenous insulin in a glucose-dependent manner (Boyle et al. 2018). This action results in a low risk of major hypoglycemia when mimicked exogenously (Boyle et al. 2018).

In Liraglutide and Cardiovascular Outcomes (LEADER) trial, the first CVOT of a GLP-1 agonist, liraglutide was compared to placebo in patients with type 2 diabetes, with or at high risk for cardiovascular disease (Marso et al. 2016a). Liraglutide was superior to placebo for MACE and all-cause mortality; there was a signal for a decrease in HHF, but this did not reach statistical significance (Marso et al. 2016a). Parenteral semaglutide was superior to placebo for MACE in an RCT of patients with established cardiovascular disease, chronic kidney disease, or both (Marso et al. 2016b). Semaglutide was non-inferior to placebo for HHF and all-cause mortality (Marso et al. 2016b).

The largest CVOT of a GLP-1 agonist compared once-weekly exenatide to placebo patients with type 2 diabetes, with or at high risk of cardiovascular disease (Holman et al. 2017). Exenatide was found to be non-inferior to placebo for MACE and HHF, but did demonstrate a statistically significant reduction in all-cause mortality (Holman et al. 2017). While most trial data exist for parenteral formulations of GLP-1 agonists, a CVOT has recently been completed for an oral formulation of semaglutide (Husain et al. 2019). This agent was shown to be non-inferior to placebo for MACE and HHF, and superior for all-cause mortality (Husain et al. 2019). As a principal limitation of prior agents has been the parenteral route of administration, this formulation of semaglutide has the potential to significantly expand the role of GLP-1 agonists, and is likely to encourage further drug development.

Multiple Cardiovascular Effects

GLP-1 agonists affect multiple organ systems in addition to the pancreas. These agents have been shown to decrease blood pressure, increase heart rate, and enhance myocardial contractility through molecular mechanisms that have not yet been defined (Boyle et al. 2018; Kalra et al. 2016). They may also play a role in reducing vascular inflammation (Boyle et al. 2018). The

interplay of these mechanisms in high-risk individuals is a postulated mechanism for the improvements seen in the CVOTs of GLP-1 agonists. These agents also slow gastric emptying, modify glucagon secretion, and enhance renal natriuresis (Boyle et al. 2018; Kalra et al. 2016).

Can Renal Complications Be Mitigated?

Diabetes mellitus is the worldwide leading cause of end-stage renal disease (ESRD) (Perkovic et al. 2019). While many patients with diabetes succumb to cardiovascular disease before developing ESRD, it has been recognized for some time that there are important overlaps in the therapies for these conditions. Blockade of the renin-angiotensin-aldosterone system (RAAS) has long been recognized as a cornerstone of therapy in patients with HRrEF; randomized trial data, such as the Reduction of endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) study, has also demonstrated that RAAS blockade reduces progression to ESRD among patients with type 2 diabetes (Brenner et al. 2001). Similarly, lipid-lowering therapy with statins has shown benefit in managing both conditions (Grant and Cosentino 2019).

Several of the recent CVOTs have demonstrated an improvement in renal endpoints, and this finding has led to the development of several renal outcome–focused trials of SGLT2 inhibitors (Zinman et al. 2015; Neal et al. 2017; Wiviott et al. 2019). The recent Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE), focusing on cases with albuminuria and significant renal disease (GFR less than 90 ml per/min/per 1.73 $m^2$2) randomized to canagliflozin or placebo, was stopped early due to benefit in the primary composite endpoint of progression to ESRD, doubling of serum creatine, or renal or cardiovascular death (Perkovic et al. 2019). This is arguably the first large positive RCT using hard renal clinical endpoints in diabetics with kidney disease.

Other renal outcome–focused trials of empagliflozin and dapagliflozin are ongoing. A systematic review and meta-analysis of SGLT2 inhibitors found a 33% reduction in progression to dialysis, renal transplantation, or death due to kidney disease in over 38,000 patients in RCTs, driven largely by the canagliflozin study that was stopped early (Neuen et al. 2019). When the three major completed SGLT2 inhibitor CVOTs were analyzed, a 45% reduction in the same composite renal endpoint occurred (Zelniker et al. 2019a). Importantly, this benefit was seen in both patients with cardiovascular risk factors and those with established atherosclerotic cardiovascular disease (Zelniker et al. 2019a).

Renal outcomes were also assessed in the major CVOTs of GLP-1 agonists (Zelniker et al. 2019b). In meta-analysis of these trials, GLP-1 agonists were found to reduce a composite renal endpoint by 18%; however, this effect was driven by a reduction in progression to macroalbuminuria (Zelniker et al. 2019b). There was no significant difference in doubling of serum creatinine, progression to ESRD, or death from renal causes with GLP-1 agonists (Zelniker et al. 2019b).

In addition to other good general medical management principles, including blood pressure and lipid control, the authors recommend SGLT2 inhibitor therapy in patients with type 2 diabetes who have established atherosclerotic cardiovascular disease or multiple cardiovascular risk factors, to prevent or limit progression of significant renal disease.

Do Guidelines Exist for Pre-Diabetes?

Hyperglycemia and insulin resistance are recognized as a spectrum of disease; while there is a designated threshold for fasting plasma glucose, oral glucose tolerance or HbA1c to make a diagnosis of diabetes, those with abnormal values below these thresholds remain at an increased risk

of adverse outcomes that is more difficult to define (Grant and Cosentino 2019). For this reason, patients with pre-diabetes should be managed with the same lifestyle recommendations as patients with diabetes. Similarly, these patients should undergo screening for hypertension, dyslipidemia, albuminuria, and electrocardiographic abnormalities, and any abnormalities should be further investigated and managed per guidelines (Grant and Cosentino 2019; American Diabetes Association 2019b; Stone et al. 2018; Tobe et al. 2018). In the management of hypertension specifically, combination therapy with a beta blocker and diuretic should be avoided, as this has been found to increase progression to a diagnosis of diabetes (Grant and Cosentino 2019).

Pharmacotherapy

A number of glucose-lowering drugs have been used to prevent or delay the progression from pre-diabetes to diabetes. Metformin has been shown to reduce the progression to diabetes in patients with impaired fasting glucose or glucose tolerance when compared to placebo, though it was not as effective as intensive lifestyle intervention (Knowler et al. 2002). Rosiglitazone was found to significantly reduce the progression to diabetes, but its use was associated with an unacceptable increase in adverse cardiovascular outcomes (Gerstein et al. 2006). Insulin glargine has been shown to reduce progression to a diagnosis of diabetes in patients with pre-diabetes by 28%, when compared to standard of care, although this is at the cost of a nearly threefold increase in the risk of major hypoglycemia (Gerstein et al. 2012). Administering a glucose-lowering drug is expected to improve indices of glycemic control and, if effective, should prevent a formal diagnosis of diabetes; the clinical relevance of this remains to be defined.

Statins and Pre-diabetes

Arguably, the diagnosis of diabetes is less important than the outcomes of the metabolic abnormalities or therapeutic interventions. For this reason, statin therapy is recommended in patients with elevated cholesterol and high proximate risk of cardiovascular disease, despite increasing the progression to diabetes, though a causal mechanism has not yet been defined (Grant and Cosentino 2019).

Ongoing Studies and Future Perspectives

Antidiabetic Agents in Normoglycemic Patients

With positive findings in the CVOTs of SGLT2 inhibitors and GLP-1 agonists in the last five years, and a number of postulated mechanisms that are independent of hyperglycemia and insulin resistance, there has been increasing interest in utilizing these agents in patients without diabetes. The Dapagliflozin and Prevention of Adverse Outcomes in Heart Failure (DAPA-HF) trial randomized patients with New York Heart Association class II to IV heart failure and a LVEF less than 40%, to dapagliflozin or placebo in addition to standard medical therapy (McMurray et al. 2019). Approximately 42% of patients in each arm had a diagnosis of diabetes mellitus (McMurray et al. 2019). Dapagliflozin was superior to placebo in a composite primary heart failure endpoint, as well as for cardiovascular mortality and all-cause mortality, regardless of whether the patients had diabetes or not. Interestingly, the hazard ratio for the composite primary endpoint was numerically better in patients without diabetes (McMurray et al. 2019). Studies are ongoing with empagliflozin in patients with heart failure with both preserved and reduced ejection fraction. If empagliflozin is shown superior to placebo in patients with heart failure with preserved ejection fraction, it would be one of the first agents to demonstrate benefit in this population.

Non-insulin Glucose-Lowering Agents in Type 1 Diabetes

While insulin is necessary in this patient population, additional agents that can enhance glycemic

control, lower body weight, and perhaps confer cardiovascular benefit are of interest, particularly as cardiovascular disease remains the leading cause of death in patients with type 1 diabetes. While several SGLT2 inhibitors are under review by regulatory bodies for use in type 1 diabetes, none have yet received this indication (Danne et al. 2019). A recent international consensus paper has suggested characteristics of patients with type 1 diabetes who would be ideal candidates for initiation of SGLT2 inhibitor therapy based on a lower overall risk of diabetic ketoacidosis, the most concerning adverse effect of these medications (Danne et al. 2019). From the perspective of the cardiovascular specialist, SGLT2 inhibitor use in this population is attractive, if the potential risks of therapy can be mitigated.

Abstract

Cardiovascular disease (CVD) in the diabetic patient is both widespread and fatal in nature. In the United States, roughly two-thirds of deaths in diabetic patients are due to CVD. In addition to the increased morbidity and mortality of CVD in a patient with diabetes, the impact of this comorbidity on health care expenditure is staggering. Unfortunately, researches on the effects of strict glycemic control on cardiovascular (CV) events have been unable to demonstrate a conclusive benefit, despite improvement for microvascular complications. Newer glycemic agents, specifically the glucagon-like peptide-1 receptor agonists (GLP-1 RA) and sodium-glucose cotransporter-2 (SGLT-2) inhibitors, have shown much more promising cardioprotective properties, and are valuable as an add-on therapy for patients who do not reach their hemoglobin A1c goal on metformin alone. Most of the drugs in GLP-1 RA and SGLT-2 inhibitor class have shown strong cardioprotective effects in well-designed cardiovascular outcome trials and all of them have demonstrated CV safety. Multiple SGLT-2 inhibitors have shown renal protective effects as well as prevent hospitalization for heart failure and hence, should be preferred over GLP-1 RAs in patients with concurrent T2DM and heart failure or CKD.

Introduction

No single diabetes comorbidity is more prevalent than cardiovascular disease (CVD). In a 2019 study by the International Diabetes Federation (IDF), it is estimated that 463 million adults between the ages of 20 and 79 years have diabetes mellitus, accounting for roughly 9.3% of the adult population (International Diabetes Federation 2019). Of those that have type 2 diabetes (T2DM), roughly 32.2%, or more than 134 million people, are also affected by CVD (Einarson et al. 2018a). The relationship between CVD and T2DM is not simply associative, but also predictive in nature. A meta-analysis of 102 prospective studies conducted by the Emerging Risk Factors Collaboration found that when compared to nondiabetics, those with diabetes have an adjusted hazard ratio (HR) of almost 2 for coronary heart disease, ischemic stroke, unclassified stroke, and deaths from vascular diseases (Collaboration TERF 2010). Furthermore, the age of occurrence of CVD in the diabetic population is unique, occurring 14.6 years earlier than in a patient with CVD alone (Booth et al. 2006).

Elevated Morbidity and Mortality

Cardiovascular disease in the diabetic patient is both widespread and fatal in nature. In the United States, roughly two-thirds of deaths in diabetic patients are due to CVD (Wang et al. 2016). Of these deaths, approximately 40% are due to ischemic heart disease and 10% to stroke (Wang et al. 2016). In diabetic patients with CVD hospitalization is also very common, with CVD accounting for 20% of hospital inpatient days spent by all diabetic patients regardless of CVD status in 2012 (American Diabetes Association 2013). When compared to all the chronic complications of diabetes, CVD accounts for roughly 46% of inpatient hospital days, 43.7% of physician office visit, and 38.2% of emergency department visits (American Diabetes Association 2013).

Heavy Financial and Social Burden

CVD is estimated to account for 27% of the total cost of treating diabetes in the United States, which is projected to be 294.6 billion in 2019 (International Diabetes Federation 2019; American Diabetes Association 2013). For an individual with T2DM, CVD greatly increases their

individual health care expenditure. A systemic review conducted by Einarson et al. revealed that a type 2 diabetic with CVD has an average health care cost of 112%, or almost $7000, more than a type 2 diabetic without CVD complications (Einarson et al. 2018b). Due to the significant morbidity, mortality, and health care expenditure related to CVD in the diabetic patient, much research has been conducted on the effect of glycemic control on CVD. Unfortunately, researches on the effects of strict glycemic control on cardiovascular (CV) events have been unable to demonstrate a conclusive impact, despite clear benefit to microvascular complications (Kant et al. 2019).

Better Therapeutic Screening

The uncertainty of these results led many researchers to begin looking at the impact of specific glucose-lowering pharmacotherapies on CVD. This research strategy was rewarded when Nissen et al. demonstrated a 43% increased risk of myocardial infarction in patients treated with rosiglitazone (Nissen and Wolski 2007). The results of this experiment not only prompted the United States Food and Drug Administration (US FDA) in 2008 to request CV outcome data for approval of all new drugs used to treat diabetes, but also sparked the interest of researchers to collect CV outcome data on glucose-lowering therapies that were currently being used (https://www.fda.gov/regulatory-information/search-fda-guidance-documents/diabetes-mellitus-developing-drugs-and-therapeutic-biologics-treatment-and-prevention). Metformin was found to be associated with cardioprotective properties; however, many glycemic agents were found to not have the positive effect on CV outcomes that was previously expected (Aldossari 2018). For example, pioglitazone, a thiazolidinedione, has been proven to reduce major adverse CV events, but increases the risk of heart failure (Sesti et al. 2018). Furthermore, two of the dipeptidyl peptidase 4 (DPP-4) inhibitors, saxagliptin and alogliptin, were also found to have the potential to increase the risk of heart failure, and sulfonylureas have been linked to an increased risk of cardiovascular events (Aldossari 2018; Sesti et al. 2018).

Glucagon-like peptide-1 receptor agonists (GLP-1 RA) and sodium-glucose cotransporter-2 (SGLT-2) inhibitors provide much more promising cardioprotective properties, and are valuable as an add-on therapy for patients who do not reach their hemoglobin A1c (A1c) goal on metformin alone (Kant et al. 2019). Therefore, it is imperative for clinicians to be aware of GLP-1 RA and SGLT-2 inhibitor's impact on adverse CV outcomes in patients with concurrent T2DM and CVD.

Glucagon-like Peptide-1 Receptor Agonists (GLP-1 RAs) and Sodium-Glucose Cotransporter-2 (SGLT-2) Inhibitors

GLP1 receptor agonists, which include drugs such as include lixisenatide, liraglutide, dulaglutide, semaglutide, and exenatide, mimic the intestinal secreted incretin hormone responsible for nutrient ingestion. By doing so, GLP-1 acts in a myriad of ways, including stimulating glucose-dependent insulin secretion and decreasing gastric emptying. GLP-1RAs are advisable if weight loss is the goal, but are associated with increased risk of pancreatitis, nausea, and diarrhea. This makes this class of glycemic agents ill-advised for a patient dealing with malnutrition or cachexia (Sesti et al. 2018). SGLT-2 inhibitors, which include drugs such as empagliflozin, canagliflozin, ertugliflozin, and dapagliflozin, act in a much different manner by decreasing the glucose reabsorption in the proximal convoluted tubule of the kidney. SGLT-2 inhibitors are limited by significant reduction in estimated glomerular filtration rate (eGFRs) and have been linked to increased risk of urinary and genital infections (Sesti et al. 2018). Both GLP-1 RAs and SGLT-2 inhibitors are valuable in that they do not increase the risk of hypoglycemia. In regard to their cardioprotective properties, the effect of these agents on the rate of major adverse cardiac events (MACE) has been studied (Tables 54.1

Table 54.1 Cardiovascular outcome trials of GLP-1 receptor agonists

CVOT trial/medication	Notable features and results
ELIXA trial/LIXISENATIDE	– Enrolled 6068 patients with T2DM and recent coronary event within 180 days – No significant difference in MACE-4 – A1c reduced by 0.6%, weight by 0.6 kg, systolic BP by 0.8 mmHg, LDL by 1.5 mg/dl and Tg by 1.8 mg/dl
LEADER trial/LIRAGLUTIDE	– Enrolled 9340 patients with T2DM and high CV risks – 13% reduction in MACE – 22% reduction in death from CV causes – 15% reduction in all-cause mortality – A1c reduced by 0.4%, weight by 2.3 kg, systolic BP by 1.2 mmHg, LDL by 1.5 mg/dl, and Tg by 1.8 mg/dl
EXSCEL trial/EXENATIDE	– Enrolled 14,752 patients with T2DM at a wide range of CV risk (27% of patients without known CV disease) – 9% reduction in MACE[a] – 14% reduction in all-cause mortality[b] – A1c reduced by 0.7%, weight by 1.27 kg, systolic BP by 1.57 mmHg, LDL by 1.5 mg/dl and Tg by 1.8 mg/dl
SUSTAIN-6 trial/INJECTABLE SEMAGLUTIDE	– Enrolled 3297 patients with T2DM and established CV disease or with high CV risks – 26% reduction in MACE – 39% reduction in nonfatal stroke – 26% reduction in nonfatal myocardial infarction[c] – 0.5 mg weekly semaglutide group: A1c reduced by 0.7%, body weight by 2.9 kg and systolic BP by 1.3 mmHg – 1 mg weekly semaglutide group: A1c reduced by 1%, body weight by 4.3 kg and systolic BP by 2.6 mmHg
REWIND trial/DULAGLUTIDE	– Enrolled 9901 patients with T2DM with previous CV event or cardiovascular risk – 12% reduction in MACE – 24% reduction in non-fatal stroke – A1c reduced by 0.61%, body weight by 1.46 kg, BMI by 0.53 kg/m2, systolic BP by 1.7 mmHg, total cholesterol by 0.07 mmol/L and LDL by 0.05 mmol/L
PIONEER-6 trial/ORAL SEMAGLUTIDE	– Enrolled 3183 patients with T2DM and high risk of CV events – No significant reduction in MACE – 51% reduction in death from CV cause – 49% reduction in all-cause mortality – A1c reduced by 1.0% and weight by 4.2 kg

[a]Nonsignificant reduction (Hazard Ratio, 0.91; 95% Confidence Interval, 0.83–1.00; $P < 0.001$ for noninferiority and $P = 0.06$ for superiority)
[b]This difference was not considered to be statistically significant on the basis of the hierarchical testing plan
[c]Nonsignificant reduction (Hazard Ratio, 0.74; 95% Confidence Interval, 0.51–1.08; $P = 0.12$)
CVOT cardiovascular outcome trial; *T2DM* type 2 diabetes mellitus; *CV* cardiovascular; *A1c* hemoglobin A1c; *BP* blood pressure; *Tg* triglycerides; *LDL* low density lipoproteins; *MACE* major adverse cardiovascular events, a composite of death from cardiovascular causes, non-fatal myocardial infarction, or nonfatal stroke; *MACE-4* MACE endpoint as above and hospitalization for unstable angina

and 54.2). MACE encompasses composite of death from cardiovascular causes, nonfatal myocardial infarctions, and nonfatal strokes. Results have shown that many GLP-1RAs and SGLT-2 inhibitors are not only CV safe but are also cardioprotective (Kant et al. 2019).

Cardiovascular Impact of Glucagon-like Peptide-1 Receptor Agonists (GLP1-RA)

In the EXSCEL trial 14,752 diabetic patients with or without CV disease were managed with extended-release exenatide (Holman et al. 2017).

Table 54.2 Cardiovascular outcome trials of SGLT-2 inhibitors

CVOT trial/medication	Notable features and results
EMPA-REG OUTCOME trial/ EMPAGLIFLOZIN	– Enrolled 7028 patients with T2DM and established CV disease – 14% reduction in MACE in pooled empagliflozin group – 38% reduction in death from CV causes – 32% reduction in all-cause mortality – 35% reduction in hospitalization for heart failure – 39% reduction in renal outcomes – A1c reduced by 0.24–0.36%
CANVAS trial/ANAGLIFLOZIN	– Enrolled 9734 patients with T2DM and either established CV disease or high risk of CV disease – 14% reduction in MACE – 33% reduction in hospitalization for heart failure – 40% reduction in renal outcomes – A1c reduced by 0.58%, weight by 1.6 kg and systolic BP by 3.93 mmHg
DECLARE-TIMI 58 trial/ DAPAGLIFLOZIN	– Enrolled 17,160 patients with T2DM and with variable CV risks (40.5% with established CV disease) – No significant difference in MACE – 27% reduction in hospitalization for heart failure – 24% reduction in renal outcomes – A1c reduced by 0.42%, weight by 1.8 kg and systolic BP by 2.7 mmHg

CVOT cardiovascular outcome trial; *T2DM* type 2 diabetes mellitus; *CV* cardiovascular; *A1c* hemoglobin A1c; *BP* blood pressure; *MACE* major adverse cardiovascular events, a composite of death from cardiovascular causes, non-fatal myocardial infarction, or nonfatal stroke

Non-inferiority, however not superiority, regarding placebo was demonstrated, as MACE did not significantly change. In this cardiovascular outcome trial (CVOT) the usual care setting was not changed, and subjects with a wide range of CV risks were included. However many subjects in the exenatide group (43%) prematurely discontinued the trial regimen. These and other difficulties notwithstanding, significance was nearly reached for the primary endpoint MACE. Metabolic and clinical variables also positively responded, with the exception of diastolic blood pressure and heart rate, which mildly increased.

Another major trial (LEADER, with 9340 patients) studied 1.8 mg daily injection of liraglutide (Marso et al. 2016a). Among diabetics with elevated cardiovascular risk, MACE effectively diminished, including less CV death by 22%, and less all-cause mortality by 15%. These benefits were documented within the first one and half years of treatment. When compared to the placebo group, the liraglutide group had fewer patients on insulin and oral antidiabetic medication which led to fewer hypoglycemic episodes, fewer number of obese patients (12.6 vs. 15.2%), and fewer number of patients with a baseline A1c >8.3% (13.7 vs. 16.1%). These differences could possibly explain liraglutide's dominance over placebo. With regard to the metabolic outcomes, from baseline to week 36, the LEADER trial showed a mean reduction in A1c by 0.4%, body weight by 2.3 kg, systolic BP by 1.2 mmHg, LDL by 1.5 mg/dl, and Tg by 1.8 mg/dl; however, similar to EXSCEL trial there was a mean increase in diastolic BP by 0.6 mmHg and heart rate by 3 beats/min.

The ELIXA trial [Lixisenatide in patients with type 2 diabetes and acute coronary syndrome] was the first CVOT among the GLP-1 RA's. It was a multicenter, randomized, double-blind, placebo-controlled trial in which 6068 patients with type 2 diabetes who had an acute coronary syndrome within 6 months before screening were randomly assigned to receive either a daily injection lixisenatide or placebo and were followed for a median of 2.1 years (Pfeffer et al. 2015). Lixisenatide achieved non-inferiority in comparison to placebo for the occurrence of MACE-4; primary composite end point of cardiovascular death, myocardial infarction, stroke, or hospitalization for unstable angina; however, it did not achieve superiority. Occurrence of MACE was

similar in lixisenatide and placebo groups. The possible explanation could have been due to enrollment of high-risk patients with recent coronary artery disease and short duration of follow-up. With regard to the metabolic outcomes, from baseline to week 12, the ELIXA trial showed a mean reduction in A1c by 0.6%, body weight by 0.6 kg, systolic BP by 0.8 mmHg, LDL by 1.5 mg/dl, Tg by 1.8 mg/dl, and a mean increase in diastolic BP by 0.6 mmHg and heart rate by 0.4 beats/min.

The SUSTAIN-6 trial [Semaglutide and Cardiovascular Outcomes in Patients with Type 2 Diabetes] was a multicenter, randomized, double-blind, placebo-controlled parallel group trial in which 3297 patients with type 2 diabetes with established CV disease were randomly assigned to receive either the weekly injection of Semaglutide or placebo with a median follow-up of 2.1 years (Marso et al. 2016b). Injectable semaglutide was found to be superior to placebo with 26% relative risk reduction in MACE. Unlike liraglutide, the reduction in MACE with semaglutide was driven by a significant reduction of 39% in nonfatal stroke and a non-significant reduction in nonfatal MI by 26%. Rates of CV death were similar in Semaglutide and control group. Diabetic retinopathy occurred at significantly higher rate in semaglutide-treated patients, with hazard ratio of 1.76. From baseline to week 104, the SUSTAIN-6 trial showed a mean reduction in A1c by 0.7% in the group that received 0.5 mg and 1% with 1 mg weekly semaglutide, a reduction in body weight by 2.9 vs. 4.3 kg according to semaglutide dose, and a mean reduction in systolic BP by 1.3 vs. 2.6 mmHg. Similarly to other GLP-1 RA's CVOT, there was a mean increase in HR by 2 and 2.5 beats/min, depending on semaglutide dose.

The REWIND trial [dulaglutide and cardiovascular outcomes in type 2 diabetes] was a multicenter, randomized, double-blind, placebo-controlled trial in which 9901 patients with type 2 diabetes who had either a previous cardiovascular event or cardiovascular risk factors were randomly assigned to receive either weekly injection of 1.5 mg dulaglutide or placebo, with a median follow-up for 5.4 years (Gerstein et al. 2019). Dulaglutide achieved superiority over placebo in the occurrence of the composite MACE with 12% reduced risk, and this was similar between participants with and without previous CV events. Like the injectable semaglutide, the reduction in MACE was primarily driven by a significant reduction in non-fatal stroke by 24%. There was no significant reduction in CV death and non-fatal MI. It is noteworthy that dulaglutide showed its CV benefits within a year of use. Unlike the other GLP-1 RAs trials, this one had a longer median duration of follow-up (5.4 vs 1.5–3.8 years) which shows that the CV benefits and improvement in metabolic profile by GLP-1 RAs persist for a longer duration than previously reported. Reduction in A1c by 0.61%, body weight by 1.46 kg, BMI by 0.53 kg/m2, systolic BP by 1.7 mmHg, total cholesterol by 0.07 mmol/L, LDL cholesterol by 0.05 mmol/L, and waist-to-hip ratio in men and women was documented. However, there was a mean increase in heart rate by 1.87 beats/min.

Oral GLP1-RA

Oral semaglutide was approved by the US FDA on September 202,019 and is indicated in treatment of adult patients with type 2 diabetes, along with diet and exercise. The tablet contains SNAC [sodium *N*-(8-[2-hydroxylbonzoyl] amino) caprylate] which acts as an absorption enhancer, by alkalinizing the stomach pH leading to increased drug solubility, and it also prevents drug degradation. In the PIONEER (Peptide Innovation for Early Diabetes treatment) trial, 8845 people with T2DM were enrolled across 10 clinical trials. Oral semaglutide was either compared with placebo and/or with one of the FDA-approved glucose-lowering agents. The CVOT is the PIONEER 6 trial in which 3183 patients with T2DM and high risk of CV events were randomly assigned to receive either oral semaglutide or placebo with a median follow-up of 15.9 months (Husain et al. 2019). Like the injectable counterpart, oral semaglutide also showed noninferiority for the occurrence of MACE but failed to show significant reduction

in MACE when compared with placebo. However, there was a significant reduction in death from CV cause by 51% and all-cause mortality by 49%. Nonfatal myocardial infarction and nonfatal stroke both occurred at similar rates in the treatment and placebo groups.

Sodium-Glucose Cotransporter-2 (SGLT-2) Inhibitors

Their unique non-insulin-dependent mechanism of action, along with weight loss benefit and a low risk of hypoglycemia, makes them a great option for second-line therapy for T2 DM after metformin. The Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients-Removing Excess Glucose (EMPA-REG OUTCOME), the Canagliflozin Cardiovascular Assessment Study (CANVAS), and the Dapagliflozin Effect on Cardiovascular Events–Thrombolysis in Myocardial Infarction 58 (DECLARE–TIMI 58) were randomized placebo-controlled trials, evaluating the effect of empagliflozin, canagliflozin, and dapagliflozin respectively, on the primary outcome of major adverse cardiovascular (CV) events (MACE) which included death from cardiovascular causes, nonfatal myocardial infarction (MI), or nonfatal stroke (Zinman et al. 2015; Neal et al. 2017; Wiviott et al. 2019).

EMPA-REG OUTCOME trial included 7028 patients with type 2 diabetes, aged 18 years or above, with established CV disease, followed for a median of 3.1 years (Zinman et al. 2015). Empagliflozin was found to be superior to placebo with 14% relative risk reduction in MACE, 38% in CV deaths, 35% in congestive heart failure (CHF) hospitalization, and 32% for all cause-mortality. No difference was noted in the rates of nonfatal myocardial infarctions or stroke. Patients on empagliflozin had significantly more genital infections in both sexes (6.4 vs. 1.8%).

The CANVAS study had two identical trials (CANVAS and CANVAS-Renal) evaluating a total of 9734 patients with type 2 diabetes (A1c 7–10.5%) with either established CV disease (aged 30 years or older) or high risk of CV disease (aged 50 years or older with 2 or more risk factors for atherosclerotic CV disease) (Neal et al. 2017). Median follow-up was 188.2 weeks. Results showed significant decrease of 14% in the primary outcome of MACE, however not for individual components of MACE, nonfatal MI, or nonfatal stroke. There was a significantly higher risk of amputation of toes, feet, or legs in the canagliflozin group (6.3 vs. 3.4 participants with amputation per 1000 patient-years); with highest absolute risk (but not relative risk) in the patients with a previous history of amputation or peripheral vascular disease.

DECLARE–TIMI 58 was the phase 3 trial to study the CV effects of dapagliflozin in patients with type 2 diabetes, and established CV disease or 2 risk factors for atherosclerotic CV disease (men aged 55 years or older or women aged 60 years or older, and one additional risk factor) (Wiviott et al. 2019). This was the largest of the 3 major CV trials for SGLT-2 inhibitors with a total of 17,160 participants, out of which 13,198 patients completed the trial, followed for a median of 4.6 years. Dapagliflozin resulted in a significant reduction of 27% in the composite outcome of CV death and hospitalization for heart failure compared to placebo, which was due to lower rate of hospitalization for heart failure. A significant decrease of 24% was also noted in the renal composite outcome. There was no difference between the groups in the rate of MACE, cardiovascular mortality, or all-cause mortality. Dapagliflozin group had significantly higher rates of diabetic ketoacidosis (0.3% vs. 0.1%) and genital infections leading to discontinuation of trial medication (0.9 vs. 0.1%), but the number of total events was low.

Dapagliflozin and Prevention of Adverse Outcomes in Heart Failure (DAPA-HF) trial was another phase 3, placebo-controlled trial, in 4744 patients, 18 years or older, with ejection fraction (EF) of <40% and NYHA class II, III, or IV heart failure; followed for a median of 18.2 months. Only 42% of the participants had diabetes at the time of screening, and an additional 3% of the patients in each group received a new diagnosis of

diabetes (McMurray et al. 2019). Patients in dapagliflozin group (10 mg daily dose in addition to recommended therapy) had 26% lower rates of primary outcome of worsening heart failure (hospitalization or urgent visit resulting in intravenous therapy for heart failure) or cardiovascular death, but the most significant difference was in the number of hospitalizations. Dapagliflozin was equally effective in patients with or without type 2 diabetes.

Ethnic and Clinical Considerations

All of these studies had approximately 70% White population, 20–25% Asians, and only about 5% of Black population. Cardio-renal effects of these medications are also unclear in patients with lower risk of atherosclerotic CV disease since all the trials had patients either with established CV disease, or with high risk of CV disease. The lack of effect on MACE in DECLARE-TIMI 58 trial may likely be due to less patients with established CV disease compared to the other trials. A meta-analysis of the above 3 trials included a total of 34,322 patients with mean age of 63.5 years and 35.1% women, 60.2% with known CV disease and 39.8% with multiple risk factors (0% in EMPA-REG, 34% in CANVAS and 59% in DECLARE-TIMI 58 trials) (Zelniker et al. 2019). SGLT-2 inhibitors reduced the risk of major cardiac event by 11%, CV death and hospitalization for heart failure by 23%, and overall death by 15%. The risk of myocardial infarction was decreased by 11% and CV death by 16%, however with a high level of heterogeneity ($I2 = 79.7\%$). SGLT-2 inhibitors also decreased the composite renal outcome of worsening of renal function, end-stage renal disease (ESRD), or renal death by 45%. All the above effects were mostly restricted to the patients with established CV disease, and no effect was found in patients with multiple risk factors except for a reduction in hospitalization for heart failure by 30%.

Renal Protection

Both EMPA-REG OUTCOME and CANVAS trials showed a significant reduction in secondary renal outcomes (worsening nephropathy or initiation of renal-replacement therapy). The Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE), a double-blind, placebo-controlled, randomized trial, was designed to evaluate the renal effects of Canagliflozin (100 mg daily dose) in 4401 patients with type 2 diabetes and albuminuric chronic kidney disease (CKD) (Perkovic et al. 2019). Median follow-up was 2.62 years. Primary composite outcome (ESRD, doubling of serum creatinine level from baseline sustained for 30 days, death from renal or CV disease) rate was significantly lower in the canagliflozin group with a 30% lower relative risk. The effects were consistent across all renal components.

Official Guidelines

Based on the data from above-mentioned trials, the US FDA approved the following new indications for these medications:

- Empagliflozin (December, 2016) to reduce the risk of CV death in adult patients with type 2 diabetes and established CV disease;
- Canagliflozin (October, 2018) to reduce the risk of MACE in adults with type 2 diabetes mellitus and established CV disease;
- Dapagliflozin (October 2019) to reduce the risk of hospitalization for heart failure in adults with type 2 diabetes mellitus and established CV disease or multiple CV risk factors; and
- Canagliflozin (September 2019) to reduce the risk of ESRD, doubling of serum creatinine, cardiovascular death, and hospitalization for heart failure in adults with type 2 diabetes mellitus and diabetic nephropathy with albuminuria.

The exact mechanisms of cardiovascular and renal protective effects of SGLT-2 inhibitors are still unclear but are thought to be multidimensional. Improvement in glycemic control would translate into decrease in microvascular complications. Other non-glucose-dependent mechanisms, including weight reduction, blood pressure reduction, natriuresis, and reduction in intraglomerular pressure, likely contribute toward their overall cardio-renal effects.

Therapeutic Recommendations for DM Patients with High CV Risk

Intensive glycemic control, with target A1c of <6%, in older patients with long-standing T2DM and established CAD or high risk for CVD, has shown to increase mortality with no significant reduction of MACE (Action to Control Cardiovascular Risk in Diabetes Study Group et al. 2008). Patients with diabetes who have experienced hypoglycemic events have higher risk for acute CV events (Johnston et al. 2011). Therefore, avoiding hypoglycemia is one of the vital goals of treating diabetes in patients with or at high risk for CVD.

Primary Approach

Guidelines recommend lifestyle changes and metformin as first-line therapies for treatment of patients with T2DM. Metformin, GLP-1 RAs, and SGLT-2 inhibitors have no to minimal risk of hypoglycemia. The consensus statement from the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) recommends GLP-1 RAs and SGLT-2 inhibitors after metformin, for medical management of patients with T2DM and clinical CVD (Davies et al. 2018).

Obesity and Renal Comorbidities

GLP-1 RAs are either daily or weekly injectable except recently approved oral semaglutide. GLP-1 RA agonists should be considered as the first injectable agent particularly in obese patients with high CV risk (Davies et al. 2018). In patients with heart failure and CKD, SGLT-2 inhibitors have stronger data demonstrating consistent benefit (Kant et al. 2019). In fact, US FDA has approved dapagliflozin to reduce the risk of hospitalization for heart failure in adults with T2DM and established CV disease or multiple CV risk factors, and canagliflozin to reduce the risk of end-stage kidney disease and CV events in patients with T2DM and CKD. Empagliflozin and canagliflozin are more suitable for patients with CKD if GFR is acceptable as these agents have shown reduction in CKD progression. However, patients with advanced stage III and IV CKD will benefit from GLP-1 receptor agonist as SGLT-2 inhibitors are less effective and not approved to be used in patients with significantly reduced renal function.

Contraindications

Differences in adverse effects and US FDA warnings should be considered while choosing a glycemic agent. GLP-1 RAs are associated with increased gastrointestinal side effects and should be avoided in patients with pancreatitis, gastroparesis, alcohol abuse, and/or high risk for medullary thyroid cancer (Davies et al. 2018). Injectable semaglutide was associated with increased risk of diabetes retinopathy (Marso et al. 2016b). On the other hand, SGLT-2-inhibitors are not advisable in patients with predisposition to fragility fractures, and/or genital or urinary infections. Canagliflozin and ertugliflozin have been associated with increased risk of leg and foot amputations (Neal et al. 2017). Patients should be counseled regarding the preventive foot care, and these medications should be cautiously prescribed in patients with high risk for amputation or known peripheral vascular disease.

Diabetes End Points and Pharmacologic Alternatives

If patients are unable to achieve their target HbA1c or tolerate GLP-1 RA and/or SGLT-

2 inhibitors, other glycemic agents should be considered for add-on therapy. Dipeptidyl peptidase 4 (DPP-4) inhibitors can be used if the patient is not on GLP-1 RA. DPP-4 inhibitors have low risk of hypoglycemia, but saxagliptin and alogliptin have been linked to increased risk of heart failure (Scirica et al. 2013; White et al. 2013; Verma et al. 2017). Similarly, thiazolidinediones (TZDs) should be avoided in patients with heart failure (Lago et al. 2007). Sulfonylureas are among the oldest and cheapest oral hypoglycemic agents; however, they are associated with increased risk of hypoglycemia, adverse CV events, and mortality (Aldossari 2018; Sesti et al. 2018).

Abstract

Wound healing in diabetes is remarkably delayed due to various underlying pathological processes. Diabetes alters all the stages of wound healing such as remodeling, proliferation, hemostasis, and inflammatory phases. In diabetic patients, minor skin lesions may lead to unhealed chronic ulcers, and ultimately result in infection, gangrene, even amputation. Physiological factors responsible for the delay of wound healing include impaired growth factor and cytokine production, angiogenic response, macrophage and neutrophil function, collagen accumulation, and variation in the ratio of collagen types leading to weakened healing response. Key molecular targets for the local/pharmacologic treatment of wound healing include growth factors and other molecules, absorbable biomaterials, and cell regeneration therapy.

Keywords

Pathogenesis · Diabetic wound · Molecular targets · Healing · Diabetic foot ulcer

Introduction

Diabetes is a major cause for slower healing in every population. Between 2019 and 2045, the global expenditures for diabetes treatment is expected to grow from 760 billion U.S. dollars to 845 billion U.S. dollars (Elflein 2019).

Diabetes is a chronic metabolic disease that affects more than 463 million persons, and it is estimated that 20% of them develop complicated diabetic wounds or foot ulcer (IDF Diabetes Atlas 9th edition 2019; Nunan et al. 2014; Patel et al. 2019). Most acute wounds heal without issue; however, as age increases, impaired blood circulation and other conditions like smoking, obesity, and chronic diseases, such as diabetes, lead to slower healing. Diabetic complications resulting from diabetes include neuropathy, arterial damage, and ischemia, which may complicate diabetic wounds (Nunan et al. 2014). Unhealed wounds are prone to infection and lower-limb amputation. Diabetes is one of the principal causes of nontraumatic lower-extremity amputation.

In diabetes, each stage of healing, i.e., hemostasis, inflammatory, proliferation, and remodeling phase, is altered. Diabetic wounds show signs of impaired healing due to an uncoordinated healing process. Elongated inflammatory phase with hindrance in the mature granulation tissue formation and reduced wound tensile strength is observed in diabetic wounds (Patel et al. 2019).

Normal Wound Healing

Multiple sequential cellular and biochemical phenomena are necessary to restore damaged tissue. Hemostasis and clot formation is conventionally the starting point, triggering the inflammatory phase, commanded by neutrophils and macrophages, during which debris and bacteria are eliminated and growth factors are secreted. True repair only begins with the proliferative phase, including revascularization (angiogenesis) and build-up of the cellular and noncellular matrix. The maturation phase is responsible for tissue strength, encompassing remodeling of the local architecture and vascular abundance (Fadini et al. 2014; Singh et al. 2011, 2013). Differently from acute injuries, chronic wounds are more indolent and don't follow the same phases. As a consequence, healing can be delayed for 12 weeks or more (Anisha et al. 2013; Mohandas et al. 2015).

Diabetic Wounds

In diabetic patients, a minor skin wound often leads to chronic, nonhealing ulcers and ultimately results in infection, gangrene, even amputation. Damage of numerous layers of dermal tissue involving epidermis, dermis, and sometimes the subcutaneous tissue is not uncommon. The prevalence of foot ulcers ranges from 4% to 10% with a lifetime incidence as high as 25% (Dadpay et al. 2012). It is the most common complication of

diabetes, greater than retinopathy, nephropathy, heart attack, and stroke combined.

In the Asian continent, the diabetic foot represents a significant health problem, provoked by the high frequency of infection and the ever-rising incidence of diabetes. Insufficiency of diabetic foot care centers, deprived foot care information, approach and practice among diabetic patients, deferred recommendation or reporting to the podiatry centers, and limited income and educational status of the patients contribute significantly to the increased frequency of diabetic foot complications (Viswanathan et al. 2005).

Etiology and Pathogenesis

There are scores of reported physiologic disorders reportedly responsible for wound healing deficiencies in diabetes. Some representative ones are listed below:

- Impaired growth factor production (Qi et al. 2018)
- Impaired cytokine production (Zubair and Ahmad 2019)
- Impaired angiogenic response (Galeano et al. 2011)
- Weakened immune response (Peleg et al. 2007)
- Decreased neuropeptide expression (Theocharidis and Veves 2020)
- Impaired macrophage and neutrophil function (Maruyama et al. 2007)
- Increased serum matrix metalloproteinase-9 (Li et al. 2013)
- Impaired collagen accumulation and variation in the ratio of collagen types (Stolarczyk et al. 2018)
- Dysregulation of procalcitonin, fibrinogen, and IL-6 (Korkmaz et al. 2018)
- Aberrant macrophage polarization and function in wound healing responses (Ganesh and Ramkumar 2020)
- Imbalance between extracellular matrix (ECM) components and remodeling by matrix metalloproteinases (Gooyit et al. 2014)
- Deficiency of thrombin-activable fibrinolysis inhibitor (Verkleij et al. 2010)
- Advanced glycation end products (AGEP) modification of platelet-derived growth factor (PDGF) (Nass et al. 2010)
- Decreased levels of chemokine receptor CXCR3 and its ligand 10, CXCL10 (Bodnar et al. 2009)

Diabetic Foot Ulcer

Peripheral vascular and neuropathy disorders are believed to be crucial for the development of diabetic foot ulcers, compromising the survival and well-being of diabetic patients (Jeffcoate 2011). Predisposing conditions include previous deformations of the foot, reduction in regional oxygenation and perfusion, poor eyesight, and obesity. Poorly compensated diabetes as well as bacterial colonization are aggravating circumstances, along with presence of resistant bacteria, which further worsen the prognosis and make the therapy expensive (Hariono et al. 2018).

Classification of Diabetic Foot Ulcer

- Wagner–Meggit
- Brodsky Depth—Ischemic
- University of Texas
- International Working Group (2019 Guidelines)
- SAD
- PEDIS
- Other classifications

Wagner–Meggit

This is one of the oldest classification systems, created for the dysvascular foot. It includes six grade systems (grade 0 to grade 5), which emphasize ulcer depth, concentration of tissue necrosis, and occurrences of gangrene (Mehraj 2018).

Depth Ischemic

This classification system is the modernized form of the Wagner–Meggit classification, aiming to show a clear difference between lesion and foot vascularity (Mehraj 2018). It consists of three grades which depend upon the presence or

absence of ischemia with total or partial gangrene.

University of Texas

The University of Texas San Antonio classification system (UTSA) measures diabetic foot wound based on the depth of wound, infection, and ischemia in the lower limb. The grading system depends upon the wound depth, while stages of the classification depend upon the ischemia occurrence, bioburden of lesions, or merger of both by eliminating neuropathy. Superior grades or stages of a wound are less prone to healing. As compared to the Wagner classification, this system looks more promising and accurate. Nevertheless, optimal use of this and other classifications is still debated (Bravo-Molina et al. 2018).

International Working Group (2019 Guidelines)

The International Working Group has updated its guidelines related to diabetic foot disease on prevention, offloading, peripheral artery disease, infection, wound healing interventions, and classification of diabetic foot ulcers. These six protocols are not included in Table 55.1; however, they can be searched in the literature.

The following variables are endorsed as relevant for classification: patient-related (end-stage renal failure), limb-related (peripheral artery disease and loss of protective sensation), and ulcer-related (area, depth, site, single, or multiple and infection). Thorough wound assessment, including severity of infection and arterial perfusion (need for revascularization), is underscored. Among existing classifications, SINBAD (Site, Ischemia, Neuropathy, Bacterial Infection, and Depth), WIfI (Wound, Ischemia, and Foot Infection), and the guidelines of the Infectious Diseases Society of America are recommended for certain purposes (Lipsky et al. 2012; IWGDF Guidelines Org 2019; Bus et al. 2020a, b; Monteiro-Soares et al. 2020).

SAD

This classification system (Size, Arteriopathy, Denervation) considers size, denervation, sepsis, and arteriopathy. It is designed for hectic clinical practice and doesn't require any specialist techniques. Even though quite old, it has been reasonably well-validated (Monteiro-Soares et al. 2014).

PEDIS

As the acronym indicates, it addresses Perfusion, Extent, Depth/Tissue Loss, Infection, and Sensation. The numerous classification grades make it complex for clinical practice use (Jain and Joshi 2013).

Other Classifications

There is no dearth of diabetic foot ulcer classifications. However, most methods were developed with relatively small series and were not widely adopted, consequently suffering from limited validation. Many are not particularly user-friendly (Monteiro-Soares et al. 2014). Current representative tools are depicted in Table 55.1.

Diagnosis and staging are fundamental; however, instrumental monitoring is not less of a priority. To this aim, neuropathy and autonomic dysfunction, peripheral vascular disease, and eventual osteomyelitis need to be investigated. 3D and hyperspectral wound imaging are equally emphasized as reliable tools for lesion measurement and ulcer (Fernández-Torres et al. 2020).

Major Factors and Key Molecular Pathways of Diabetic Wounds

Molecular factors/targets for the management of diabetic wounds include cytokines, growth factors, clotting factors, prostaglandins, free radicals, nitric oxide, insulin-like growth factor (IGF-1) signaling axis including gangliosides, neuropeptides, mi-RNAs, lactoferrin, stromal cell-derived factor (SDF-1α), Hypoxia inducible factors (HIFs), thymosin beta 4, substance P, endopeptidase cathepsin D, and RANKL (Martí-Carvajal et al. 2015; Dam and Paller 2018; Zubair and Ahmad 2019; Liu et al. 2020). These agents directly or indirectly modulate vascularization, innervation, matrix reconstruction, and

Table 55.1 Examples of classifications of diabetic foot wound

Wagner-Meggit classification system					
Grades	**Foot wound**				
0	No open wound or cellulitis				
1	Superficial ulcer				
2	Deep ulcer upto tendons and joint tissue				
3	Deep ulcer with abscess, osteomyelitis, and joints sepsis				
4	Local gangrene forefoot or heel				
5	Gangrene of entire foot				
Depth ischemic classification					
Depth grade	**Definition**		**Ischemia grade**	**Definition**	
0	At risk, foot with the previous ulcer that may cause a new ulcer		A	No ischemia	
1	Superficial noninfected ulcer		B		
2	Deep ulcer with tendon or joint exposed (±infection)		C	Partial forefoot gangrene	
3	Extensive ulcer with bone exposed or deep abscess		D	Total foot gangrene	
University of Texas Classification					
Stages	**Grades**				
	0	**1**	**2**	**3**	
A	Healed pre- or post-ulcerative lesion completely epithelialized	Superficial wound not involving bone, tendon, or capsule	Wound penetrating tendon or capsule	Wound penetrating to bone or joint	
B	With infection	With infection	With infection	With infection	
C	With ischemia	With ischemia	With ischemia	With ischemia	
D	With infection and with ischemia	With infection and with ischemia	With infection and with ischemia	With infection and with ischemia	
(AD) SAD system					
Grades	**Area**	**Deep**	**Sepsis**	**Arteriopathy**	**Denervation**
0	Skin intact	Intact skin		Pedal pulse	Intact
1	Lesion <1 cm^2	Superficial (skin and subcutaneous tissues)	No infected lesions	Pedal pulse reduce or miss	Reduced
2	The lesion from 1 to 3 cm^2	Lesion penetrating to tendon, periosteum, and joint capsule	Cellulitis-associated lesions	Absence of both pedal pulses	Absent
3	Lesion >3 cm^2	A lesion in bone or joint space	Osteomyelitis-associated lesions	Gangrene	Charcot joint
PEDIS classification					
Risk factor group	**Characteristics**				
0	No neuropathy, no PVD				
1	Neuropathy, no deformity PVD				
2	Neuropathy and deformity, and/or PVD				
3	History pathology				

reepithelialization, including keratinocyte migration and proliferation on an extracellular matrix. All of these can be defective in diabetic wounds (Martí-Carvajal et al. 2015; Dam and Paller 2018).

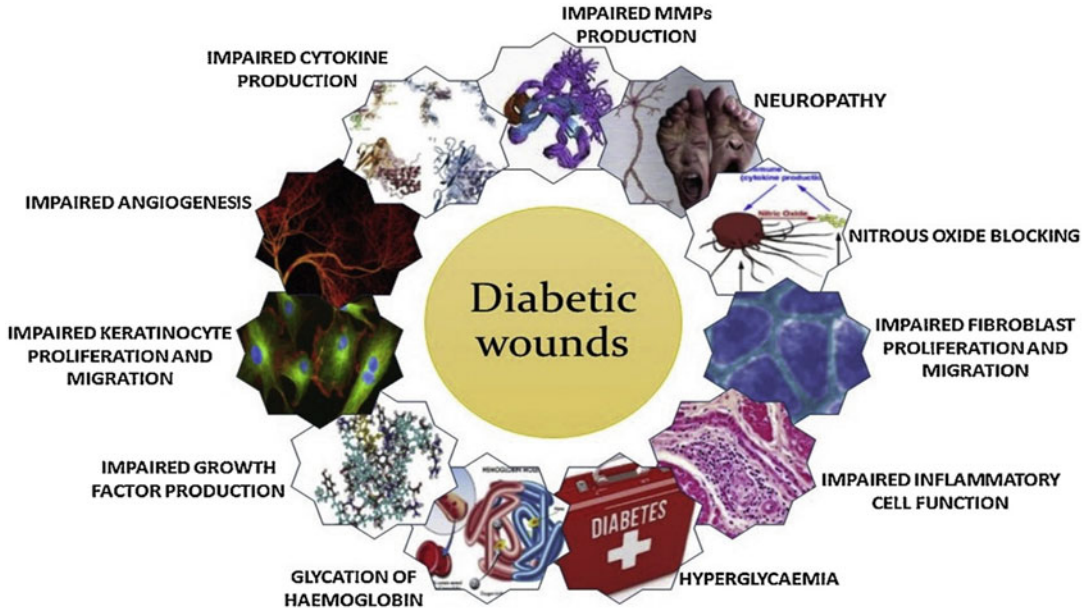

Fig. 55.1 Factors responsible for diabetic wounds [Adopted and reproduced from Patel et al. 2019]

It is important to emphasize that despite encouraging experimental results, few of these biomolecules have been investigated in large randomized trials. Indeed, a Cochrane Systematic Review a few years ago, addressing 11 growth factors for diabetic wounds, concluded that all increased the likelihood of healing of foot ulcers in diabetic patients. Such optimism notwithstanding, the disclaimer was that protocols suffered from high risk of bias, and side effects were possibly underreported (Martí-Carvajal et al. 2015). More clear-cut positive outcomes were detected for recombinant human epidermal growth factor (rhEGF), both intralesionally and topically applied, in a meta-analysis covering 6 trials and 530 patients (Bui et al. 2019). There are several factors that responsible for diabetic wounds are mentioned in Fig. 55.1.

Mitochondrial Overproduction of Reactive Oxygen Species

Advanced glycation end-products (AGEs) are a consequence of deranged glucose homeostasis. Transcription factors involved in inflammation and protein kinase C can be activated in such circumstances, and nerve protein glycation can occur, in conjunction with tissue oxidative stress and ischemia. Wound healing can be impaired because of these aberrations, including diminished local sensation which potentially results in additional injury (Patel et al. 2019; Shaikh-Kader et al. 2019).

Alteration of Growth Factors

Growth factors are pharmacologically active polypeptides. In all phases of wound healing, they promote relevant biological and molecular events. In the granulation phase of tissues, growth factors contribute to the early inflammation stage (Patel et al. 2019). Compromised wounds often demonstrate a defect in the kind and quantity of growth factor, due to alteration in the occurrence, enhancement in the degradation, reduction in the trapping, release, and production. Extracellular matrix (ECM) synthesis is categorized by a balance between matrix formation and matrix degradation, for optimal healing. Some of the factors influencing the formulation of ECM are VEGF,

IGF-I, IGF-II, TGF-β23, KGF24, PDGF25, EGF26, FGF27, TNF-α, and IL-6, which can be diminished in diabetic person, including suppression of receptors along with quick degradation of growth factors (Fui et al. 2019; Su et al. 2019; Patel et al. 2019; Zubair and Ahmad 2019).

Platelet-Derived Growth Factor

At the early stage of wound healing, platelets synthesize the platelet-derived growth factor (PDGF). PGDF is an essential mitogen that promotes the proliferation of fibroblast, matrix production, along with the maturation of connective tissue. In all stages of wound healing, PDGF continuously activates various cellular responses. PGDF binds with a receptor of tyrosine kinase and triggers various signaling pathways, leading to the enhancement of migration and proliferation of the cell. For the inflammatory cell and fibroblast, PDGF acts as a chemoattractant and encourages the production of collagen, glucosamine, and proteoglycan. In diabetic wound patients, there is a reduction in the expression of PDGF and PDGF receptors (Ishihara et al. 2019).

Vascular Endothelial Growth Factor

The wound healing process is affected by the concentration of VEGF as it supports the rate-determining steps in angiogenesis and vasculogenesis. With the help of the protease, it causes the degeneration of a three-dimensional network of an extracellular macromolecule of active vessels. In the case of diabetic wounds, it could enhance the density of capillary and develop the perfusion rate of blood along with the metabolism in wounded tissue. In a small series of diabetic foot ulcers, managed by hyperbaric oxygen therapy (HBOT), VEGF became elevated. The author defends that HBOT aids lesion epithelialization, both directly and indirectly, through VEGF upsurge and TNF-α downturn (Semadi 2019).

Transforming Growth Factor Beta

It has been reported that in diabetic patients there is a decrease in the amount of TGF β in wounded tissue that leads to retardation of the wound healing process. At the promoter site, MMP-encoded genes show the TGF-β1-dependent inhibitory element with a decrease in gene expression. The decrease in expression of TGF-β and upregulation of MMPs lead to destruction of growth factor transcription factors like Smad-2, Smad-3, and Smad-4, which also activate and repress TGF-β target genes. TGF-β1 activates Smad-2 and Smad-3 for the production of collagen (Hozzein et al. 2015). The decrease in the level of TGF-β1 causes increased recruitment of activated inflammatory cells, predisposing to a delayed inflammatory phase till the proliferation phase of the healing process in DWs (Heublein et al. 2015). Decreased levels and expression of those growth factors could contribute to poor and prolonged wound healing processes in diabetes (Patel et al. 2019).

Matrix Metalloproteinase 9

The central role of the extracellular matrix in the tissue remodeling processes involved in wound healing has already been alluded to. Endopeptidase enzymes degrade such matrices, and inappropriate conduction of this phenomenon can seriously affect the healing sequence. Matrix metalloproteinase 9 (MMP9) is actually a cluster of different crystal structures highly expressed in diabetic foot ulcer healing. Inhibitors have been identified and their binding mode was elucidated. In this sense, they could play a pharmacologic role in the handling of such complication (Hariono et al. 2018).

Defective Cytokine Production

Elevated interleukin-6 (IL-6) in diabetic foot ulcers has been demonstrated, and these levels decrease as the ulcers heal (Korkmaz et al. 2018). In experimental animals, similar lesions treated with IL-22 heal more rapidly, due to better vascularization, reepithelialization, granulation tissue formation, and VEGF release, with less keratinocyte differentiation. Pharmacologically, interleukin-22 seems to be superior to PDGF and VEGF, because of gene induction related

to reepithelialization, innate host defense mechanism, and tissue remodeling (Zubair and Ahmad 2019).

Abnormal Cellular Activity

At the start of the healing process, neutrophils appear, followed by monocytes which differentiate into macrophages. Endothelial cells, fibroblasts and keratinocytes, are analogously involved in the restoration of damaged tissue (Patel et al. 2019; Krzyszczyk et al. 2018). Macrophages and neutrophils are often increased in diabetic wounds. Macrophages in diabetic patients have reduced clearance activity; reduced capability to phagocyte the dead cells. Decreased T cells, increased B cells, dysregulation of the proliferation of macrophages, fibroblasts, endothelial cells, and keratinocytes are all reported. Infiltration of macrophages and neutrophils is prolonged in diabetes, and macrophages produce a reduced level of cytokines.

Mesenchimal stem cells are a promise to overcome such overlapping deficiencies, given their potential for multilineage differentiation. In-vivo and in-vitro protocols have availed themselves not only of direct cell therapy, but also of indirect intervention with the help of micro RNA (miRNA) and long noncoding RNA (lncRNA) (Li et al. 2020).

Neuropathy

Peripheral neuropathy mainly alters the sensory, motor, and autonomic function. An insensate foot can lead to injury, including skin irritation and pressure sores. Alteration of autonomic function predisposes to a delayed healing process due to arteriovenous shunting, impaired circulation, and edema (Theocharidis and Veves 2020). Due to the lack of protective sensation, many wounds remain unnoticed and progressively become worse.

The polyol pathway, along with many others, has been implied in the pathogenesis of diabetic neuropathy. In this sense, they could serve as potential targets for pharmacotherapy (Dewanjee et al. 2018).

Nitric Oxide Interventions

In diabetes, hyperglycemia can decrease the production of nitric oxide by inhibiting endothelial nitric oxide synthase (NOS) activation, which can favor the accumulation of reactive oxygen species, mainly superoxide. In the presence of metals ion like ferrous or cuprous ions, reactive oxygen species are converted to the highly reactive and damaging hydroxyl radical. In addition, they are also involved in the oxidization of sulfhydryl groups in proteins, lipid peroxidation, and the generation of reactive aldehydes and nitrogen oxide. These radicals disrupt the endothelium, which affects vascular function like vasoconstriction response, platelet aggregation, abnormal growth, and inflammation. Nitric oxide is a potent vasodilator, and local administration could positively influence indolent wound healing.

The hypothesis that a deficiency of NOS in diabetic patients leads to poor vascularization, peripheral neuropathy, and foot ulcers has been entertained (Walton et al. 2019). There is evidence that the genotype eNOS distribution is not different between diabetics with and without foot ulcers. Incidentally, in the same experience VEGF gene polymorphism wasn't different either (Erdogan et al. 2018). Nevertheless, transdermal nitric oxide (NO) treatment, in the form of NO donors, iNOS induction, and other pathways, has received attention in the recent literature (Erdogan et al. 2018; Walton et al. 2019).

Vascular Disease

The association of vascular disease and nonhealing of foot ulcer is well-established. Such circumstances notwithstanding, indications

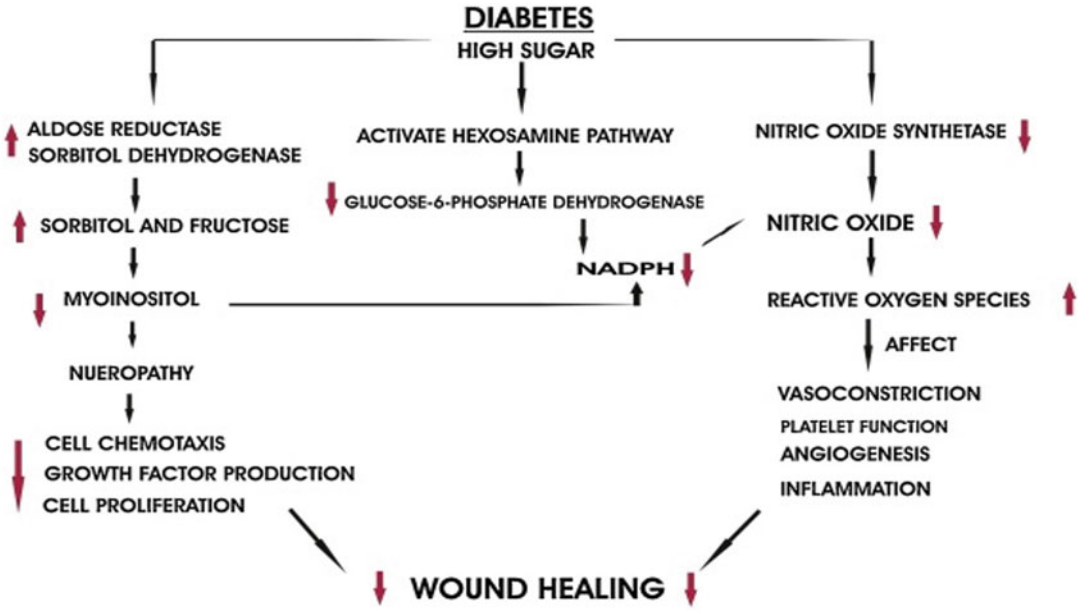

Fig. 55.2 Major pathways responsible for decreased wound healing in diabetes [Adopted and reproduced from Patel et al. 2019]

and outcomes of revascularization surgery are still controversial. One of the largest reviews, conducted by the International Working Group of the Diabetic Foot, covered over 13,000 patients. Results concerning part of this investigation point out towards fairly good response with both open and endovascular operations. Approximately 60% of all wounds were healed after 1 year, and amputation rate was about 10% after the same follow-up period. Revascularization interventions are, therefore, recommended when there is clear evidence of peripheral artery disease and ulcer; however, the best technique is still open to debate (Forsythe et al. 2020). The major mechanisms responsible for the decline in the wound healing process in case of diabetes are mentioned in Fig. 55.2.

Preventive Care

Traditional handling of diabetic foot ulcers is associated with inadequate efficacy, prolonged morbidity resulting in high direct and indirect cost, insufficiently documented side effects, and relapse rate as high as 50%. Hence, prevention of diabetic foot ulcers is the most important challenge.

According to the IWGDF guidelines (Bus et al. 2020b), screening of asymptomatic cases for peripheral neuropathy and arteriopathy is the first concern. If low risk is estimated, education and self-care by the patient should be highlighted, and pre-ulcerative signs should be treated. Additionally for those with moderate to high risk, footwear should be carefully selected, and monitoring of foot skin temperature is advised.

Indeed, footwear that relieves plantar pressure is useful for secondary prevention as well, reducing recurrence rates. Refractory cases should be surgically managed, and access to a multidisciplinary, integrated center should be a priority, whenever feasible (Bus et al. 2020b).

Therapeutic Approaches: Standard Care Versus Cells, Biomaterials, and Growth Factors

Many innovative local approaches are being assayed for patients with complex, recurrent, or refractory lesions, including stem cell therapy, photobiomodulation, and nanotherapy, in order to restore function and prevent amputation. Wound dressings, as well as scaffolds made of absorbable biomaterials, often impregnated with growth factors, nitric oxide and other pharmacologic agents, have been designed (Shu et al. 2018; Zarei et al. 2018; Erdogan et al. 2018; Zubair and Ahmad 2019;Walton et al. 2019).

Secondary infection is not uncommon, sometimes by resistant bacteria, and antibiotics are an integral part of the therapeutic arsenal in such context, within the recommendations of the Infectious Diseases Society of America (Lipsky et al. 2012). Revascularization surgery, as already mentioned, is indicated for those with demonstrated vascular impairment. Debridement and amputation, along with eventual flap rotation and skin grafting, once comparatively common among diabetics, should be reserved for carefully selected acute/chronic cases or for certain acute/urgent foot ulcers (Monteiro-Soares et al. 2014; Forsythe et al. 2020).

Acknowledgments The authors are thankful to the Director, University Institute of Pharmacy, Pt. Ravishankar Shukla, University Raipur, Chhattisgarh, for providing necessary infrastructure facilities and DHR-ICMR project no. V.25011/286-HRD/2016-HR for financial support.

Efficiency in Public Health Through the Promotion of Diabetes Day Hospitals: A Regional Proposal

56

Ascensión Barroso, Ramón Sanguino, Victoria Barroso, and M. Isabel Sánchez-Hernández

Contents

Abstract

Efficiency in public health implies cost reduction and improvements in citizens' quality of life. Diabetes negatively affects the quality of life of the people suffering from this disease. It is considered one of the main public health problems worldwide because it has a high prevalence and is a direct cause of death, disability, and high expenditures. Focusing the attention on some regional experiences in Spain, we analyze the advantages of the creation of a Diabetes Day Hospital (DDH) as a way to rationalize costs and, at the same time, to promote improvements in the quality of life of people with diabetes. Within the context of general healthcare services, technical efficiency was calculated with reference to the relationship between the resources used and the expected savings per patient as a health output. The strength of this approach is the possibility to ensure a better coordination of the different agents involved in the treatment of the disease and the possibility to reduce costs in the regional healthcare delivery system.

Efficiency in Public Health

Everyone deserves equal rights and opportunities and this includes the right to good health. However, inequities in health remain both in

J. Faintuch and S. Faintuch (eds.), *Obesity and Diabetes*, https://doi.org/10.1007/978-3-030-53370-0_56

developing and developed countries that are most of the times avoidable and unnecessary and always unjust.

Public health spending in Spain during 2016 was 71,477 million euros, or 9% of GDP. Public participation was 71.2%, the remainder being in charge of private parties (IDIS Report 2019). This is slightly above the OECD average of 8.9% (Organization for Economic Cooperation and development/OECD Health Statistics 2019). These data are very similar worldwide, around 10% of GDP, according to The Global Health Expenditure Database (2020).

The main stakeholders in the healthcare sector are urging the governments to promote new initiatives to ensure the viability of the national health system, seriously questioned because of its high deficit. Since the 1980s, Spain drags an annual deficit with healthcare around 6000 million Euros, which represents up to 11% difference between the budgeted and the really spent money (El Economista 2018).

Many national governments worldwide must assess the efficiency of their health sectors to ensure that public money is used to best effect. The technical efficiency approach (Cylus et al. 2017) is based on Farrell's concept that a hospital that produces the maximum amount of output from a given input is technically efficient (Farrell 1957). Hospital efficiency is crucial as they are primary consumers of health resources.

Day Hospital Concept

One of the bets to improve efficiency in the public health sector is through the day hospitalization. Day hospital (DH) is a new healthcare modality, both in public and private sphere, which has experienced a great development in recent years, notably increasing efficiency in the attention to patients who were previously admitted to conventional hospitals (Ministry of Health and Social Policy 2009). In Spain, within the network of public hospitals, there are 16,820 day hospital places (36.2 places per 100,000 inhabitants), a resource that is progressively increasing in line with the increase in ambulatory care (Ministry of Health, Consumption, and Social Welfare 2017).

Day Hospital (DH) is defined as the assembly of healthcare procedures which are performed in a hospital for a few hours, either for diagnosis, clinical investigation, or treatment that cannot be performed in a consulting room, yet not requiring hospitalization (Royal Decree 1277/2003, Ministry of Health and Social Policy 2009).

The dissemination and consolidation of the day hospital, the diversity of organizational, structural, and functional configurations, as well as its repercussion in terms of quality and patient safety, prioritize its inclusion in the actions included in the quality plan of the national health system together with the elaboration of quality and safety criteria (Ministry of Health and Social Policy 2009).

There are some documents containing standards and recommendations of quality to set up DH in Spain (Ministry of Health and Consumer Affairs 2008). They serve to key aspects of the DH such as the security and rights of the patient, organization and management, physical structure, and resources. Other countries like United Kingdom, United States, or Canada have similar standards and recommendations .

In Spain, the main applicable guidelines are Law 14/1986 and Law 16/2003. In addition, according to the Royal Decree 1277/2003 (Government of Spain 2003), for the authorization of a DH it would be necessary to make a modification of the plan of the general hospital, which must be previously authorized. In connection with them, two different regulations are observed: (1) on authorization and registration, which assesses healthcare centers before they come into operation, and (2) on accreditation, for evaluation of operational centers.

Only four regions have legislation and official programs for accreditation based on voluntary external assessment. Others have specific accreditation programs (organ transplants, assisted reproduction, hemotherapy treatments, continued training). So far, there is no specific accreditation system for DHs.

Four modalities of DH are currently defined: medical (including oncological), psychiatric,

geriatric, and surgical (Ministry of Health, Social Services and Equality 2016, 2017). Recognition of diabetes day hospital (DDHs) is still expected.

Social Impact of Diabetes

Diabetes is considered one of the main public health problems worldwide, mainly due to its high prevalence, the high economic cost to the public health system, and the number of premature deaths (Giusti et al. 2020). Diabetes Mellitus (DM) is a metabolic disorder of multiple etiology characterized by chronic hyperglycemia with alterations in the metabolism of carbohydrates, fats, and proteins, resulting from defects in the secretion of insulin, in the action of insulin, or both (American Diabetes Association 2014). Diabetes requires continuous medical care with multifactorial risk-reduction strategies beyond glycemic control. Ongoing patient self-management education and support are critical to preventing acute complications and reducing the risk of long-term complications (American Diabetes Association 2019).

An improvement in the care of DM would help to increase the life expectancy of the people who suffer it, given that it would reduce the likelihood and frequency of diabetes-related complications. Derived costs would also diminish. Numerous investigations tried to identify the risk factors for diabetes such as lifestyle, environment, or genetic traits (Zhang et al. 2020). The identification of these factors could allow the development of measures of primary prevention, which could have long-term consequences for public health policies (Harder et al. 2009) as they could reduce health spending and increase efficiency. The importance of an efficient use of public health resources for regional economic growth and stability and for the well-being of patients has been studied in recent years (Zhang et al. 2015). According to Crespo et al. (2013), 14.8% of all hospital discharges in Spain include a diagnosis of diabetes, with a cost of 1934 million Euros (33% of the total cost of the disease).

Diabetes Day Hospital

As alluded to, diabetes is a complex, chronic illness requiring continuous medical care with multifactorial risk-reduction strategies beyond glycemic control (American Diabetes Association 2019). Moreover, the identification of the risk factors for diabetes could allow the development of measures of primary prevention, which could have long-term consequences for public health policies (Harder et al. 2009) as they could reduce health spending and increase efficiency. Therefore, DDHs pave the way for an improvement in the quality of life of these cases (Zhang et al. 2015).

The DDH is specialized, as it aims to offer patient care 24 h a day. It requires synchronization with primary care units and the other services in the hospital (Morales 2014). It is normally located close to the endocrinology outpatient clinics because it functionally depends on the endocrinology service. Principal facilities are a waiting room, a medical consultation office, a treatment room, a group education room, a retinography room, a warehouse, and toilets. Figure 56.1 shows an example of how the DDH could be distributed:

The DDHs assist to patients: with recent onset of type 1 diabetes mellitus, with type 2 diabetes mellitus to schedule the insulin treatment, with decompensation in diabetes mellitus, woman with gestational diabetes, to implement and monitor insulin infusion pumps and continuously monitor glucose, to detect and diagnose chronic complications of diabetes mellitus, and to offer therapeutic diabetes education (Government of Extremadura 2007; Government of Andalusia 2013; Health Parc of Barcelona 2015).

The staff of the DDH is an endocrine physician and nurses who are also experts in diabetes nutrition and education. Moreover, the Public Sanitary System also includes psychologists, who can help to maintain therapeutic adhesion if necessary. The DDHs operate uninterruptedly at least 12 h a day. If the patient remains in the DDH during meal times, the nurses prepare the diets and request the corresponding food from the hospital kitchen.

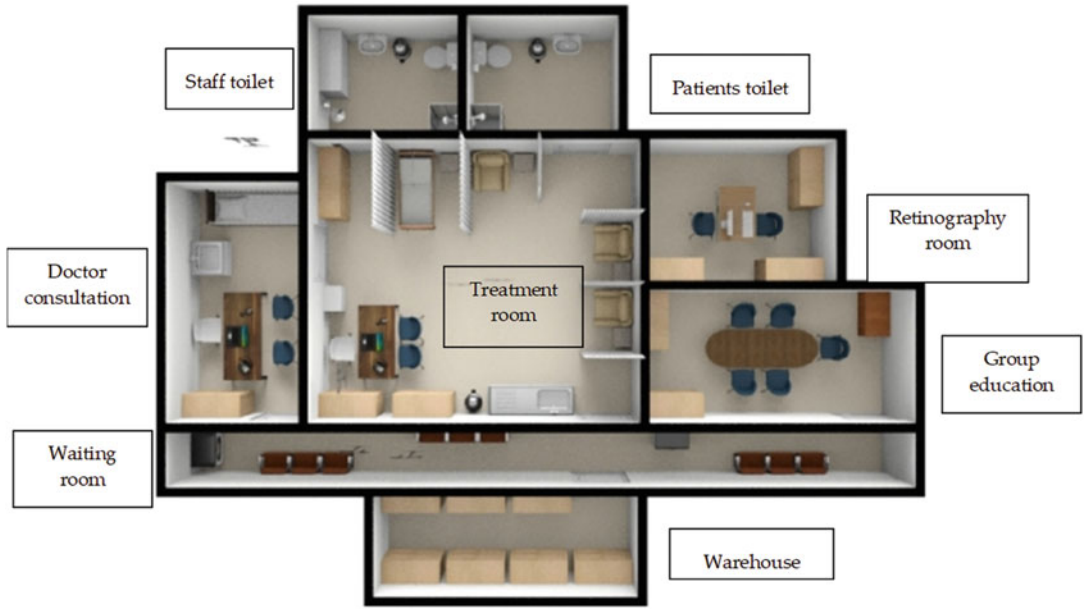

Fig. 56.1 Diabetes day hospital distribution

Barroso et al. (2019) calculated the costs of creating a DDH, considering the total investment imputed annually (material resources 23.655 euros and remodelling 15.000 euros). The cost of human resources was about 155.950 euros and meals (breakfast and lunch) 66.000. The total estimated cost was 860,520 Euros. The cost per patient in this case, following Morales (2014) and encompassing five new consultations as well as 18 returns per day, was 194,82 euros. The expected savings were 645,16 euros per patient per day.

Final Remarks

In this protocol, we point out how the creation of DDHs contributes to the efficiency of the Regional Public Health Services, detailing the structure, functioning, and related costs. A reduction of costs has been demonstrated through the work of Barroso et al. (2019), by evaluating the economical efficiency of the DDH to meet the needs and expectations of healthcare managers and policymakers.

In addition, the DDH offers an excellent opportunity to improve the care of people with diabetes and thus increasing their quality of life, by offering a better coordination between all the parties involved in the monitoring and treatment of the process of the disease.

We want also to emphasize the role of nurses as a key element in the care, education, and nutrition of patients. In fact, the DDH will contribute to the specialization of the nursing staff, creating a group of qualified professionals.

The efficiency in the specific regional healthcare could be improved and must be improved in line with the social responsible culture of the territory. The effective implementation of the DDH should contribute to an improvement in the optimization of resources since unnecessary expenses can be avoided and chronic complications should be effectively treated, thereby reducing the costs derived from them.

According to the previously mentioned percentage of declared diabetes, DDHs seem to be relevant for social justice purposes. For the near future, it is realistic to expect that the next regional public budgets will consider executing day hospitals. Otherwise, failure to pursue the

efficiency of the public health system will jeopardize the sustainability of the regional and national health system.

Bariatric and Metabolic Surgery

Surgical Options in Obesity and Diabetes 57

Jaime Ruiz-Tovar and Lorea Zubiaga

Contents

Abstract

Obesity is a chronic, progressive, and multifactorial disease. Hypocaloric diet associated with lifestyle modification and physical exercise represents the first step of treatment for obesity, but weight loss and remission of comorbidities are difficult to maintain in the long term. Bariatric surgery has demonstrated to be the most effective therapy in the long term for severely obese patients and for the treatment of type 2 diabetes mellitus (T2D) in obese subjects. There are different bariatric techniques, with important differences between them, related to the weight-loss effect, complication rates, and postoperative evolution of the different comorbidities and nutritional sequelae. *In this chapter, we will review the actual evidence about the mechanism of action of the different bariatric techniques and their clinical results in*

Obesity · Type 2 diabetes mellitus · Bariatric surgery · Restrictive procedures · Malabsorptive procedures · Sleeve gastrectomy · Adjustable gastric band · Roux-en-Y gastric bypass · One Anastomosis gastric bypass · Biliopancreatic diversion

Introduction

Obesity is a chronic, progressive, and multifactorial disease involving genetic, metabolic, psychological, and endocrinology-related factors. It is a risk factor for type 2 diabetes mellitus (T2D), high blood pressure, dyslipidemia, cardiovascular and respiratory diseases, psychosocial disorders, and several types of cancer (Salas-Salvado et al. 2007).

Proper hypocaloric diet associated with lifestyle modification and physical exercise represents the first step of treatment for obesity. However, several studies have shown that weight loss and glycemic control are difficult to maintain in the long term, even with intensive lifestyle intervention (Look et al. 2013). Bariatric surgery has demonstrated to be the most effective therapy in the long term, for severely obese patients (BMI $\geq$ 35 kg/m^2) with associated metabolic diseases and for morbidly obese patients (BMI $\geq$ 40 kg/m^2). In addition, there is increasing literature that supports the inclusion of bariatric surgery for the treatment of T2D in obese subjects (Salas-Salvado et al. 2007).

There are different bariatric techniques, which are universally considered as procedures that are efficient regarding obesity-associated comorbidities and weight loss (Daigle et al. 2018).

Classification of Bariatric Operations

Due to differences in nutritional and metabolic outcome, an individualized treatment taking into account the characteristics of each patient is necessary (Magouliotis et al. 2018; Tice et al. 2008; Colquitt et al. 2014; Rachlin and Galvani 2018). Globally, bariatric procedures can be divided into three groups (Colquitt et al. 2014) (Fig. 57.1):

- Restrictive procedures (sleeve gastrectomy, adjustable gastric banding): Imply a functional or anatomic reduction of the gastric volume, and consequently, reduce the amount of food intake.
- Malabsorptive procedures (biliopancreatic diversion, duodenal switch, one anastomosis gastric bypass, single anastomosis duodenum-ileal bypass): All of them coincide in a major change in the intestinal anatomy, bypassing a substantial length of the gut and consequently limiting the absorption of the nutrients.

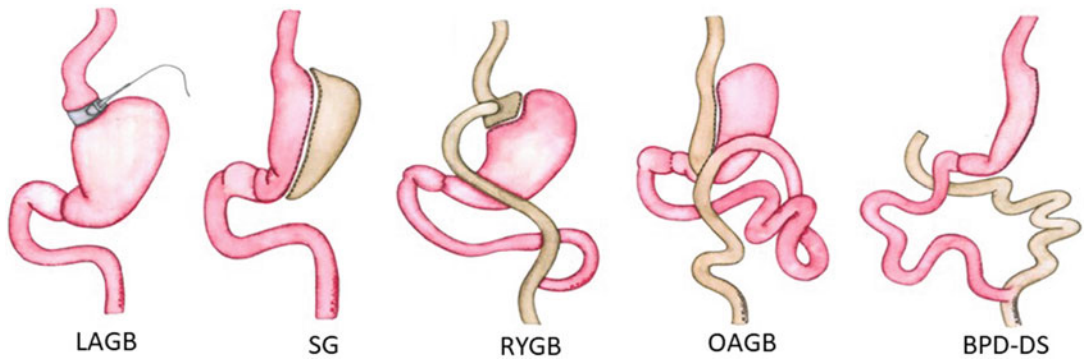

Fig. 57.1 Graphic representation of the main techniques in bariatric/metabolic surgery

– Mixed procedures (Roux-en-Y gastric bypass—classic and modified modalities): Imply a rather balanced combination, with partial reduction of the gastric volume, and some limitation of the absorption of nutrients due to intestinal bypass.

Over the last decades, the Roux-en-Y gastric bypass (RYGB) has been considered the gold standard, as it is associated with low morbidity and mortality rates and obtains excellent short- and mid-term weight loss with remission of comorbidities. However, long-term follow-up series have demonstrated a weight regain at 10-years follow-up, with over 30% of the patients presenting a BMI > 35 kg/m^2, and with less than 20% of the subjects nutritionally healthy (Higa et al. 2011). Although there is extensive literature that claims beneficial health effects with RYGB, these procedures are not exempted from long-term complications related to nutritional deficiencies. In general, all procedures involving malabsorption at any degree will have a risk of micronutrient and macronutrient deficiencies. Consequently, RYGB patients are at risk as well of developing nutrient deficiency-related disorders, such as anemia and certain types of neuropathies or osteoporosis (Kim et al. 2015; Rodriguez-Carmona et al. 2014).

The fear of nutritional consequences has led to the exponential growth of sleeve gastrectomy, a mostly restrictive procedure, which is currently the most performed bariatric intervention worldwide. With this technique, nutritional deficiencies are less frequent; however, it suffers from disadvantages, such as the appearance of de novo acid gastro-esophageal reflux disease and mid- and long-term weight regain (Felsenreich et al. 2019).

Some bariatric surgeons look for durability of the results, even if assuming the risk of nutritional consequences, thus selecting malabsorptive procedures. Among them, the one anastomosis gastric bypass has shown an exponential growth during the last decade, mainly based on excellent long-term results, technical ease, and low complication rate. At this moment, it represents the third most frequently performed bariatric procedure worldwide, after sleeve gastrectomy and RYGB (Ruiz-Tovar et al. 2019).

Metabolic Operations

They are performed on patients with class I obesity (BMI 30–35 kg/m^2), presenting associated metabolic comorbidities, mostly T2D. The American Society for Bariatric and Metabolic Surgery (ASMBS) has recently published their recommendations. Patients with class I obesity and obesity-related comorbidities, with previous failure of conservative therapies, are candidates. Surgical treatment is specially indicated in patients with T2D. Such interventions are as safe and efficient as on patients with greater BMI. However, they do not suggest an ideal procedure for metabolic surgery and defend that any bariatric procedure can be applied with these aims (Aminian et al. 2018).

Laparoscopic Adjustable Gastric Band (LAGB)

This was a technique of choice in the last decades of the twentieth century, due to low mortality rates and technical ease of performance. Absence of organ transection and alteration of the continuity of the intestinal transit are positive elements that promoted the reversibility of the technique.

LAGB involves placement of an adjustable silicone band around the upper portion of the stomach. This band is filled with sterile saline, which is injected through a special device in the adjacent abdominal wall. LAGB artificially creates a small gastric pouch above the band, and the size of the opening between the upper stomach and the lower chamber can be adjusted depending on the amount of injected fluid, in order to manipulate the restrictive level of ingested food. Adjustment of the band is performed in the outpatient clinic (Dixon et al. 2008).

Metabolic benefits are mainly restriction and satiety, which result in a decrease in calorie

consumption. Accompanied by dietary control, LAGB can achieve acceptable rates of adiposity loss, modulating metabolic signals that improve the lipid and carbohydrate profile. However, long-term follow-up studies reveal late complications such as band erosion, slippage, gastro-esophageal reflux, esophageal dilatation, and port infection, along with high variability in weight loss, partly related to noncompliance with dietary measures. These were the most influential factors leading to the sharp decline in the use of LAGB in Europe, and at most US bariatric centers (Kindel et al. 2014; Angrisani et al. 2018).

Clinical Results

Excess BMI Loss (EBMIL) ranged from 35.5% to 43.3% at 1 year, with Excess Weight Loss (EWL) of 16–50% and Total Weight Loss (TWL) of 12–13.7%. Mean BMI reduction at 1 year ranged from 5 to 8.4 kg/m^2 (40.7 0 93.8 kg) (Panagiotou et al. 2018). Moon et al. (2016) evaluated weight-loss failure, defined as EWL less than 30%. At the time of last follow-up, 58.8% of the patients failed to achieve weight loss and 4.4% gained weight. According to Loy et al. (2014), EWL increased up to >40% at 2 years after surgery, then remained stable between years 2 and 3, and increased again in years 4 and 5. However, the number of patients followed 5 years after surgery declined up to less than 20%, so that these results are not fully representative.

Complete remission of T2D is one of the lowest, ranging between 24.4% and 29.4% at 1 year, but it increases up to 37.5% after 3 years (Panagiotou et al. 2018; Keogh et al. 2013). Remission of dyslipidemia was achieved in around 65–70% of the patients (Lee et al. 2016a).

Laparoscopic Sleeve Gastrectomy (LSG)

This modality was initially conceived as the first phase from a Duodenal Switch. However, at the first International Consensus Summit on this technique, its validity as a stand-alone technique was established (Deitel et al. 2008). Since 2014, LSG is the most performed procedure in the world, representing more than 50% of all primary bariatric interventions (Angrisani et al. 2018).

The basis of LSG performance includes the resection of the ~80% of the lateral side (major curvature) of the stomach in a vertical fashion, leaving a remaining long, tubular gastric tube (Hutter et al. 2011). Several metabolic benefits outside of restriction have been described in LSG, and various mechanisms of actions have been reported. The new stomach in sleeve shape signifies a substantially smaller volume of the stomach capacity compared to a normal one. This reduction helps to significantly reduce food and calories intake.

Another mechanism of action is the drop in ghrelin levels. Ghrelin is a hormone secreted mainly in the gastric fundus that is responsible for appetite stimulation, increases gastric motility and secretion, increases growth hormone secretion, and reduces fat utilization. If this hormone is reduced, effects fall drastically, mainly appetite stimulation (Madsbad et al. 2014). Another effect of this surgery is the acceleration of the passage of food into the intestine, which avoids the mechanic digestive processes that are present in the gastric camera. Absence of space for creation of chyme justifies some malabsorptive effects to LSG. If the nutrients are not properly transformed, they cannot be totally absorbed.

Resection of gastric tissue also predisposes to the deficit of certain molecules, such as Intrinsic Factor. Moreover, accelerated passage of the nutrients to the gut has been associated with increase of incretin secretion, bile acid signal changes, and modifications in microbiota density. However, these effects do not seem to be permanent, and adaptation to the initial changes can justify the loss of effectiveness in the long term (Cavin et al. 2016). In fact, the hormonal effects of LSG appear to be greater in the first 12–36 postoperative months, and then becomes more dependent on lifestyle changes. Thus, longer-term cohorts refer to weight regain, especially in those patients operated on for more than 5 years, if they have not been able to modify their eating habits (Felsenreich et al. 2019).

The main strengths of LSG are short operation time, absence of foreign material, elimination of intestinal anastomosis, and possibility of being converted into multiple other bariatric procedures, if necessary in the future. Conversely, the main disadvantage is irreversible removal of a substantial portion of the stomach, however with the long-term possibility of compensatory dilatation. In addition, LSG is associated with gastro-esophageal reflux, which seems to have increased the incidence of esophageal metaplasia and Barrett's esophagus. In this sense, frequent endoscopic follow-up is recommended (Angrisani et al. 2018).

Clinical Results

Mean EBMIL is around 60% at 1 year (EWL 26%–74.3%, TWL 5.5%–26.5%) (Panagiotou et al. 2018). Lee et al. (2016b) reported mean BMI reduction at 1 year of 7.9 kg/m^2 (24.4 kg). According to Moon et al. (2016), 20.5% of the patients fail to achieve 30% weight loss (weight failure). Sherman et al. (2016) reported that weight loss was sustained up to 3 years after surgery; however, later on weight regain was observed. Lee et al. detected complete T2D remission of 30.2%, and resolution of dyslipidemia in 73.7% of the patients at 1 year follow-up. Our group has recently published a prospective randomized clinical trial comparing SG, RYGB, and OAGB. In our sample of SG patients, the complete remission rate of T2D at 1 year was 86.9% and at 5 years was 82%, while the remission of dyslipidemia was 41.4% and 28.6, respectively (Ruiz-Tovar et al. 2019).

Roux-en-Y Gastric Bypass (RYGB)

It is still considered the 'gold-standard' bariatric-metabolic surgery and was also the most frequently performed technique at the end of the twentieth century. The procedure consists of two phases: firstly, the performance of a small gastric pouch of ~30 cm^3 by separating the upper stomach, just below the gastro-esophageal junction, from the remaining stomach. The second phase includes the division of the small intestine: the first portion from 60 to 100 cm distal to the ligament of Treitz which represents the biliary limb (for the drainage of bile and pancreatic enzyme secretion) and a second segment 100–150 cm of the previous mark. This distal end of the divided bowel is brought up (alimentary limb or Roux limb) typically in an ante-colic manner (on top of the colon) and anastomosed to the constructed gastric pouch (Nguyen and Varela 2017).

RYGB is considered as a mixed technique, which works by several mechanisms that are independent of weight loss. The newly constructed gastric pouch is considerably smaller than the normal stomach, which facilitates the consumption of less food and fewer calories. Additionally, nutrient malabsorption occurs to some degree, which leads to less absorption. In the control of T2D, the exclusion of the duodenum and proximal jejunum has an undeniable benefit, as this intestinal portion is responsible for the rapid absorption of carbohydrates which determines many of the body's metabolic responses. On the other hand, early presence of undigested nutrients traveling to the distal small bowel can stimulate secretion of the incretin hormones, such as glucagon-like peptide 1, which leads to the improvement of different responses including gastric empting, satiety, and insulin resistance.

Other mechanisms of action unveiled during experimental analysis encompass modification of the entire hepatic cycle of bile acids, shifts in the composition and function of the microbiota, and above all, the increase in the intrinsic metabolic machinery of the intestine (Stefater et al. 2012).

The large number of patients operated with this technique display a solidity and reproducibility of the data and outcomes. However, more and more patients regain weight and relapse into their comorbidities. Certain degrees of vitamin and mineral deficiencies due to the malabsorptive component can occur. Likewise, patients with hyperinsulinemic hypoglycemia are occasionally reported, in some circumstances requiring reoperation and recovery of food transit through the

excluded segments of the intestine (Malik et al. 2016).

Clinical Results

After RYGB, the mean EBMIL ranged from 73.1% to 80.6% at 1 year (EWL 41.4%–82.8%, TWL 25%–31.8%). The mean BMI reduction at 1 year ranged from 16.5 to 13.4 kg/m^2 (40.7–93.8 kg) (Panagiotou et al. 2018; Van Nieuwenhove et al. 2016). At last follow-up, 14% of the patients failed to achieve 30% weight loss (Moon et al. 2016). In our clinical trial, BMI was 28.7 kg/m^2 and EBMIL 81.2% 1 year after surgery, whereas 5 years postoperatively 29.9 kg/m^2 and 77.1% were registered (Ruiz-Tovar et al. 2019).

The complete remission rate of T2D was 65.9% in the manuscript of Lee et al., while dyslipidemia remission rate was 100% at 1 year. Our group obtained complete remission rate of T2D of 84.3% at 1 year and 73.5% at 5 years, while for dyslipidemia values were 79.7% and 71% at 1 and 5 years, respectively (Ruiz-Tovar et al. 2019).

One Anastomosis Gastric Bypass

The concept unifies a group of bariatric-metabolic techniques characterized by duodenal exclusion and the rapid transit of the nutrients to the distal intestine, however without a Roux (alimentary) limb. The techniques of one anastomosis has received different names, depending on where the digestive tract is interrupted and where the anastomosis is located: minigastric bypass, omega bypass and SASI (single anastomosis sleeve ileum bypass) (Mahawar et al. 2019). The International Federation for the Surgery of Obesity and Metabolic Disorders (IFSO) Scientific Committee in 2018 recommended that techniques derived from a single anastomosis procedure should be called OAGB (De Luca et al. 2018). However, the important anatomical differences between the diverse techniques within this group establish a great variability of the maneuvers to perform them, as well as generate difficulties to compare outcomes. Many of these differences are surgeon-dependent, and until now, none of the hypotheses proposed to defend one OAGB modality over another has been totally convincing. In spite of this, in the last IFSO survey, the OAGB techniques have increased in popularity, becoming the third most performed option in the world (Angrisani et al. 2018).

In Spain, the most widespread OAGB-type technique is the BAGUA ("bypass gastrico de una anastomosis") local style. This technique does not perform gastric resection during sleeve preparation (similarly to RYGB). The section for the gastric tube begins 3 cm before the pylorus, allowing a long tube of more than 18 cm. Then, the gastro-ileal anastomosis is located on the lateral side of the gastric tube. The length of the intestine to be excluded is determined by the total length of the intestine, maintaining a constant percentage: 55% biliary limb and 45% common limb (a long biliary limb is analogous to other malabsorptive procedures, such as biliopancreatic diversion). The same mechanisms of action that are attributed to RYGB occur in OAGB. The main difference is that OAGB involves large portions of excluded intestine, which generate significant malabsorption of nutrients. Therefore, intensive postoperative nutritional surveillance is mandatory (Carbajo et al. 2017).

Performing the OAGB techniques implies certain technical advantages, such as minimizing the risk of leakage, fistulas, stenosis, or anastomotic ulcers. With no mesenteric dissection, there is less risk of internal hernias and intestinal obstruction. The lower anastomosis decreases the tension between tissues, and the absence of an alimentary limb reduces operating times and complications of the loop foot (Carbajo et al. 2017).

However, the absence of the alimentary limb triggered the alarm about biliary reflux, which forced the abandonment of popular techniques, such as Billroth II subtotal gastrectomy, a long time ago. Different studies have confirmed the efficacy and safety of OAGB procedures, without higher incidence of gastric cancer, so there must be other elements in these new derivative techniques that are protective, unlike Billroth II

gastrectomy. However, frequent endoscopic follow-up is recommended, as with LSG.

Clinical Results

In the series of Peraglie (2016), EWL at 1, 2, 3, 4, 5 and 6 years after surgery was 52%, 67%, 70%, 68%, 66%, 67%, and 72%, respectively. In our study, mean BMI was 25 kg/m^2 with an EBMIL of 100.4% at 1 year, 24.8 kg/m^2 and 104.3% at 2 years, and 25.1 kg/m^2 and 97.9% at 5 years, respectively (Ruiz-Tovar et al. 2019). Carbajo et al. (2017) reported a mean BMI of 29.9 kg/m^2 with a mean EWL of 70%, 12 years after surgery.

Our group documented complete remission of T2D of 94.2% at 1 year and 95.7% at 5 years. Resolution rate of dyslipidemia was 100% at both timepoints (Ruiz-Tovar et al. 2019). Carbajo et al. (2017) observed complete remission of T2D of 94% and of dyslipidemia of 96% at 12 years.

The Biliopancreatic Diversion (BPD)

BPD consists of a horizontal distal gastrectomy, closure of the duodenal stump, and a distal gastroileostomy creating a common 50 cm long channel. Some years later, the horizontal gastrectomy was modified by a LSG in an attempt to reduce some complications of BPD in relation to the tension produced by raising a short ileum to the supramesocolic area, especially in patients with mesentery thickened by fat infiltration. This new variant is known as Duodenal Switch (DS). The duodenum is divided just past the pylorus. A segment of the distal ileum is then divided at 250 cm proximal to the ileo-cecal valve and brought up and anastomosed to the duodenum in a Roux-en-Y configuration. Another anastomosis of the ileo-ileostomy is performed at 100 cm proximal to the ileo-cecal valve to complete the operation (Dapri et al. 2011).

In the 2016 IFSO survey, the percentage of both variants (separately or as BPD-DS) was less than 2% of the total number of surgeries performed in the world. The technical complexity in comparison with other bariatric techniques, the higher rates of complications and mortality, and especially, the refusal of patients to perform a second intervention when the surgery was scheduled in 2 times (first LSG and then intestinal time) made the technique lose followers. However, in all the surveys and in the different meta-analyses carried out so far, these procedures continue to have the best long-term results and are considered the best options for patients with refractory diabetes and in super-obese patients (Angrisani et al. 2018).

In both techniques, there could be a summing effect of performing a gastric resection (the same effects as LSG) to which are added the effects of deriving large portions of intestine that do not absorb. In addition to malabsorption, it must be remembered that this intestine is more demanding from a bioenergetics point of view. In fact, the main mechanism of action of the BPD has been recently described, comparing patients who underwent either BPD or RYGB and were matched for postoperative weight loss. The BPD patients resulted in an important reduction of the rate of appearance of ingested glucose into the circulation, and the postprandial increases in plasma glucose and insulin concentrations were markedly blunted after BPD compared to after RYGB. Insulin sensitivity, assessed as glucose disposal rate during insulin infusion, was 45% greater after BPD than RYGB, whereas ß-cell function was not different between groups (Harris et al. 2019).

However, nutritional deficits also increase, forcing a strict follow-up of these patients throughout their lives. The difference between the dimensions of the limbs excluded in the RYGB and in the BPD-DS has forced surgeons to reconsider which is the ideal limb length to exclude and the need to measure the entire bowel extension in each patient, since the variability of the total bowel length seems to be a determining factor when it comes to preventing complications due to malnutrition or preventing technical failures due to insufficient weight loss. Studies in this sense are being carried out in different parts of the world, coming to the conclusion that, more than specific lengths of intestine, percentages should be considered, bearing in

mind that the common limb is the determining factor in the degree of aggressiveness of the derivative techniques (Murad et al. 2018).

Clinical Results

Michaud et al. (2016) described that EWL increased between surgery and the second postoperative year and then remained stable until 5 years. Over a mean follow-up of 7.1 years, the mean EWL was 72.2%. In addition, 82.9% of patients lost more than 50% of their initial excess weight (successful weight loss), and only 0.9% lost less than 25% percent of their initial excess weight. Baltasar et al. (2017), in a series of 1475 patients with 15-year follow-up, reported a mean EBMIL of 96% at 15 years. Bolckmans and Himpens described a TWL of 40.7% 10 years after surgery, confirming that this technique is the one obtaining greatest weight loss and maintained during long-term follow-up (Bolckmans and Himpens 2016).

Referring to remission of comorbidities, Bolckmans and Himpens reported a complete remission of T2D of 87.5% at 10 years after surgery. Dyslipidemia remission rates were 93.3% for total cholesterol, 89.7% for triglycerides, and 95% for low-density lipoprotein cholesterol (Bolckmans and Himpens 2016).

Comparative outcomes between the different bariatric techniques 1 year after surgery are summarized in Table 57.1.

Conclusion

There are diverse surgical bariatric techniques that can be offered to a patient. Given that there is no universally accepted gold-standard, the election of the technique must be based on the individual features of the patient, the experience of the surgeon, and the decision of the patient once he has received all the information about advantages and drawbacks of each technique.

Restrictive procedures are technically more simple and associated with lower complications rates and few nutritional deficiencies, but they obtained lower weight loss and remission of comorbidities and there is a risk of long-term weight regain. RYGB is a mixed procedure with restrictive and malabsorptive components. It obtains better weight loss outcomes and remission of comorbidities than pure restrictive techniques, but it is also associated with long-term weight regain. Malabsorptive approaches are the most effective techniques to achieve significant and maintained weight loss and resolution of comorbidities, but are associated with severe nutritional deficiencies.

Table 57.1 Comparative outcomes between the different bariatric techniques 1 year after surgery

	Weight loss	Remission of T2D	Remission of DL
AGB	EBMIL 35.5–43.3% EWL 16–50% TWL 12–13.7% Failure 58.8%	24.4–29.4%	65–70%
SG	EBMIL 60–64.6% EWL 26–74.3% TWL 5.5–26.5% Failure 20.5%	30.2–86.9%	41.4–73.7%
RYGB	EBMIL 73.1–80.6% EWL 41.4–82.8% TWL 25–31.8% Failure 14%	65.9–84.3%	73.5–100%
OAGB	EBMIL 52–100.4%	94.2%	100%
BPD-DS	EWL 72.2%	87.5%	93.3%

Abstract

Bariatric surgery is the most effective treatment for obesity, producing massive and durable weight loss. One anastomosis gastric bypass (OAGB) is a restrictive and malabsorptive procedure that is rapidly gaining in popularity; it is simpler technically than other common procedures and has a low rate of complications. OAGB has similar, if not better, weight loss results than Roux-en-Y gastric bypass and biliopancreatic diversion, likely because of the exclusion of a longer biliopancreatic limb. In addition to weight

J. Faintuch and S. Faintuch (eds.), *Obesity and Diabetes*, https://doi.org/10.1007/978-3-030-53370-0_58

loss, OAGB has been shown to improve many of the commonest metabolic abnormalities associated with obesity such as insulin resistance. Recent studies using traditional analytical techniques, however also more advanced metabolomics techniques, provide important insights into the potential mechanisms for the physiological effects of OAGB, including improved lipid profile (normalization of triacylglycerol and cholesterol levels), reduced concentrations of total free fatty acids however increased branched-chain fatty acids, decreased branched-chain amino acid levels, and increased circulating bile acids. All these changes likely contribute to improved glucose homeostasis and cardiometabolic health.

Omega-loop gastric bypass · Mini gastric bypass · Fatty acid profile · Branched chain fatty acids · Branched chain amino acids · Bile acids

Introduction

Obesity has evolved into a global epidemic according to the World Health Organization (WHO), which reports that the worldwide prevalence of obesity nearly tripled between 1975 and 2016 (WHO 2018). Globally, a total of 1.9 billion adults were estimated to be overweight (609 million of whom were obese) in 2015, representing approximately 39% of the world's population (Chooi et al. 2019). Obesity is quite an expensive disease from both a "health currency" and a real currency perspective, for the patients themselves and the society as a whole. At the individual level, patients with obesity have increased risk to suffer from major health problems including hypertension, osteoarthritis, dyslipidemia, type 2 diabetes, coronary heart disease, stroke, gallbladder disease, sleep apnea, and respiratory problems, as well as some cancers (endometrial, breast, and colon) (Bhoyrul and Lashock 2018).

As a result, obesity increases mortality from many causes, and in fact, it is one of the most important reasons for reduced life expectancy in the modern world (Prospective Studies Collaboration et al. 2009). It is well-known that obesity results in suboptimal health and premature death (Tremmel et al. 2017). Obesity does not only impair the physical and mental health of people, but has many economic consequences as well. Obesity-related comorbidities require high medical costs for patient management and treatment, thereby directly increasing healthcare expenditures. On the other hand, obesity indirectly undermines economic wealth of the society, as it reduces effective labor power and timespan. Policy makers in health services and health professionals in medicine and other related fields, therefore, have important roles when it comes to the prevention and treatment of this contemporary epidemic (Çakmur 2016).

Metabolic Abnormalities Associated with Obesity

Dyslipidemia with increased triacylglycerol (TAG) and low-density lipoprotein (LDL) cholesterol concentrations, along with decreased high-density lipoprotein (HDL) cholesterol concentrations, dysregulation of glucose homeostasis with fasting and postprandial hyperglycemia and hyperinsulinemia, multi-organ insulin resistance, and liver steatosis, are the hallmark features of obesity-related metabolic dysfunction (Klein et al. 2002; Conte et al. 2012; Fabbrini and Magkos 2015). Currently, several other alterations in lipid and lipoprotein metabolism have been identified in obese individuals (Magkos et al. 2008). Quantitative and qualitative changes in lipid profile may be the result, however also the cause, of metabolic disorders or a side effect from various therapeutic activities (Bray 2004).

We have recently described the alterations of specific lipid classes in the serum of obese individuals (Mika and Sledzinski 2017). Obesity is associated with increased free fatty acid (FFA) concentrations and fatty acid release rates into the bloodstream (Mittendorfer et al. 2009) that may lead to insulin resistance, and eventually, type

2 diabetes (Carswell et al. 2016). A handful of studies have demonstrated obesity-related alterations in serum fatty acid profiles; however, also in adipose tissue fatty acid composition. Typically, increased content of monounsaturated fatty acids (MUFA) and decreased content of polyunsaturated fatty acids (PUFA) are reported (Rössner et al. 1989; Okada et al. 2005; Pakiet et al. 2020). Moreover, morbidly obese patients have a greater n-3/n-6 PUFA ratio that is highly correlated with systemic inflammation, e.g., increased circulating concentrations of C-reactive protein (CRP), which is very common in obesity (Kaska et al. 2014).

The analysis of complex groups of lipids revealed various alterations in the serum of obese subjects including changes in fatty acid composition of phospholipids and sphingolipids, increased levels of circulating ceramides, sphingosine-1-phosphate and, of course, TAG (Mika and Sledzinski 2017). However, it should be noted that some studies provided contradictory results, which may be the result of different populations studied or analytical techniques used. Another lipid class which may be of particular interest regarding obesity-related metabolic dysfunction are the bile acids (Kaska et al. 2016). Some data indicate that increased body weight is associated with decreased serum bile acid concentrations (Jahnel et al. 2015). There are also some metabolomic studies showing obesity-related alterations in serum amino acids concentrations (Pennetti et al. 1982; Zhou et al. 2013; Moran-Ramos et al. 2017). Interestingly, decreased concentrations of branched-chain fatty acids in obese subjects may be related to increased levels of branched-chain amino acids, since these amino acids may be converted into branched-chain fatty acids in adipose tissue (Pakiet et al. 2020).

Obesity Treatment and the Role of Bariatric Surgery

The cornerstone of obesity treatment consists of changes in lifestyle including adoption of an energy-prudent diet and increased physical activity, in order to promote a negative energy balance and induce weight loss (Klein et al. 2002; Bray et al. 2018). Despite the short-term success of many available diet and exercise regimens, their long-term efficacy remains limited due to the eventual weight regain and gradual return to baseline weight in most patients (Franz et al. 2007). Bariatric surgery is the most effective treatment for obesity, readily reducing weight and—despite some regain inevitably occurring—keeping much of it off for a prolonged period of time, often exceeding 10–20 years after surgery (Pories et al. 1995; Sjöström et al. 2012). Due to the global epidemic of obesity and the apparent long-term efficacy of bariatric surgery, demand for surgical treatment has increased significantly during the last decade (The MarketWatch News Department 2019).

There are many different surgical procedures, the commonest ones being Roux-en-Y gastric bypass (RYGB), adjustable gastric banding, sleeve gastrectomy (SG), and biliopancreatic diversion (Bradley et al. 2012), which differ in rates of weight loss and other outcomes. Overall, bariatric surgery appears to be a reasonably safe and cost-effective intervention for individuals with moderate to severe obesity compared with nonsurgical interventions (Gloy et al. 2013). Surgical treatments produce durable excess weight loss (EWL), reduce or at least improve comorbidities and significantly improve quality of life (QoL), and increase lifespan (Picot et al. 2009). In fact, bariatric surgery is considered a powerful "disease modifier" and not merely a strategy for weight loss, for example, given its widespread beneficial effects on metabolic homeostasis.

Many of the metabolic comorbidities of obesity and particularly type 2 diabetes improve after bariatric surgery, sometimes even before major weight loss occurs. However, why this happens remains unclear, and exploring the metabolic signatures after bariatric surgery is an area of active investigation in the attempt to better understand the mechanisms for the improvement in metabolic function after the surgical treatment of obesity (Palau-Rodriguez et al. 2018).

One Anastomosis Gastric Bypass

Surgical Technique, Weight Loss, and Complications

One anastomosis gastric bypass (OAGB) is a relatively new malabsorptive procedure that, according to IFSO Global Surgery Report, is the third commonest bariatric technique (Angrisani et al. 2017; Welbourn et al. 2019). OAGB was innovated by Robert Rutledge in 1997 as a modification of the Mason's loop gastric bypass (Rutledge 2001). Several other terms have been used in the past to describe the OAGB procedure such as omega-loop gastric bypass or mini gastric bypass. OAGB is a restrictive and malabsorptive surgical procedure with excellent weight loss results compared to biliopancreatic diversion (BPD) and even better results than RYGB. Improved weight loss efficacy is likely due to the exclusion of a longer biliopancreatic limb (Solouki et al. 2018).

Besides similar or better weight loss outcomes, OAGB is considered a simpler technique with shorter learning curve and operative time, similar rates of remission of comorbidities, and lower percentage of complications (Taha et al. 2017). This procedure involves the formation of a long narrow gastric pouch with a single gastrojejunal anastomosis (omega-loop). From the technical point-of-view, it is basically an omega-loop anastomosis between a long and vertical lesser curvature-based gastric pouch and the jejunum, at 150–200 cm from the ligament of Treitz.

During the initial stages of its clinical implementation, OAGB fell into disrepute due to high probability of bile reflux, leading to Barrett's esophagus and serious nutritional deficiencies (Fisher et al. 2001; Motamedi et al. 2017). Later studies have reported some advantages of OAGB over other bariatric procedures, such as one less anastomosis, shorter operative time and hospital stay, lower risk of anastomotic leakage, and easy reversibility. Despite severe criticisms, OAGB compares favorably among other bariatric procedures regarding effects on weight loss and obesity-related comorbidities (Chevallier et al. 2015) and should be considered for obese or super obese individuals who can be highly compliant to the postoperative nutritional supplementation.

A long-term observational study of 1054 morbidly obese patients undergoing OAGB reported mean excess weight loss (EWL) of 85% at the 6-year follow-up (Kular et al. 2014). In a total of 12,807 patients who underwent OAGB and were followed from 6 months to 12 years, mean EWL ranged from 60% to 78% (Parmar and Mahawar 2018). Alongside weight loss and minimal weight regain, OAGB leads to remission of type 2 diabetes in about 84% to 93% of patients, which is similar to other surgical procedures such as RYGB (remission of type 2 diabetes in 80–90% of patients) and somewhat better than SG (Kular et al. 2014; Parmar and Mahawar 2018). In parallel, OAGB results in significant improvements in the blood lipid profile and lowers risk of cardiovascular complications (Carbajo et al. 2017).

Surgical Complications

A comparative study of 1107 patients undergoing three different bariatric operations (339 had SG, 473 had OAGB, and 295 had RYGB) reported respective mortality rates of 2.1%, 0%, and 0.3% and respective leak rates of 1.5%, 0%, and 0.3% (Jammu and Sharma 2016). Among the OAGB group of patients, bile reflux was observed in fewer than 1% and no weight regain was observed (Bhandari et al. 2019). These results indicate that OAGB is an effective and safe surgical procedure and compared favorably to SG and RYGB. Among 1054 morbidly obese patients who underwent OAGB, 49 of them (4.6%) suffered early minor complications and only two exhibited major ones—anastomotic leak (0.2%) (Kular et al. 2014). For late complications, marginal ulceration was observed in 5 patients (0.6%) and anemia—the most frequent late complication—in 68 patients (7.6%) (Jammu and Sharma 2016). Likewise, an early (up to 30 days) mortality rate of 0.1%, leak rate of 1.0%, marginal ulcer rate of 2.7% (0–10%), and malnutrition rate of 0.7% were reported in a

large series of OAGB patients (Parmar and Mahawar 2018).

The rate of nutritional deficiencies and complications depends on the length of the biliopancreatic limb. The operating procedure should be individualized based on the patient's ability to follow nutritional supplementation recommendations and attend long-term follow-up visits. Nevertheless, compliance is often challenging, and there are some instances when revision surgery is required, oftentimes involving conversion from OAGB to RYGB. Overall, both types of gastric bypass, OAGB and RYGB, are associated with low and comparable rates of postoperative complications. OAGB is associated with a lower incidence of leaks due to the longer and wider gastric tube, leading to low intramural pressure and reflux (Mahawar et al. 2018).

Standardized Interventions

Recent surgical guidelines have been published (Parmar and Mahawar 2018). A standard of anatomic configurations of surgical procedures was established in 2018 at the Bariatric Metabolic Surgery Standardization (BMSS) World Consensus Meeting. The BMSS process was undertaken as a first step in developing evidence-based standard bariatric metabolic operations, with the main aim of improving consistency in surgical techniques, data collection, comparison of procedures, and outcome reporting. Based on BMSS standards, the OAGB configuration should consist of a gastric pouch 12–19 cm long and 2.5–3.0 cm wide, with a volume of 50–75 ml, whereas the length of biliopancreatic limb should be based on the patient's body mass index (BMI): 200 cm for individuals with BMI >50 kg/m^2 and 150 cm for those with BMI <50 kg/m^2. A meta-analysis published in 2019 including 16 studies that comparatively evaluated RYGB and OAGB concluded that OAGB is associated with shorter operative time, better resolution of diabetes, and greater EWL at 1, 2, and 5 years, with similar perioperative and postoperative effectiveness, feasibility, and safety (Magouliotis et al. 2019).

Metabolic Effects

There is relatively little research on the metabolic effects of OAGB, whether using traditional or more advanced analytical chemistry methodologies.

Fasting Lipid Profile and Postprandial Lipemia

It is well-documented that all types of bariatric surgery lead to improvements in the fasting lipid profile, including a reduction in serum TAG and total and LDL cholesterol concentrations, and an increase in HDL cholesterol concentration. Studies evaluating the effects of OAGB on the standard lipid profile parameters confirm these beneficial changes (Carbajo et al. 2017; Nabil et al. 2019). Milone et al. (2015) compared SG and OAGB and found similar effects on serum lipid concentrations 1 year after surgery, and similar probability of normalization of the blood lipid profile. In our recent study, we also observed improvements in total and LDL cholesterol and TAG concentrations; however, we did not find any significant changes in HDL cholesterol levels 6–9 months after OAGB (Pakiet et al. 2020).

Plasma Fatty Acid Profile

Fatty acids comprise a largely heterogeneous group of molecules, varying in carbon chain length, the number and position of double bonds, and functional group(s), thereby making them particularly susceptible to the effects of various metabolic factors (Repetto et al. 2012). Not only elevated concentrations of FFA in plasma, but also alterations of fatty acid composition can occur in obesity and can increase risk for metabolic and cardiovascular diseases. Fatty acid composition in serum is the result of endogenous synthesis occurring in the body, dietary intake, and release of FFA from adipose tissue. The fatty acid profile of fasting blood reflects the composition of fat stored in adipose tissue, which in turn

Table 58.1 Short-term and long-term effects of one anastomosis gastric bypass (OAGB) on the serum fatty acid composition of obese patients; the corresponding effects of the presurgical low-calorie diet are also depicted for comparison (Mika et al. 2020; Pakiet et al. 2020)

reflects long-term dietary fatty acid intake (Hodson et al. 2008). A diet rich in carbohydrate induces de novo synthesis of fatty acids in the liver (i.e., lipogenesis) and contributes to the formation and accumulation of TAG in plasma and adipose tissue and probably also to the subsequent expansion of adipose tissue when energy balance is positive (Mika and Sledzinski

2017). Despite the significance of fatty acid profile for the metabolic manifestations of obesity, only a handful of studies have been conducted to evaluate the effects of OAGB surgery. In a studies conducted in our laboratory (Pakiet et al. 2020) (Mika et al. 2020), we evaluated the short-term (after 2 weeks) and long-term (after 6–9 months) effects of OAGB surgery on fatty acid profile; Table 58.1 summarizes these findings, together with the effects of low-calorie diet that patients follow for 2–3 months before surgery.

Determination of the fatty acid profile in the serum of obese patients after OAGB revealed many statistically significant and potentially clinically relevant changes. Studies conducted 2 weeks after OAGB showed decreased levels of α-linolenic acid (ALA), eicosapentaenoic acid (EPA) from n-3 PUFA and linoleic acid (LA) from n-6 PUFA groups, total odd-chain fatty acids (OCFA), as well as stearic acid and some other acids present in smaller amounts in blood. By contrast, palmitic acid and arachidonic acid (ARA) were increased (Mika et al.2020). It should be noted that the fatty acid classes that are predominantly depleted from serum after OAGB surgery are essential PUFA (consumed from the diet) and OCFA (that originate from diet, i.e., dairy products) (Mika et al. 2016).

This suggests that the short-term effects of OAGB on serum fatty acid profile reflect the acute reduction in food intake. A decrease in PUFA levels has also been observed in the short term after SG, which may be the result of reduced dietary intake or malabsorption of fat (Lin et al. 2016). Reduced levels of some PUFA were also observed in the long-term, 6–9 months after OAGB (Table 58.1). The lowering of ARA after OAGB can be considered beneficial, given the pro-inflammatory properties of ARA derivatives (i.e., eicosanoids) and the link between inflammation and obesity (Shearer and Walker 2018). Accordingly, OAGB decreases serum CRP levels (Chiappetta et al. 2018; Pakiet et al. 2020), but not the n-3/n-6 ratio, which is also associated with systemic inflammation (Kaska et al. 2014). Decreases in ALA, LA, and EPA concentrations have also been observed 6 months after RYGB (Forbes et al. 2016), although some authors reported elevated levels of PUFA 12 months after RYGB (Walle et al. 2017). Regardless of the type of surgery and the time after surgery, changes in the fatty acid profile are quite variable depending on the characteristics of the patient as well as the postsurgical treatment and diet.

Increased levels of some fatty acids after OAGB may be the result of reverse transport of fatty acids from different body fat depots during weight loss (Lin et al. 2016). For instance, OAGB increases branched-chain fatty acids (BCFA) 6–-9 months after surgery (Table 58.1) (Pakiet et al. 2020), which may have health-promoting properties. BCFAs increase the fluidity of cell membranes, similarly to unsaturated fatty acids, but are less susceptible to oxidation (Vlaeminck et al. 2006). They are also endowed with antibacterial, anti-inflammatory, and anti-cancer properties (Mika et al. 2016). Su et al. (2015) also demonstrated an increase in adipose tissue BCFA levels 1 year after RYGB surgery and an inverse association between adipose tissue BCFA levels and obesity-related insulin resistance.

Excessive Free Fatty Acids

Esterification of fatty acids on a glycerol backbone and conversion to TAG for storage in adipose tissue depots is thought to be a protective metabolic response to excessive dietary calorie and/or fat intake. TAG are chemically inert molecules, whereas fatty acids are highly reactive and can cause oxidative stress and lipotoxicity. Excessive fat intake ultimately leads to excessive FFA release from increased adipose tissue lipolysis (Redinger 2007) and increased availability of FFA in the systemic circulation, which is known to cause insulin resistance (Boden 1997). Unpublished data from our laboratory demonstrate that OAGB significantly reduces FFA concentrations in serum by about 50% (Fig. 58.1). This effect may contribute to the increase in insulin sensitivity observed after OAGB (Kaska et al. 2015).

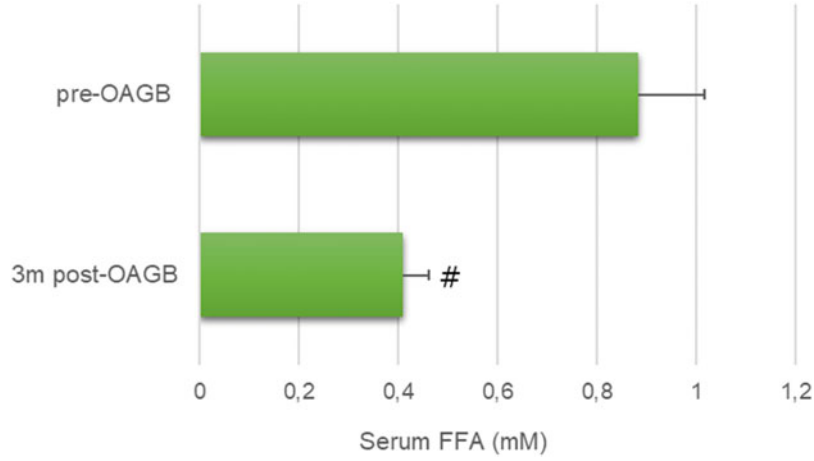

Fig. 58.1 Fasting plasma FFA concentrations before and 3 months after OAGB surgery (unpublished data). $^{\#}p < 0.01$ compared to before surgery

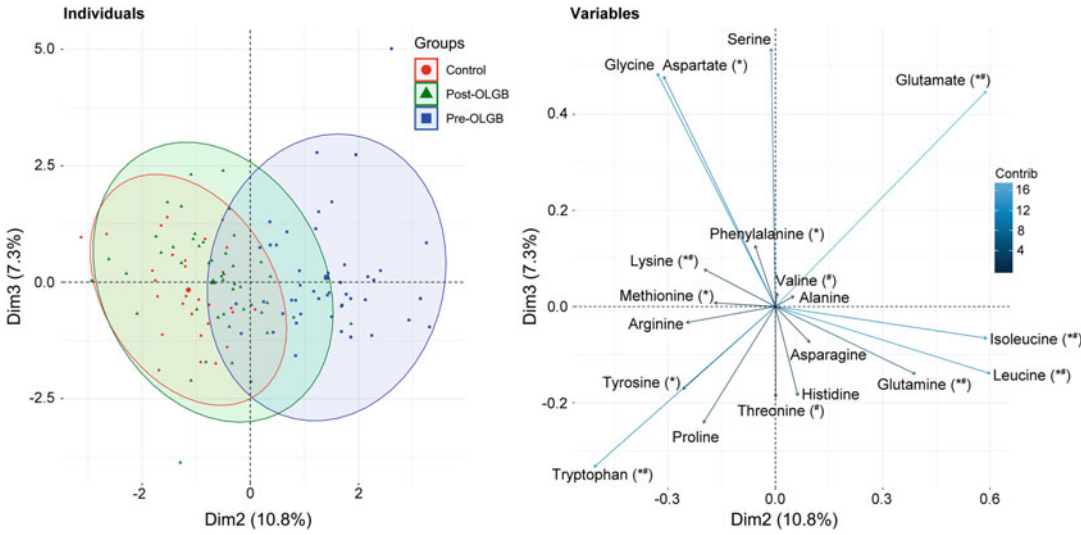

Fig. 58.2 Results of principal component analysis (PCA) based on the common amino acid profile: score plot of cases (left) and variables (right) for the second and third principal complement. Variables marked with (*) displayed statistically significant differences in their average concentrations between lean subjects (the control group) and OAGB patients before surgery, while variables marked with (#) displayed significant differences in patients before and after OAGB surgery (Halinski et al. 2020).

Interestingly, studies in animal models have shown that, among several bariatric surgical procedures applied to diet-induced obese Long-Evans rats—including OAGB, RYGB, SG, and single-anastomosis duodenal switch—the greatest decrease in circulating FFA was recorded at 15 weeks after OAGB (Arble et al. 2018).

Plasma Amino Acid Profile

Nonessential amino acids are synthesized de novo in the human body and their abundance does not depend on dietary intake. Essential amino acids, on the other hand, cannot be synthesized de novo and need to be obtained from the diet. However,

Table 58.2 Long-term effect of one anastomosis gastric bypass (OAGB) on plasma amino acid composition (Halinski et al. 2020)

"Baseline" refers to a sample collected on the day of surgery. Symbols: ↑ increase, ↓ decrease, ↔ no significant change

under conditions of stress or in catabolic states, some nonessential amino acids become essential—these are the "conditionally essential" amino acids (Morris et al. 2017). We have recently observed that OAGB surgery modified the serum concentrations of amino acids and normalized plasma amino acid profile in obese patients relative to lean controls (Fig. 58.2) (Halinski et al. 2020).

Essential amino acid concentrations decreased after OAGB (Table 58.2), which suggests that patients after this type of bariatric surgery should increase protein intake from food, at least in terms of quality if not quantity. Furthermore, we found

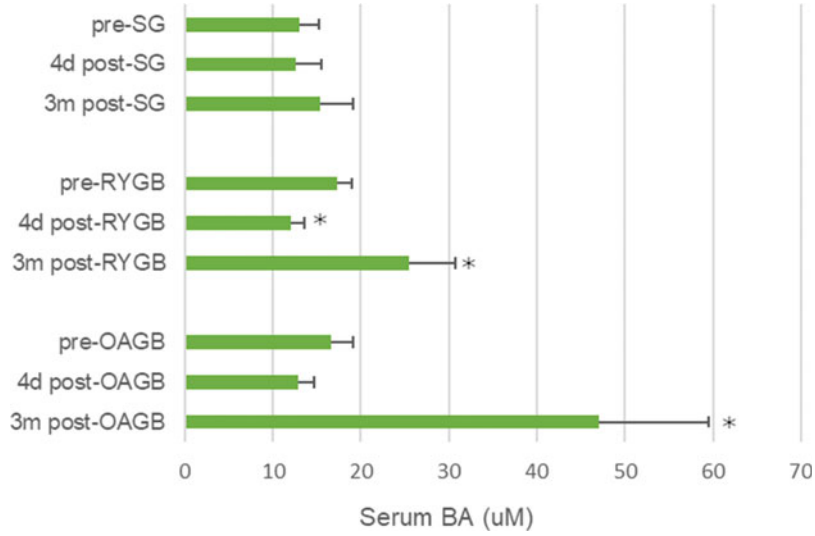

Fig. 58.3 Short-term and long-term effects of sleeve gastrectomy (SG), Roux en Y gastric bypass (RYGB), and one anastomosis gastric bypass (OAGB) on fasting serum concentration of total bile acids. $^{*}p < 0.05$ compared to before surgery (Mika et al. 2018).

decreased concentrations of branched-chain amino acids (BCAA) 6–9 months after OAGB, which may also contribute to a reduction in risk for developing type 2 diabetes. Reduction in BCAA levels was also observed after RYGB and SG, with patterns of change being similar to those after OAGB (Wijayatunga et al. 2018; Palau-Rodriguez et al. 2018).

Bile Acids

Resolution of insulin resistance and hyperglycemia, and remission of type 2 diabetes, can be observed even before the reduction of body weight, just within hours or days after the surgical intervention (Buchwald et al. 2009; Thaler and Cummings 2009; Arble et al. 2018). The exact mechanisms underlying the beneficial effects of bariatric surgery on glucose metabolism are not fully understood; however, some evidence suggests an important role for serum bile acids (Sinclair et al. 2018). Bile acids are a heterogeneous group of cholesterol derivatives with different biological functions and chemical properties. An increase in serum bile acid concentrations after bariatric surgery may be beneficial, as it has been associated with improvements in glucose metabolism (Kaska et al. 2016). Weight loss caused by calorie restriction also affects bile acid and glucose homeostasis (Jansen et al. 2011; Simonen et al. 2012).

Some studies indicated that RYGB may increase the concentrations of primary, secondary, and conjugated bile acids (Scholtz et al. 2014), whereas SG was reported to exert smaller effects or have no effect at all (Steinert et al. 2013). A recent study by our group demonstrated a greater improvement in insulin sensitivity after OAGB compared to RYGB (Kaska et al. 2015). What is more, OAGB provided better glycemic control than RYGB and SG (Lee et al. 2014; Deitel 2018; Mika et al. 2018). A comparative study of the short-term and long-term effects of OAGB, RYGB, and SG on circulating bile acids has demonstrated that differences in bile acid concentrations are greatest 3 months post-surgery; both RYGB and OAGB increased bile acid concentrations, but the increase after OAGB was almost twice as great as after RYGB, whereas SG had no effect (Fig. 58.3) (Mika et al. 2018).

Conclusions

We and others published studies on the metabolic effects of OAGB using more advanced metabolomics techniques, which provide important insights into the potential mechanisms for the physiological changes occurring after bariatric surgery. Serum fatty acid profile analysis revealed a decrease of essential PUFA that may be considered an adverse effect of OAGB. However, improved traditional lipid profile parameters (normalization of TAG and cholesterol levels), reduced circulating FFA as well as increased BCFA and bile acids, and decreased BCAA are all beneficial changes, which likely contribute to better cardiometabolic health. Results from a number of recent studies help increase our understanding of the cellular and molecular mechanisms underlying the beneficial effects of OAGB surgery; however, there are several unresolved issues. Future studies along these lines will with no doubt help improve the surgical treatment of obesity.

Abstract

Obesity is a global problem and surgery remains the most effective tool to treat this chronic disease. Minimally invasive surgery is the standard of care for performing operations for metabolic control and weight loss. The robotic digital platform overcomes the limitations of traditional laparoscopy which are amplified in the morbidly obese population with improved visualization, precision, and surgeon ergonomics. Current robotic systems utilize a master-slave relationship where the surgeon is operating at a distance from the patient, known as telepresence. The da Vinci® robot from Intuitive Incorporated currently has the monopoly for robotic bariatric procedures performed worldwide, though this status is being challenged by emerging robotic platforms and manufacturers. New technology is costly and has its own distinctive learning curve. Despite the inherent benefits of the robotic platform, there is no conclusive evidence to suggest its superiority over conventional laparoscopy. Eagerly awaited is a cost reduction in robotic-assisted surgery driven by competition and the advent of artificial intelligence to provide safer surgery.

Introduction

Obesity is considered the most prevalent noninfectious epidemic of our generation. Currently, more than two thirds of the adult population are considered overweight or obese (Organisation WH 2018). Obesity is often a chronic, progressive disorder leading to poor health, unwarranted stigma, and increased mortality (Kleinert and Horton 2019). Surgery is the most effective tool for the long-term management of obesity and the reduction of obesity-related health conditions (Colquitt et al. 2014). Bariatric surgical procedures are almost entirely performed using a minimally invasive approach, with 99.1% of procedures performed laparoscopically according to current registry data (IFSO 2019a).

Operative technical difficulties for bariatric surgeons include dealing with thick abdominal walls, limited intra-abdominal space, enlarged fatty livers, and increased visceral adiposity. A robotic digital platform as an extension of the minimally invasive surgeon's armamentarium would seem to be ideally suited for this patient group (Wilson and Sudan 2013). The United States Food and Drug Administration (FDA) approved the da Vinci® Surgical System (Intuitive Surgical Inc., Sunnyvale California) for use in general laparoscopic surgery in 2000. This robotic platform and company retain the monopoly status on robotic bariatric procedures performed worldwide.

Technically, robotic surgery differs from standard laparoscopic surgery in that the console surgeon remotely controls camera and up to three instruments. Surgeon ergonomics are improved which results in less fatigue (Lee et al. 2014). Three-Dimensional (3D) vision is retained and the instruments are wristed with seven degrees of freedom (Fig. 59.1), allowing improved dexterity for surgical tasks such as intracorporeal suturing (Hernandez et al. 2004; Yohannes et al. 2002). There is, however, a loss of tactile feedback which is in part compensated by visual clues (Hagen et al. 2008).

While the clinical advantages of the robot are still being studied, the true advantage may be more evident for complex, lengthy procedures

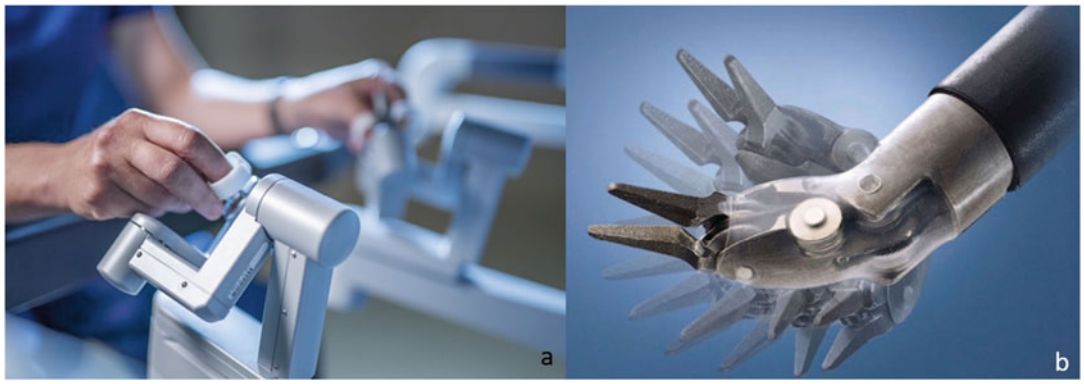

Fig. 59.1 da Vinci® instruments (**a**) ergonomically controlled at the surgeon console with (**b**) seven degrees of freedom (with permissions from Intuitive Surgical, Inc.)

that include a sutured anastomosis such as the Roux-en-Y gastric bypass (RYGB) (Tieu et al. 2013). Furthermore, the incidence of revisional surgery is on the rise, and therefore, more complex procedures may also benefit from a robotic-assisted approach (Tieu et al. 2013).

Unlike traditional surgery, robotic surgery requires a distinct learning process not limited to the operating surgeon, but also applies to the entire surgical team and institution. This new technology needs to be introduced safely to minimize patient harm, during the transition from traditional laparoscopic surgery to operating on a digital surgical platform. Currently, the manufacturer provides most of the training with formal robotic training, fellowships, and credentialing requirements still in its infancy.

Importantly, the widespread application of robotic bariatric surgery would have major cost implications unless it results in better long-term patient outcomes. The da Vinci® robotic system is now utilized in every continent with general surgical procedures (Fig. 59.2) having the highest rate of growth (Intuitive 2018).

In the United States of America, over 6% of primary bariatric procedures in centers of excellence are now performed robotically (Acevedo et al. 2019). Robotic bariatric surgery as a specialty is certainly well-established. Given this establishment, has the da Vinci® robot lived up to its hype as the dominant fully operational system? Are we being driven by industry, patient demand, or surgeon preference? Is robotic bariatric surgery enabling technology that advances human health care and surgical proficiency, or is it just a disruptive innovation?

History and Evolution of Robotic Minimally Invasive Surgery

Robotic surgery is a story of the amalgamation of the work of innovative surgeons, the military, NASA, entrepreneurs, and engineers to create useful and needed technology. The initial need for a robot was to provide remote surgical care in the battlefield for soldiers and in space for astronauts. Telepresence, which uses virtual technology to operate machinery by remote control, was deemed to be the solution. A further aim was to alleviate surgeon fatigue, while aiding procedures which require greater precision.

Historically, the first surgical procedure performed with a robot was for a neurosurgical biopsy using the Programmable Universal Manipulation Arm (PUMA), as shown in Fig. 59.3, in 1985.

The initial telepresence surgical system was developed with military funding by Stanford Research Institute (SRI). The SRI telepresence system had manipulators with force-sensing elements that transmitted pressure sensations, or haptic feedback, to the surgeon controllers (George et al. 2018). Dr. Fred Moll founded Intuitive Surgical Incorporated in 1995 having obtained SRI's intellectual property, with the focus shifting from telepresence to a platform that facilitated minimally invasive surgery. The first Intuitive surgical system to be used on humans was called MONA, upon which Dr. Jacques Himpens performed the first robotic cholecystectomy in Belgium in 1997. Prominent

Fig. 59.3 PUMA robotic arm at NASA (no copyright restrictions) (NASA 1990)

journals refused to publish this landmark event due to disbelief in the robotic technology (George et al. 2018). Dr. Himpens was finally successful in publishing the inaugural robotic-assisted gastric band operation in the journal *Obesity Surgery* in 1998 (George et al. 2018). In 1999, the more recognisable da Vinci® robotic platform was introduced, differing from its predecessors in having a stand-alone cart for the patient (slave) and a surgeon console (master), connected by a fiber-optic cord (George et al. 2018).

In parallel to the work at Intuitive, Computer Motion Inc., founded by Dr. Yulin Wang, developed the Automated Endoscopic System for Optimal Positioning (AESOP) robotic device, which is a camera that could be moved by voice or foot pedal commands allowing for independent laparoscopic surgery. Dr. Wang received military funding to add additional arms to his robotic device which he later called ZEUS. ZEUS was used for the first ever trans-Atlantic robotic-assisted cholecystectomy telesurgery in 2001. Dr. Jacques Marescaux controlled the master console in New York, while the patient was operated

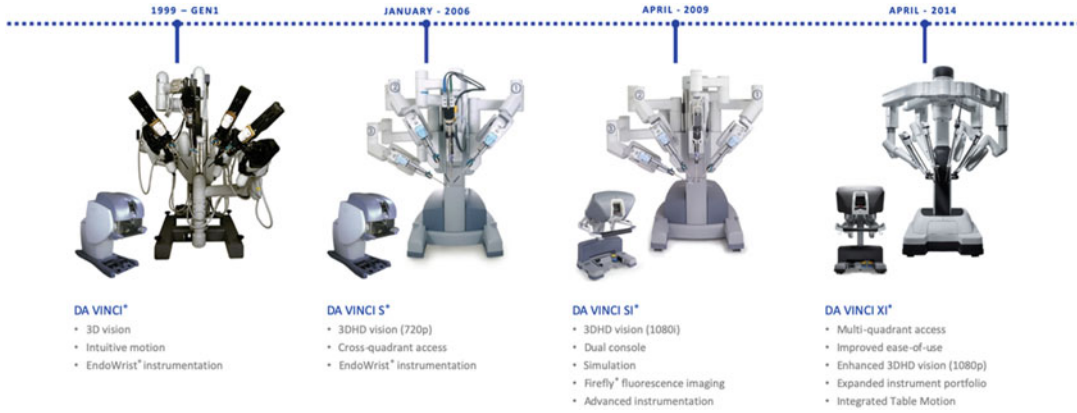

Fig. 59.4 Evolution of the da Vinci® Surgical System (with permissions from Intuitive Surgical, Inc)

on by the slave robot in Strasbourg, France (Kalan et al. 2010).

Shaping this robotic landscape was a seminal legal battle lasting three years between Computer Motion and Intuitive Surgical over the intellectual property rights of these parallel developments. Intuitive Surgical won the lawsuit, which resulted in a merger of the two companies in 2003. While ZEUS had been phased out of production, many of its elements have been integrated into later versions of the da Vinci® platform (George et al. 2018).

Figure 59.4 illustrates the da Vinci® robot evolution from its original prototype in 1999 to the Xi version with its ever-increasing abilities and features (Fig. 59.4). There is also a da Vinci® SP (single port) model which has a single boom for a single 2.5 cm cannula, which allows for control of 3 wristed instruments and a wristed endoscope. Currently, only the Si, Xi, and SP versions of the da Vinci® robot are in operation.

The da Vinci® Surgical System

The da Vinci® surgical system comprises of three integral parts; (1) the surgical console, (2) the patient-side cart, and (3) the electronic or vision cart as illustrated below (Fig. 59.5).

The Surgeon Console is the control center of the system that allows the surgeon to view the surgical field and control the movements of the camera and up to three instruments. The surgeon can adjust the console to suit personal ergonomics. This is a stable operating platform where the hand and the eyes of the surgeon are aligned in a single plane, with the surgeon's forearms being supported, therefore reducing visual and muscular fatigue. There is a magnified *3D* view with the *zoom* feature, *motion scaling* up to a 3:1 ratio and a *tremor reduction* feature. The surgeon can switch between white light modes to near infrared wavelength (i.e., *firefly mode*), to benefit from the fluorescence of a compound called Indocyanine Green (ICG).

As a safety feature, the instruments can only move when the surgeon's head is in the console as detected by infra-red sensors. The robotic instruments (see Fig. 59.6) are wristed (i.e., *Endowrist*®) and controlled with a pincer grip allowing for seven degrees of freedom.

The Patient-Side Cart has articulated mechanical arms which support the instruments and the camera arms. The robotic arms dock onto specific ports that feature a *Remote Center Control (RCC)*, a black marked zone on the port which should be placed in the patient's abdominal wall (Fig. 59.7). The RCC reduces the trauma to the abdominal wall caused by movements of the port during surgery and negates the effect of thick abdominal walls associated with a higher BMI.

The Electronic Cart or Vision Cart contains supporting hardware and software components, such as the electrical surgical unit, suction/

irrigation pumps, insufflator, and light source for the endoscope. It also has a touch screen that can receive auxiliary images or videos to use in multi-image mode called *Tilepro*. One benefit is that the supervisor can draw on the touch screen as a training tool.

Introduction of New Technology

The introduction of new technology in surgery is a careful balance between ensuring technology that can benefit patients is not delayed unnecessarily and preventing harm from its early adoption (Brown et al. 2019). The da Vinci® robot is an excellent illustration of outstanding technology introduced into an evidence-free environment (Maddern 2019). The da Vinci® robot was approved by the FDA in the USA in 2000, after it was determined that it did not represent a major deviation from current laparoscopic techniques. The Learning Curve as described for laparoscopic RYGB is that 30 to 70 cases are required for competency, 100 cases for proficiency, and up to 500 cases to become a master of that procedure (Wehrtmann et al. 2019). Similarly, hours of practice and training are required to overcome the learning curve for robotic procedures.

Safeguards to increase comfortability and remediate learning curve effects include having a constant surgical team for initial cases with an experienced bedside assistant. It is also important to start with less technical procedures such as the sleeve gastrectomy (SG) or to perform "hybrid" robotic/laparoscopic procedures, for example where the robot is only used for the gastro-jejunal anastomosis in a RYGB, with the remainder of the procedure performed laparoscopically.

Overall, it is important that industry has a responsibility to ensure safe integration of their device into medical institutions. Intuitive Surgical had termed this integration as the "da Vinci® Ecosystem" which is summarized in the diagram in Fig. 59.8.

Training Pathway for the da Vinci® Robot

There are several pathways for training on the da Vinci® robot. There is the *Video-based online training* where surgeons are required to log onto the web portal (i.e., www.davincisurgerycommunity.com/) and complete online modules to learn about the system components, its instruments, and advanced technologies. Online assessments need to be performed prior to progressing to the next training step to ensure knowledge competency. *Hands on training* is provided in-house by the da Vinci® representatives to practice docking, port placement, instrumentation, use of the surgeon console, and emergency procedures to power off the device. Ideally, this is performed as a team to gain

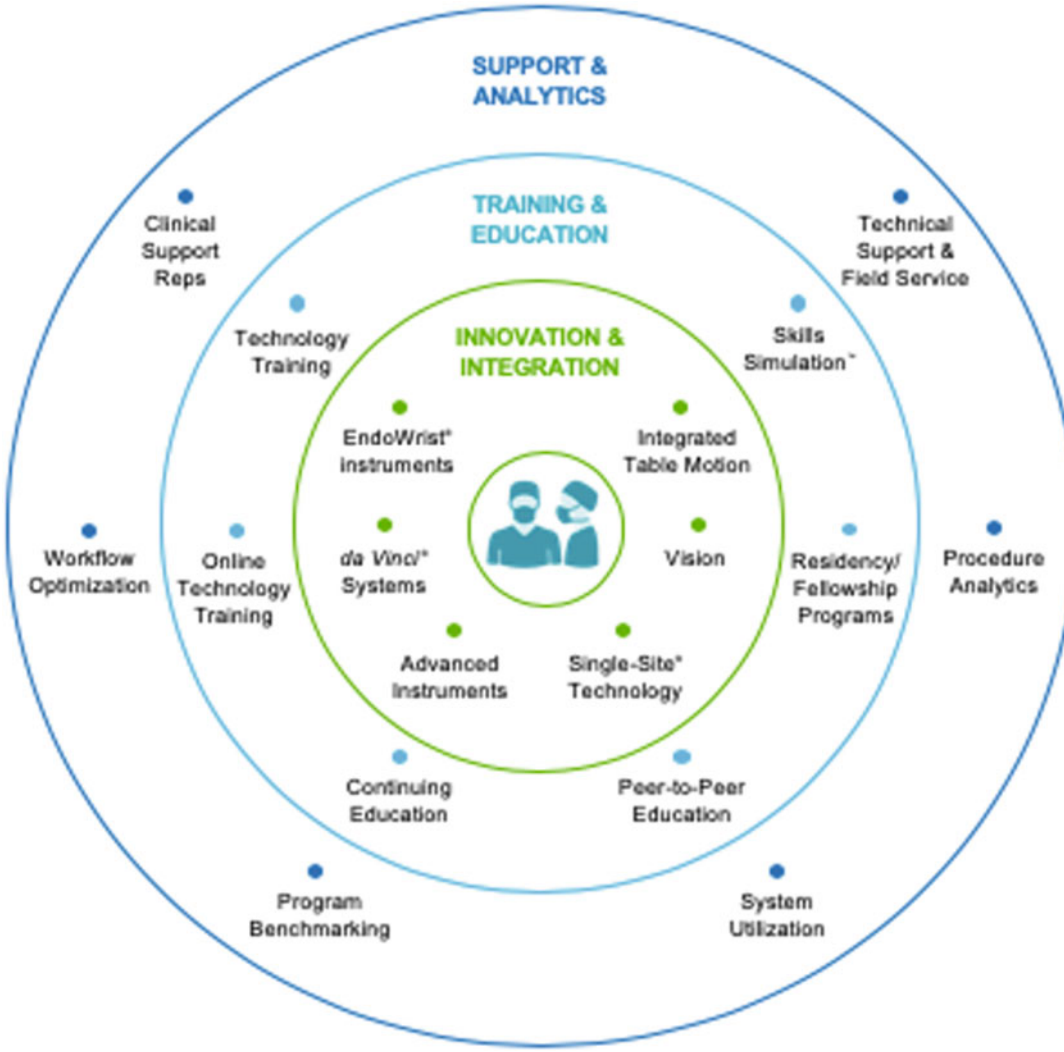

Fig. 59.8 The da Vinci® Ecosystem (with permissions from Intuitive Surgical, Inc)

proficiency and fluidity in docking prior to live cases. Additionally, *Simulation training* (Fig. 59.9) is becoming an increasingly popular training method, which may facilitate shortening of the learning curve without jeopardizing patient safety. Specific tasks can be practised which are relevant to bariatric surgery (Fantola et al. 2014).

Case observation involves watching an experienced robotic bariatric surgeon perform cases and provides the opportunity for real-time learning, while *Wet labs* (i.e., cadaver or animal) are supported by Intuitive personnel and are carried out at medical training facilities such as The Royal Prince Alfred Surgical and Robotic Training Institute in Sydney, Australia. *Proctored* Cases are essential and advantageous with the Proctor providing feedback to the administration on the safety and the quality of the care of the patient, in order to appropriately credential the surgeon for future robotic surgery (Heit 2014). Finally, *Continual Audit and Review* is a process of measuring outcomes such as operative time and patient complications, with an aim of improving in these parameters over time.

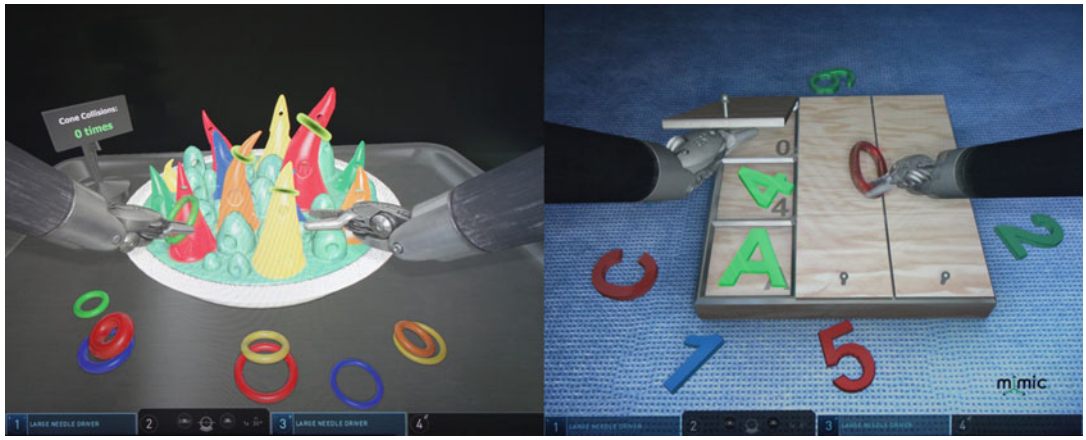

Fig. 59.9 Screenshots of simulation programs available when training with the da Vinci® surgeon console

The Advantages and Disadvantages of Robotic Surgery

The adoption of robotic devices has been reported as being somewhat cost-ineffective. This is due to several factors, which are not uncommon when adopting new technologies, including the initial capital outlay and the learning curves required for proficiency when doing bariatric cases. There are also some unique hazards that the robotic technology presents in this surgical field.

Monetary Costs

The initial capital outlay for the robotic system is 0.5 to 2.5 million US dollars (US$) dependant on the model, configuration, and geographical location of the da Vinci® System (Perez and Schwaitzberg 2019). Then there are additional costs for servicing and consumables. When examining data from the USA HealthCare Cost and Utilization Project, robotic procedures incurred an additional cost of US$1600. If one also counts the initial purchase price of the robot, this additional cost comes in at US$3200 compared to a standard laparoscopic procedure (Service USDoHaH 2019).

In addition to hardware expenses, the team learning curve also should be considered. Robotic procedures typically lead to increases in operating theater time. Applying estimates of operating room time costs of US$37 per minute is a further cost consideration, when evaluating the overall expenses of the robot (Childers and Maggard-Gibbons 2018).

Despite these cost disadvantages, they may be offset by various advantageous factors, including: the (i) patient's reduced length of stay, (ii) reduced surgical-related complications, (iii) avoiding the use of stapling devices, and (iv) operating theater time, which is also important to the health economist.

The cost factor analysis is both specific to the institution and health system. From the model of the Swiss Health Care system, Hagens et al. (2017) found a cost reduction for robotic RYGB when factoring the expense of complications such as leaks. Also, by utilizing hand-sewn anastomosis for the gastro-jejunostomy and jejuno-jejunostomy, there was cost avoidance for not utilizing the stapling device (Hagen et al. 2017).

One cost advantage, which is not easily measured, is the ergonomic improvement for surgeons. Laparoscopy is physically taxing, particularly for bariatric surgeons who have a 66% prevalence of musculoskeletal pain, which can hamper performance (AlSabah et al. 2019). Theoretically, surgeon attrition rates can be decreased by using a robotic platform.

A profitable robotic program would seek to use the robot to its full potential to offset its initial cost. This is analogous to airlines seeking to maximize revenue by keeping their aircrafts in the air as much as possible (Veilleux et al. 2019).

Learning Curve/Operating Theater Time

The learning curve effect has two realms in relation to robotic bariatric surgery. The first is the learning curve of introducing the robot to an established laparoscopic bariatric service. The second is how the learning curves of complex bariatric procedures such as the RYGB may be positively affected by surgeons using robotic technology.

Operating times for robotic RYGB have been found to be consistently longer than for laparoscopic cases (Acevedo et al. 2019; Celio et al. 2017; Li et al. 2016). Unfortunately, longer operations can cause more patient complications such as deep venous thrombosis and surgical site infections. Hence, shorter operative times are associated with better outcomes in bariatric surgery (Reames et al. 2015). Increases in operating time are due to the robot docking times and increased surgeon console times. Experienced teams can achieve the docking component in a matter of minutes. The learning curve for this component is typically achievable within 20 cases (Vilallonga et al. 2012). Robotic surgery may take longer if meticulous dissection is performed or if additional suturing of anastomosis or staple lines is applied.

The question remains whether the da Vinci® robot can aid a surgeon to transition through the learning curve for a complex procedure such as the RYGB. The literature is conflicted in this regard. The robotic learning curve for RYGB cases varies from 14 cases for an experienced laparoscopic surgeon new to RYGB (Buchs et al. 2012), to 84 cases for a surgeon experienced in laparoscopic RYGB (Renaud et al. 2013). In the latter series, the experience of the bedside assistant was an independent predictor of operative time.

Presently, there is only one randomized trial comparing robotic to laparoscopic RYGB. The new fellows' first 50 RYGBs were randomized to totally robotic or laparoscopic procedures, and both groups utilized a hand-sewn gastrojejunostomy. Overall, this study demonstrated a reduction in operating time for the robotic cases, which was amplified as the patient's BMI increased (Sanchez et al. 2005).

Unique Hazards

One hazard is that there is no haptic feedback in robotic surgery. Sutures can break and needles can be bent by the force of the robotic instruments. There has also been concerns raised that automated instruments can pose potential safety hazards. The literature reports robotic mechanical failure or malfunction rates between 0.4 to 4.6% (Agcaoglu et al. 2012). Most malfunctions can be avoided and detected early, through a comprehensive evaluation of the system before starting the procedure. Despite the complexity of the da Vinci robotic system, the fact to date that there have been no reported patient injuries or death due to robotic failure reflects positively on the safety of robotic surgery (Agcaoglu et al. 2012).

Driving Forces Behind the Improvements in Bariatric Surgery

The outcomes of bariatric surgery continue to improve (Wittgrove et al. 1994). The factors responsible for this include improvements in equipment, such as stapler and haemostatic devices, improvements in technique, post-fellowship training in bariatric surgery, surgery being performed in high volume centers by high volume surgeons, improvements in perioperative care including Enhanced Recovery After Surgery (ERAS) protocols, and learning curve effects for surgeons and their institutions. Most published articles comparing robotic to laparoscopic bariatric cases compare robotic cases to laparoscopic historical cohorts, so any advantage seen needs to be viewed with that perspective.

Two other important forces that are driving improved outcomes in bariatric surgery are ERAS programs and improved data collection systems with national and international registries.

Enhanced Recovery After Surgery (ERAS) Programs

ERAS describes multimodal perioperative pathways that are protocoled and provide benefits to the outcomes of surgery. ERAS protocols include a limit on preoperative fasting, deep neuromuscular blockade during general anaesthesia, avoidance of drains, avoidance of opiate analgesia, early post-surgical mobilization, and early return to oral nutrition. When delivered, they result in improved patient outcomes, particularly perioperative pain and nausea, with earlier patient discharge (Ruiz-Tovar et al. 2019). For robotic cases, anaesthetists are especially aware of the need for deep neuromuscular blockade, to avoid any patient movement while the robotic arms are docked. Deep neuromuscular blockade leads to improved surgical conditions and less postoperative pain. ERAS is considered the standard of care and should be implemented prior to deciding whether to replace standard laparoscopy with a robotic digital platform (Slim and Mattevi 2018).

Databases

The primary aim of databases and registries for bariatric surgical patients is to measure outcomes on bariatric surgery and provide quality and safety data. The International Federation for the Surgery of Obesity and Metabolic Disorders (IFSO) has just published its 2019 Global Registry Report, with the three most popular procedures being sleeve gastrectomy (SG) making up 47% of all procedures, RYGB 35%, and gastric band 8% (IFSO 2019b).

The Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP) was rolled out in 2014, and it is the largest bariatric-specific prospective database in the world. It records 30-day outcomes from around 900 American Society of Metabolic and Bariatric Surgery (ASMBS) accredited centers in the USA and Canada, totalling 150,000 annual procedures. Its benefit relates to power and national representation of bariatric surgery. Its limitations are that the database lacks information on procedure-related costs, surgical techniques are not standardized, hybrid robotic/laparoscopic cases are not accounted for, and there is a lack of metrics on surgeon experience (Lundberg et al. 2019). Preceding the MBSAQIP database was the Bariatric Outcomes Longitudinal Database (*BOLD*) which ran from 2007 to 2013 (Celio et al. 2017).

Robotic Bariatric Procedures

The RYGB is historically the most established bariatric procedure, with the original open procedure performed and described by Mason and Ito in 1967 (Mason and Ito 1996), and the laparoscopic procedure first performed by Wittgrove in 1993 (Wittgrove et al. 1994). The RYGB, despite its popularity, is complex and difficult to master. The RYGB has only recently been overtaken by the SG as the most common obesity operation. The SG is popular due to its relative simplicity, low complication rates, and good long-term efficacy (Li et al. 2019). The LAGB has been declining in popularity secondary to the modest weight loss results of this procedure, high rates of revision, and long-term complications (Li et al. 2019). The Biliopancreatic diversion with Duodenal Switch (BPD-DS) is a rarely performed operation, as it is more malabsorptive than the other procedures and is considered the most technically difficult. These four procedures will be discussed below, illustrating the evolution of technique and also outcomes of robotic versus laparoscopic procedures. The SG, RYGB, LAGB, and BPD-DS procedures are illustrated in Fig. 59.10.

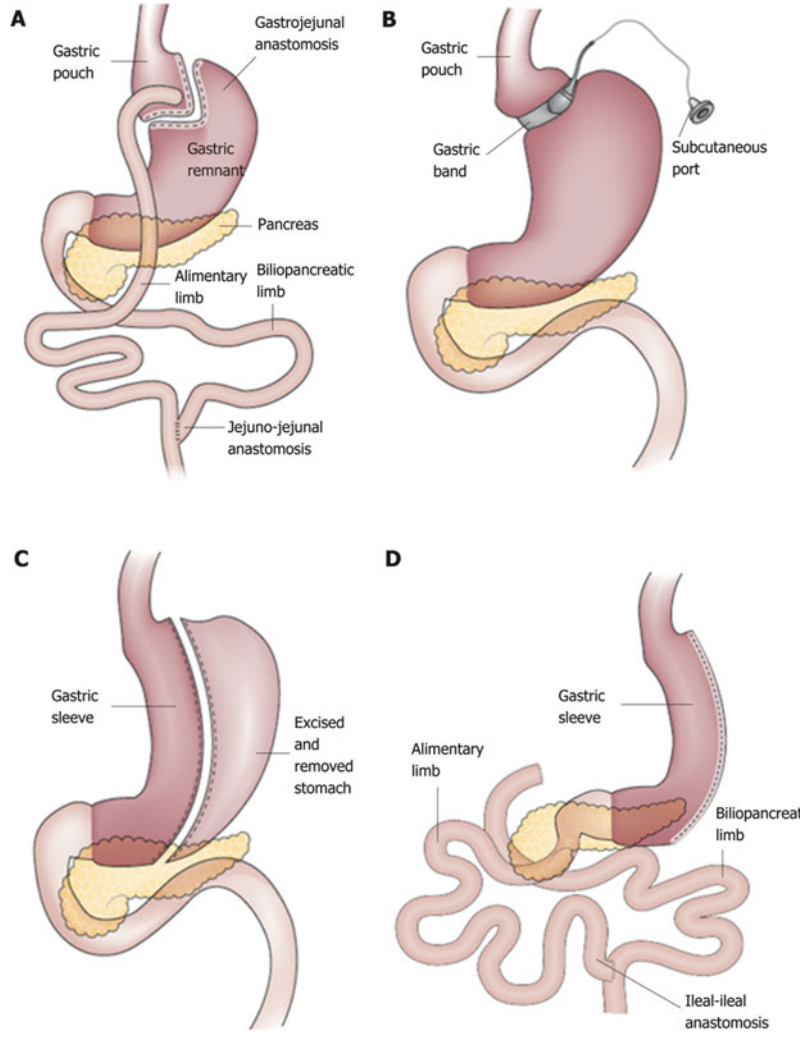

Fig. 59.10 Illustration of the four procedures: (**a**) RYGB, (**b**) LAGB, (**c**) SG, and (**d**) BPD-DS (with permission from Baishideng Publishing Group)

Robotic Sleeve Gastrectomy: The Evolution of Technique from Laparoscopic, Hybrid Procedures to Totally Robotic

The SG involves resecting most of the greater curve of the stomach after it has been devascularized. This leaves a narrow tube of stomach between the gastro-esophageal junction and the pylorus. The SG is considered an ideal training procedure for introducing the robot into a bariatric surgical practice (Silverman and Ghusn 2017) (Figs. 59.11 and 59.12). It is a relatively short operation, so increases in operating time during the learning curve are less clinically relevant. It has even been used as a training procedure for residents (Ecker et al. 2016).

Laparoscopic-assisted robotic SG can be performed with the robot docked for the entire procedure, although the stapling is performed by a skilled bedside assistant, with the console surgeon controlling the tension and alignment of the stomach. The robotic EndoWrist® Stapler was FDA-approved in 2012, initially with 45 mm length staplers. Recently, the more appropriately sized 60 mm staplers are available. The totally

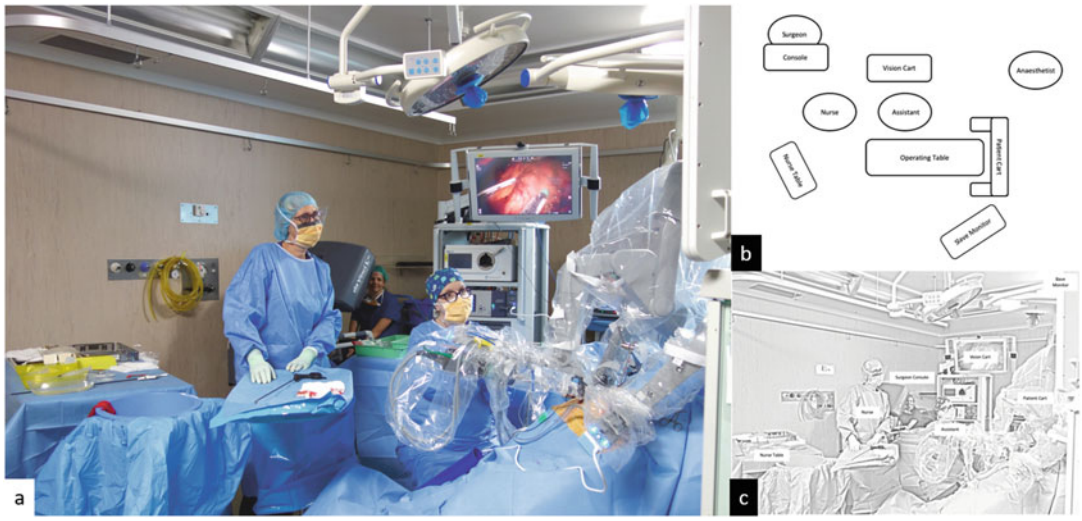

Fig. 59.11 (**a**) Actual OT setup, (**b**) schematic diagram, (**c**) labels on the actual setup

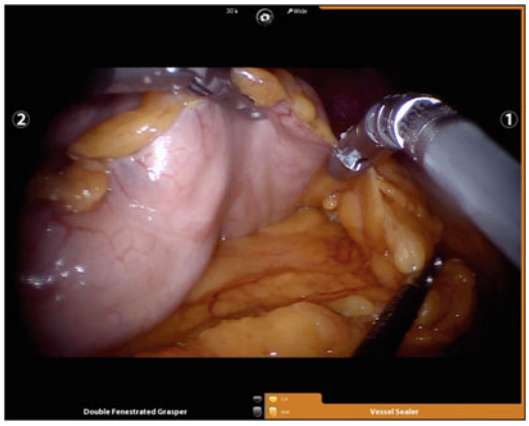

Fig. 59.12 The vessel sealer used to divide short gastric vessels in a sleeve gastrectomy

robotic SG is where the console surgeon can perform the stapling independent of the bed side assistant (Fig. 59.13).

Outcomes of Robotic Sleeve Gastrectomy

A recent systematic review and meta-analysis by Magouliotis et al. (2017) analyzed 16 studies and 29,787 patients and found a longer operating time and length of stay for patients who underwent robotic procedures. A higher cost of robotic SG compared to laparoscopy was demonstrated, without significant differences in patient outcomes including complications and excess weight loss (Moon et al. 2016). Typically, the Learning Curve for performing a SG on the *da Vinci*® system is around 20 cases for an experienced bariatric surgeon (Vilallonga et al. 2012).

Using the MBSAQIP (2016) database of 107,726 patients who underwent a SG, 7% were performed robotically. Overall, robotic-assisted procedures had a longer mean operating time of 89 min compared with 63 min for laparoscopic procedures. There was a doubling of the risk of organ space infection in the robotic group. Organ space infection includes staple line leaks which is a most feared complication. The limitations of this data are that variables of surgeon experience and operative technique such as stapler type (robotic *EndoWrist*® *stapler* or that applied by the bed side assistant) were not accounted for (Lundberg et al. 2019).

Overall, robotic SG can be considered an ideal training procedure to introduce the da Vinci® robot into a bariatric practice. However, increased cost and operative time impede generalized applicability. To date, an empirical benefit of robotic over laparoscopic SG has not been shown. Some caution is warranted with respect to increased infectious complications from recent MBSAQIP data (Lundberg et al. 2019).

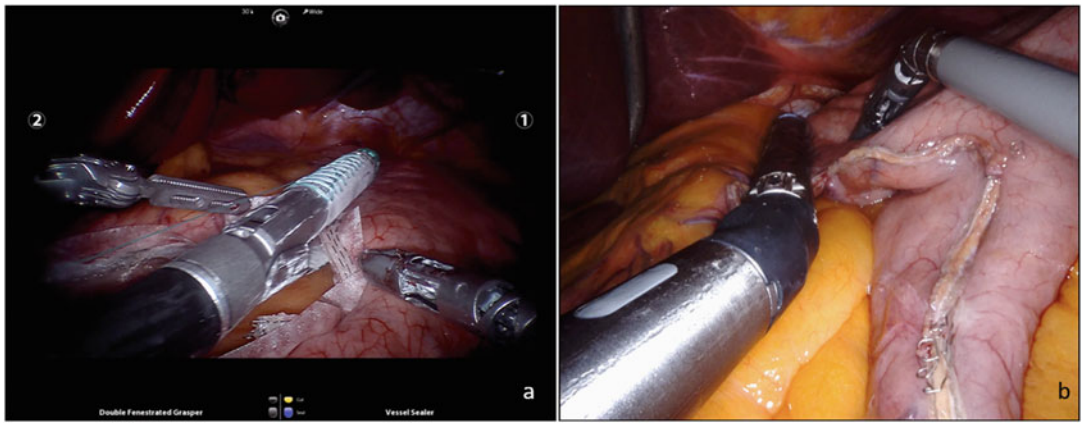

Fig. 59.13 A comparison of (**a**) laparoscopic stapler through the assistant port in the Si, and (**b**) wristed stapler through the robotic port in the Xi

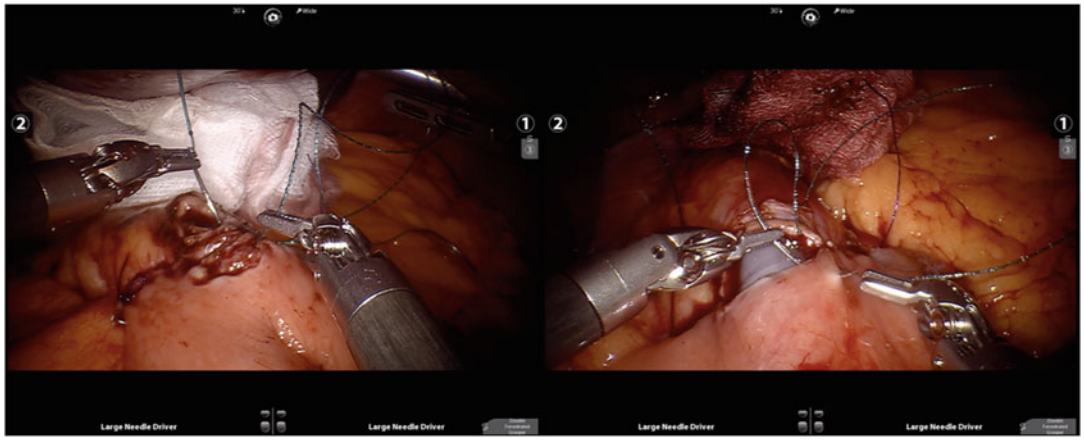

Fig. 59.14 Intraoperative picture of a robotic hand-sewn gastro-jejunostomy

Robotic Roux-en-Y Gastric Bypass: The Evolution of Technique: From Laparoscopic, to Hybrid Laparoscopic/Robotic, to Totally Robotic RYGB

The gastric bypass involves creating a small proximal gastric pouch and rerouting the small bowel (alimentary limb) to connect to this pouch via the gastro-jejunal anastomosis. Secretions of the gastric remnant mix with the bile and pancreatic juices via the biliopancreatic limb which joins the alimentary limb at the jejuno-jejunal anastomosis, forming the common channel. Today, there are many variations of this minimally invasive technique. In regard to the formation of the gastro-jejunal anastomosis, the circular stapler technique, although the most time-efficient, has been hampered by increased complications such as stricture, bleeding, and port site infections. The linear stapled technique and totally hand-sewn gastro-enterostomy have been demonstrated as a preferred technique (Rogula et al. 2018). A totally hand-sewn anastomosis (Fig. 59.14) is the most time-consuming and technically demanding laparoscopically, and this is where the robot excels.

A hybrid approach where the robot is used exclusively for the gastro-jejunal anastomosis

Table 59.2 Meta-analyses and systematic review results of robotic versus laparoscopic RYGB

Author	Patients	Findings
Marker et al. (2011)	1686	Reduction in stricture for robotic cases
Bailey et al. (2014)	2557	Equivalent outcomes through increased cost with robotic cases
Economopoulos et al. (2015)	5145 patients (3189 robotic, 1956 laparoscopic)	Robotic RYGB has lower rates of stricture, reoperations, and a reduced length of stay
Li et al. (2016)	27,997	Similar results through slightly improved stricture rates, reoperations, leak rate, and length of stay for robotic cases
Celio et al. (2017)	137,455 1.8% robotic	Increased morbidity in robotic group. Higher leak rate, stricture, reoperation, and 90-day reoperation rate with longer operating times for robotic procedures
Lundberg et al. (2018)	39,425 7.8% robotic	Equal safety through longer operating time for robotic procedures

has been a starting point for many robotic surgeons. These hybrid, robotic-assisted RYGB were described by Horgan and Vanuno in 2001 (Horgan and Vanuno 2001). Mohr et al. described the first "totally robotic" RYGB in 2005 (Mohr et al. 2005), though the first truly robotic approach would have only been feasible after the market launch of the Endowrist® stapler in 2014 (Jung et al. 2017).

Outcomes of Robotic RYGB

Many studies have compared robotic with laparoscopic RYGB, mostly from single institutions or meta-analysis of fewer than 3000 patients, with mixed results. *Comparative studies* show potential benefit of the robotic approach, especially when a hand-sewn gastro-jejunal anastomosis is performed (Jung et al. 2017). In the largest cohort series of two surgical sites, Tieu et al. (2013) reported 1100 patients operated on robotically with only one gastro-jejunal leak, which equated to a 0.09% leak rate (Tieu et al. 2013). Currently, there is only one single *randomized trial of RYGB outcomes* which was underpowered; however, did find a reduction in operative times during the learning curve on the robotic platform (Sanchez et al. 2005). Table 59.2 summarizes the current *meta-analyses* and *systematic reviews* on Robotic RYGB versus Laparoscopic RYGB.

In summary, RYGB robotic procedures now offer surgeons a safe modification to conventional laparoscopic RYGB, though at the expense of surgical time and money.

Robotic Adjustable Gastric Band

An adjustable gastric band is a restrictive bariatric procedure where a silicone band is placed one to two centimeters below the gastro-esophageal junction, with the device being secured with a suture on the gastric wall. Placement of an adjustable gastric band requires minimal dissection, tissue handling, and suturing. Due to its declining use in bariatric surgery, the number of robotic gastric band cases performed is limited, and robotic technology did not add any benefit to this procedure (Alibhai et al. 2015). However, a study by Edelson et al. did report an advantage when performing those procedures robotically in patients with a BMI over 50 kg/m^2 (Edelson et al. 2011).

Robotic Biliopancreatic Diversion with Duodenal Switch (BPD-DS)

Sudan and Podolsky reported the first BPD-DS as a hybrid robotic procedure in 2000, initially as a multiple docking procedure and finally with a single docking approach (Sudan and Podolsky 2015). The Xi version of the da Vinci® robot with its integrated table motion, robotic

arm-controlled staplers, and improved mobility has enabled this single docking robotic procedure.

Revisional Bariatric Procedures

Revisional bariatric procedure numbers are increasing as a percentage of procedures performed, having doubled in number from 2011 to 2015 (El Chaar et al. 2018); MBSAQIP data show they represent 11.9% of bariatric procedures performed (Clapp et al. 2019). Revisional cases are challenging, take longer to perform, and are associated with higher patient morbidity (El Chaar et al. 2018). It is in this setting the da Vinci® robot would be expected to excel. Single site performance analyses have indicated excellent results, with complication rates from revisional RYGB being equivalent to outcomes for primary bariatric procedures (Snyder et al. 2013). MBSAQIP data from 2015, however, have not demonstrated an advantage for the robotic platform in revisional cases (Clapp et al. 2019).

Future Directions of Robotic Technology in Bariatric Procedures

We are on the precipice of new technologies in surgical robotics, with the promises of nanotechnology and the applications of big data. Big data is defined as a set of data so large that traditional data processing applications are ineffective (Taragona and Batista 2018). Big data is now driving Artificial Intelligence, Machine Learning, and Automaticity (Lazar 2019). Robotic surgery has an important role in big data acquisition. Every surgical movement on a robotic platform is a data point. Machine learning enables machines to make predictions by recognizing patterns (Hashimoto et al. 2018). This could effectively create a "*collective surgical consciousness*" as, while operating, you provide information which helps to decide the future (Rodriguez Luna and Vilallonga 2019).

Augmented Reality

Under this platform, the robot would anticipate the surgeon's next move with real-time prediction and avoidance of adverse events, with decision support akin to an intraoperative Global Positioning System. Advances in computer vision now enable augmented reality, created by fusing images and the use of fluorescence in real-time. Similarly, the worldwide introduction of 5G technology with wireless transmission and real-time data analytics may allow robotic surgery to be made available in remote areas to standardize surgical care. Data can aid in better value-based healthcare to determine what instruments and devices are actually required. The true potential of Artificial Intelligence is difficult to predict, and its ability is limited by the quality of the data analyzed (Dibbs and Hollier 2019).

Autonomous Surgery

Technical skill augmentation with task deconstruction and autonomous performance of tasks such as suturing is already here with robots that outperform humans in bowel anastomosis on experimental models (Hashimoto et al. 2018). Natural Orifice Transluminal Endoscopic Surgery (NOTES), also known as scar-less surgery, is where the abdominal cavity is entered via the stomach, vaginal vault, or rectum to perform procedures. Due to the technical limitations of current endoscopic systems, only transvaginal-assisted SG and LAGB have been performed with this approach (Erridge et al. 2016). Improved robotic platforms may allow NOTES anastomotic procedures to become feasible. In the future, "Nanobots" (nanosize robotic machines) could allow patients to swallow a surgical device and undergo genetic manipulation or molecular medicine diagnosis, with the help of novel miniaturized vehicles.

New Robotic Platforms and Manufacturers

With less than 5% of global procedures performed robotically, the space is open for the digitalization and mechanization of minimally invasive surgery, and the race is on for industry to fill this void. The global market for Robotic-Assisted Surgery is predicted to have a compound annual growth rate of 10.4%, from US$3.9 billion in 2018 to US$6.5 billion by 2023 (Review RB 2019). New robotic systems now display features of modularity, improved affordability, and data acquisition with consumer feedback using a decreased physical footprint (i.e., size reduction), when compared with the da Vinci® System. Two exciting new robots are the Senhance™ by Transenterix and the Versius™ by Cambridge Medical Research (CMR), both FDA-approved and available on the market (Perez and Schwaitzberg 2019).

Senhance™ (Transenterix Inc., Morrisville, NC, USA)

The Senhance™ has haptic feedback and an open footprint with the surgeon in a seated position, wearing 3D glasses. A stand-out feature of this system is that the endoscopic camera is controlled with the surgeon's eye movements. The instruments are reusable, though not wristed (Fig. 59.15). Currently, this robot has found its way into the Japanese market (Transenterix 2019). In the USA, it has limited (510 k) clearance by the FDA for some surgical modalities; however not including bariatric operations.

Versius (Cambridge Medical Research, Cambridge, UK)

The Versius™ is portable and modular, with the aim of working interchangeably with laparoscopic equipment. It has five arms which are self-contained, each weighing 25 kg, with intelligence and sensing capability for surgeon control and assistant staff. The surgeon console is open, slim, and portable, and the surgeon has the option of sitting or standing for optimal ergonomics. It is supplied as a service including the robot, instruments, and maintenance at a fixed annual cost, with the aim to keep costs similar to laparoscopic systems. Galaxy Care Hospital in Pune, India, was the first to use the Versius™ robot (Fig. 59.16). The company is committed to monitoring all outcomes on their system and has initiated the world's first clinical registry for surgical robotic systems (Network MD 2019).

Additionally, there are the eagerly anticipated offerings from the company VerbSurgical Inc. (Bayshore, CA, USA), which is a partnership

Fig. 59.15 Senhance™ robot operating room setup (with permission from Transenterix Inc.)

Fig. 59.16 Versius™ robotic system setup in the operating room (with permission from CMR)

between Johnson & Johnson and Google. This well-funded start-up company aims to create a new paradigm in digital surgery with a connected platform between the surgeon and patient, for all phases of patient care (VerbSurgical 2019). Despite these aspirations, they are yet to divulge information about their soft tissue robotic system, which is pegged for commercial release in 2020 (Biotech 2019).

Robotic devices beginning to emerge are summarized in Table 59.3.

Authors' Perspective

A surgeon's ability to transition from a pure laparoscopic surgeon to a robotic surgeon requires access to a da Vinci® robot at their institution and the intrinsic drive to immerse in this technology. The training phase takes time and commitment, though provides a unique challenge via the complete disruption of the traditional surgeon-to-patient interface.

The initial cases are exhilarating with a sense of accomplishment to be operating in a foreign way. Having a specialist proctor for the first few cases and performing less technically demanding procedures, such as the SG, can ease the stress during this transition. Every member of the team has their own robotic learning curve so that patience, leadership, and a focus on positive communication to support team dynamics are important.

Next comes a phase of disillusionment as realities set in. Administrative frustrations, such as a lack of access to the robot, additional "technology" fees, and insurance not covering costs for example, need to be overcome. Often business cases need to be drawn up and robot access issues resolved via consistent negotiations with hospital administration and other surgeons.

The time spent in this phase depends not just on volume alone, but on the frequency of operations performed, the complexity of the cases, and also the consistency of the operating team. Coaching, mentoring, and video analysis are important tools for advancement and competency.

After the learning curve for simple procedures has passed, the robot can be used for more complex and revisional procedures. These later cases appear more precise, and operative times are improving. Importantly, there is less physical fatigue after completing a robotic case.

The robotic platform can be used across various surgical specialty groups (e.g., general

Table 59.3 Summary table of emerging robotic-assisted surgery platforms

Product	Unique features	Prototype	Regulatory clearance
Single Port Orifice Robotic Technology SPORT™*, Titan Medical	– Single port system with flexible endoscopic 3D camera – Two wristed instruments can be used together with the camera		FDA in 2020
Hugo™ *, Medtronic	– Open surgeon console – Up to five minimally invasive robotic-assisted modular arms, incorporating elements of MiroSure – Tower and visualization system, generator, process, and endoscopy can be used for laparoscopy or open surgery		FDA in 2021
REVO-I™ *, Meere Company	– Similar in design and concept to da Vinci® Si – Haptic feedback to be introduced in new version		South Korea,2017
Verb Surgical™ *, Johnson & Johnson, Google			FDA in 2020
Vicarious™ *, Vicarious Surgical	– In-vivo robot fully inserted into patient through thumb-sized incision – Controlled wirelessly by surgeon wearing virtual reality goggles – Full suite of proprietary instruments including staplers, energy devices, and retractors		–

SPORT is a Trade Mark of Titan Medical; Hugo is a Trade Mark of Medtronic; REVO is a Trade Mark of Meere Company; Verb Surgical is a Trade Mark of Johnson & Johnson; Google Vicarious is a Trade Mark of Vicarious Surgical

surgery, colorectal surgery, hernia surgery, urology, gynaecology, and head and neck surgery), and hence, requires its own service line of administrative support. Efficiencies can be gained by working together, improving communication, collaboration, and having goals that are measurable and achievable (Fagin 2014).

Membership with the Clinical Robotics Surgery Association and the Facebook group Robotic Bariatric Collaboration ensures well-rounded learning with vicarious peer-to-peer interactions and video reviews (Myers et al. 2018).

Two-dimensional laparoscopic skills are required for port placement and division of adhesions and to allow the robotic ports to be inserted. There is also a need to train fellows and residents in laparoscopy. For most institutions, the da Vinci® robot is only available in usual working hours for elective cases. Emergency and weekend use of the robot is, however, possible with considered planning and availability of trained staff. This would expand the applications of the robot (Sudan and Desai 2012).

Presently, robotic surgery in bariatrics will not replace standard laparoscopy. Interestingly, it has been commented on that being a robotic surgeon can make you a better laparoscopic surgeon (Wilson and Sudan 2013), and this is certainly applicable to my robotic journey. Instead of

viewing the robotic platform as one that needs to delineate traditional methods, the use of the robot can be viewed as a complementary adjunct to performing surgery on difficult cases, with the added benefit of less surgical fatigue and providing different and emerging stimuli for surgical skill acquisition (Wilson and Sudan 2013).

Abstract

The prevalence of both obesity and osteoarthritis is increasing. Obesity is an independent risk factor for osteoarthritis. Both mechanical and inflammatory factors contribute to this risk. The gold-standard treatment for end-stage knee and hip osteoarthritis is total joint arthroplasty. Patients with obesity have worse outcomes than patients with normal weight following total joint arthroplasty. There is a dearth of information on the effects of bariatric surgery on the incidence of total joint arthroplasty, and the impact on outcomes is limited with mixed results. Further study on total joint arthroplasty in patients with obesity is needed to determine optimal risk stratification, bariatric procedure selection, and timing of bariatric surgery relative to total joint arthroplasty.

Keywords

Bariatric surgery · Lower extremity osteoarthritis · Arthroplasty · Outcomes

Introduction

In 2016, the prevalence of obesity in America was 39.8% among adults (Hales et al. 2017), with an estimated 7% reaching morbid obesity, defined as a body mass index (BMI) >40 kg/m^2 (Sturm and Hattori 2013). Osteoarthritis (OA) is also highly prevalent. It is estimated that 25.9% of the projected total adult population will have doctor-diagnosed arthritis by 2040 (Hootman et al. 2016). The lifetime risk of end-stage knee osteoarthritis alone is 13.3% for men and 18.8% for women (Ogden et al. 2014). Knee OA is the second most prevalent cause of disability in the world (GBD 2016 Disease and Injury Incidence and Prevalence Collaborators 2017). The risk of OA-associated disability is as elevated as of cardiac conditions (Wang et al. 2016) and is the most prevalent of all diseases in the elderly (Yokota et al. 2015). In terms of hospital charges, osteoarthritis is more expensive than pneumonia, stroke, or complications from diabetes (Teichtahl et al. 2009).

Obesity is an independent risk factor for osteoarthritis (Gu et al. 2019). Patients with grade II obesity have 4.7 times the likelihood of developing knee osteoarthritis compared to those with normal weights (Reyes et al. 2016). Research suggests this risk is due to both biomechanical and systemic inflammatory effects on joints (Koonce and Bravman 2013). These effects eventually lead to total joint arthroplasty (TJA) in an increasing number of patients with obesity (Belmont et al. 2014; Fehring et al. 2007; Kremers et al. 2014). In the United States, over one million total knee and total hip replacement procedures are performed yearly.

Patients with obesity are known to have a higher risk of complications for total joint arthroplasty (Salih and Sutton 2013; Belmont et al. 2014). The American Association of Hip and Knee Surgeons suggests weight loss prior to TJA for patients with BMI >40 kg/m^2 (Workgroup of the American Association of Hip and Knee Surgeons Evidence-Based Committee 2013). While diet and exercise are important for a healthy lifestyle, these methods will not achieve a significant sustained weight loss. Bariatric surgery has been shown to provide sustained weight loss, as well as resolution of many obesity-related comorbidities, including type II diabetes, gastroesophageal reflux, and hyperlipidemia (Sharples and Mahawar 2019). Data investigating the effect of prior bariatric surgery on postoperative TJA outcomes is mixed.

Impact of Obesity on Lower Limb Osteoarthritis

In the United States, 31% of those with obesity were diagnosed with arthritis, while only 16% of normal weight individuals carried the diagnosis (Center for Disease Control and Prevention 2018). Obesity has been shown to be an independent risk factor for osteoarthritis (Gu et al. 2019). In a Swedish study by Jarvholm et al.,

15–67 year-old male construction workers were found to be more likely to undergo knee or hip replacement as BMI increased, even when controlling for age and tobacco use (Jarvholm et al. 2008). Data from the Nurses' Health Study, which included over 121,000 female nurses, revealed those with a BMI >35 kg/m^2 were twice as likely to undergo total hip arthroplasty (THA) compared to those with BMI <22 kg/m^2. Interestingly, those with a higher BMI at age 18 years had the highest risk of undergoing THA (Karlson et al. 2003).

Weight-Bearing Forces

Joint "wear-and-tear" secondary to mechanical and structural factors has classically been suggested as the mechanism for osteoarthritis. While these factors surely contribute, recent studies suggest they cannot solely account for the relationship between obesity and osteoarthritis (Sowers and Karvonen-Gutierrez 2010). For example, in a systematic review and meta-analysis by Long et al., both lean and fat mass in subjects with knee osteoarthritis were higher than in those without osteoarthritis. While fat mass percentage was positively associated with knee osteoarthritis, lean mass percentage was negatively associated with knee osteoarthritis. Increased fat mass was also associated with hand joint osteoarthritis (Long et al. 2019). The increased incidence of non-weight-bearing joint osteoarthritis in individuals with obesity has led to investigation into inflammatory factors.

Mechanical Factors

Abnormal loading of the knee and hip joint can lead to changes in the composition, structure, and mechanical characteristics of articular cartilage (Maly et al. 2005; Mundermann et al. 2005).

Joint load during walking is directly related to body weight. Peak *in vivo* hip contact forces during normal walking have been noted to be 2–3 times body weight (Heywood et al. 2019). So, as body weight increases, so do joint contact forces. The knee joint is especially vulnerable in the population with obesity where there is a high fat:lean mass ratio. The quadriceps muscle may fail to adequately absorb forces on the knee joint, leading to an increased load on the articular cartilage and subsequent progressive degeneration (Maly et al. 2005). Knee joint loads during walking and stair climbing have been shown to be higher than loads across the hip joint (Taylor et al. 2004).

Gait Changes

Gait disturbances are also common in patients with obesity. In a systematic review, Runhaar et al. found that patients with obesity had altered lower extremity biomechanics for everyday movements including walking, standing, and rising from a sit-to-stand position. When walking, patients with obesity took shorter, wider steps and chose a slower pace. During standing, individuals with obesity had greater toe-out angles. When transitioning from sitting to standing, those with obesity had less hip flexion and greater foot displacement. These adjustments lead to alterations in the regions of the articular cartilage within the joint that bears the load and higher loads across the hip and knee joints (Runhaar et al. 2011). While gait alterations are likely adaptations adopted as a means to temporarily offload the hip and knee joints, studies show that joint loads in excess of 4 times body weight can occur regularly. Furthermore, stumbling can result in loads over 8 times body weight (Bergmann et al. 2001).

Inflammatory Factors

Obesity has been shown to be associated with a chronic inflammatory state. Specifically, where adipocytes were previously seen as solely storage vesicles, they are now known to be metabolically active cells that secrete a multitude of factors, termed adipocytokines. Many of these adipocytokines are thought to play a role in cartilage homeostasis. Because obese patients have a

higher adipocyte mass, the secondary changes in the adipocytokine milieu are thought to contribute to the degradation of cartilage, and therefore, the development of osteoarthritis (Francisco et al. 2018b).

Research on adipocytes and adipocytokines aims to determine why obesity is associated with a range of comorbidities, including osteoarthritis. Adipocytokines of interest include leptin, adiponectin, resistin, visfatin, lipocalin-2, chemerin, and apelin (Fig. 60.1) (Sowers and Karvonen-Gutierrez 2010; Francisco et al. 2018a).

It is unknown why some patients with obesity develop osteoarthritis while others do not, despite all these patients experiencing increased joint loads and most having altered gait characteristics. However, the conglomerate of comorbidities associated with metabolic syndrome may have an interrelated etiology. Karvonen-Gutierrez et al. showed that cardiometabolic biomarkers are associated with knee osteoarthritis regardless of BMI. In this report, mid-aged women with both obesity and two or more cardiovascular risk factors were more than 6 times more likely to have knee osteoarthritis when compared to women without obesity or cardiometabolic risk factors (Karvonen-Gutierrez et al. 2012).

Association of Inflammation with Mechanical Stress

There is evidence that increased load on the knee joint experienced by individuals with obesity may lead to the release of cytokines, growth factors, and metalloproteinases triggered by mechanoreceptors on the surface of chondrocytes (Sowers and Karvonen-Gutierrez 2010), which may contribute to the inflammatory milieu in addition to the increased adipocytokine production by adipose tissue.

Leptin

One of the most studied adipokines that likely plays a role in the development of osteoarthritis is leptin. Leptin is classically known as a metabolic adipocytokine that acts to reduce food intake and increase energy expenditure. It is known to be present in both plasma and synovial fluid in higher concentrations in individuals with obesity (Dumond et al. 2003). Griffin et al. showed that leptin-deficient mice could develop an obese phenotype without increasing the incidence of osteoarthritis, suggesting a key role for leptin in the development of osteoarthritis (Griffin

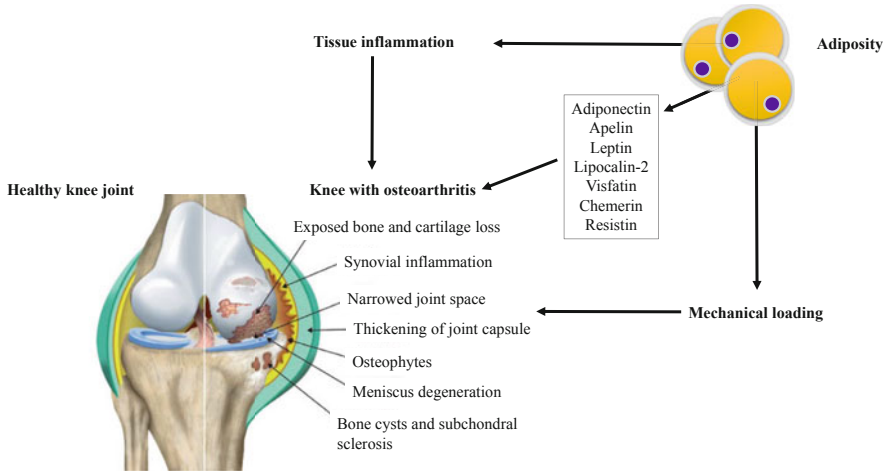

Fig. 60.1 Illustration depicting the effects of increased fat mass and dysregulation in cartilage degradation (Adapted from Uhalte E, Wilkinson JM, Southam L, Zeggini E. Pathways to understanding the genomic aetiology of osteoarthritis. Hum Mol Genet. 2017;26(R2):R193-R201)

et al. 2009). Leptin has a synergistic relationship with pro-inflammatory cytokines which leads to increased production of several inflammatory factors, growth factors, and matrix metalloproteinases by chondrocytes (Francisco et al. 2018a). Leptin also has been shown to affect chondrogenic progenitor cells by reducing their ability to migrate, changing their differentiation pathway, and modifying their cell cycle, ultimately altering their ability to maintain cartilage homeostasis and replace damaged tissue (Francisco et al. 2018b). Leptin likely has a dose-dependent relationship with manifestations of osteoarthritis. Leptin expression in cartilage, subchondral bone, synovial tissues, and osteophytes has been associated with the degree of cartilage degeneration and radiologic severity of osteoarthritis (Fig. 60.2) (Simopoulou et al. 2007; Francisco et al. 2018b).

Adiponectin

Adiponectin is a protein structurally similar to collagen that is synthesized by adipose tissue, although circulating levels are inversely related to weight. Using knockout mice, adiponectin has been associated with preventing insulin resistance and lipid accumulation in muscles when the mice are placed on a high fat/sucrose diet (Francisco et al. 2018a). Adiponectin receptors have been found in cartilage, bone, and synovial tissues (Sowers and Karvonen-Gutierrez 2010). Conflicting data exists regarding the role of adiponectin in the development of osteoarthritis with some studies suggesting a protective effect (such as inhibition of pro-inflammatory factors, stimulation of osteoclast proliferation, and mineralization), while others suggest a negative effect (such as increased production of

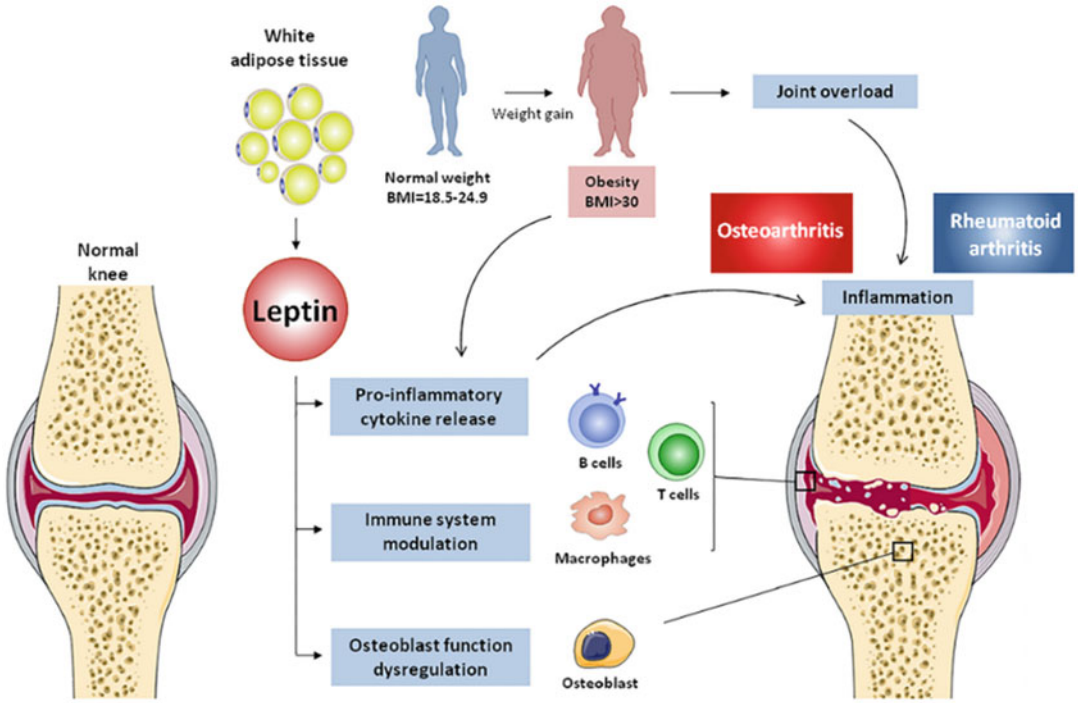

Fig. 60.2 Effects of adipose tissue-derived leptin on osteoarthritis and rheumatoid arthritis. Body weight gain, accompanied by white adipose tissue expansion, leads to obesity and subsequent increase of mechanical load, resulting in cartilage degradation and osteoarthritis onset. Adipose tissue-derived leptin causes osteoblast dysregulation in subchondral bone, thus promoting joint destruction. Additionally, leptin induces pro-inflammatory cytokine release from innate and adaptive immune cells, generating an inflammatory environment that prompts cartilage damage and rheumatoid arthritis (Reprinted from Francisco V, Pino J, Campos-Cabaleiro V, et al. Obesity, Fat Mass and Immune System: Role for Leptin. Front Physiol. 2018;9:640)

pro-inflammatory factors, inhibition of osteoclast differentiation, promotion of apoptosis) (Francisco et al. 2018a).

Studies have shown an increase in adiponectin in patients with osteoarthritis compared to heathy controls, as well as in patients with the radiologically most severe osteoarthritis disease. Both exercise and mechanical loading have been shown to increase adiponectin levels and its receptors in skeletal muscle, suggesting that adiponectin may play a protective role in preventing bone loss (Francisco et al. 2018a).

Resistin

Serum resistin levels have been shown to be increased in obesity and associated with adipose tissue inflammation. While in rodents the main source of resistin is adipocytes, in humans it is macrophages. Both serum and synovial fluid levels of resistin have been found in higher concentrations in patients with osteoarthritis compared to healthy controls; however, its correlation to radiographic damage is unclear, with conflicting evidence. Resistin is a pro-inflammatory cytokine that has been associated with increased levels of other cytokines and chemokines and with increased osteoblast proliferation (Francisco et al. 2018a).

Other Adipocytokines

Other adipokines that may contribute to the development of osteoarthritis in the population with obesity include visfatin, lipocalin-2, chemerin, and apelin. In patients with osteoarthritis, visfatin production was noted in several joint structures including the infrapatellar fat pad, synovium, and osteophytes. Visfatin is more prevalent in the serum and synovial fluid of osteoarthritis patients, where it increases both the production of pro-inflammatory factors and the degradation of joint connective tissue and extracellular matrix (Francisco et al. 2018a). Lipocalin-2 is a glycoprotein that circulates in a covalent complex with matrix metalloproteinase-9, whose main source is adipose tissue. Lipocalin-2 is expressed in joint tissues and found in elevated levels in patients with obesity as well as in patients with osteoarthritis. It has been shown to stimulate pro-osteoclastogenetic factors, inhibit anti-osteoclastogenic factors, and reduce chondrocyte proliferation. Levels have been correlated with fracture risk in the geriatric population (Francisco et al. 2018a).

Chemerin and its receptor are both expressed in adipose tissue, and levels are correlated with BMI in humans. The adipokine has been shown to be upregulated in adipose tissue of obese rats with type 2 diabetes mellitus. It is suspected to serve as a bridge between innate and adaptive immunity and possibly plays a role in osteoblast differentiation (Francisco et al. 2018a). Apelin is thought to be a pro-inflammatory adipokine that is found in higher levels in synovial fluid in individuals with osteoarthritis and has been positively correlated with severity of disease. It increases expression of catabolic factors in chondrocytes and decreases proteoglycan in articular cartilage (Francisco et al. 2018a).

Impact of Obesity on Arthroplasty

The risk of complications after total joint arthroplasty is particularly high once BMI reaches 40 kg/m^2. In a cohort followed for 10 years, mortality was higher in both genders, whereas risk of revision and dislocation increased in men only, contrasting with risk of reoperation, elevated in women (Tohidi et al. 2019). Short-term postoperative complications are likely related to the increased incidence of comorbidities in patients with obesity, as well as increased intraoperative difficulty, such as technical errors, surgeon reported difficulty, and problems that occur during surgery (Jarvenpaa et al. 2010; Nunez et al. 2011). Type II diabetes and obstructive sleep apnea, common comorbidities in the population with obesity, have both been associated with an increase in serious postoperative complications after TJA (Jamsen et al. 2012).

Severe obesity is noted to be associated with an increased risk of surgical site infections, respiratory complications, thromboembolic events, and hospital length of stay (Zusmanovich et al. 2018).

In the most comprehensive systematic review and meta-analysis on the effect of obesity on postoperative outcomes of TJA for osteoarthritis, 31 studies from 18 different countries were included. Patients without obesity were found to have fewer postoperative infections and fewer deep venous thromboses after either total hip arthroplasty (THA) or total knee arthroplasty (TKA) when compared to patients with morbid obesity (Pozzobon et al. 2018).

Late Postoperative Abnormalities

Long-term complications are likely associated with the mechanical and structural effects of obesity on artificial joints over time. The differences in joint load and daily movements between individuals with obesity versus normal weight, mentioned in the prior section, lead to increased risk for accelerated bare surface wear, early prosthesis failure, implant loosening, need for revisional joint surgery, and component malposition in the population with obesity after TJA. Likely due to the increased load in the knee compared to the hip joint, these effects are particularly evident after TKA (Abdel et al. 2015; Kerkhoffs et al. 2012).

Revisions after TJA have been shown to be higher in individuals with obesity versus those without obesity, with more discrepancies after TKA than THA (Chee et al. 2010; Foran et al. 2004). Patients with obesity are also at increased risk of prosthetic dislocation after THA (Watts et al. 2016). In a systematic review by Barrett et al., THA outcomes were compared between 66,238 patients who were morbidly obese and 705,619 patients with a BMI <30 kg/m^2. The overall revision rate was 7.99% in patients with morbid obesity versus 2.75% in patients without obesity (Barrett et al. 2018).

Functional Outcome

Poorer functional results are likely due to the conglomerate effect of short-term and long-term complications experienced. In the same comprehensive systematic review and meta-analysis mentioned above, participants without obesity reported less knee pain at both short-term (<6 months) and long-term (>6 months) follow-up after TKA, and less hip pain at short-term follow-up after THA. Patients without obesity also reported less disability at long-term follow-up for both TKA and THA (Pozzobon et al. 2018). The functional outcome, quantified using the Harris Hip Score, was comparable between patients with and without obesity. However, the individual studies that looked at quality of life did report lower Short-Form scores in patients with obesity postoperatively (Barrett et al. 2018).

Impact of Weight Loss and Bariatric Surgery on Osteoarthritis

A 5–10% weight loss significantly improves pain, self-reported disability, and quality of life in adults with both obesity (BMI 33–36 kg/m^2) and mild to moderate knee osteoarthritis (Chu et al. 2018).

In-hospital complications after hip and knee arthroplasty, and 90-day troubles after knee arthroplasty, diminish in patients who underwent prior bariatric surgery (McLawhorn et al. 2018a, 2018b). As many as 91% of patients undergoing gastric bypass or sleeve gastrectomy experienced a resolution of arthropathy by 21 months after surgery (Nelson et al. 2006). All patients undergoing sleeve gastrectomy had resolution of their joint pain 1 year after surgery, in another experience (Moon Han et al. 2005).

Studies assessing the specific effect of bariatric surgery on osteoarthritis progression suggest several benefits including: radiographic improvement of disease, decreased frequency and intensity of joint pain, improved physical function, and improved range of motion (Groen et al. 2015).

Improvements have also been noted in postural stability and sway during walking, which may decrease the magnitude and frequency of abnormal joint loads experienced by patients with obesity (Ponta et al. 2014).

Improved gait parameters including decreases in step width in the frontal plane, increases in step length, decreased torque around the hip and knee joint, and increased self-directed walking speed were noted after bariatric surgery. However, other studies suggest weight loss leads to increased torque across joints due to the increased stride length and gait velocity that accompany weight loss (Vartiainen et al. 2012; Vincent et al. 2012).

Impact of Bariatric Surgery on Arthroplasty

Because of the increased short-term and long-term complications, poorer functional outcomes, and increased cost of TJA in patients with morbid obesity compared to patients with normal BMI, the American Association of Hip and Knee Surgeons suggested to strongly recommend consideration for weight loss prior to TJA in patients with BMI > 40 kg/m^2 (Workgroup of the American Association of Hip and Knee Surgeons Evidence Based Committee 2013). Bariatric surgery has been shown to be the only reliable method of weight loss and comorbidity resolution for patients in this BMI range, though the effect of bariatric surgery on TJA outcomes shows mixed results.

The three most recent systematic reviews evaluating the effect of bariatric surgery prior to TJA include the same 13 studies in different combinations. Gu et al. reported conflicting evidence on the impact of bariatric surgery prior to TJA on in-hospital complications, 30-day complications, 90-day complications, revision rates, and hospital length of stay (Gu et al. 2019). Similarly, Stavrakis et al. reviewed 7 studies, 6 of which were included in the meta-analysis by Gu et al., to describe the conflicting evidence regarding the effect of bariatric surgery on TJA outcomes (Stavrakis et al. 2018). A third review and meta-analysis by Smith et al. which was included in the review by Stavrakis, included 5 of the studies used by Gu et al. No significant differences in the incidence of superficial wound infection, deep wound infection, deep vein thrombosis, pulmonary embolism, reoperation, joint revision, or mortality were found between the two groups in this meta-analysis. There were, however, more medical complications in patients who did not undergo bariatric surgery prior to TJA (Smith et al. 2016).

There are several individual studies reporting advantages to undergoing bariatric surgery prior to TJA. In-hospital complications after hip and knee arthroplasty, and 90-day troubles after knee arthroplasty, diminish in patients who underwent prior bariatric surgery (McLawhorn et al. 2018a, 2018b). A large study by Werner et al using a Medicare database with 78,036 patients compared the 90-day complication rate in three groups: (1) patients without obesity, (2) patients with morbid obesity who did not undergo bariatric surgery, and (3) patients with morbid obesity who underwent bariatric surgery prior to TKA. They found a decreased rate of both major and minor complications in patients with morbid obesity who underwent bariatric surgery when compared to patients with morbid obesity who did not undergo bariatric surgery prior to TKA (Werner et al. 2015). Watts et al compared the outcome of THA in patients with morbid obesity who did and did not previously undergo bariatric surgery in a matched cohort study. They found a decrease in reoperations and revisions for patients who underwent bariatric surgery prior to THA (Watts et al. 2016b). Kulkarni et al found that patients with obesity who underwent bariatric surgery prior to TJA had 3.5 times lower likelihood of wound infection and 7 times lower likelihood of hospital readmission compared to those who underwent TJA alone (Kulkarni et al. 2011). Nearing et al found operative time and length of hospital stay were decreased for patients who had arthroplasty performed after bariatric surgery. Early complications and late reinterventions were similar (Nearing et al. 2017).

While the decrease in joint loading and improvement in gait mechanics account for a portion of the improvement in joint pain and osteoarthritic progression, the changes in the hormonal milieu secondary to bariatric surgery are

also likely to contribute. There have been studies investigating the changes in leptin secondary to bariatric surgery. Chen et al. found that levels of several adipocytokines and related factors decreased over the course of the first year after bariatric surgery. Even more interestingly, leptin reduction and stabilization corresponded closely with the initial reduction and stabilization in osteoarthritic knee pain (Chen et al. 2018). This suggests that a decrease in leptin, initiated by bariatric surgery, is directly associated with an improvement in osteoarthritis symptoms and potentially joint damage.

There are also a few studies that suggested worse postoperative TJA outcomes in patients who had prior bariatric surgery. A New York statewide cooperative study over a 10-year period revealed that 90-day postoperative complications after total joint arthroplasty were increased in obese patients who previously underwent bariatric operations. Immediate hospital costs were also more substantial (Liu et al. 2019). In a previous article with the same global database, they found that bariatric surgery was not a risk factor for nonelective readmissions at 30-days, 90-days, or 1 year and did not change overall cost. Nevertheless, it did predict an increase in elective admission for up to 1 year (Liu et al. 2018).

Within a similar perspective, a controlled investigation using the Medicare database unveiled about twice the risk of dislocation, as well as revision surgery, in the bariatric population compared to no weight-reducing operation in obese or lean controls. However, the bariatric patients in this study were significantly more comorbid than the non-bariatric population, calling to question the real reason for these differences in outcome (Nickel et al. 2018).

Lee et al. used Medicare 5% part B data from 1999–2012 to identify patients who underwent THA or TKA. A history of prior bariatric surgery as well as the presence of comorbid conditions such as diabetes, hypothyroidism, impaired renal function, osteomalacia, and Cushing's syndrome was identified for all patients. Kaplan-Meier risk of revision of THA or TKA within 0.5, 1, 2, and 5 years was evaluated for each condition, including the presence of prior bariatric surgery. Bariatric surgery prior to THA was not associated with an increased overall risk for revision, but was associated with an increased risk for revision for periprosthetic infection. Patients undergoing TKA following bariatric surgery were at increased overall risk for revision, but not at increased risk for revision for periprosthetic infection (Lee et al. 2018).

Bariatric Surgery and Total Arthroplasty: Which Comes First, the Chicken or the Egg?

While it is possible that immobility secondary to osteoarthritis contributes to the development of obesity, evidence does not suggest that TJA will lead to postoperative weight loss. Despite increased mobility after TJA, most patients maintain and many actually gain weight postoperatively (Springer et al. 2017). While in one study, postoperative weight loss was most strongly associated with preoperative BMI (Inacio et al. 2014), this may just indicate better results of TJA when concurrent metabolic syndrome is earlier in its course. TJA is not suggested as a treatment for significant weight loss.

The timing of bariatric surgery relative to TJA may have an effect on TJA outcomes in patients after bariatric surgery.

Schwarzkopf et al. used the Healthcare Cost and Utilization Project California State Inpatient Database to identify patients who underwent TJA following bariatric surgery from 2007–2011. There were 330 patients who underwent bariatric surgery followed by THA and 1017 patients who underwent bariatric surgery followed by TKA with 19% of patients having THA within 6 months of their bariatric procedure and 10% of patients having TKA within 6 months of their bariatric procedure. There was no association found between time of bariatric surgery and THA or TKA and 90-day complications in multivariate logistic regression analysis. However, patients undergoing THA more than 6 months after bariatric surgery were significantly less likely to have a 90-day readmission compared to patients

undergoing THA within 6 months of bariatric surgery (Schwarzkopf et al. 2018).

Severson et al compared the outcomes of three groups of patients: (1) patients with TKA prior to bariatric surgery (n = 39) (2) patients who underwent TKA less than 2 years after bariatric surgery (n = 25) (3) patients who underwent TKA more than 2 years after bariatric surgery (n = 61). They found patients in group 3 had shorter anesthesia time, total operative time, and tourniquet time while 90-day complication rates and duration of hospital stay did not differ among groups (Severson et al. 2012).

More study is needed in this to determine the optimal timing between bariatric surgery and TJA.

Mobility and Access to Care

There are potential advantages to performing bariatric surgery prior to TJA other than postoperative outcomes, such as potential increased access to care and decreased costs. Many rural facilities will refer patients with obesity to tertiary medical centers to undergo TJA. This requires increased transportation costs and difficulty with follow-up. If a patient with osteoarthritis was able to lose weight with bariatric surgery, the patient may be able to undergo TJA at an institution closer to home, improving access to care and eliminating some of the complexities of follow-up (Springer et al. 2017).

Financial Issues

McLawhorn et al. compared the cost of performing bariatric surgery prior to TKA in patients with morbid obesity and osteoarthritis to TKA alone in BMI-matched patients. Costs included costs of treatment, complications, and 90-day follow-up. Quality-adjusted-life-years (QALY) were also calculated for both groups. While performing bariatric surgery prior to TKA was more expensive than TKA alone, the QALY was also higher. Given this, the incremental cost-effectiveness ratio between the two groups was found to be $13,910 per QALY. This value was significantly less than the $100,000 per QALY used as the threshold willingness to pay, leading to the conclusion that performing bariatric surgery prior to TKA is cost-effective (McLawhorn et al. 2016). Kremers et al. found that, for every 5-unit increase in BMI over 30 kg/m^2, hospitalization cost increased $300 for TKA and $650 for revisional TKA, even when adjusting for comorbidities and complications (Kremers et al. 2014).

Culler et al. used the Medicare Provider Analysis Review file to show that any adverse event for TJA increased mean hospital cost by $3429 and increased hospital length of stay by 1 day. Given these findings, in the setting of bundled payment for TJA, these authors suggested undertaking all possible complication-reducing measures to decrease the risk of complications and therefore reduce hospital cost (Culler et al. 2016; Kremers et al. 2014).

Conversely, Giori et al. demonstrated that for patients with BMI >40 kg/m^2 who undergo TJA, there is only one complication for every 14 complication-free operations. These authors suggested not using a strict BMI cutoff for patients who otherwise qualify for TJA. Similarly, Springer et al. followed 289 patients with BMI >40 kg/m^2 and end-stage osteoarthritis for 2 years. They found that requiring weight loss prior to TJA in this population most often leads to these patients remaining morbidly obese and never undergoing TJA. Only 20% of patients underwent bariatric surgery. These authors suggested increasing the resources and coordinated care to facilitate patients' weight loss (Giori et al. 2018).

Ongoing Trials and Future Perspectives

There is currently no consensus on the utility of bariatric surgery for weight loss prior to TJA, and no prospective or randomized controlled trials on the topic. In addition, no prospective studies have evaluated whether reduced biomechanical strain on lower extremity joints after bariatric surgery eliminates the need for TJA in certain patients, or if, conversely, the increased mobility and exercise capability of patients who lose significant weight

from bariatric surgery lead to an increase in TJA in this population.

The Surgical Weight-Loss to Improve Functional Status Trajectories Following TKA (SWIFT) Trial (NCT02598531) is the first prospective, controlled, multicenter trial comparing postoperative outcomes in patients with severe obesity who undergo TKA with a well-matched cohort of patients who undergo weight loss surgery prior to elective TKA. This trial is currently recruiting patients (Surgical Weight-Loss to Improve Functional Status Trajectories Following Total Knee Arthroplasty/SWIFT Trial n.d.) (Benotti et al. 2018).

Future Directions

Important areas for study include: comparing the effects of surgical weight loss and medical weight loss on TJA necessity and outcome, comparing the effect of different surgical weight loss procedures on TJA necessity and outcome, investigating risk stratification protocols for patients with obesity and end-stage osteoarthritis, determining a safe and cost-effective BMI cutoff for TJA, and ultimately determining an appropriate weight management algorithm and multidisciplinary approach for obese patients with end-stage osteoarthritis. In addition to studies investigating the effect of bariatric surgery on osteoarthritis and TJA outcomes, further investigation into the mechanisms that regulate peripheral and central adipokine activity and their contribution to the development of osteoarthritis may lead to novel treatments for osteoarthritis in the morbidly obese population.

Contents

Abstract

The use of nonclinical but also laboratory tools to predict type 2 diabetes (T2D) remission after metabolic/bariatric surgery has been extensively researched. Basal fasting C-peptide level is an accessible test, but it cannot predict the chances of remission alone and is biased in patients with more severe diabetes. So, other robust biological and clinical predictors of T2D remission after surgery have been proposed. After assessing the predictive factors and acknowledging the risk of non-remission and relapse, a pathway to adequate clinical management is necessary, particularly for cases with recurrent T2D. Revisional surgery has been widely discussed as an option for those cases, despite the lack of robust evidence. Interestingly, inadequate weight loss or weight regain that usually indicates the reoperation is not always linked with T2D recurrence. Pharmacological agents such as GLP1 analogs may be an add-on alternative to reach glycemic control, if revisional surgery is insufficient.

Introduction

Type 2 Diabetes mellitus (T2D) is a chronic and progressive disease characterized by

J. Faintuch and S. Faintuch (eds.), *Obesity and Diabetes*, https://doi.org/10.1007/978-3-030-53370-0_61

hyperglycemia, insulin resistance, and relative impairment of insulin secretion. It is strongly associated with obesity in all ethnic groups (Mokdad et al. 2001).

The prevalence of T2D is increasing worldwide. The relationship between this disease and obesity is well-established as 80% of T2D patients are overweight or obese (Schauer et al. 2012).

As a multifactorial disease, understanding its pathogenesis and its treatment is challenging. Although insulin resistance can be traced back to its genetic background, the epidemic of diabetes is related to the epidemic of obesity and physical inactivity as both are insulin-resistant states (Sha and Laferrère 2017).

Pathogenesis of T2D

It is currently known that eight factors play a role in the development of glucose intolerance in T2D individuals (DeFronzo 2009). Genetically, individuals prone to develop T2D evolve to insulin resistance that presents itself in multiple organs. In the liver, it leads to an overproduction of glucose, despite fasting hyperinsulinemia and by reduced suppression of hepatic glucose production in response to insulin. In the muscle, it decreases glucose uptake after carbohydrate ingestion resulting in postprandial hyperglycemia. Thus, decreased insulin sensitivity stimulates insulin production by the pancreatic ß-cells. Over time, the ß-cells become fatigued, losing function progressively and reducing circulating insulin levels, consequently increasing plasma glucose concentration leading to the onset of diabetes. In addition to the muscle, liver, and ß-cell, several other cellular dysfunctions are part of T2D pathogenesis, with the involvemet of fat cells (accelerated lipolysis), gastrointestinal tract (incretin deficiency/resistance), alfa cells (hyperglucagonemia), kidney (increased glucose reabsorption), and brain (insulin resistance).

As complex as the pathogenesis, the treatment of this disease is also challenging. Randomized clinical trials have indicated that metabolic/bariatric surgery achieves rapid and better glycemic control than medical therapy alone in obese patients with T2D. Accordingly, metabolic/bariatric surgery is recommended in the treatment algorithm of T2D in patients with a body mass index of 30 kg/m^2 and over and endorsed by over 50 worldwide medical and scientific associations (Rubino et al. 2017).

How to Predict Metabolic/Bariatric Surgery Outcomes

As the goals of metabolic/bariatric surgery are the control of T2D and related metabolic conditions, high remission rates are expected. Due to the use of different remission criteria, rates are very variable in the literature. The rate of T2D remission varies from 24% to 95% at 2 years, depending on the type of surgery, the definition of remission, and the characteristics of patients enrolled in the studies (Yan et al. 2017; Maleckas et al. 2015).

The main goal of metabolic/bariatric surgery, as described above, is to keep the American Diabetes Association (ADA) triple endpoint under control (Table 61.1) (Standards of Medical Care in Diabetes 2020). Therefore, as T2D is a progressive disease, the ADA are targeted with the correct association of surgery and the best medical treatment available.

Several studies tried to identify the best protocols to manage these patients peri and postoperatively (Sjostrom 2013). The main objectives

Table 61.1 Summary of the American Diabetes Association for glycemic, blood pressure, and lipid control for adults with diabetes (Standards of Medical Care in Diabetes 2020)

A1c	<7%
Blood Pressure	<130/80 mmHg
Lipids	
LDL cholesterol	<100 mg/dl

were identifying responders and the development of preoperative scores that could shed a light on achieving the best outcomes.

Different trials reported some clinical issues that could predict T2D recurrence after surgery. One study showed that one third of severely obese diabetes adults who underwent gastric bypass surgery experience relapse after diabetes remission in five years (Schauer et al. 2014).

A retrospective cohort study that included 345 patients with obesity and type T2D, submitted to Roux-en-Y gastric bypass (RYGB), with a minimum 3-year follow-up since surgery, assessed the factors associated with T2D remission and relapse. The predictors of remission were younger age, preoperative glycemic control, and duration of diabetes at baseline. Of the patients in remission, 12% experienced T2D recurrence. Predictors of recurrence were preoperative use of insulin, or any anti-diabetes agents other than metformin (Mingrone et al. 2012; Arterburn et al. 2013a).

Predictive Scores

Despite some limitations, a model of score based on clinical variables for the preoperative prediction of T2D remission following RYGB surgery was proposed (DiaRem). In a retrospective cohort study of 2300 patients who underwent RYGB surgery, predictive factors of remission were evaluated to produce a score that predicts the probability of diabetes remission within 5 years. This score uses as prediction factors age, Hba1c, use of diabetes medications beyond metformin, and use of insulin (Oliveira et al. 2018; Dixon et al. 2013).

Young age and low BMI (25–35 kg/m^2) are also predictors of long-term T2D remission, while the use of insulin and high glycated hemoglobin A1c (HbA1c) levels are predictors of decreased rates of remission after surgery. Glycemic response to RYGB has also been correlated with BMI, duration of diabetes, fasting C-peptide, and weight loss (Brethauer et al. 2013; Arterburn et al. 2013b).

DiaRem is a well-validated tool with easy clinical use (Still et al. 2014). However, one of the drawbacks related to this score is the fact that it does not use the duration of diabetes to calculate the prediction of disease remission after surgery. The DiaRem 2, updated its first version. It added the time of history of T2D and changed the remission groups from 5 to 3 categories (low, intermediate, and high) which allowed the score to improve its accuracy (Still et al. 2019; Pucci et al. 2018).

A prospective single center, nonblinded, randomized controlled trial including 45 obese patients with T2D showed the potential use of baseline circulating succinate to predict T2D remission after metabolic/bariatric surgery. Succinate baseline concentrations were an independent predictor of T2D remission (Ceperuelo-Mallafre et al. 2019). Succinate is a metabolite that signals metabolic stress and inflammation. Microbiota-produced succinate has also been related to intestinal glucose metabolism and metabolic activity of brown adipose tissue. This study reported that patients who achieved remission after 1 year had lower levels of baseline succinate.

Nevertheless, more studies are needed to incorporate the use of succinate as a tool to help identifying remission chances. Moreover, the need to standardize this test in daily practice is also required (Ceperuelo-Mallafre et al. 2019).

A pilot study to access the genetic predisposition risk scores in T2D in order to predict the better response to metabolic/bariatric surgery in terms of either weight loss or diabetes remission showed highly sensitive and specific genetic predictive scores of responses to surgery in terms of weight loss and T2D remission and the long-term sustainability of these effects (Ciudin et al. 2019).

Further studies are needed to justify the applicability of genetic analysis as a predictor of metabolic response. However, the available current studies mentioned above have already given some clues towards precision medicine that can

help clinicians to select even better candidates for metabolic/ bariatric surgery.

Revisional Bariatric and Metabolic Surgery

Metabolic surgery is the most effective treatment for medically uncontrolled type 2 diabetes (T2D), leading to a meaningful improvement in glycemic control as good as 70% of diabetes remission early after surgery (Panunzi et al. 2015). However, T2D recurrence rate five years after surgery is not low (Mingrone et al. 2015). The main apparent reason for those outcomes is that almost all metabolic surgery trials have been designed using T2D remission without antidiabetic medications as an endpoint (Gloy et al. 2013).

As T2D is a chronic disease, consequently it is not reasonable to have medication withdrawal as a treatment target. On the contrary, the main goal is the reduction of micro and macrovascular complications and mortality, regardless of medication use (Cohen et al. 2017).

Although there is some data supporting revisional surgery for insufficient weight loss or weight regain, the literature is scarce, with weaker levels of evidence about the benefits of revisional metabolic surgery. Because of potentially higher complication rates, and modest weight loss after bariatric surgical revisions (Mor et al. 2013; Sudan et al. 2014), a careful evaluation of its necessity is mandatory, and many times, the treatment with new antidiabetic medications, as glucagon peptide 1 (GLP-1) analogues, can be better options. Gravitas, a randomized controlled trial comparing liraglutide versus placebo in 80 patients with persistent or recurrent type 2 diabetes at least one year after surgery, demonstrated a decrease of 1.22% in HbA1c and 4.23 kg after 26 weeks of treatment (Miras et al. 2019).

Any given surgical technique has distinct mechanisms of action. It was demonstrated that rerouting the proximal bowel leads to a more powerful metabolic improvement after surgery. Therefore, depending on the index surgery and the choice of the second operative technique, it is expected that the metabolic outcomes potentially will change (Brethauer et al. 2013).

In 2017, a review (Yan et al. 2017) summarized all the evidences published to determine if there is metabolic improvement after revisional surgery. The authors demonstrated that converting restrictive procedures as the vertical banded gastroplasty (VBG) or adjustable gastric banding (AGB) to Roux-en-Y gastric bypass (RYGB) leads to T2D improvement or remission in 79% and 72%, as well as a decrease of 15–25% and 13–26% in BMI, respectively. Similarly, two studies reported outcomes converting AGB into sleeve gastrectomy (SG) with 65% of T2D improvement or remission.

Moreover, procedures as SG and RYGB are not purely restrictive because other mechanisms, besides the weight loss, underlie the improvement of glucose metabolism. Nevertheless, studies showed that, when converting SG into RYGB, T2D improves or remits in 62% among patients with residual disease. These results are even better when converting SG into duodenal switch (79% of diabetes improvement).

In patients submitted primarily to RYGB, reoperative techniques lack compelling positive data. Better results were reported after trimming/ redoing the gastric pouch and/or increasing the malabsorptive component. The first option shows heterogeneous results in different studies (50 to 100% of diabetes improvement), maybe because of the diversity of techniques employed. Only one study reported that all patients with T2D recurrence after RYGB ($n = 11$) presented improvement after distalization of the common channel.

The authors concluded some interesting points after that narrative review of the literature. Around 80% of patients are diabetes-free at the time of the surgical revision and inadequate weight loss or weight regain that usually indicates the reoperation is not always linked with T2D recurrence. In spite of the lack of quality data and the limitations of the included studies, revisional surgery seems to be effective in reducing weight and improving T2D among patients with inadequate weight loss or weight regain accompanied with T2D relapse.

Recently, Aleassa et al. (2019) published a retrospective study with the most significant series of 81 patients with T2D relapse after the primary bariatric operation submitted to revisional surgery in an academic medical center. T2D remission was defined as glycated hemoglobin (HbA1c) < 6.5% and fasting plasma glucose (FPG) < 126 mg/dL without diabetes medications. T2D improvement was considered when patients presented a reduction in HbA1c (by >1%) and FPG (by >25 mg/dL), or reduction in HbA1c and FBG accompanied by a decrease in antidiabetic medications.

Patients were divided accordingly to the type of primary and revisional bariatric procedures. The median follow-up was 22 months. Among 20 patients submitted to a conversion of VBG to RYGB, a median additional total weight loss (TWL) was 20.5% and T2D remission and improvement rates were 35% and 55% with a 44.4% reduction of patients using insulin. Among AGB conversions, 14 were converted into RYGB with a median of 22.4% of additional TWL and 35.7% of T2D remission and 35.7% of improvement in 43.5 months of median follow-up. In 7 cases, the second procedure was a SG, with modest results and a median of 13.5% of additional TWL and HbA1c decrease from 7.2% at baseline to 6.7% after median of 38 months. Only 2 patients were converted to duodenal switch (DS) with an additional weight loss and T2D improvement, but in a short follow-up.

Sleeve gastrectomy was converted to RYGB in 13 patients with a median additional TWL of 11.3% and T2D remission and improvement rates of 23.1 and 30.8%, respectively, but the HbA1c change was not statistically significant. Conversion to DS was performed only in three patients leading to significant T2D improvement and weight loss.

In a median length of 12 months of follow-up, revising the pouch after RYGB resulted in a median of total weight loss of 14.1%, 22.7% of T2D remission, and 50% of improvement.

Analyzing 115 patients converted to RYGB (82 from AGB and 33 from SG) matched in a 1:1 ratio, including T2D as matching criteria, with control patients who underwent primary RYGB, Vallois et al. (2019) found similar early and late morbidity between groups and no mortality. Although the revisional group presented less weight loss compared with primary RYGB group (mean % excess weight loss 67.4 ± 20.7 vs. 72.7 ± 22.9, $p = 0.023$) after 1 year, improvement of hypertension (62.5 vs. 70.5%; $p > 0.05$), diabetes (73.7 vs. 79%; $p > 0.05$), and obstructive sleep apnea syndrome (100 vs. 97%; $p > 0.05$) was similar between groups. Differently from previous data, this study showed that the revisional procedure was as safe as the primary one and showed similar significant improvement in comorbidities, as T2D, even with less weight loss.

Finally, a systematic review and meta-analysis published in 2018 (Pędziwiatr et al. 2018) assessed 21 studies comparing outcomes after primary versus revisional RYGB and included 11,720 and 3043 patients, respectively. Seven studies reported results on T2D and hypertension remission, and there were no differences between groups ($p = 0.61$). It is important to notice that the majority of patients in the revisional group had a VBG or AGB as the primary procedure. Weight loss was significant in the primary RYGB group (20% more excess weight loss than revisions). The analysis showed higher rates of morbidity and mortality in revisional procedures, although the numbers are still relatively low (0.2 versus 0.6% of mortality). However, there were no differences in the case-matched subgroup.

Revisional surgery for Type 2 diabetes relapse still lacks quality data. Keeping in mind that T2D is a chronic and progressive disease, maintaining glycemic endpoints under the target is important to prevent micro and macrovascular complications. Metabolic surgery is recommended when the best medical treatment fails. However, the optimal strategy to mitigate recurrence, analog to cancer treatment, when oncological surgery is often associated to radio/chemotherapy, is to keep the best medical treatment after surgery. So far, there are no accurate scores to predict T2D outcomes after metabolic interventions. Those available are good tools to help the clinician to refer the best patients to surgery.

Operations that reroute the food through the gastrointestinal tract deliver long-term better outcomes than those that don't. Currently, based on the mechanisms behind the "bypass" operations, it seems that converting SG or AGB to RYGB or DS is efficacious to achieve glycemic control and added weight loss, but always keeping along the best medical treatment.

In most cases of postoperative T2D recurrence after RYGB or DS, if there is no anatomical complication to be fixed (as gastro-gastric fistulas), adding pharmacological agents as GLP1 analogs may be an alternative to reach glycemic control.

Abstract

Obesity and malnutrition appear to be at the opposite ends of the spectrum. But in reality, obesity in itself is a form of malnutrition associated with nutritional deficiencies. Attempts to lose weight by various special diets complement the preexisting nutritional deficiencies. Bariatric surgical procedures are well-accepted for sustained remission of obesity. The physiological basis of these procedures is either gastric reduction (restrictive) or diminished absorption of nutrients (malabsorptive). In both types, the weight loss is associated with worsening of the preexisting nutrient deficiencies or creating new deficiencies of macro- and micronutrients. A well-defined protocol-based pre- and post-operative nutritional assessment is needed for minimal adverse effects. Clinical guidelines and recommendations are provided in the present chapter.

Introduction

Obesity and malnutrition are presently considered as two sides of one crisis or "a double burden of malnutrition," the coexistence of nutritional deficiencies along with overweight and obesity.

A recent study has projected that nearly 1 in 2 US adults will be obese by 2030 (Ward et al. 2019). It also showed that severe obesity would affect nearly 1 in 4 adults by 2030, particularly women and certain disadvantaged populations. China and India also are facing the obesity crisis, especially in the middle and upper class, contrasting with a high prevalence of malnourished poor.

Deficiencies Across All Classes

A dogmatic view of the past is that malnutrition is the consequence of the chronic consumption of an insufficient quantity of inferior quality diet as a result of poverty or disease. However, it has become clear that malnutrition does not spare the rich. The excessive use of high calorie foods and drinks along with sedentarism is relevant. The available solutions to the problem of obesity are many, including various calorie-restricted diets and bariatric surgical procedures designed to induce malabsorption. All of the above cause malnutrition and malabsorption of nutrients with varying amounts as side effects.

Definition of Obesity and Its Types

In several Asiatic countries, BMI of 23.0–24.9 kg/m^2 *and* $\geq$ *25* kg/m^2 are adopted for *overweight and obesity, respectively (*World Health Organization 2014*;* Gronroos et al. 2010*;* Misra et al. 2009*). The traditional WHO classification is predominantly applicable to the people of European ancestry.*

Abdominal fat accumulation has a more ominous prognosis than gluteo-femoral fat, raising doubts about reliability of BMI alone (Adab et al. 2018; Kissebah et al. 1982; Després et al. 1990). Even visceral fat signals cardiovascular complications at different proportions among Asians and other Americans (Demerath et al. 2007; Lim et al. 2011).

Metabolic Obesity

New clinical modalities encompassing metabolically healthy but obese (MHO), metabolically obese but normal weight (MONW), and metabolic or central obesity have thus been devised (Karelis et al. 2004; Hamdy et al. 2006). A normal waist to hip ratio ($<$ 0.95 for men, $<$ 0.86 for

women) rules out metabolic obesity. Based on waist-hip ratio, obesity is classified as pear-shaped when the waist-hip ratio is <0.8 in women and 0.9 in men. An apple-shaped obesity is characterized as a higher waist to hip ratio compared to the pear shape, implying that the accumulated fat on an apple-shaped body is mostly around the abdomen or waist (central obesity) and is more often related to cardiovascular and metabolic problems.

Obesity and Muscle Wasting

Sarcopenic obesity is not uncommon (Choi 2016), and aging, undernutrition, consumptive illnesses, or disuse atrophy are common precipitants. Functional and clinical aberrations are observed, including propensity towards increased adiposity (Dufour et al. 2013; Lee et al. 2016), whereas obesity itself as an inducer of sarcopenia has also been proposed, suggesting some common pathways (Gregor and Hotamisligil 2011). Glucose homeostasis and other metabolic conditions could be negatively affected, thus demanding a more structured approach.

Types of Bariatric Surgery

Bariatric interventions can be restrictive, malabsorptive, and mixed (restrictive and malabsorptive). Most operations are surgical (laparoscopic), along with emerging endoscopic maneuvers (Table 62.1). More aggressive modalities (malabsorptive) generally feature more nutritional deficits.

Nutritional Deficiencies

Among Western populations, industrialized meals are preferred, with an excessive amount of undesirable calories and sodium and insufficient fiber and micronutrients (Damms-Machado

Table 62.1 Types of bariatric surgical procedures

Laparoscopic or surgical procedures[89, 90] (Indication: BMI $\geq$ 40 or $\geq$ 35 kg/m^2 with clinically significant comorbidities)			
Type	Mechanism	Procedural details	% TWL (Mean)
Adjustable gastric banding	Restrictive	A balloon encircles the upper stomach	11.8
Vertical sleeve gastrectomy (VSG)	Restrictive	The entire greater curvature is resected	15.4
Roux-en-Y gastric bypass (RYGB)	(Restrictive and malabsorptive)	A proximal pouch is anastomosed to a gastrojejunostomy. A Roux-en-Y biliopancreatic conduit joins 75–100 cm downstream	20.1
Biliopancreatic bypass with duodenal switch (BPDS)	Restrictive and malabsorptive	After sleeve gastrectomy, the ileum is anastomosed to the duodenum	36.7
Endoscopic bariatric procedures[91] Indication: mild to moderate obesity (BMI 30–40 kg/m^2), or more severe cases who refuse surgery			
Space occupying devices	Restrictive	Promote gastric distension and reduced emptying	10.2 (Orbera balloon)
Aspiration assist device	Unique class	A gastrostomy for removing gastric contents after meals	14.2
Endoscopic sleeve gastroplasty	Restrictive	Endoscopic sutures to collapse the greater curvature and diminish gastric volume	18.6
Primary obesity surgery endoluminal	Restrictive	Endoscopic sutures that reduce accommodation of the gastric fundus.	4.9

%TWL (total weight loss) = % total weight loss which is computed as 100% × (pre-surgery BMI—post-surgery BMI at the time of measurement)/pre-surgery BMI

et al. 2012). Obesity could by itself trigger certain deficits (Kaidar-Person et al. 2008), whereas crash diets and other radical attempts to lose weight could be equally deleterious.

Deficiencies Post-Bariatric Surgery

1. Restrictive interventions diminish nutrient intake and could lead to an imbalanced diet.
2. Vertical sleeve gastrectomy can be additionally followed by loss of appetite (reduced ghrelin), abnormal iron, and vitamin B12 absorption (less intrinsic factor, less acidification of the duodenum).
3. Up to one quarter of dietary protein and three quarters of fat intake can be lost with malabsorptive techniques, along with associated micronutrients. Frequent stools can further compromise nutritional status.
4. A combination of some of the features of restriction and malabsorption can be detected after RYGB (Roux-en-Y gastric bypass) (Kizy et al. 2017).

Nutritional Deficiencies Before and After Bariatric Management

Dietary shifts, clinical comorbidities and treatments, along with the profile of the operation itself modulate the advent and course of nutritional deficits. Current recommendations are listed in Tables 62.2 and 62.3 (Mechanick et al. 2013; Parrott et al. 2016; Thibault et al. 2016).

Protein

Protein is essential for the synthesis of tissues, enzymes, hormones, albumin, hemoglobin, and other biomolecules. Severe protein deficit can occur in 3–21% of patients after BPDS and up to 13% following RYGB, depending on the length of the Roux-limb (Faintuch et al. 2004). Some bariatric patients develop an intolerance to proteins due to altered gastrointestinal anatomy and function, with inadequate digestion and absorption. Early low-caloried liquid diets and eventual vomiting could further contribute to depletion.

Protein deficiency conducts to skin atrophy and decreased muscle mass, besides classic hypoalbuminemia and even generalized edema. Impairment of growth, wound healing, immune competence, and other essential functions can trigger multiple complications.

Current consensus guidelines suggest additional protein along with all modalities of exercise. Daily consumption of 60–120 g after RYGB, 60–80 g or 1.1 g/kg of ideal body weight after LSG, and 90 g following BPDS is advised. Enteral nutrition should be considered in case of significant undernutrition.

Essential Fatty Acids

Both omega 6 linoleic acid (LA) and omega 3 fatty acids, including alpha-linoleic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA), are considered essential for humans, even though some interconversions among the omega 3 family are recognized. Vegetable oils are the most important sources of omega 6 fatty acids (EFAs) and ALA, whereas EPA and DHA are usually ingested in the form of fish. EFAs are required for the formation of various eicosanoids (biologically active lipids). Patients after bariatric surgeries (particularly malabsorptive procedures) are susceptible to EFAs deficiency due to aberrant intestinal fat processing (Forbes et al. 2016).

Dermatologic disorders, slow wound healing, and increased susceptibility to infections are some of the features of EFAs deficiency. Associated zinc deficit (which also presents with dry scaly rash) is a possibility which should be promptly recognized (Mogensen 2017).

EFAs deficiency can be managed by supplementing unsaturated omega-6-rich

Table 62.2 Symptoms of micronutrient deficiencies and their laboratory indices

Micro nutrients	Recommended daily intake	Sources	Symptoms of deficiency	Lab range	Additional lab indices
Vitamin D	31–70 years: 15 mcg (600 IU) >70: 20 mcg	Sunlight, cod liver oil, egg yolk, fortified foods	Rickets in toddlers Osteomalacia in adults	25 (OH) D > 30 mg/mL (> 75 nmol/L)	↓ Serum phosphorus, urinary calcium ↑ Serum PTH, N-telopeptide, osteocalcin
Thiamine	M: 1.2 mg F: 1.1 mg	Enriched, fortified, or whole-grain products, cereals	Wet beriberi: heart failure; dry beriberi: increased reflexes, neuropathy, ataxia, convulsions Wernicke's encephalopathy	Plasma: 4–15 nmol/L; blood: 70–180 nmol/L Transketolase >150 nmol/L Erythrocyte trasketolase coefficient < 1.15	↑ pyruvate or ↓ lactate, urinary thiamin
Vitamin B12	2.4 μg	Fortified cereals, meat, fish, poultry	Pernicious anemia, paresthesia, sore tongue, demyelination and axonal degeneration tinnitus, dementia	Serum B12 (cobalamin) 200–1000 pg/mL	↑ Serum methyl malonic acid (MMA) ↑ Serum homocysteine (tHcy)
Folate	400 μg	Grains, whole grain products, fortified cereals, dark leaves	Macrocytic anemia, neural tube defects, skin and mucosa changes	Folate 340–1020 ng/mL for age ≥ 18 year	Normal MMA ↑ Serum tHcy
Vitamin B6	1.5 mg	Fortified cereals, chickpeas, meats	Dermatitis glossitis, cheilitis, conjunctivitisneurological symptoms	Pyridoxal-5′-phosphate: 5–24 ng/mL	RBC glutamic pyruvate oxaloacetic transaminase; urinary 4-pyridoxic acid
Vitamin A	M: 900 mcg (3000 IU) W: 700 mcg	Liver, dairy products, fish, dark fruits, leaves	Night blindness, endophthalmitis, other eye changes	Plasma retinol 20–80 μg/dL	Retinol-binding protein
Vitamin E	15 mg	Vegetable oils, cereals, nuts, fruits, meats	Myelopathy, polyneuropathy ophthalmoplegia, nystagmus	Plasma alpha-tocopherol	Plasma lipids
Vitamin K	M: 120 μg W: 90 μg	Green leaves, brussel sprouts, cabbage, plant oils, margarine	Easy bleeding	PT 10–13 s	↑ Des-gamma carboxyprothrombin; ↓ plasma phylloquinone
Iron	8 mg (Men and postmenopausal women) Females: 18 mg	Fruits, vegetables fortified foods; *Heme iron:* Meat and poultry	Microcytic anemia, immune depression, abnormal nails, glossitis, dysphagia	Serum iron: 60–170 μg/dL Transferrin 200–360 μg/dL saturation: 20–50% Ferritin: 12–300 ng/mL (male), 12–150 ng/mL (females)	↑ TIBC Soluble transferrin receptor

Table 62.3 Micronutrient assessment before and after bariatric surgeries

Micronutrient	Deficiency in obesity	Deficiency after bariatric surgery	Screening post-bariatric surgery	Supplementation post-bariatric surgery	Comments
Thiamine	15.5–29%	<1% to 49%	High-risk patients	12–50 mg once or twice daily	Begin on day 1
Vitamin B12	2–18%	At 2–5 year of RYGB-(<20%) VSG- (4–20%)	Every 3 months for 1 year, and then yearly	IM or SQ: 1000 μg monthly Orally or sublingual: 350–500 μg daily	Begin 0–3 months after surgery
Folate	Up to 54%	up to 65%	Routine screening	400–800 μg daily 800–1000 μg for fertile women	>1000 mg could mask low vit. B12
Vitamin D/calcium	25–90%	20–100%	Routine screening	LAGB, VSG, RYGB: 1200–1500 mg/day BPDS: 1800–2400 mg/day; Vit. D3: 3000/day	Day 1–30 Calcium should be given in divided doses
Vitamins A, E, K	Vitamin A 14% Vitamin E 2.2%	Within 4 years of RYGB and BPDS—up to 70%	Vitamin A: first year RYGB, BPDS, undernutrition Vitamin E, K: symptomatic patients	LAGB: Vit A 5000 IU/d Vit K 90–120 μg/d; RYGB and VSG: Vit A 5000–10,000 IU/d, Vit K 90–120 μg/d; BPDS: Vit A 10,000 IU/d Vit K 300 μg/d Vit E 15 mg/d(all)	2–4 weeks; Higher doses with history of deficiencies
Iron	Up to 45%	AGB (14%); SG (Up to18%); RYGB (20–55%); BPD (13–62%); DS 8–50%	Every 3 months for 1 year, and then yearly	Males: 18 mg;menstruating females: 45–60 mg	Day 1; Avoid Simultaneous acid, calcium, Polyphenols, or phytates
Zinc	24–28% overall 74% BPDS	BPD (45 to 91%); RYGB (15 to 21%); LSG (11 to 14%).	Annually (RYGB or BPDS); anemia with normal iron	LABG/VSG: 8–11 mg/d; RYGB: 8–22 mg/d; BPDS: 16–22 mg	Day 1; Suggested 1 mg copper: 8–15 mg zinc (copper deficit risk)
Copper	Up to 70% BPD women	BPDS- (Up to 90%); RYGB- (10–20%)	Annually RYGB or BPDS	LAGB/VSG: 1 mg/d;RYGB or BPDS: 2 mg/d	Day 1 of discharge
Magnesium	35%	32%	BPDS (eventually others)	Magnesiumcitrate, 300 mg/day	–

25 (OH) D 25-hydroxyvitamin D, *PTH* parathyroid hormone, *MMA* serum methyl malonic acid, *tHcy* serum homocysteine, *PT* prothrombin time, *TIBC* total iron-binding capacity, *DXA* dual-energy X-ray absorptiometry

vegetable oils, as well as omega-3-rich fish oil, for patients tolerating oral diet. For intravenous nutrition-dependent patients, injectable fat emulsions containing both omega 6 and omega 3 fatty acids are available in the market (Mogensen 2017). The lipid injectable emulsion infusion can be considered periodically for these patients.

Vitamin D

This is a major fat-soluble nutrient, with relevance in a variety of benign and malignant conditions (Charoengam et al. 2019; Bouillon and Carmeliet 2018; Amrein et al. 2020). Deficiency is defined as levels of 25 (OH)D less than 20 ng/mL (50 nmol/L), whereas less than 12 ng/mL (30 nmol/L) characterize severe deficiency

(Bouillon and Carmeliet 2018; Amrein et al. 2020).

Diagnosis in populations with excessive adiposity is extremely common, with an estimated prevalence of 25–90% (Bouillon and Carmeliet 2018; Amrein et al. 2020; Xanthakos 2009; Lespessailles and Toumi 2017). As body fat accumulates, 25(OH)D proportionally moves down (Arunabh et al. 2003; Vimaleswaran et al. 2013). Volumetric dilution of the nutrient, and reduced exposure to sunlight on account of sedentarism and avoidance of beaches and swimming pools, could contribute to it. Importance of dietary intake, however, is unclear. Liver steatosis and certain cytokines could be detrimental for endogenous production as well (Mohapatra et al. 2019).

Following malabsorptive bariatric procedures, an estimated 17–52% (2 years) and 50–63% (4 years) exhibit deficiency (Hamoui et al. 2003; Newbury et al. 2003; Slater et al. 2004; Bloomberg et al. 2005). After bypass procedures, the altered anatomy and reduced biliary-pancreatic processing decrease the absorption of all fat-soluble vitamins. Rapid transit time after VSG could similarly be deleterious.

Severe deficiency is predominantly detected as rickets/osteomalacia (Charoengam et al. 2019). Asymptomatic or oligosymptomatic cases are the majority; however, secondary hyperparathyroidism can be damaging to bones, with the possibility of fractures. Such endocrine reaction is not uncommon with vitamin D levels $\leq$30 ng/mL. Dietary calcium processing is impaired when the upper small bowel is excluded in RYGB and BPDS (as little as 20% only) (Hamoui et al. 2003; De Prisco and Levine 2005), potentially resulting in calcium resorption and weakened bones.

Patients should be routinely monitored to inhibit secondary hyperparathyroidism. Yet, paracellular migration of calcium through the small bowel occurs even during vitamin D deficiency, raising questions about the real role of such prescriptions.

Baseline calcium and vitamin D are mandatory. Calcium citrate (1200 to 1500 mg) and 3000 IU of vitamin D, or more in case of deficiency, are necessary as well. As much as 50,000 units 1 to 3 times weekly, and eventually calcitriol (1,25—dihydroxy vitamin D), have been suggested for refractory cases. Associated hypophosphatemia is frequent and demands prevention (1.5 to 2.5 mg/dL). Besides vitamin D measurements, bone densitometry every two years is advocated after mixed or malabsorptive interventions.

Vitamin B1 (Thiamine)

The prevalence of thiamine deficiency is 16–29% in preoperative patients who undergo bariatric surgery (Carrodeguas et al. 2005; Flancbaum et al. 2006). Thiamine can get depleted rapidly within as little as 2–3 weeks (Lonsdale 2006). Large intakes of simple carbohydrates consume available thiamine, further precipitating its depletion.

Several case reports of Wernicke's encephalopathy are reported in post-bariatric patients (Mohapatra et al. 2019). Beriberi is not entirely unknown either. The prevalence of thiamine deficiency ranges from $<$1% to 49% according to population and intervention (Parrott et al. 2016). Thiamine deficiency can be attributed to duodenal malabsorption, metabolic demand, and decreased dietary intake, particularly with frequent vomiting. Altered intestinal bacterial composition could also enhance production of thiaminases (Lakhani et al. 2008).

Carbohydrate-rich prescriptions in the form of intravenous fluids as well as enteral or parenteral nutrition can also be risky in certain circumstances due to elevated thiamine consumption by such substrates. Routine monitoring and supplementation are therefore advised (Mechanick et al. 2013).

Acute cases may require thiamine, 500 mg IV/d, for 3 to 5 days, followed by 250 mg PO/d for 3 to 5 days or more. In these patients, long-term oral supplementation with 100 mg/d is advocated. For less stringent circumstances, 7–14 days of IV thiamine, 100 mg/d, is an alternative.

Individuals with irregular or insufficient diet and possibility of nutritional imbalances,

digestive diseases, comorbidities including furosemide prescription, alcohol abuse, or neuropsychiatric conditions need follow-up for 6 months and for even longer if suspicions remain (every 3–6 months).

Vitamin B12 and Folate

About 2–18% of those with excessive adiposity suffer from these deficiencies, and it is debated whether there are links between the two conditions (Parrott et al. 2016; El-Qudah et al. 2013; Yagan et al. 2016). Vitamin B12 containing animal protein is not always appreciated by the obese, a possible contributing factor. Certain medications such as metformin and proton pump inhibitors affect B12 absorption and stores. Serum 5-methyltetrahydrofolate and unmetabolized folic acid are inversely associated with BMI; (Bradbury et al. 2014) however, not RBC folate (Bird et al. 2015). Obese pregnant women very often exhibit low serum folate (da Silva et al. 2013; Knight et al. 2015), which predisposes to obesity in the offspring (Wang et al. 2016).

Restrictive bariatric interventions are not associated with vitamin B12 or folate deficits (Alvarez-Leite 2004), contrasting with RYGB after which the opposite occurs with vitamin B12. Lack of intrinsic factor, achlorhydria, and insufficient intake of B12 are the putative mechanisms (Ponsky et al. 2005). Folate deficiency is registered after RYGB patients; however, it seems much less common (MacLean et al. 1983; Boylan et al. 1988). Available supplements usually prevent both abnormalities.

Pre- and postoperative vitamin B12 and folate screening are necessary every 3–6 months until 12 months or longer when required. Because serum B12 can be misleading, serum methylmalonic acid (MMA) with or without homocysteine should be checked.

Dosages of vitamin B12 for supplementation encompass 1000 mcg/day orally, 1000 mcg monthly (IM or SQ), or eventually nasal spray. Being water-soluble, it is promptly excreted with a low risk of overdose. About 400–800 μg of folic acid, or 800–1000 μg for women of reproductive age, should be added.

Vitamins A, C, E, K

It is still debated whether antioxidants such as beta-carotene, alpha-tocopherol, and vitamin C correlate or not with BMI (Stryker et al. 1988; Schectman et al. 1989; Drewnowski et al. 1997; Wallström et al. 2001). More evidence is available regarding retinol, which becomes depressed as BMI increases (Viroonudomphol et al. 2003; Switzer et al. 2005).

We recommend baseline screening of vitamins A, C, E, and K during the preoperative period. Regardless of the symptoms, those submitted to mixed or malabsorptive interventions deserve subsequent vitamin A monitoring, with more selective indication for the other, less frequently deranged vitamins.

Prescriptions after surgery are listed: LAGB: Vitamin A 5000 IU/d and vitamin K 90–120 μg/d. RYGB and SG: Vitamin A 5000–10,000 IU/d and vitamin K 90–120 μg/d. LAGB, SG, RYGB, BPDS: Vitamin E 15 mg/d DS: Vitamin A (10,000 IU/d) and vitamin K (300 μg/d). Personalized attention may be required for certain conditions.

Iron

Iron deficiency (ID) is the principal predisposing factor for anemia (Lopez et al. 2016), being detected in as much as one sixth of humankind (Lopez et al. 2016). A 35% prevalence is occasionally observed in the obese (Schweiger et al. 2010). Hepcidin, a pro-inflammatory adipokine promoted by obesity, could aggravate the problem by linking to iron transporter ferroportin, which is already less abundant in the small bowel of this population (Girelli et al. 2016). The opposite phenomenon, possibly triggered by hepcidin dysfunction as well, is "Dysmetabolic iron overload syndrome (DIOS)," featuring elevated ferritin with normal or mildly elevated transferrin saturation. This is not rare in metabolic

syndrome (15%) and even more frequent (50%) with fatty liver disease (NAFLD) (Bozzini et al. 2005).

Also, after bariatric treatment, iron deficiency ranks among the most common troubles (30–60%) (Muñoz et al. 2009). Hypochlorhydria, duodenum bypass, dietary shifts, and bacterial interference (*H.pylori*, intestinal microbiota) are the most frequently mentioned drivers (Topart 2008; Hershko et al. 2005).

Baseline iron and transferrin saturation, total iron-binding capacity, and ferritin are advised. Daily iron supplementation should be given. Iron monitoring schedule should be every 3–-6 months (first year) and annually thereafter, if there are no abnormalities. Complete blood count, iron panel, total iron-binding capacity, ferritin, and soluble transferrin receptor are useful as well.

Zinc

Zinc deficiency is not uncommon (up to 50%) in bariatric candidates (Mahawar et al. 2017). Insulin pathways require zinc, and there is experimental evidence that it could enhance leptin expression, as well as macrophage infiltration into adipose tissue (Liu et al. 2013). Weight loss is associated with restoration of zinc concentrations (Ishikawa et al. 2005).

All bariatric interventions have some negative repercussions on zinc measurements, often detected quite early due to lack of reserves, with emphasis on the malabsorptive modality (45–91%) (Gehrer et al. 2010; Sallé et al. 2010; Balsa et al. 2011; Saif et al. 2012). DMT-1 (divalent metal transporter-1) is the most relevant mediator of absorption, expressed in the duodenum and proximal jejunum; therefore circumstances that shorten or eliminate food passage at this level exert negative impact. In large doses, all major nutritional metals, namely zinc, copper, and iron, can compromise absorption of the others, therefore reciprocal monitoring is advised (Bowley et al. 2017).

The majority of patients with mild to moderate deficiency remain asymptomatic. Advanced cases could present with dermatologic changes, immune deficiency, neurohormonal disorders, diminished appetite, and slow wound healing.

Zinc should be tested in candidates for mixed or malabsorptive procedures, and every year thereafter. Low findings do not necessarily require intervention (Marreiro et al. 2002) unless there are symptoms. Anemia with normal iron demands investigation, along with persistent diarrhea. Routine prescription is advised after these operations.

Copper

This is a cofactor for redox enzymes and contributes to antioxidant defense, immune function, and neuropeptide synthesis (Uriu-Adams 2005). Ceruloplasmin, relevant for iron metabolism, is a Cu-dependent ferroxidase.

As occurs with iron, gastric acid and the duodenum are relevant for copper absorption. Consequently, the same malabsorptive operations previously alluded to represent risk factors for such deficiency (9.6%) (Gletsu-Miller et al. 2012). Unsupplemented intravenous nutrition could occasionally be a precipitant as well (Shike 2009). Anemia with neutropenia, myeloneuropathy, and unusually optic neuropathy have been documented in severe cases (Shah and Tamhankar 2014).

The same testing routine as alluded to for zinc should be adopted for copper and ceruloplasmin. During acute-phase conditions such as fever or inflammation, spurious elevation can occur. Erythrocyte superoxide dismutase changes earlier during copper deficiency and could represent an alternative. Non-iron deficiency anemia demands copper screening, along with other nutrients.

Oral (2 mg/d), or IV copper (2–4 mg/d), for advanced deficiency can be adopted until normalization. Around 1 mg of copper is suggested for each 8 to 15 mg of zinc prescription, as high zinc precipitates copper reduction.

Abstract

The emergence of modern food systems has been causing unhealthy changes in the dietary patterns of millions of consumers worldwide. Nowadays, ultra-processed foods and beverages represent an increasing fraction of the total daily energy intake in both advanced and emerging economies. Most of these products are typically low in nutrients but high in one or more added ingredients, such as in the case of sugar-sweetened beverages (SSBs) usually rich in free sugars. The regular consumption of SSBs has been associated with adverse health outcomes, including obesity, type 2 diabetes, and cardiovascular diseases. Taxes are an increasingly popular approach to attempt reducing the overconsumption of SSBs. This chapter provides a non-technical description of the rationale, mechanisms, and current worldwide status of taxes on SSBs.

Keywords

Tax strategies · Soda sales · Price elasticity · Industry sugar tax · Government sugar tax · Regressive taxes

Introduction

The production of ultra-processed foods and beverages is a common feature of modern food systems (Monteiro et al. 2018a). Nowadays, an increasing fraction of world population has access to a large variety of convenient (i.e., durable and ready-to-consume) products, in the form of hyper-palatable and relatively inexpensive calorie-dense foods and beverages (Baker and Friel 2016; Monteiro et al. 2018b; Pan American Health Organization 2019). Most of these products are typically low in nutrients but high in one or more added ingredients (such as sugar, salt, and industry-created fats). Various types of additives and preservatives, as well as neo-formed contaminants derived from the production processes and the packaging materials (e.g., acrylamide and bisphenol A), are also present (Monteiro et al. 2019).

A traditional balanced and diversified diet is based on the regular consumption of fresh and minimally processed foods. In contrast, a 'Western-style' dietary pattern relies heavily on ultra-processed foods and beverages and is regarded as one of the key drivers of the growing worldwide burden of the leading noncommunicable diseases, such as obesity, cardiovascular diseases, diabetes, and some types of cancer (WHO 2014; Chazelas et al. 2019; Lawrence and Baker 2019). In the current food environment, a popular source of 'empty calories' comes from soft (non-alcoholic) drinks and, more specifically, from sugar-sweetened beverages (SSBs), (Martinez Steele et al. 2016). The world's most consumed SSBs include regular (i.e., non-diet) sodas, fruit juices, fruit, and milk-flavored drinks, ready-to-drink tea and coffee, flavored water, and energy, functional, and sports drinks (Singh et al. 2015a).

SSBs are defined as all types of carbonated and non-carbonated beverages containing free sugars (British Medical Association 2015). The World Health Organization (WHO) defines free sugars as all monosaccharides (e.g., glucose and fructose) and disaccharides (e.g., sucrose) inherent in the food plus any added sugars (WHO 2015). A given amount of sugar is naturally present in certain types of SSBs (e.g., fruit juices). One key feature of SSBs is a large amount of free sugar added by the manufacturer (The Nutrition Source 2019). The beverage industry adds free sugars, usually in the form of refined beet and cane sugar, or by using high-fructose corn syrup, a liquid sweetener derived from the processing of corn starch (Public Health Law and Policy 2011). These added sugars are incorporated to improve the products' palatability (Goldfein and Slavin 2015). Hence, SSBs are also called 'sugary drinks'.

Drink Composition

There are notable differences in the sugar content of these products, both across and within beverage categories. In general, the total quantity of sugar may range from 1 g to more than 50 g per 8-oz serving. A typical 8-oz serving of regular

soda contains about 29 g of free sugars. One teaspoon provides approximately 4.2 g of sugar. On this basis, drinking a standard 8-oz serving of soda is equivalent to eating more than 7 tsp. of table sugar (Harris and Schwartz 2014).

In the same 8-oz serving of other popular SSBs, for example, fruit and energy drinks, the average sugar content equates to about 22 g of free sugars (around 5 tsp). Similarly, in flavored water and ready-to-drink tea/coffee, there are typically 10 and 15 g of sugar, around 2.3 and 3.5 tsp. of table sugar, respectively. However, great diversity exists even within the same beverage category. Some regular sodas contain less than 10 g of sugar per 8-oz serving, and others, more than 45 g. Likewise, fruit drinks may contain from 1 g up to 57 g (about 13.5 tsp) of sugar per 8-oz serving (Harris and Schwartz 2014).

Despite the differences between products, the regular consumption of one or more SSBs in the everyday diet normally results in an abnormal high free-sugars intake (WHO 2015). Furthermore, studies on the health impacts of frequent SSB consumption address not only the total sugar content of these products, but also the proportion of the different types of sugars (e.g., the actual fructose content of high-fructose corn syrup) added to the beverages (Ventura et al. 2011). The most documented adverse health effects associated with SSB consumption include: (1) a greater likelihood of unhealthy weight gain (thus, an increased risk for becoming overweight or obese); (2) a greater incidence of type 2 diabetes; and (3) a higher risk of hypertension (Vartanian and Brownell 2006; Te Morenga et al. 2012).

During the last two decades, the daily consumption of SSBs is one of the modifiable risk factors responsible for the increase in global attributable deaths and disability-adjusted life-years (GBD 2017 Diet Collaborators 2019; Rico-Campà et al. 2019). In order to prevent the negative health effects of an excessive intake of free sugars, the WHO (2015) suggests reducing their consumption preferably to less than 5% of the daily energy intake. This limit corresponds to about 6 tsp. of table sugar for adults per day.

Tax Strategies

Substantial research supports the need for action to curb the unhealthy habit of consuming too much sugar from SSBs (Hu 2013; Tedstone et al. 2015). Indirect taxes are an increasingly popular approach to promoting healthy eating habits by changing the relative prices of the different foods and beverages available on the market (Mytton et al. 2012; Powell et al. 2013).

Excise taxes are taxes on the sale of a specific category of goods and services, such as tobacco, alcohol, and unhealthy foods and beverages. These taxes usually target products deemed harmful to human health, but that society does not want to completely ban (Samuelson and Nordhaus 2010). Specifically, taxes on SSBs (SSB taxes) are excise taxes imposed by national or local governments for three main reasons: One, to discourage the excessive consumption of free sugars from SSBs; Secondly, to encourage producers to develop healthier soft drinks; and thirdly, to raise revenue to finance comprehensive policy programs, devoted to promoting healthy eating habits (WHO 2017).

The main motivation behind implementing SSB taxes is that the tax will increase the shelf price. This price rise will result in a decline in regular consumption of SSBs, which, in turn, will reduce the incidence of the harmful effects of an excessive intake of free sugars. Regular sodas are usually the most common SSBs. Hence, these taxes are often called ‘soda (or sugar) taxes’.

The Demand for Sugar-Sweetened Beverages (SSBs)

Due to the combination of rising disposable income and declining prices during the last 25 years, SSBs have become more affordable in more than 80 countries worldwide (Blecher et al. 2017). The affordability of SSBs is measured by the percentage of consumer’s disposable income required to buy a given amount (e.g., 1 l) of

product. As a result, it captures changes in SSB prices and consumers' income simultaneously (Ferretti and Mariani 2019). Considering the same share of income, a typical world consumer could buy about 70% more SSBs in 2016 than 1990. This percentage has risen above 85% in many emerging economies, in which the affordability of SSBs has nearly doubled in less than three decades (Blecher et al. 2017).

Affordability and Risk Exposure

According to the Global Burden of Disease (GBD) study, during around the same time frame (1990–2016), the 'summary exposure value' (SEV) of SSBs increased by more than 40% (GBD 2016 Risk Factors Collaborators 2017; Singh et al. 2015b). The SEV measures the population's exposure to a specific risk factor, by considering both the extent of exposure by risk level and the severity of that risk's contribution to disease burden (Institute for Health Metrics and Evaluation 2019). For a given content of free sugars, the SEV of products such as SSBs is mainly affected by the average level of SSBs' consumption among the general population. Research has consistently shown that the amount of SSBs consumed in each population primarily responds to SSB market prices, and all else being equal, prices and consumption are negatively related (Andreyeva et al. 2010; Goryakin et al. 2017). The curve labeled *D* in Fig. 63.1a illustrates this inverse relationship.

Practical Example

Let's assume that only one type of SSB is available in the market, for example, a carbonated soft drink containing 39 g of free sugars (about 9.3 tsp) per 12-oz (335-ml) serving. In Fig. 63.1a, the vertical axis of the graph shows the average retail price (*P*) of the soda, measured in U.S. dollars (USD). The horizontal axis shows the total quantity of soda demanded in the market (*Q*), measured in units per period (e.g., cans per day). Finally, *D* is the demand curve that shows how many cans of soda consumers are willing to buy per day as the price per unit changes, *ceteris paribus*.

The demand curve for SSBs slopes downward. A relatively lower price may encourage consumers who have already been buying the soda, to purchase more cans per day. Likewise, it may allow other consumers who were previously unable to afford the product to begin buying it. As shown in Fig. 63.1a, if the average price per decreases from P_1 to P_2, the quantity demanded increases from Q_1 to Q_2 and *vice versa*. Overall,

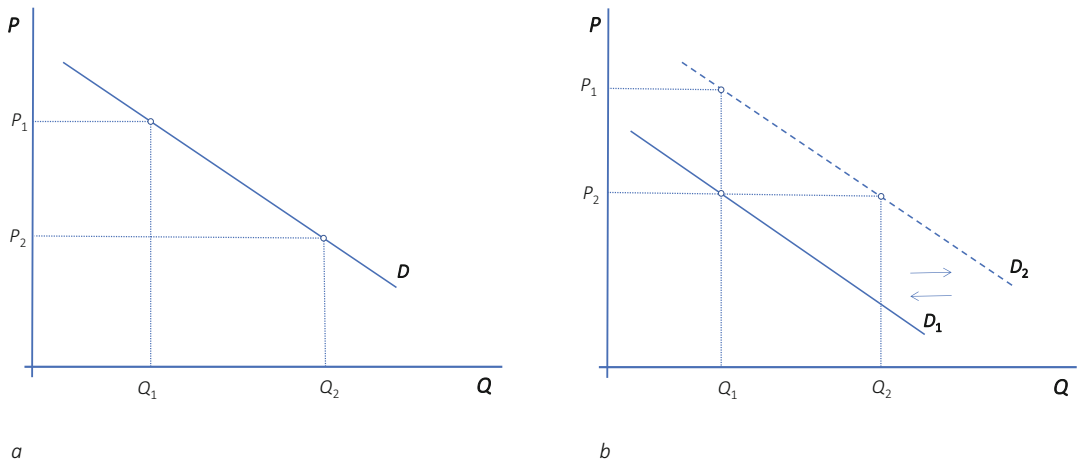

Fig. 63.1 (**a** and **b**) The demand curve for sugar-sweetened beverages (SSBs)

changes in price result in changes in the quantity demanded, that is, in movements along a given demand curve (such as D).

The quantity of soda that consumers are willing to buy in this market depends on many other factors besides its price, among which consumers' income is especially important. A good whose consumption increases when income rises is called a 'normal good'. Empirical evidence indicates that the consumption of SSBs varies substantially by income groups. Up to a threshold level of disposable income, low-income consumers tend to buy more SSBs when their incomes rise (Singh et al. 2015a; Allcott et al. 2019; Ferretti and Mariani 2019).

Consumption Scenarios

The effects of changes in income are shown in Fig. 63.1b. If soda is a 'normal good', and there are no changes in the price of soda when consumers' income increases, then consumption also increases. This increased consumption occurs independently of the market price. Consequently, the demand for soda changes. That is, there is a shift to the right of the entire curve (in Fig. 63.1b, this is shown as a shift from the solid D_1 curve to the dashed D_2 curve). In other words, with higher incomes, consumers are willing to pay a higher price (P_1 instead of P_2) to buy any given quantity (Q_1) of sodas.

Along with disposable income, the market for soda is also shaped by consumers' tastes. Changes in taste will affect the number of sodas that consumers want to purchase, given their disposable income and the soda market price. If consumers become aware of the negative health effects of SSBs, then they will be willing to buy fewer sodas at any given price. As exemplified in Fig. 63.1b, this will shift the entire demand curve to the left (from D_2 to D_1). Conversely, a successful industry's advertising strategy shapes consumers' tastes and shifts the demand curve outward again to D_2.

More generally, besides the market price, any other factor influencing purchasing behavior will result in a change in demand, and thus, in a shift of the entire demand curve. Understanding the difference between changes in the quantity demand and changes in demand is essential to improve a soda tax, and to design an effective and comprehensive policy program to reduce SSBs' consumption. Specifically, a change in the quantity demand is a movement along a given demand curve that occurs as a result of changes in the good's price. A change in demand is a shift of the entire demand curve, caused by a change in a determinant of demand other than the good's price.

Tax and Soda Sales

In Fig. 63.2, it is assumed that at price P, consumers buy Q cans of soda per day (point A on the solid demand curve D_2). To discourage SSBs' consumption, the government introduces an excise tax that raises the shelf price of each can of soda from P to P_{TAX}. Without changes occurring in their incomes and tastes, consumers respond to the higher price by reducing the quantity demanded from Q to Q_{TAX}. In Fig. 63.2, this corresponds to an upward movement along the D_2 demand curve until point B.

However, producers might be able to 'sterilize' the impact of the tax, for instance, by developing an aggressive price discount strategy to keep the retail price almost unchanged at the original level P. In this case, the quantity demand remains nearly Q. The tax has little or no impact on consumers' behavior, and so little or no impact on the population's intake of free sugars, because government policy only affects the quantity demand. Conversely, if the revenue collected with the tax is used to implement an effective program to enhance consumers' nutrition and health education, consumers' tastes are affected. As a result, the entire demand curve shifts to the left. This scenario is illustrated in Fig. 63.2. It

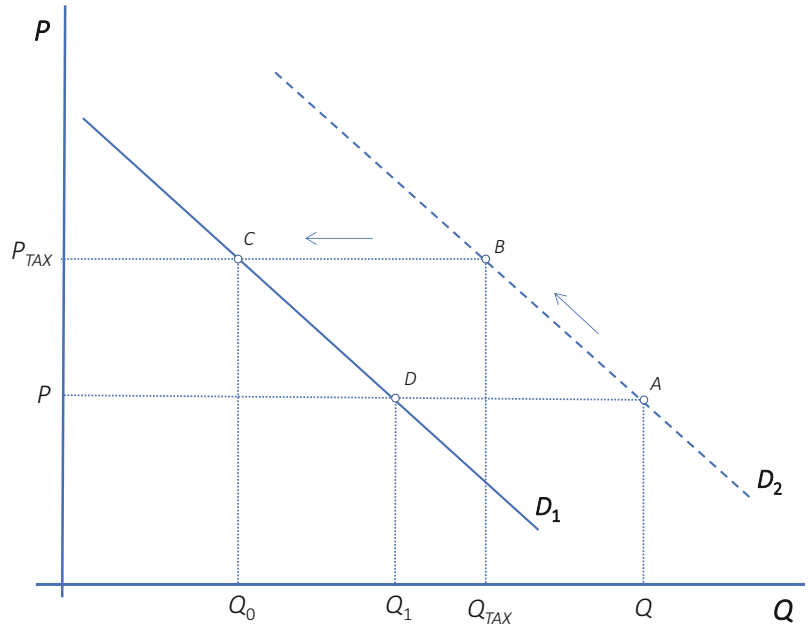

Fig. 63.2 The impact of an excise tax on sugar-sweetened beverages (SSBs)

shows that the tax decreases the quantity demand (from Q to Q_{TAX}), and the education program decreases the demand (from D_2 to D_1). Eventually, the daily consumption of soda becomes Q_0 (point C on the D_2 curve) as a result of changes in price and tastes, respectively.

Multi-pronged Strategy

If producers attempt to 'sterilize' the effect of the tax by reducing the price back to its pre-tax level P, then the strategy will have little effect on Q. The reason being that better-educated consumers are willing to buy fewer cans of soda per day at any given price. Thus, a decrease in price from P_{TAX} to its original level P increases the quantity demand. This effect is shown as a downward movement along the new D_1 curve from Q_0 only to Q_1 (point D), which is well below the initial level of consumption Q. In other words, the use of taxes as economic tools to affect health-related purchasing behavior should be part of a comprehensive policy approach.

Taxing Sugar-Sweetened Beverages (SSBs): Rationale

Sometimes consumers tend to ignore the adverse health effects of their consumption patterns (Bernheim 2016). There are two main reasons for the overconsumption of SSBs. Either the consumers are misinformed, or they deal with problems of self-control and time-inconsistency. In the former case, consumers do not know that free sugars can damage their health. In the latter case, consumers prioritize the immediate satisfaction of drinking SSBs, over future negative consequences.

In both cases, consuming high levels of free sugars from SSBs has two main effects. First, it harms consumers of SSBs by damaging their health. The direct negative effects of SSBs on consumers' health lead to various monetary and non-monetary costs, such as not-reimbursed out-of-pocket health care expenses, as well as wage loss and reduced income, due to poorer health conditions (for instance, obesity and diabetes). These are called 'internality costs' because they are borne directly by SSB consumers. Second, the

unhealthy habit of consuming SSBs generates indirect costs that spread to the whole economy, *via* the public (or private) health system. These are called 'externality costs' because they are unintended and uncompensated costs that SSB consumers impose on the entire health system, primarily in the form of increased health care expenditure on treating SSB-attributable diseases (Allcott et al. 2019).

The Pitfalls of Wrong Perceptions

Internality and externality indicate that there is a divergence between the perceived and actual costs of consuming SSBs. This divergence leads individuals to consume more SSBs than they would if they were able to consider all the direct and indirect costs. As a result, society faces a market failure, namely a misleading market reality. A situation that occurs when the individual pursuit of self-interest leads to adverse results for the collectivity as a whole (Perloff 2015). The attempt to correct this market failure is the economic rationale underlying the government intervention in the market for SSBs. In this context, a 'sugar tax' is an economic tool used to close the gap between the price that the consumer pays for a can of sugary drink at the time of purchase, and the total (i.e., internal and external) cost associated with SSB consumption (American Heart Association 2016; Griffith et al. 2016).

These corrective taxes are also named 'Pigouvian taxes' after the Cambridge economist A.C. Pigou, who emphasized their usefulness to correct market failure, as early as the beginning of the twentieth century (Pigou 1920). SSB taxes are thus policy tools designed to discourage activities that yield internal and external costs. Essentially, by affecting the price paid by the consumers and received by the producer, these taxes are economic signals, a piece of information that helps people make better economic decisions (Perloff 2015).

Taxing Sugar-Sweetened Beverages (SSBs): Mechanisms

The mechanisms through which a 'sugar tax' is supposed to operate are illustrated in Fig. 63.3. The government decides to discourage SSB consumption by levying an excise tax on the beverage industry. Some fraction of the excise tax is passed on to distributors, and, in turn, on to the final consumers in the form of a higher retail price. The remaining fraction of the tax (along with its administrative costs) falls on producers. Consumers respond to the higher price by reducing the quantity demand (i.e., by moving upward along the demand curve). Given the SSBs' nutrition facts, a lower consumption means fewer calories from free sugars, resulting in better health outcomes (Institute of Economic Affairs 2016).

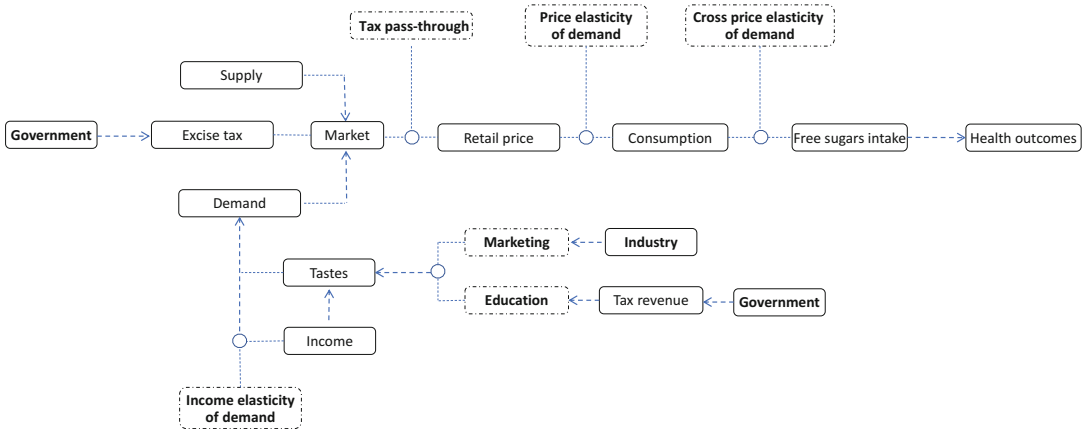

Fig. 63.3 Taxing sugar-sweetened beverages (SSBs): Mechanisms

A Comprehensive and Enlightened Approach

In addition to these basic static effects, the tax may help in triggering a virtuous cycle of a gradual reduction in SSB consumption. The revenue collected with the 'sugar tax' is used by the government to implement nutrition education programs. Increasing public awareness about the health implication of SSB consumption decreases the demand for SSBs (i.e., the entire demand curve shifts to the left). A declining demand encourages the beverage industry to develop healthier products, to avoid taxes and meet emerging trends in consumers' health-related lifestyles. As a result of all these demand and supply changes, the consumption of SSBs falls, reducing people's exposure to the harmful effects of free sugars and decreasing the incidence of SSB-related diseases (Heise et al. 2016).

However, as highlighted in Fig. 63.3, several links in this complex chain of events deserve careful consideration from policymakers (Allcott et al. 2019; Francis et al. 2016). The quantity demand decreases only if the tax results in a higher shelf price. In other words, the direct impact of the tax on SSB consumption depends primarily on the extent to which the tax is passed on to consumers. Besides the question of who will bear the administrative costs of the tax (i.e., the time and money spent to compute and pay the tax to the government), the tax incidence indicates how the economic burden (i.e., the amount of the tax) is divided between consumers and producers (Mankiw 2016).

Sugar Tax in the Real World

The burden of an excise tax is usually shared by both buyers and sellers. The tax drives a wedge between the price paid by consumers and the price received by producers. The consequence of this wedge is that consumers pay more, and producers receive less. As a general rule, the tax falls more heavily on the side of the market that is less responsive to price changes (Mankiw 2016). The beverage industry, however, is dominated by large multinational corporations that set the product prices based on their direct costs per unit of output, plus a mark-up to cover overhead costs and profits. In theory, these firms can absorb some or all of the tax, by offering discounts and reducing their profit margins (Powell and Maciejewski 2018).

Even when the tax is mainly (or fully) paid by the consumers, the quantity demand only decreases if consumers are sufficiently responsive to price changes. This responsiveness is usually measured by the price elasticity of demand, computed as the ratio of the percentage change in quantity demanded to the percentage change in price (Perloff 2015).

Price Elasticity of Demand

Specifically, the price elasticity of demand provides the percentage change in the quantity demanded that results from a 1% increase in price. Thus, it captures the willingness of consumers to leave the market when conditions become unfavorable. If consumers have particularly strong preferences for SSBs, the demand will be very inelastic (i.e., the price elasticity is well below one). In this instance, a tax-induced price change would be an ineffective strategy to nudge consumer behavior toward healthier dietary habits (Powell and Maciejewski 2018).

The impact of SSB taxes on health outcomes also depends on consumers' choice of alternative foods and beverages. Consumers might react to higher SSB prices by shifting their demand toward other unhealthy, but untaxed products. If consumers have developed strong preferences for sugary tastes, they could buy more untaxed sugar-sweetened foods and drinks (such as ultra-processed snacks, fruit juice or smoothies).

Cross Price Elasticity of Demand

The direction and strength of these 'cross effects' are captured by the cross-price elasticity of demand, which measures the percentage change in one good's quantity demanded (e.g., a fruit juice) that results from a 1% change in the price

of another good (e.g., a regular soda). This coefficient can be a positive or negative number, depending on whether the two goods are substitutes or complements. For instance, if SSBs and bottled water are substitutes, a sugar tax that raises SSB price will increase the demand for bottled water. *Vice versa*, if two goods are complements, as the price of one rises (falls), the demand for the other falls (rises). Thus, if regular sodas and ultra-processed snacks are complements, an excise tax on soft drinks will decrease the demand for unhealthy snacks (Mankiw 2016).

The General Economy

The impact of a tax that increases the retail price may be offset by a rising disposable income. In emerging economies SSBs tend to be 'normal goods', and the income per capita increases rapidly. Hence, a small excise tax is likely to have only a limited and transitory effect on SSB consumption, and virtually no impact on health outcomes. The reason is that the increase in demand, due to the higher income, outweighs the decrease in the quantity demand due to the tax. In such situations, SSBs become more affordable, and the resulting net effect is an increase in SSB consumption despite the excise tax (Ferretti and Mariani 2019).

Behavior of the Industry and the Government

Producers may react with a collective advertising strategy designed to offset the impact of the tax. Producers may also choose to reformulate their products by switching from regular to diet (i.e., no calories) beverages, in order to avoid the tax. Although the diet versions are without added sugars, these products have no nutritional value, and their health effects are still uncertain. Finally, the government may promote healthy dietary patterns, by using the revenue collected with the tax to finance nutrition education programs. These programs tend to reinforce the impact of the tax, because better-educated consumers are normally less exposed to industry advertising strategies (Obesity Policy Coalition 2018).

Current Worldwide Status

In many countries, sugar has been heavily taxed, or even a state monopoly, for centuries. The origins of a tax on SSBs, however, date back to the beginning of the last century. A specific excise tax on soft drinks was first proposed in 1914 by U.S. President Woodrow Wilson, to replace declining revenue from import tariffs (Blakey 1917; Brownlee 1985). An excise tax on SSBs was then introduced in Denmark during the mid-1930s, and Finland in the 1940s (Global Food Research Program 2019).

At those times, the governments were not concerned about public health issues. These taxes were levied merely to collect revenue in order to balance the national budget. The modern history of SSB taxes began in the early 1980s in Norway, but most of the currently existing SSB taxes were established after 2010, notably during the last 5 years. Nowadays, SSB taxes have been implemented in more than 35 countries worldwide, and seven U.S. local municipalities (Global Food Research Program 2019; Wan et al. 2017).

Apart from minor differences, current SSB taxes share a common design. They are usually collected from producers or distributors (i.e., the legal burden to remit the tax normally falls on manufacturers or retailers), and consumers simply see the tax as somewhat higher retail price. Overall, an excise tax can be specific, or *ad valorem*—that is, a given amount per beverage unit (e.g., 10 cents per liter) or a given percentage of the beverage price (e.g., 10% of the price of 1 l). SSB taxes are mostly specific and typically computed on a volumetric basis (a constant rate per unit of product). In some U.S. cities, for example, the average SSB tax is 1.5 cents per ounce of liquid (Global Food Research Program 2019; Wan et al. 2017).

Less frequently, SSB taxes directly target the amount of sugar content (for example, 0.5 cents

per gram of sugar) or adopt a tiered tax design, which applies different tax rates depending on the sugar content. This is the case, for example, in the U.K., which has two tax bands. One is for SSBs with more than 5 g of sugar per 100 ml and the other for more than 8 g of sugar per 100 ml, taxed at 18 and 24 pence per liter, respectively (Global Food Research Program 2019; Wan et al. 2017).

Over the past 5 years, seven U.S. cities have introduced an excise tax on SSBs. A tax was first established in 2014, in Berkeley, followed in November 2016, by three other Californian cities (Albany, Oakland, San Francisco), and then by Seattle (Washington) in 2017. Since 2016, Boulder (Colorado) and Philadelphia (Pennsylvania) have also implemented a tax on SSBs. All these cities use a tax rate that ranges from 1 to 2 cents per ounce, levied on all SSBs, except milk products and 100% fruit juice. Philadelphia is the only U.S. city that also taxes diet drinks (Allcott et al. 2019).

A picture of the worldwide status of SSB taxes is shown in Fig. 63.4. At the end of 2019, of the 39 countries that have implemented a tax on SSBs, ten are in Europe, seven in the Americas, eleven in the western Pacific region, and the remaining are spread throughout African, eastern Mediterranean, and Southeast Asian countries. The governments of several countries (such as Australia, Canada, Singapore, and Italy) have recently announced plans to imminently introduce a tax on SSBs. Besides the U.K., also in France, and Portugal taxes on SSBs are proportional to the sugar content, but other countries have typically set a constant rate per volume of product (Global Food Research Program 2019; Wan et al. 2017).

Empirical evidence indicates that producers usually do not attempt to 'sterilize' the tax. They normally pass along the supply chain down to the final consumers and raise the retail price by around the same amount of the tax. In countries such as Denmark, Mexico, and France, a 100% pass-through of the tax on the retail price was found. In some U.S. cities (Philadelphia, Boulder, and Berkeley), the percentage of the tax that falls on the consumer ranges from 75% to 90%, depending on the product variety and store type (Cawley et al. 2019; Powell et al. 2013).

Studies (Cawley et al. 2019) indicate that SSBs exhibit a price elasticity that varies widely with product types and consumer groups. Responsiveness of consumers is estimated to be, on average, around one (specifically, between 0.8

Fig. 63.4 The worldwide status of sugar-sweetened beverages taxes. Figure based on data from Global Food Research Program 2019 and Allcott et al. 2019

and 1.2). It means that an excise tax that raises the shelf price, for instance, by 20%, is expected to decrease the quantity demand for that good by 20% too, *ceteris paribus* (Muhammad et al. 2019; Powell et al. 2013).

Sugared Drinks in Mexico

In the Organization for Economic Cooperation and Development (OECD), Mexico is one with both high consumption of SSBs and high prevalence of obesity and diabetes (WHO 2011). In 2012, about 30% of the Mexican population was obese, and diabetes mellitus affected around 10% of the adult population. The prevalence of obesity and diabetes has been growing rapidly during the last decades, along with the consumption of SSBs, which exceeded 160 l per capita in 2013 (Colchero et al. 2017).

According to preliminary studies, an increase of 20% in the retail price of SSBs would have decreased consumption from 163 to 120 l per capita, which is a 26% reduction (Donaldson 2015). In January 2014, Mexican authorities passed a 1 peso (about 0.12 USD) per liter excise tax on all SSBs, which increased the price paid by the consumers by about 10%. During the following 2 years, the consumption of SSBs declined by 7.6% (5.5% in 2014 and 9.7% in 2015) among the general population, and by more than 11.5% among consumers with the fewest resources (Colchero et al. 2017).

Other Consequences in Mexico

These results imply a price elasticity of 0.76 and 1.5, respectively, and indicate greater price responsiveness in relatively poorer consumers (Pan American Health Organization 2015). Conversely, the consumption of untaxed beverages increased, on average, by more than 2% during the same period. Specifically, research has found a cross-price elasticity for water and unhealthy snacks of +0.10 and − 0.23, respectively. In other words, these 'cross effects' improved the positive effects of the tax on consumers' behavior. Moreover, in 2 years, the tax has generated revenue of more than 2.6 billion USD, part of which might be used to finance measures promoting healthy habits, such as the installation of drinking fountains at schools and public spaces (Colchero et al. 2017; Pan American Health Organization 2015).

Unjust and Regressive Taxes?

A regressive tax is one that takes a larger fraction of income from the underprivileged than from high-income groups. Overall, all excise taxes are inherently regressive because they do not vary with an individual's financial status. Furthermore, SSBs often behave as inferior goods, so that lower- and middle-income consumers spend a larger fraction of their income on SSBs than richer consumers. In the U.S., for instance, people with a household income above 75,000 USD per year, on average, consume about 117 cal per day from SSBs, roughly half of those consumed by people with a household income below 15,000 USD per year (Allcott et al. 2019).

The Broader Context

There are three main reasons why this regressive effect may be negligible. First, even in low-income groups, expenditure on SSBs is usually a very small part of household budgets (Duckett et al. 2016). Second, the responsiveness to SSB taxes tends to be greater in low-income consumers. In Berkeley (California), for example, the consumption of SSBs dropped by about 52% among low-income residents in the 3 years after the implementation of a tax of 1 cent per ounce on all SSBs, excluding diet drinks (Lee et al. 2019). Third, the health benefits of reducing SSBs tend to be greater for low-income individuals, who are usually the most disadvantaged in access to high-quality health care services. In other words, strong progressive health benefits are likely to overcome the 'mildly regressive' direct impact of the tax on low-income consumers' expenditures (Allcott et al. 2019; Grummon et al. 2019).

Conclusions

The first attempts to quantify tax effects indicate a persistent reduction in SSB consumption in favor of healthier alternatives. It thus suggests that fiscal policy may be an effective tool to promote healthy dietary patterns (Lee et al. 2019; Teng et al. 2019; Vecino-Ortiz and Arroyo-Ariza 2018; Veerman et al. 2016).

Some guiding principles should be followed (Allcott et al. 2019; Lloyd and MacLaren 2019; Jou and Techakehakij 2012). The excise tax should be levied on all kinds of soft drinks with added sugar and implemented statewide to avoid both substitution effects (increase in demand of untaxed SSBs), and cross-border shopping. As the harmful health effects of SSBs come from sugar, the tax should be based on the quantity of sugar contained in the beverages, rather than on the amount of liquid. This strategy will encourage consumers and producers to switch to low-sugar drinks (Grummon et al. 2019).

The tax should reduce as well the gap between the private and social costs of consuming SSBs. The socially optimal tax rate is the one needed to offset both the internality and the externality costs of consuming an additional unit of sugar from SSBs. This scenario usually implies an increase of at least 10% to 20% of the average retail price. The revenue collected by SSB taxes should be used to foster health and nutrition education among children and adults. Finally, SSB taxes should be a component of a more comprehensive policy . Such a plan should include effective controls to reduce people's exposure to SSB marketing, phasing out SSBs from schools, workplaces, and all public institutions, and social campaigns to promote healthy lifestyles (Allcott et al. 2019; Backholer et al. 2017; Lloyd and MacLaren 2019; Jou and Techakehakij 2012).

Abstract

Overweight and obesity are significant global public health problems. Developing evidence-based and novel health promotion interventions is greatly needed. One emerging area of research that holds promise for managing weight in overweight and obese populations involves mHealth. This chapter reviews the current evidence-base for mHealth for weight loss including the latest studies in different populations, commercial weight loss apps, use of theory and behaviour change techniques, consumer preferences, and emerging areas of research. mHealth holds promise for weight loss and weight-related behaviours in diverse populations. Current commercial weight loss apps are suboptimal in quality and lack empirical research on evidence of effectiveness. To ensure consumer satisfaction and sustainable use, considering consumer mHealth preferences and barriers is important. New and exciting areas of research merge the mind with the body, through mindfulness delivered via mHealth for weight loss. Current evidence indicates that this new area of research holds promise for targeting stress-related weight behaviours, which may in turn lead to weight loss.

mHealth · Weight loss · Diet · Exercise · Behaviour change · Eating behaviour · Obesity · Mindfulness

Introduction

mHealth Overview

Overweight and obesity are highly prevalent global public health problems, that are significant risk factors for premature mortality and morbidity from diseases such as cancer, cardiovascular disease, and diabetes (CDC 2015; WHO—Obesity and Overweight Fact Sheet 2015). They are also risk factors for osteoarthritis and mental illness (CDC 2015; WHO—Obesity and Overweight Fact Sheet 2015). The global mortality attributable to obesity and overweight was 3.4 million in 2010 (The G. B. D. Obesity Collaboration et al. 2014). Developing novel and effective health promotion interventions to tackle overweight and obesity through behaviour change interventions, that target their determinants such as diet and exercise (WHO—Healthy Diet Fact Sheet 2015; WHO—Physical Activity Fact Sheet 2015) are greatly needed.

One novel method for delivering a behavioural change intervention for weight loss is through mobile health. mHealth is mobile healthcare on the go, which has the convenience of portability and increased accessibility to valuable health information, and monitoring of health behaviours at any time and place for consumers (Lefebvre 2009; World Health Organization 2011). Users can gain instant access to health promotion educational content and interventions even with a busy schedule. The devices that fall under the umbrella of mHealth include smartphones,

personal digital assistants (PDAs), iPads, and iPods or MP3 players. Smartphone interventions can include apps, text messages or short message service, and phone coaching calls (Lefebvre 2009; World Health Organization 2011).

Usage and Trends

Delivering health promotion interventions through mHealth is particularly scalable due to their ubiquitous nature (Lefebvre 2009; World Health Organization 2011). The majority of people across the globe use a mobile phone and send daily text messages. There were seven billion people who subscribed to a mobile phone in 2017 (ITU 2015). Research also indicates that the number of text messages that users sent per month totalled 350 billion around the world in 2014 alone (Open University 2014).

Recent reports indicate that half of all smartphone users regularly use a health app, mostly in the wellness lifestyle category (Krebs and Duncan 2015; State L 2017). According to the mHealth economics report, there were 78,000 new health apps that were made in 2017 alone ((R2G) RG 2017). There is a massive market of health apps worth 23 billion US dollars (Reuters 2017) due to the demand and drive by consumers, with a 16% increase in health app downloads totalling 3.7 billion downloads in 2017 ((R2G) RG 2017). Findings in the mHealth economics report indicate that the leading health apps that are being made by developers based on demand are for diabetes, depression, and obesity ((R2G) RG 2017).

Research indicates that mHealth can save international health systems 370 billion US dollars a year by managing chronic health conditions on a global scale (Reuters 2017). Although there was mostly interest from non-health industry personnel when mHealth first emerged in 2008, there has been a recent increase in the enthusiasm and interest of healthcare practitioners in adopting and recommending mHealth for their patients ((R2G) RG 2017). The leading countries where health practitioners are interested in using mHealth for their patients are the UK (European share 47%), USA (North American share 36%), and the Asia Pacific region (11%) ((R2G) RG 2017).

Thus, given the massive use of smartphones, willingness of users to download health apps, and the rising willingness of health practitioners to become involved, there is much potential to deliver weight loss and weight-related behaviour change interventions via the mobile phone medium.

mHealth for Weight Loss in General Populations

Recent meta-analyses have found that mobile devices are effective for assisting with weight loss or weight-related behaviours, such as dietary intake and physical activity in various populations (Lyzwinski 2014). Table 64.1 summarizes the major meta-analyses for various populations. My previous meta-analysis found a medium effect size (Cohen's $D = 0.43$; p-value<0.01) (95% CI = 95% CI = 0.252–0.609), which favoured the mHealth interventions for weight loss over the control groups (Lyzwinski 2014). My meta-analysis included all interventions that targeted diet and exercise for weight in different populations.

Since my work on mHealth, some newer studies have also confirmed that mHealth is effective for assisting with weight loss and maintaining weight (preventing weight gain) after behaviour change (Chin et al. 2016). A recent review found a modest significant effect of mHealth for weight loss in obese and overweight populations, with a mean weighted standardized weight loss of 2.66 kg in the intervention, compared with the control at six months (Park et al. 2019).

Special Populations

Pregnancy

The study by Chan and Chen (2019) similarly found a medium effect size of mobile devices

Table 64.1 Summary of major meta-analyses of mHealth for weight loss in populations

Population, design, reference	Weight and Weight-related Behavioural Outcomes	Quality Appraisal, Publication Bias	Studies used Theory and BCTs with a Clear description of the content?
All General Adults >18, RCTs (Lyzwinski 2014)	The results favoured mHeath for weight loss Improvements in dietary and physical activity indices	Cochrane Risk of Bias Grading Tool Overall Quality = Moderate Funnel Plot: Studies with small sample sizes and + findings more likely to be published Effect would be smaller but still significant	Yes Most common BCTs: Goal setting, self-monitoring, feedback, tips, prompts, encouragement, social support, health education Most common theories: Social Cognitive Theory Others: Self-monitoring theory, Implementation Intentions, Self-Regulation Model, Action Belief Model
Pregnant and Post-partum Women, RCTs (Chan and Chen 2019)	The results favoured mHealth for weight loss	Yes 8-item checklist: the study design, sample size calculation, form of randomization, details of the intervention, eligibility (participant details), outcome measures, and statistical analysis Quality = Moderate Low Risk of Bias Funnel Plot: Studies with small sample sizes and + findings more likely to be published	Yes Most Common Theories: social cognitive theory social learning theory, combined models of behaviour prediction and behaviour persuasive design, and stage theories of decision-making Most Common BCTs: were encouragement, reminders, goal setting self-monitoring feedback health education, and social support
Adolescents ages 10–19, RCTs, and non-RCTs (Shin et al. 2019)	No significant weight loss compared with the controls Significant reduction in sugar-sweetened beverages Significant reduction in screen time Significant increase in physical activity	Cochrane Risk of Bias Grading Tool of RCTs And Risk of Bias for Non-Randomized Controlled Trials Quality = Weak High risk of Bias No publication bias assessment	No A few studies reported details of the intervention content Theory used and BCTs only in a few studies Theories: BCTs:

for assisting with weight loss in pregnant and in post-partum women (Cohen's $D = 0.45$) (p-value<0.05) (95% 0.16–0.074). Interestingly, they found that both mHealth (9/15 studies) and social media interventions (6/15) were equally effective for weight loss. Additional professional consultations or support did not modify the effect, and it was postulated that this was likely due to the fact that the mHealth interventions already had a strong health educational component, which did not require further professional guidance. However, they found that studies which utilized a self-monitoring wearable band in addition to the use of mHealth, were more effective for weight loss (Cohen's $D = 0.97$). Thus, it could be that additional behavioural self-monitoring increases motivation and reminds users to continue to engage in behaviour change.

Adolescents

There was a recent meta-analysis of mHealth for weight and weight-related behaviours in adolescents ages 10–19 years by Shin et al. (2019). While they did not find a significant effect of mHealth on weight loss, there were only three studies that assessed this outcome in the teen population. Thus, more studies are needed that may better ascertain whether mHealth is feasible and acceptable in adolescents. Their meta-analysis of nine studies that examined the effects of mHealth on BMI also did not have significant effect sizes. Given the large age group gap, it could be that the effectiveness of mHealth is contingent upon the involvement of parents for younger children, compared with those in their mid to late teens. More research is needed to better understand this.

However, they found support for the effectiveness of mHealth for physical activity, screen time, and sugar-sweetened beverage intake, which are weight-related behaviours. They found a moderate effect size for physical activity in six studies (standard differences in means = 0.341) (95% CI = 0.019–0.664). They found larger effect sizes for SMS interventions over app interventions, in tandem with single over multiple complex interventions involving different elements besides simple SMS (Shin et al. 2019).

They further found that mHealth is effective for reducing screen time in their pooled analysis of five studies (Cohen's $D = -0.198$) (95% CI = −0.317 to −0.078). Effects were larger for app interventions over SMS, and interventions involving multiple components rather than singular ones (Shin et al. 2019).

They additionally found support for mHealth for reducing sugar-sweetened beverages, in their pooled analysis of three studies. The standardized difference in means (SMD) was −0.40 (95% CI = −0.759 to −0.040), and shorter interventions were more effective than lengthier ones (over six months) (Shin et al. 2019). Given the positive findings for weight-related behaviours, studies of longer duration could be needed in order for the weight-related behaviours to influence weight (Shin et al. 2019).

An earlier review found equally little studies, with mixed results for weight loss in adolescents and children. They did find some support for goal setting and motivational behaviour (Quelly et al. 2016). As attitudes precede behaviours, which in turn translate into weight, it is plausible that more time is needed before the benefits in weight may be observed (Barber 2011).

Quality Assessment

The quality of the studies across the major meta-analyses was variable. My previous meta-analysis in the general adult population only included randomized controlled trials (Lyzwinski 2014). They were appraised using the Cochrane risk of bias grading tool, which includes a consideration of blinding (participants and outcome assessors), quality of randomization, allocation concealment, and attrition (and intention to treat analysis) (Higgins and Green 2011; Higgins et al. 2011; Hannes 2011). Overall, most of the studies in my meta-analysis were of moderate quality, meeting 3/5 of the main domains (Lyzwinski 2014). The meta-analysis in adolescents (Shin et al. 2019) also used the Cochrane risk of bias grading tool to appraise the studies (Shin et al. 2019). They also assessed non-randomized trials, using the risk of bias grading for non-randomized controlled trials (Shin et al. 2019). They found that their studies were weak in quality, as many were lacking in the following domains: allocation concealment, blinding, attrition, and not controlling for cofounding (in non-RCTs). This may possibly explain some of the discrepancies in the negative findings relative to the positive findings in other reviews.

The meta-analysis in pregnant and postpartum women used a checklist of eight items to appraise the studies, which included a consideration of the study design, sample size calculation, form of randomization, details of the intervention, eligibility including participant details, outcome measures, and statistical analyses. They found that the quality of the studies was moderate and that there was a low risk of bias (Chan and Chen 2019).

Consideration of Publication Bias

My previous systematic review found some evidence of publication bias of studies, with small sample sizes with positive results (Lyzwinski 2014). However, the funnel plot also indicated that without the bias, the effect would have still been significant, though smaller (Lyzwinski 2014). The meta-analysis by Chan et al. also found that there was some publication bias to keep in mind when interpreting the results, as studies with smaller sample sizes and positive findings were also more likely to be published (Chan and Chen 2019).

Integration of Behaviour Change Techniques

Abraham and Michie developed a list of 26 behaviour change techniques in interventions that shape behaviour (Abraham and Michie 2008). Many successful interventions in my meta-analysis had integrated a wide range of behaviour change techniques, highlighting their importance. The most common ones were health education (Brindal et al. 2013; Haapala et al. 2009; Hurling et al. 2007; Patrick et al. 2009; Prestwich et al. 2010; Shapiro et al. 2012; Turner-McGrievy and Tate 2011; Turner-McGrievy et al. 2009), goal setting (Chan and Chen 2019; Brindal et al. 2013; Haapala et al. 2009; Hurling et al. 2007; Prestwich et al. 2010; Shapiro et al. 2012; Burke et al. 2012; Carter et al. 2013; Napolitano et al. 2013; Spring et al. 2013), self-monitoring (Brindal et al. 2013; Haapala et al. 2009; Hurling et al. 2007; Prestwich et al. 2010; Shapiro et al. 2012; Turner-McGrievy and Tate 2011; Turner-McGrievy et al. 2009; Burke et al. 2012; Carter et al. 2013; Napolitano et al. 2013; Spring et al. 2013), and feedback (Brindal et al. 2013; Haapala et al. 2009; Hurling et al. 2007; Prestwich et al. 2010; Shapiro et al. 2012; Burke et al. 2012; Carter et al. 2013; Napolitano et al. 2013; Spring et al. 2013). Other important techniques included intention formation (Brindal et al. 2013; Hurling et al. 2007; Prestwich et al. 2010; Napolitano et al. 2013), social support (Hurling et al. 2007; Turner-McGrievy and Tate 2011; Turner-McGrievy et al. 2009; Carter et al. 2013; Napolitano et al. 2013), encouragement (Brindal et al. 2013; Hurling et al. 2007; Patrick et al. 2009; Shapiro et al. 2012; Carter et al. 2013; Napolitano et al. 2013), barrier identification (Brindal et al. 2013; Patrick et al. 2009; Shapiro et al. 2012; Napolitano et al. 2013), prompts (Brindal et al. 2013; Haapala et al. 2009; Hurling et al. 2007; Patrick et al. 2009; Prestwich et al. 2010; Shapiro et al. 2012; Carter et al. 2013), and tips (Brindal et al. 2013; Patrick et al. 2009; Turner-McGrievy and Tate 2011; Turner-McGrievy et al. 2009; Burke et al. 2012; Spring et al. 2013), One used rewards (Brindal et al. 2013) and one used stress management strategies (Napolitano et al. 2013).

The meta-analysis in pregnant women (Chan and Chen 2019) also used behaviour change techniques; however, they were not as extensive. The most common ones across the included studies were encouragement (Choi et al. 2016; Dodd et al. 2018; Fiks et al. 2017; Kennelly et al. 2018; Mackillop et al. 2018; Olson et al. 2018), reminders (Dodd et al. 2018; Mackillop et al. 2018; Olson et al. 2018; Herring et al. 2014), goal setting (Dodd et al. 2018; Mackillop et al. 2018; Olson et al. 2018; Herring et al. 2014), self-monitoring (Choi et al. 2016; Dodd et al. 2018; Fiks et al. 2017; Kennelly et al. 2018; Mackillop et al. 2018; Olson et al. 2018; Herring et al. 2014, 2016; Gilmore et al. 2017; Redman et al. 2017; Yang et al. 2018), feedback (Choi et al. 2016; Mackillop et al. 2018; Olson et al. 2018; Gilmore et al. 2017; Herring et al. 2016; Redman et al. 2017), health education (Choi et al. 2016; Dodd et al. 2018; Fiks et al. 2017; Kennelly et al. 2018; Olson et al. 2018; Herring et al. 2014, 2016; Gilmore et al. 2017; Redman et al. 2017; Yang et al. 2018), and social support (Choi et al. 2016; Fiks et al. 2017; Herring et al. 2016).

The authors of the meta-analysis in adolescents did not identify many intervention details nor behaviour change techniques (Shin et al. 2019). Upon reviewing the independent studies, a few studies used some techniques, though the details of the interventions were

scarce. A few used the following techniques: goal setting (Abraham et al. 2015; Babic et al. 2016; Mameli et al. 2018; Thompson et al. 2016), self-monitoring (Abraham et al. 2015; Babic et al. 2016; Mameli et al. 2018; Thompson et al. 2016; Chen et al. 2017a, b; Vidmar et al. 2019), feedback (Abraham et al. 2015; Mameli et al. 2018; Thompson et al. 2016; Chen et al. 2017b), and education (Abraham et al. 2015; Babic et al. 2016; Mameli et al. 2018; Chen et al. 2017b; Vidmar et al. 2019; Direito et al. 2015). One used semi-personal tailoring (Abraham et al. 2015). It is important to understand what features and techniques were used in an intervention, in order to better understand if it was based on evidence-based features, and what features worked or need to be improved.

Use of Theory

The use of theory to inform an intervention is important, as psychological theories are the foundations for testing whether certain targets such as attitudes, motivation, and other relevant constructs will impact behaviour change (Lyzwinski 2014). Many studies in my meta-analysis were informed by an explicit theory, while the rest used implicit theories. The most common explicit theory was social cognitive theory (Shapiro et al. 2012; Turner-McGrievy and Tate 2011; Turner-McGrievy et al. 2009). Other theories included self-monitoring theory (Patrick et al. 2009), implementation intentions (Prestwich et al. 2010), self-regulation model (Burke et al. 2012), and the health action model (Brindal et al. 2013). A few combined several theories (Haapala et al. 2009; Hurling et al. 2007).

Theories were also used in the studies in the meta-analysis of mHealth in pregnant and postpartum women (Chan and Chen 2019). These included social cognitive theory (Choi et al. 2016; Kennelly et al. 2018; Herring et al. 2016), social learning theory (Fiks et al. 2017), combined models of behaviour prediction and behaviour persuasive design (Olson et al. 2018), and stage theories of decision-making (Dodd et al. 2018).

The use of explicit theory was not often mentioned in the studies in the meta-analysis of mHealth in adolescents (Shin et al. 2019). Four studies mentioned the use of an explicit theory which included social cognitive theory (Chen et al. 2017b; Lubans et al. 2016) and self-determination theory (Babic et al. 2016; Thompson et al. 2016).

Emerging Research in Other Populations

There have been emerging studies in other populations including paediatric obesity prevention. One SMS study found that mothers significantly engaged in greater breastfeeding, had increasing awareness of the WHO's breastfeeding guidelines, and were less prone to introduce solid foods to their infants before four months, compared with the control (Jiang et al. 2014). However, a follow-up study did not find any effect of mHealth on an infant's BMI or weight relative to the control (Jiang et al. 2019).

Studies in older adults have been scarce. There is a current protocol for a study in a senior population of adults that will examine the effectiveness of mHealth for lifestyle, weight-related behaviours, and weight in adults over the age of 60 (Fuchs et al. 2018).

In postmenopausal women, two studies observed that mHealth assists with weight loss in this population. The 12-week study by Buckworth et al. (David et al. 2012) which combined daily phone calls with a pedometer found significant weight loss, with a mean reduction of 0.93 kg and a mean BMI reduction of 0.28 kg/m^2. Another twelve-week SMS study by Park and Kim (2012) also found weight loss of 2 kg and reduction in waist circumference by 3 cm, while the controls gained weight and experienced an increase in their waist circumferences.

Commercial Weight Loss Apps

Reviews of commercially available weight loss apps have been undertaken in the adult and

adolescent populations, available in the iTunes and Google Play stores in different countries. The results are summarized in Table 64.2.

App Quality

Chen et al. (2015) preliminarily screened the top 200 rated apps in the health and fitness app category in both stores in Australia. They appraised 28 apps against a set of criteria which included accountability, use of technology-enhanced features, and scientific validity of information. Most apps were weak overall in quality, with weak scores for accountability as there was no information about whether the developers had medical research backgrounds, or their affiliations. There was also little scientific information as well as references that backed up the educational content.

Most apps utilized some technology-enhanced features, such as use of energy intake and expenditure input methods with graphic feedback (79%). Social media and support were integrated in 43% of apps. They gave the apps a score of 5 out of 14 for usage of technology-enhanced features. Usability wise, they received suboptimal quality scores of 13.5/20 (Chen et al. 2015).

Additionally, few incorporated behaviour change techniques (BCTs), with a mean score of 6.3/26 in total. The main BCTs used were self-monitoring with feedback. They lacked stress management, prompts, and personal tailoring among other important techniques (Chen et al. 2015).

Another review by Breton et al. appraised the top 204 apps in the app store (Breton and Abroms 2011). Criteria included a comprehensive set of evidence-informed practice guidelines, informed by the Centre for Disease Control, The National Institutes of Health, The Food and Drug Administration, and the US Department of Agriculture. They assessed whether the apps had a food diary, assessed weight, helped maintain calorie balance, encouraged journaling, included portion control, included nutrition facts and encouraged reading labels, encouraged regular physical activity, and whether they educated people about a diet rich in fruits and vegetables. They further assessed whether the apps had meal planning, promoted drinking water over soda, assisted with loss of 1–2 pounds per week, and integrated social support.

Most apps had a food diary (43%), assessed weight (36%), and had info on maintaining caloric balance (34%). Around a quarter of the apps had info on physical activity, including encouraging the use of a journal and regular exercise, as well as information on portion control and nutrition labels. Only 12% of apps had information on eating a diet rich in fruit and vegetables, and less than 10% of apps had information on meal planning. Only seven per cent encouraged water drinking over soda. Only 6% encouraged weight loss of 1–2 pounds per week, and just 3% had any kind of social support in them (Breton and Abroms 2011).

The appraisal by Schoffman et al. reviewed 57 commercially available weight loss apps for teens and children in iTunes (Schoffman et al. 2013). A set of expert-recommended strategies for paediatric obesity prevention were used. These included calculating and plotting BMI over time, incorporating strategies for obesity treatment, incorporating motivation to change behaviours, personally tailoring the intervention, setting goals, discussing the influence of the built environment, incorporating the whole family in the intervention, and setting behavioural targets for sugar-sweetened beverage reduction and consumption of fruit and vegetables. They further assessed whether the apps targeted both diet and exercise, encouraged a reduction of screen time, home-made meals over fast food, family meal eating and daily breakfast, and physical activity for over an hour a day (Schoffman et al. 2013).

The overall quality of the apps was very poor, as 61.4% did not utilize any expert-recommended strategies. Over a quarter of the apps set goals like screen time limits. Only 5% plotted BMI and calculated it. None of the apps discussed the role of environmental determinants. Less than 10% of apps encouraged physical activity for more than an hour a day in children. Only 12% of the apps involved the family, and less than 2% encouraged eating with the family at home and preparing

Table 64.2 Summary of critical appraisals of commercial weight loss apps in different populations

Population, app type, platform, reference	Appraisal criteria	Appraisal findings	Top Rated Apps
General adults Australia, weight loss, iTunes and Google Play (Chen et al. 2015)	Accountability, use of technology-enhanced features, and scientific validity of information Incorporation of behaviour change techniques (BCTs)	Weak Overall Weak areas include: lack of professional references and referenced information Poor use of BCTs (score = 6.3/26) Usability Weak (Score = 13.5/20) Technology Enhanced Features Weak (Score = 5/14)	Noom Weight Loss Coach, Calorie Counter Pro and Control my Weight by Calorie King
General adults, weight loss, iTunes (Breton and Abroms 2011)	Evidence-informed practice guidelines Criteria: food diary, assessed weight, calorie balance, journaling, portion control, nutrition facts, reading labels, regular physical activity, info about a diet rich in fruits and vegetables, meal planning, drinking water over soda, weekly weight loss goals, and social support.	Weak Strong areas: assessed weight (43%) Info on maintaining caloric balance (36%) ~25% info on physical activity including, journal regular exercise, portion control and nutrition labels. Diet rich in fruit and vegetables (12%) <10% of apps information on meal planning. Water drinking over soda (7%) Social Support (3%)	Calorie Tracker Livestrong (9/13) Tap and Track Weight Calorie Exercise Tracker (8/13)
Adolescents, weight loss and weight-related behaviours, iTunes (Schoffman et al. 2013)	Expert Recommended Strategies Plotting BMI over time, Strategies obesity treatment Motivation to change behaviours, personal tailoring Setting goals The built environment The whole family Involved Sugar-sweetened beverage, fruit and vegetables Target both diet and exercise, reduction of screen time, home-made meals, family meal eating and daily breakfast, physical activity >1 hour/ day	Weak 61.4% did not adopt expert strategies >25% of the apps set goals (screen time limits) 5% plotted BMI and calculated it. 	Guided eating examples, increased self-awareness of hunger and fullness cues (over extra stressor triggers), mindfulness through a diversity of media. Real-life mindful eating examples and tips, dietary guidelines	eating examples, real-life eating tips and examples, tuning in with one's body and hunger, and little integration of BCTs	

meals at home. Only 15% focused on reducing sugar-sweetened beverages and increasing fruit and vegetable intake (Schoffman et al. 2013).

Mindfulness and Weight Loss

Lyzwinski et al. reviewed mindful eating apps in the iTunes store (Lyzwinski et al. 2019a). Mindfulness is a form of present moment meditation which involves both formal meditation practice and informal practice, where one is actively present in one's daily interactions (Chiesa and Malinowski 2011). Mindfulness and mindful eating have been linked with healthier weight-related behaviours such as lower binge eating, emotional eating, and weight loss (O'Reilly et al. 2014; Olson and Emery 2015). Given the high number of commercial apps, my colleagues and I decided to appraise their quality. The Mobile App Rating Scale (MARS) (Stoyanov et al. 2015) was used to assess the apps across the following domains: functionality, aesthetics, information, engagement, and a subjective score of whether one would actually get the app (not included in the total score). In addition to this, privacy policy was added as an extra domain, adapted from the Enlight criteria (Baumel et al. 2017). Therapeutic effectiveness was also adapted from the Royal College of Physicians and surgeons health informatics guidelines (Physicians RCo 2019).

Additionally, my colleagues and I developed a set of appraisal criteria specific to mindful eating, including whether the apps offered guided eating examples, whether they increased self-awareness of hunger and fullness cues (over extra stressor triggers), and whether they taught mindfulness through a diversity of media. Other domains that were assessed included whether the apps offered real-life mindful eating examples and tips, whether they utilized mindful eating self-monitoring techniques, whether they had information about balanced dietary guidelines, and whether they integrated a range of behaviour change techniques (BCTs) (Lyzwinski et al. 2019a).

The majority of the mindful eating apps received moderate scores in the MARS scale (72% moderate). The scores ranged from 1.96 to 3.75 out of 5. The apps had average scores for aesthetics and functionality. They had weak scores in the domain of quality of information about mindful eating, which was often limited and not backed up by scientific research.

The majority of the mindful eating apps (86%) were rated as weak with regard to the mindful eating specific appraisal. Many did not teach mindful eating using guided audios and a range of media. They also did not tune users in with their hunger and fullness cues. Many did not incorporate behaviour change techniques. Most did not offer any real-life tips or advice about how to eat mindfully (Lyzwinski et al. 2019a). Improvements need to be made in particular in the areas of evidence-based information, expert recommendations, and behaviour change techniques (BCTs).

Top-Ranked Apps

The top-ranked commercial apps according to the appraisal by Chen et al. were Noom Weight Loss Coach, Calorie Counter Pro, and Control my Weight by Calorie King (Chen et al. 2015). Calorie Tracker by Livestrong (9/13), and Tap and Track Weight, Calorie, and Exercise Tracker (8/13) were the first in the review by Breton and Abroms (2011). The top-ranked apps for weight in teens and children in the appraisal by Schoffman et al. (2013) were HyperAnt, Ideserve2, and Smash Four Food. These apps had information on healthy dietary intake and servings for children; however, the reviewers argued that the apps could have had more healthy tips and information in them. The top-ranked mindful eating apps in the review by Lyzwinski et al. (2019a) were Am I Hungry by Dr. May, In the Moment, and Eat C. None of the apps in any of the reviews received a perfect score in any of the appraisals.

Evidence for Effectiveness

The scientific evidence on the effectiveness of these commercial apps is scarce. The researchers argue that while apps like My FitnessPal or Lose It! are popular, they were no more effective than the control in randomized controlled trials, highlighting the discrepancy between evidence and popularity (Chen et al. 2015). Likewise, there was no evidence of any effectiveness studies of the apps that were reviewed in the appraisal by Breton and Abroms (2011). They also critiqued the apps for not including any SMS or notifications, given that the prevailing literature had found that SMS is effective for weight loss (Breton and Abroms 2011). Likewise, the review by Schoffman found that none of the apps for children were tested in trials for effectiveness, and they felt that the lack of sufficient information and behaviour change in the apps would make them unlikely to be effective when tested in trials (Schoffman et al. 2013).

Similarly, none of the mindful eating apps in our appraisal were empirically tested in randomized controlled trials (Lyzwinski et al. 2019a). The lack of scientific validity coupled with low quality of information and aesthetics was also found in a review of general mindfulness apps (Mani et al. 2015). Thus, there is insufficient evidence to recommend the commercially available apps until they are proven to be effective in quality randomized controlled trials.

Privacy Issues

My review of mindful eating apps found that privacy is a major issue with existing apps (Lyzwinski et al. 2019a). There is a need for clear and explicit privacy information in apps for weight loss and weight-related behaviours, in order to protect consumers (Lyzwinski et al. 2019a).

Consumer Preferences for mHealth

Gaining insight into consumer preferences for mHealth for weight loss is valuable for promoting continued interest and use. Thus, my colleagues and I undertook the first meta-synthesis of qualitative studies that examined user perceptions, barriers, and facilitators of use (Lyzwinski et al. 2018a). Figure 64.1 Illustrates the benefits that should be maximized, and the barriers that should be minimized in consumers.

User-Friendly Features

Three themes were identified for app preferences which included simplicity in design and ease of use, personalization, and engagement or entertainment. Users wanted apps that would be user friendly to navigate without any major hindrances or difficulties. They also wanted personal tailoring in the apps. They further wanted the apps to be fun or engaging for them.

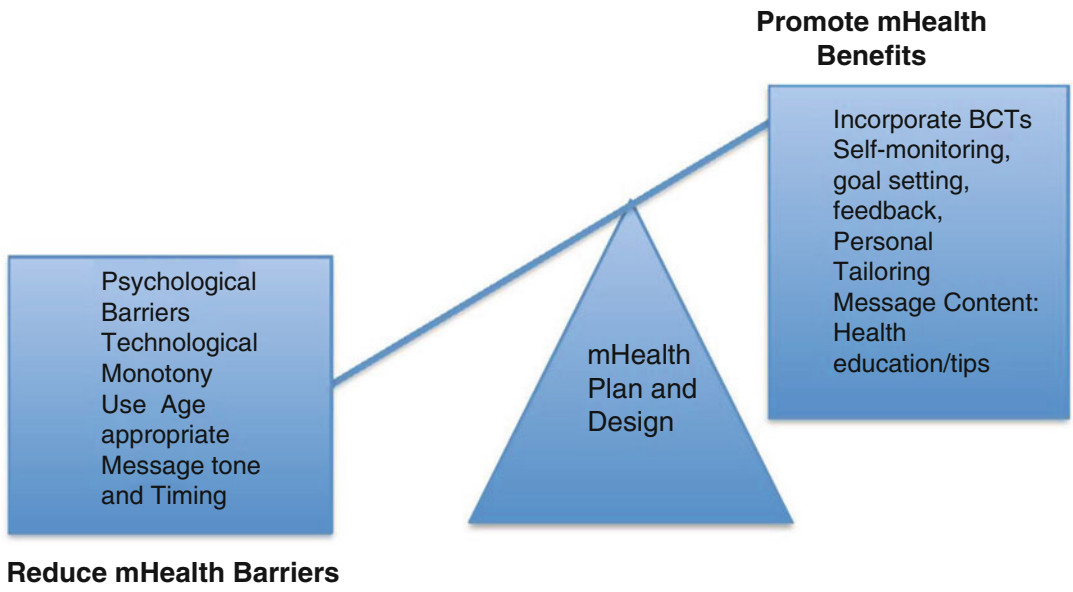

Fig. 64.1 mHealth for weight loss consumer perspectives model

Five themes were identified for consumer preferences for text messages in mHealth weight-loss interventions (Lyzwinski et al. 2018a). Consumers wanted personally tailored messages. They further wanted messages to be considerate of tone. An overtly judgemental tone or one that pressured them could instil psychological roadblocks. These included guilt or fear of failing. The importance of message phrasing and structure was also brought up as a theme for users. They wanted the messages to be short and professional. Teenagers had a dislike of imperative wording, colloquial abbreviations, and phrasing messages in a non-professional way, that sounded like the way their peers would message one another. Message content was also raised as an important theme. Consumers wanted the text messages to be filled with educational material and practical health tips.

Barriers

Several barriers and benefits of mHealth for weight loss were identified as themes by the consumers (Lyzwinski et al. 2018a). Consumers liked the integration of a wide variety of behaviour change techniques, which were viewed positively by them. They found that goal setting, self-monitoring, encouragement, social support, reminders/prompts, and health education were valuable. A few barriers were also identified which were psychological, technological, and engagement related. Consumers wanted encouraging messages over ones that could create excessive pressure or guilt. They also expressed technological concerns in remote areas. Older adults felt that modern technology could be a barrier. Some consumers expressed privacy concerns. Finally, excessive engagement through sending too many messages, or monotonous apps that lacked engagement, was viewed as barriers to continued use.

Challenges with mHealth

Research indicates that most users cease using health apps after a period of time (Krebs and Duncan 2015).

The main reasons are usually the cost of the app if it requires a subscription, and lack of sufficient engagement in order to keep them interested in sustained use (Krebs and Duncan 2015). This is

in congruence with research which found that brief SMS messages for sugar-sweetened beverages over six months, were more effective than longer ones (Shin et al. 2019).

Another factor to consider involves the psychological and mental health component. Only one study in my previous meta-analysis had anything for stress management (Napolitano et al. 2013). Likewise, one review also found that there were not any studies that employed stress management techniques (Chen et al. 2015). My previous research has linked stress with maladaptive coping behaviours that are associated with weight which include binge eating, emotional eating, craving junk food, eating fast food, and low levels of exercise (Lyzwinski et al. 2018b).

New Areas of mHealth Research

Research has found that mindfulness is beneficial for mental health (Hofmann et al. 2010) as well as stress, weight, and weight-related behaviours (O'Reilly et al. 2014; Olson and Emery 2015; Chiesa and Serretti 2009; Lyzwinski et al. 2018c). Given that mindfulness targets stress, it is possible that behaviour change and app usage may be sustained over longer periods of time during fluctuating periods of stress.

Despite the large number of studies involving face-to-face interventions and the large number of mindfulness apps in the app stores, my colleagues and I found that there were no RCTs that examined mindfulness for weight and weight-related behaviours using mHealth (apps or SMS), in our previous systematic review (Lyzwinski et al. 2018d).

Preliminary Student Analysis

Prior to undertaking a trial, exploratory focus groups were undertaken to better understand consumer preferences, and any potential barriers and facilitators of use (Lyzwinski et al. 2018e). Most students wanted a mindfulness weight loss app that would be simple and easy to use. Their preferred colour was blue like the sky or ocean for a splash screen. They also wanted the app to have plenty of educational material and health tips. Certain barriers were identified which were technological, psychological, and time related. Students were concerned about technological distractions such as the phone ringing or having pop up ads. They also did not want the app to pressure them into changing dramatically. Finally, they were concerned that some mindfulness exercises might be too long, and they would not do them given their busy schedules. Thus, the app was made with these suggestions in mind, along with consulting key evidence-based mindfulness-based stress reduction (MBSR) and mindful eating books (Albers 2006; Kabatt-Zinn 2016; Somov 2008; Stahl and Elisha 2010, 2015).

Randomized Trial of a Mindfulness App

Following this, my colleagues and I undertook the first randomized controlled trial of a mindfulness-based mHealth app for weight, weight-related behaviours, and stress in university students at the University of Queensland in Australia (Lyzwinski et al. 2019b). The RCT was 11 weeks in duration.

The app had mindfulness-based stress reduction techniques, derived from MBSR and mindful eating as well as mindful exercise (Albers 2006; Kabatt-Zinn 2016; Somov 2008; Stahl and Elisha 2010, 2015). It had formal mindfulness meditation including the body scan, breathing exercises, sitting meditation (loving kindness and concentrative), walking meditation, and choiceless awareness mindfulness meditation, in addition to informal exercises. There were also tailored eating meditation audios. The app used a range of behaviour change techniques including sending push notifications that reminded, educated, and prompted students to practice mindfulness in addition to health education tips, self-monitoring, and stress management. The app taught mindfulness through a diversity of media including educational articles, audios, videos, and games.

Protocol Inclusion Criteria and Methods

All healthy students who wished to lose weight were eligible to participate. A priori sample sizes were calculated and 90 students enrolled in the study. Weight was measured objectively with a digital scale at baseline and follow-up. Weight-related behavioural patterns were assessed using valid and reliable surveys. Students were randomized to either the mindfulness app or to a control group, which received an electronic diary for self-monitoring of diet and exercise. Allocation was concealed as an independent statistician randomized the participants using a 1:1 simple parallel randomization sequence.

There was no weight loss in either group. However, neither the mindfulness app group nor the e-diary group gained weight either. This finding is nonetheless relevant, as university students are at risk of weight gain during their studies (Crombie et al. 2009). Behavioural self-monitoring using a diary has long been established as a method of weight control, which explains why the control group also did not gain weight (Burke et al. 2011).

When compared with the control, the mindfulness app intervention had lower levels of emotional eating by 1.088 points ($F = 5.893$; p-value < 0.05) in the analysis of covariance. The app intervention also had significantly lower levels of uncontrolled eating compared with the control, by 2.047 points ($F = 5.974$; p-value < 0.05) (Lyzwinski et al. 2019b).

Furthermore, mindfulness app intervention also had lower levels of stress in the adherer analysis by 3.21 points ($F = 5.943$; p-value < 0.05). In addition to this, they also had higher levels of mindful eating by 0.295 points ($F = 21.035$; p-value < 0.01) and mindfulness by 3.104 points ($F = 14.580$; p-value < 0.01) than the control.

It could be that changes in weight will be observed in studies of longer duration, as it takes times for weight-related behaviours and changes in attitudes to lead to weight changes. Thus, there is a need for studies of longer duration.

Most students enjoyed the app (94%), and there was a high retention of 80%. Adherence was a challenge as regular usage of the app was low, and most students used it periodically (61%).

Perspectives for Future Improvement

Several themes were identified from the post-trial focus groups that could be used to ameliorate the app (Lyzwinski et al. 2018f). The first few themes were about the control group e-diary. Many found the diary to be helpful and that it increased accountability and knowledge about guidelines; however, time was a barrier. Most students enjoyed using the app and found that it made mindfulness much more accessible to them. Previous myths about meditation being difficult were debunked. Students also felt that their attitudes towards a healthy lifestyle (diet and exercise) had improved as a result. The short breathing audios were preferred by students, due to their time convenience. Many felt that the app reduced their stress. They also felt that they were more mindful as a result of the app. Barriers included finding the time to meditate and getting into the habit of meditating. Students wanted more push notifications in the app and more healthy tips.

Relevance of the e-Diary

Most students wanted a mindfulness weight loss app that would have an e-diary for diet and exercise like the control group had. The control diary group had higher levels of moderate to vigorous MET physical activity ($F = 10.016$; p-value < 0.01 than the app group, highlighting the potential benefit of incorporating exercise self-monitoring into the mindfulness app (Lyzwinski et al. 2018f). This would likely increase the benefits.

Since this trial, a few other trials have been undertaken. There was an Acceptance and Commitment Therapy (ACT) app study, which found that using food as a reward decreased and intuitive eating increased. They did not find that stress modified this relationship, though the app was not

MBSR based which targets stress (Jarvela-Reijonen et al. 2018). Another study in teens found that the mindfulness app increased awareness of weight-related behaviours (Turner and Hingle 2017). There was also a mobile phone mindfulness coaching study, which found significant decreases in binge eating and experiential avoidance (indicator of emotional eating). Both the mindfulness intervention and the active control group (which also received a weight loss intervention) lost weight, with no differences between groups. Adherers of the mindfulness intervention lost the most weight (Carpenter et al. 2019). Indeed, adherence is an issue for mindfulness weight-loss interventions which needs to be tackled in the future.

Conclusion

mHealth holds great promise for weight loss across different populations. More studies are needed in teens and children in order to ascertain their effectiveness in this population, and whether other strategies such as parental involvement need to be implemented. Current commercial mHealth weight loss apps are weak in quality and lack an evidence base. More work needs to be done to create apps that are of higher quality and that are empirically tested for effectiveness in trials. It is important to consider consumer preferences and minimize barriers, in order to ensure long-term sustainable use and behaviour change as well as consumer satisfaction. Mobile mindfulness weight-loss interventions are a new area of mHealth which is very exciting and filled with potential, as they target the underlying psychological factors involved with weight-related behaviours. More studies of longer duration are needed to confirm their effectiveness.

Biomarkers and Machine Learning Applications in Obesity

65

Olga Tsave and Ioannis Kavakiotis

Contents

Abstract

Next-generation sequencing, multi-omics, high-resolution medical imaging technologies, and a wide range of (smart) sensors have led the biosciences into the big data era. To this end, machine learning approaches are more than ever indispensable to transform all this data into valuable knowledge. This chapter aims to address the current state, progress, and challenges in biomarkers discovery in obesity with respect to anthropometric measurements, biochemical and omics approaches, and to discuss the most representative studies relative to the application of machine learning emphasizing prediction tools, feature extraction and closely related factor evaluation, nutrition-driven applications, bariatric surgery, and

childhood obesity. The mapping, and hence understanding, of invasive and noninvasive biomarkers extraction and utility along with its limitations, could offer valuable insights into pathophysiology, prevention, and treatment.

Keywords

Machine learning · Data mining · Obesity · Childhood obesity · Disease prediction models · Biomarker(s) identification

Introduction

Recent advances in both analytical techniques and artificial intelligence have given rise to time- and cost-efficient tools. Numerous sensor-based devices such as smartphones (utilizing gyroscope, cameras, accelerometers), smartwatches, and several wireless (nano)networks enable continuous health monitoring (Majumder and Deen 2019; Tsave et al. 2019). High-throughput data derived from genomics, transcriptomics, proteomics, metabolomics, lipidomics, and from medical imaging techniques such as positron emission tomography (PET), single-photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI) have led to the development of integrated strategies that give systematic and mechanistic insight in numerous pathophysiological conditions (Kavakiotis et al. 2017; Severin et al. 2019).

The management of obesity and/or its related complications along with the delineation of its causal mechanisms stand as a challenge in the twenty-first century (World Health Organization 2016; Nguyen et al. 2012). Machine learning, an artificial intelligence field utilizing methodologies for extracting useful knowledge from databases, could be helpful to this aim.

Background Knowledge

Knowledge Discovery in Databases (KDD) and Data Mining

KDD is a multistep process (Fayyad and Piatetsky-Shapiro 1996), depicted in Fig. 65.1, focusing on data management and extraction of useful information. A definition of KDD is given by Fayyad et al. (Fayyad and Piatetsky-Shapiro 1996): *KDD is the nontrivial process identifying valid, novel, potentially useful, and ultimately understandable patterns in data.* The most important step is data mining, in which algorithms from machine learning and statistics are employed in order to extract patterns from data. Alpaydin (Alpaydin 2004) states that application of machine learning methods to large databases is called data mining.

At the very beginning of the KDD process, stands the definition of the problem and the understanding of the field, which is performed in close collaboration between the application's field and KDD experts. Moreover, various aspects of the analysis are sought such as restrictions that may apply in the application domain.

Data Selection Nowadays, in the big data era, it is common that heterogeneous data are included in a study, such as electronic health records

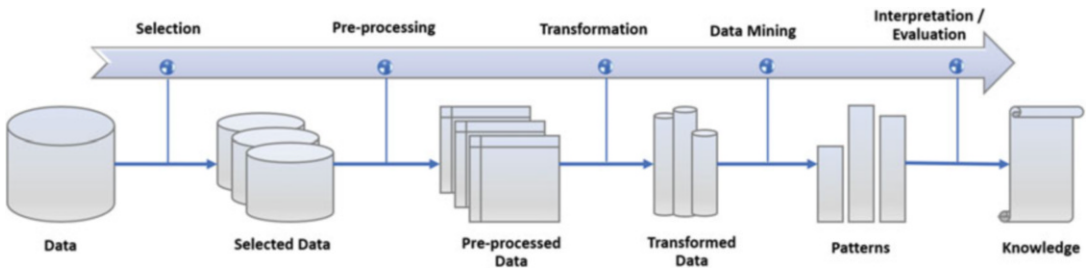

Fig. 65.1 The basic steps of the knowledge discovery in databases (KDD) process (Kavakiotis et al. 2017)

(EHR), next-generation sequencing of DNA/RNA, and metabolomic data. Those data are not organized in a way that expedites the KDD process. The first step is to select and export the appropriate data from the originating resources and to organize them into simpler, appropriate structure.

Pre-processing This is also called the data cleaning step. Collecting data from different resources may result in inconsistencies concerning the features (i.e., the descriptors) of the data. Such inconsistencies include different measurement units for the same quality of information (e.g., blood glucose levels), or even missing essential data. The preprocessing step aims at the correction or removal of erroneous data and acquisition or prediction of missing data.

Data Transformation Data are transformed in an effort to expedite the extraction process either by reducing the number of features (dimensionality reduction) or the number of values that a feature can have (variability reduction), thus providing more comprehensible results. Feature selection is the reduction of the number of features (dimensionality reduction). This technique embodies many advantages, such as a) better visualization and understanding of the data, b) reduction of the analysis duration, and c) better prediction accuracy (Guyon and Elisseeff 2003; Witten et al. 2011). It is the process of selecting a subset from the available features of the dataset, which are more relevant and informative for the construction of a model. Other data transformation techniques include discretization of the data, which is the conversion of integer or real values to categorical values, and the integration of variables, to reduce the complexity of the data.

Data Mining The appropriate machine learning algorithm is applied to the transformed data in order to produce the desired results. There are two general categories of outcomes from a data mining process: informative patterns and predictive models.

Interpretation—Evaluation In the last step of the KDD process, various visualization techniques are employed for the presentation of results (e.g., graphs, plots). These techniques offer to the field expert, e.g., medical doctor or biologist, the flexibility to summarize and draw more solid conclusions.

Machine Learning

For the data mining step, information is extracted through predictive models, utilizing supervised learning, and informative patterns through unsupervised learning. A formal definition of machine learning is given by Mitchell (1997): A computer program is set to "learn" from experience (E) based on some class of tasks (T) and performance measure (P), if its performance at tasks in (T), as measured by (P), improves with experience (E). Different protocols can be adopted (Severin et al. 2019; Witten and Frank 1999; Russell and Norvig 2003): (a) supervised learning, inferring a predictive model from labeled data; (b) unsupervised learning, during which unlabeled data are employed; (c) reinforcement learning, based on a dynamic environment.

Supervised learning Input-output pairs, analyzed by an algorithm, are used for the development of a predictive model (function), with the help of labeled examples (training data). The resulting model is subsequently applied to unknown examples (input features only). In supervised learning, learning tasks are divided into classification (predicting classes) and regression (predicting numbers) models. Decision trees (DT), rule learning, and instance-based learning (IBL) such as *k*-nearest neighbors (*k*-NN), genetic algorithms (GA), artificial neural networks (ANN), support vector machines (SVM), all belong to the supervised category.

Unsupervised Learning Clusters are informative patterns occurring through clustering, i.e. the separation of a whole dataset into groups of data, so that instances belonging to the same

group are as similar as possible, and instances belonging to different groups differ as much as possible (Han et al. 2011).

Biomarkers

Nutritional strategies against obesity encompass a) general dietary interventions, b) control of macronutrient composition (e.g., low-fat diets), c) calorie restriction (low and very low-calorie diets), and d) lifestyle interventions (weight loss-physical exercise along with beneficial dietary styles) (Parsanathan and Jain 2019). Pharmacological options are also available, as well as bariatric surgery and endoscopically introduced intragastric balloons (Lukas et al. 2019). Current available therapies remain important in treating obesity but are still limited.

Since obesity has a fundamental, causal effect in developing numerous complications and comorbidities, robust and reliable clinical biomarkers would be welcome to improve (a) diagnosis and classification of the disease, (b) early diagnosis or prediction of the risk to develop secondary events, and (c) more personalized and precise medical treatment.

Biomarkers are defined as biological measures of a certain clinical state. The ideal biomarker should be easy to measure, safe (non-invasive), cost-efficient, specific, sensitive, and predictive. Biomarkers are used as monitoring, screening, diagnostic, and prognostic tools, whereas they can also be considered as potential targets of drugs or other therapies (Lukas et al. 2019; Kosaka et al. 2010). Currently available biomarkers suffer from low specificity, sensitivity, and false-positive outcomes. New molecules (such as miRNAs, metabolites etc.) gain significance in this context (Shih and Lin 2018; Musaad and Haynes 2007). Several circulating molecules have been proposed as mediators of obesity, namely adipose-derived hormones and adipokines such as adiponectin and leptin (Pischon 2009; Pan and Yeh 2008; Nimptsch et al. 2019).

Anthropometric Predictive Indices

Indicative anthropometric measurements or calculations that have been used as markers or features at the clinical level include Visceral Adiposity Index (VAI), epicardial fat thickness (EFT), the density of both visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT), body fat distribution (BFD), waist circumference, waist-to-hip ratio, and waist-to-height (Okorodudu et al. 2010; Tsave et al. 2018a, b). Most of the aforementioned indicators are used in combination with specific phenotypes such as the presence of hypertension, hypertriglyceridemic waist (HTGW) phenotype, or blood glucose levels, in an effort to improve diagnostic and prognostic value (Okorodudu et al. 2010; Tsave et al. 2018a, b).

Genetics

Genes involved with obesity include human leptin receptor gene, proprotein convertase subtilisin/kexin type 1 (PCSK1; also known as PC1) gene, brain-derived neurotrophic factor (BDNF) and its receptor, tyrosine receptor kinase B (encoded by NTRK2), genes encoding the glutamic acid decarboxylase enzyme (GAD2), peroxisome proliferator-activated receptor gamma(PPAR-γ) gene, cannabinoid receptor 1 (CNR1), dopamine receptor 2 (DRD2), serotonin receptor 2C (HTR2C), and SLC6A4 genes among others (Fall and Ingelsson 2014; Jackson et al. 1997; O'Rahilly et al. 1995; Deeb et al. 1998). As a chronic inflammatory condition, inflammation-related genes are generally upregulated in obesity. Adipogenic genes are often downregulated since the physiology of adipocytes is altered (lipotoxicity, adipose tissue excess) leading to cardiometabolic disorders and the onset of type 2 diabetes (T2D) (Wells 2012).

Epigenetics

Epigenetic patterns, reversible impacts of chromatin, encompass DNA methylation, acetylation, phosphorylation, histone modification, and noncoding RNAs (ncRNAs), and can be passed on mitotically (cell division) or meiotically (transgenerational inheritance) (Lopomo et al. 2016). Among individuals with excessive adiposity, they depend on alimentation patterns and other environmental influences. Multiple elevations of cellular micro-RNAs such as miR-148a, miR-26b, miR-30, and miR-199a were detected in specialized mesenchymal or adipose cells in patients with excessive body weight (Van Dijk et al. 2015; Zhang et al. 2012; Graham et al. 2015; Ouyang et al. 2017). Also in pediatric populations with adipose tissue accumulation, elevated miRNAS (miR-199a-3p/miR-199b-3p and miR-4454) regulating hundreds of genes were unearthed, which could feed a machine learning protocol.

Biochemical Markers and Proteins

Alterations in protein and metabolite profile (e.g., insulin, blood glucose, triglycerides, cholesterol, and related pathways) also provide mechanistic insight in the underlying mechanisms that lead to obese phenotype. Proteomics is defined as the mapping of the expression patterns of proteins at a given time in response to a specific stimulus or disease state and is used for the determination of the functional protein networks that exist at the cellular, tissue, or organism level (Masood et al. 2018). The construction of the proteome is a data-driven approach applied in both untargeted and targeted proteomics workflows, generating qualitative and quantitative datasets of protein expression levels, composition, and post-translational alterations.

In a cohort of 36 male patients, with or without abdominal obesity and diabetes, seven matched protein spots (alpha-1-antichymotrypsin, alpha-1-antitrypsin, apolipoprotein A-I, haptoglobin, retinol-binding protein 4, transthyretin, and zinc-alpha2-glycoprotein) were different between normal and prediabetes/diabetes patients. Network analysis followed by functional annotation revealed that most proteins were involved in lipid transport, lipid localization, and the regulation of serum lipoprotein particles (Kim et al. 2019).

Two large series of roughly 500 subjects each were proteomically analyzed. Plasma protein pattern for age, gender, and general variability was defined, and associations with insulin, glucose, and other markers were unearthed or confirmed (Cominetti et al. 2018). Matrix correlation, one of the available preliminary tools for machine learning development, was applied to 200,000 relationships of 1700 proteins, detected in a cohort of 47 obese patients submitted to bariatric surgery (Roux en Y gastric bypass). Certain proteins changed as early as one week after surgery, whereas in others that occurred as late as after more than 2 years, indicating quite specific patterns for each of them. Elevations, reductions and other behaviors were demonstrated, depending on the analyzed molecule. Altered proteins were mostly markers of systemic inflammation and lipid metabolism (Wewer Albrechtsen et al. 2018).

The Gut Microbiome

In the review of Castaner et al. (Castaner et al. 2018), it was shown that species from the Firmicutes phylum namely *Blautia hydrogenotrophica, Coprococcus catus, Eubacterium ventriosum, Ruminococcus bromii, and Ruminococcus obeum* were associated with obesity. In a systematic review regarding bariatric surgery, some representatives from the phyla Bacteroidetes, Fusobacteria, and Verrucomicrobia increased after surgery, whereas the Proteobacteria phylum encompassed both elevated and diminished components. Reduction of

Firmicutes was also evidenced. *Faecalibacterium prausnitzii, Lactobacillus,* and *Coprococcus* are highlighted as often beneficial (Guo et al. 2018). Although machine learning was not employed in these protocols, the massive numbers of the gut microbiome are good candidates for such technique. Incidentally, *F. prausnitzii* along with *Akkermansia muciniphila* are being investigated as novel probiotics, with potential indications in obesity.

One protocol with 75 men suggests that circulating gut permeability biomarkers, such as lipopolysaccharide-binding protein (LBP) and soluble CD14, together with bacterial metabolites (short-chain fatty acids), more robustly correlate with obesity than fecal microbial community structure, as evidenced by sequencing of 16S rRNA originated from the gut microbiome. LBP, LBP/CD14 ratio, propionic, and butyric acids were independent determinants of BMI. These and other variables explained 39–47% of BMI variability, consistent with the hypothesis that both microbiome-related and independent biomarkers are involved in obesity risk (Barengolts et al. 2019).

Metabolomics

Metabolomic elucidation of the underlying pathways in obesity and obesity-associated comorbidities is currently one of the most actively pursued roads. The metabolome, analogously to several omics techniques, can be constructed through the employment of high-resolution analytical chemistry, for instance, nuclear magnetic resonance (NMR) or liquid chromatography in tandem with mass spectrometry (LC-MS), combined with multivariate biostatistics such as pattern recognition techniques, including principal component analysis (PCA).

Serum metabolomics in obesity usually reveals correlations with blood glucose and cholesterol profile, apart from body weight and dietary regimen, consistent with metabolic pathway changes in lipogenesis, lipid oxidation, energy utilization, protein and amino acid metabolism (Palau-Rodriguez et al. 2020). Given the growing interest in multi-omics data, integrating inputs from metabolomics, genomics, microbiomics, and other fields, automated pipelines/approaches are already emerging. In a large series, the system was able to demonstrate two additional metabolic pathways, namely benzoate degradation and phosphotransferase system, as linked to obesity (Ni et al. 2020). The M2IA platform streamlines the integrative data analysis between metabolome and microbiome, including statistical analysis and biological interpretation (M2ia 2020). Within an experimental setting, machine learning analysis applied to serum metabolomics pointed to deoxyhexose sugars as predictors of gradual loss of β-cells, in prediabetic mice that genetically progress to diabetes. The deoxyhexose 1,5-anhydroglucitol displayed the most substantial changes. Robust markers of β-cell mass in obesity and diabetes are not currently available and would have important clinical applications. Further studies in humans are eagerly anticipated (Li et al. 2019).

Machine Learning Tools: Obesity

Predictive Tools in Obesity

The most diverse and common task found in the applications of machine learning in obesity research is prediction. Gerl et al. (2019) aimed at predicting different measures of obesity, i.e., body mass index (BMI), waist circumference (WC), waist-hip ratio (WHR), and body fat percentage (BFP) based on the plasma lipidome employing several models (Cubist, Lasso, partial least squares, stochastic gradient boosting, and random forest). Lasso was finally employed for the analysis as it exhibited the best performance. Childhood clinical, environmental, and genetic risk factors served as background for early prediction of adulthood obesity. The genetic risk

factors were 97 single-nucleotide polymorphisms (SNPs) associated with BMI in over 100,000 genotyped individuals or a 19 SNPs subset of the initial superset. The analysis was performed using gradient boosting machines which are a representative example of ensemble learning (Seyednasrollah et al. 2017).

In a protocol addressing serum FFA levels, gut microbiota, diet, and obesity through a machine learning model based on a regression tree, a gender-independent non-obese profile was generated, with serum EPA $>$ 0.235 μg/mL and *Bacteroides* $>$ 9.1 log cells per g of feces. Regarding obesity, *Bacteroides* group was much less involved (20% importance). Serum EPA and gender (100% and 80%, respectively), along with palmitic acid, *Bifidobacterium,* and *Faecalibacterium* explained >30% (Fernandez-Navarro et al. 2019). In another related work that utilizes both genetic sequencing and support vector machines (SVM), the model exhibited 70.8% accuracy, 80.1% sensitivity, and 63.0% specificity. The specific work showed that selected SNPs were effective in the detection of obesity risk. Additionally, the ML-based method provides a feasible mean for conducting preliminary analyses of genetic characteristics of obesity (Wang et al. 2018).

Feature Extraction and Closely Related Factor Evaluation

Easily available scanned facial data, submitted to feature extraction, have shown robust correlation with anthropometrically relevant markers of excessive body weight. With a different approach (deep learning/convolutional neural networks), satellite geographical images (Google Static Maps API) were analogously used to trace populations with increased adiposity (Pascali et al. 2016; Maharana and Nsoesie 2018). Demographic, social-economical, and lifestyle variables also conducted, by means of machine-learning tools, to findings concerning regional distribution of elevated body weight populations (Scheinker et al. 2019).

Diet and Food-Driven Applications

Personal diet management, automated monitoring, and analysis of eating behavior patterns can be useful in fighting the obesity epidemic and its comorbidities. The advances in smartphones and wearable sensor technologies, including machine learning systems, can be used for meal microstructure analysis (Papadopoulos et al. 2018), for tracking the user's dietary and physical activities (Silva et al. 2018), to monitor dietary intake using automate image classification (McAllister et al. 2018), or to provide just-in-time adaptive interventions to prevent dietary lapses (Forman et al. 2019).

Country-level food sales information can be obtained from suppliers inexpensively, rapidly, and on a regular basis. Only a small subset of food and beverage categories can be used, utilizing support vector machines, random forests, and extreme gradient boosting to predict country-level obesity prevalence. The top three categories in predicting country-level obesity were baked goods/flours, cheese, and carbonated drinks (Dunstan et al. 2019).

Bariatric Surgery

Algorithms (Sheikhtaheri et al. 2019; Cao et al. 2019) including logistic regression, linear discriminant analysis (LDA), quadratic discriminant analysis (QDA), decision trees, k-nearest neighbor (KNN), SVM, multilayer perceptron (MLP), and deep neural networks can be selected for diagnosis, prognosis, or complication prediction have extensively been used in bariatric cohorts. Ensemble methods should be mentioned as well, namely adaptive boosting (AdaBoost) logistic regression, extra trees, gradient trees, or support vector machine (SVM), bagging LDA, bagging QDA, random forest, extremely randomized (Extra) trees, gradient regression tree, bagging KNN, and bagging MLP. Deep learning showed superior performance in comparison to other machine learning algorithms.

Childhood Obesity

Electronic health records (EHR) are a valid substrate for tracking information for the specific population (obese chirdren) (Lingren et al. 2016; Hammond et al. 2019), as well as neuroimaging features extracted from resting-state functional magnetic resonance imaging (rs-fMRI) datasets (Park et al. 2019). Apparently, nonspecific demographic, psychological, behavioral, and cognitive variables could also allow for excessive weight surveillance (Gray et al. 2019). Social and physical attributes of the school environment similarly impact such disease and could be endowed with predictive value (Hinojosa et al. 2018). The importance of potentially modifiable psychosocial, dietary, and environmental mechanisms and their influence on weight gain in adolescent girls, addressed in a large-scale regression model, is the fact that they are potentially amenable to change, thus pointing towards prophylactic interventions (Narla and Rehkopf 2019).

Abstract

The purpose of the present chapter was to compare performance and accuracy of three different approaches to diabetes mellitus risk prediction. It was shown, in particular, that a multilayer perceptron, logistic regression, and random forest classifier can be successfully employed for prediction of the T2DM risk using the electronic medical record (EMR) system data with a relatively large number of individuals, albeit a limited dimension of predictor parameters space. Further improvement of the models should be addressed through the following avenues: application of machine and deep learning models for analysis of greater set of factors and derived parameters from the EMR system, including biometric, socioeconomic, geographical, ethnical, and genetic parameters.

Keywords

Big data · Machine learning · Risk prediction · Diabetes mellitus

Introduction

To date, a vast number of predictive models of type 2 diabetes mellitus (T2DM) were reported. Most of them use basic logistic regression (LR) as the underlying mathematical method for obtaining the final model, and include several biochemical, anthropometric, and environmental parameters of the individual as predictor variables. During past decades, a number of machine learning methods were implemented in diabetes risk prediction. However, most of the models widely used in clinical practice were developed based on classical LR and employ a limited number of predictor parameters.

A wider spectrum of parameters and further optimizing computational methods are currently needed. Increasing the reliability and reproducibility of medical data employed for model training is another priority. This can be achieved by extensive application of data stored in electronic medical record (EMR) systems, which become increasingly popular both in medical institutions and in general practices. Measurements being uploaded directly from a certain instrument/device to a data cloud are less prone to errors due to human factors, thus making it possible to develop a more accurate and sensitive model for risk predictions.

Diabetes Etiology and Biochemistry

According to the American Diabetes Association, there are four general types of diabetes (Standards of Medical Care in Diabetes 2018):

- Type 1 diabetes (T1DM), that is a manifestation of autoimmune pancreatic β-cell destruction, ultimately leading to complete loss of insulin secretion. A key biochemical feature of T1DM is presence of autoantibodies against pancreatic antigens, such as insulin, glutamic acid decarboxylase (GADA), insulinoma-associated autoantigen 2 (IA2A), and zinc transporter 8 (ZnT8A) (Atkinson et al. 2014).
- Type 2 diabetes, a condition associated with a progressive impairment of β-cell insulin secretion ability and general insulin resistance. Type 2 diabetes dominant biochemical aspects include lipid metabolism dysfunction,

inflammation, oxidative stress, and impaired mitochondrial metabolism (Ma et al. 2011).
- Gestational diabetes mellitus (GDM), a type of diabetes, diagnosed during pregnancy (the second or third trimester). This condition includes undiagnosed preexisting diabetes and so-called true GDM (Mirghani Dirar and Doupis 2017).
- Other types of diabetes that develop as a result of action of various specific causes (monogenic diabetic conditions, malfunction of exocrine pancreas, chemically-induced diabetes) (Schwitzgebel 2014).

All types of diabetes are traditionally diagnosed by fasting plasma glucose (FPG) or the 2-h plasma glucose (2-h PG) combined with oral glucose tolerance test (OGTT), or A1C glycated hemoglobin levels. If necessary to specify the diagnosis, additional tests (for example, genetic testing) may be performed.

Biomarkers of Diabetes

Despite the fact that T2DM risk factors are well-established, risk assessment and stratification are still a challenge. Traditional methods fail to identify individuals that display low risk according to conventional scales, but nevertheless are prone to development of T2DM. Use of novel biomarkers (genomic, genetic, epigenetic, metabolomic) and computational methods is a promising direction of future research. Currently used clinical biomarkers include:

- anthropometric measurements (weight, BMI, waist circumference, waist-to-hip ratio),
- biochemical, metabolic, and clinical markers (triglycerides, total cholesterol, HDL (high-density lipoprotein) cholesterol, LDL (low-density lipoprotein) cholesterol, use of lipid-lowering drugs, fasting glucose, 2-h glucose, fasting insulin, estimates of insulin resistance, estimates of β-cell function, HbA1c, liver enzymes, uric acid, leukocyte count, C-reactive protein, adiponectin, systolic blood pressure, diastolic blood pressure, use of antihypertensive drugs.
- lifestyle variables: physical inactivity, dietary components (red meat, fats, fruits, vegetables, fiber, coffee), smoking, alcohol consumption.
- socioeconomic factors (Herder et al. 2011).

Genetics of Diabetes

Both type 1 and type 2 diabetes are polygenic disorders. At least 40 genetic loci are described as responsible for T1DM development (Atkinson et al. 2014), and the contribution of genetic component to T2DM pathogenesis is estimated to be 40–80% (Dorajoo et al. 2015; Florez 2016; Talmud et al. 2010). Genetic mechanisms of T2DM pathogenesis include differentially expressed genes, genetic variants (SNPs or single-nucleotide polymorphisms), and the combined effect of SNPs and differentially expressed genes (Das and Rao 2007). The knowledge of SNPs in T2DM has been expanded by genome-wide association studies (GWAS) (Mahajan et al. 2014).

Epigenetic Biomarkers of Diabetes

All known epigenetic hallmarks, such as chromatin modification, DNA methylation, and non-coding RNA involvement (Allis and Jenuwein 2016), are shown to have an effect on T2DM development. It has been shown that chromatin activity can be modulated by certain metabolic signals in diabetes, determining the reaction of genome to stimuli (Rosen et al. 2018). Expression of genes involved in glucose metabolism pathways is greatly influenced by their methylation state that affects overall pancreatic activity; moreover, epigenetic patterns may influence the inheritance of T2DM (Rosen et al. 2018; Sommese et al. 2017; Jerram et al. 2017). MicroRNAs, small non-coding RNAs that regulate gene expression, are essential players in diabetes pathogenesis. Of all several thousands

known human microRNAs (miRs), some were shown to be critical for maintaining pancreatic β-cell function, proliferation, and survival (Backe et al. 2014; Filios and Shalev 2015; Avnit-Sagi et al. 2012). Due to relatively simple mechanism of action (complementary inhibition of target mRNA), they possess qualities of a promising biomarker. For example, by manipulating expression of certain miRs, it has been shown possible to enhance insulin secretion in response to glucose (Soni et al. 2014).

Statistical Methods (Logistic Regression)

Logistic regression (Bagley et al. 2001) is a statistical method for predicting binary outcome (dependent or response variable), based on independent variables (predictors). Logistic regression is applicable in cases when dependent variable has only two possible values. The goal of regression analysis is to describe the relationship between a set of parameters and an outcome, and to assess the fitness of the resulting model. This approach assumes that all predictors are independent from each other, and that the outcome is a linear combination of all predictors taken with some coefficient. The latter is called regression coefficient or weight of the variable. One can describe logistic regression by the following equation

$$Logit(p) = \propto + \sum_{i=1} \beta_i x_i$$

where α is the intercept of the logistic regression model, x_i is the predictor variable, and β_i is the regression coefficient for each predictor variable.

Regression coefficients are usually initialized with zero values and then are repeatedly optimized using cost function. Several methods of optimization of variable weight using different cost functions were described. Log-loss (or cross-entropy), Huber, and Kullback-Leibler loss functions along with the gradient descent are commonly used for weights optimization.

In order to obtain predictions, which are probabilities that the entity described by the given set of variable values belongs to one of two classes, one should use sigmoid function that maps output of the logistic regression to the probability. Sigmoid function is described by the following equation:

$$S(p) = \frac{1}{1 + e^{-p}}$$

where p is the output of logistic regression, e.g., $\propto + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3$, $S(p)$ is the probability estimate, and e is the base of natural logarithm.

The process of classification itself relies on the use of a threshold parameter. The latter allows identifying a class to which a given object is supposed to belong. This parameter is 0.5 by default, which means that if S(p) is equal or greater than 0.5, the object belongs to one class, and to another if otherwise. However, this parameter for the particular model could be adjusted in order to obtain a desired specificity and sensitivity. This can be done by employing a calibration plot, which allows visualizing dependency between specificity, sensitivity, and a threshold value. Adjusting threshold is important for development of predictive models in a healthcare sector because, depending on the application, one would like to maximize sensitivity by sacrificing specificity and vice versa.

Performance of the model is usually reported in literature using C-statistic and area under receiver operational curve (AUC). The C-statistic provides a general idea of the model, while AUC combines information about specificity and sensitivity of the model.

Logistic regression has been widely used in medical studies for developing risk models of important groups of conditions. Abassi et al. showed that logistic regression is one of the most frequently used techniques for assessing risk of diabetes mellitus (Abbasi et al. 2016). However, choice of computational method and the set of predictors may dictate different approaches, which can perform better.

More than 170 diabetes mellitus risk models have been developed and published from 1993 to

2019. Most of the papers describing these models report performance in terms of C-statistic or D-statistic, as well AUC, with the latter being in the range from 0.61 to 0.91. Most of them are based on logistic regression and use both invasive and noninvasive biomarkers along with reports of questionnaires as independent variables. One of the most comprehensive meta-reviews of diabetes mellitus risk prediction models was performed by Lucaroni et al. (Lucaroni et al. 2019). It is worth noting that age and fasting glucose levels are the main predictors in most regression-based models, displaying the best comparable performance (measured by AUC or C-statistic).

Machine Learning

Artificial neural networks (ANN) (Haykin 1999) are mathematical models inspired by organization of neurons in brain. ANNs form layers and nodes. These nodes take some value as an input, pass it through a hidden activation function provided with weighted links, and use its result as an output.

Weights of the connections are generally calibrated to the input patterns, and ANNs learn with growing experience. Among multiple designs of ANNs, we adopted a multilayer perceptron-based ANN (MLP-ANN) (Ncibi et al. 2017). Within this system, there are only connections between adjacent layers (Heidari et al. 2016). Single-layer MLP-ANN consists of one layer of adaptive weights, with full connectivity between inputs and hidden units, and between hidden units and output.

Let $feature_i$ be the variables given to ANN. The first layer forms M linear combinations, which result in the activation a_j

$$a_j = \sum_{i=1} w_{ji} feature_i + w_{j0}$$

where $j = 1, \ldots, M$. w_{ji} represents the first layer weight matrix, and w_{j0} is the bias figures of the hidden units j. The variables a_j are converted by the activation. Employing ReLU activation function, the outputs correspond to $z_j = \max(0, a_j)$ where $j = 1, \ldots, M$.

The model described above is relevant for the hidden and the output layers. Each unit in one layer connects with a certain weight matrix, to every unit in the following layer. There is one output in the last layer of ANN. After passing through the activation function, it returns the final value to be between 0 and 1. In medical applications, this is the disease risk value. Similar to logistic regression, output of the ANN is the probability that an entity described by a set of variable values, belongs to one of two classes (e.g., "high risk"-"low risk"). Therefore, similar adjustment of a threshold can be performed, in order to achieve a desired balance of sensitivity and specificity.

Deep Learning

A class of deep learning methods can also be used for diagnosis and treatment. To date, several deep learning strategies were implemented for type 2 diabetes mellitus (T2DM) (Talaei-Khoei and Wilson 2018; Miotto et al. 2016; Bernardini et al. 2019; Nguyen et al. 2019; Spänig et al. 2019), with limited success. Methods such as Adaboost, decision trees, and bagging were employed for T2DM risk prediction, as reported by Perveen et al. (2016).

Various deep learning approaches were employed for detection, prediction, and classification of diabetic retinopathy (DR), mainly via analyzing retinal images (Ting et al. 2017; Gargeya and Leng 2017; Abràmoff et al. 2016). The utility of deep learning in screening and classification of diabetic retinopathy is reviewed by Grzybowski et al. (2019; Cheung et al. 2010). However, to our best knowledge, currently there are no published studies describing use of machine learning approaches for prediction of DR based on noninvasive or biochemical biomarkers, or on data extracted from EMR.

Deep learning-based natural language processing system HYPE was developed for prediction of hypoglycemic events, in patients treated for diabetes (Jin et al. 2019). This system uses unstructured data stored in electronic medical records. Several studies describe use of convolutional neural networks, support vector machines for forecasting blood glucose levels in diabetics for short-term (30–60 min) (Li et al. 2019a; Li et al. 2019b) and mid-term (up to one day) periods (Faruqui et al. 2019). Current advances are reviewed by Woldaregay et al. (2019)

Personal Experience

Study participants were recruited among patients of MedExpert medical center (Voronezh, Russian Federation), examined within a 7-year period from 2010 to 2017. Informed consent was obtained from all the participants, and the research was approved by Voronezh State University Ethics Committee. All measurement results, biometric data, and diagnoses were extracted from the Numedy medical information system database, which is used in MedExpert medical centers.

Biomarkers and Their Derivatives

We computed the rate of change over time (if applicable) for all biomarkers controlled in this study. Thus, time-dependent change in biomarker values, expressed in days, went through a simple linear regression (i.e., $f(x) = kx + b$), with a slope coefficient being representative of this biomarker rate of change, to be used in a subsequent analysis.

Dataset Preparation and Experimental Design

The aim of the present study was to compare performance and accuracy of three different approaches to diabetes risk prediction. In order to do this, we compared artificial neural network, namely multilayer perceptron (MLP), logistic regression (LR), and random forest (RF) (Breiman 2001) classifiers. Same training and testing subsets of the dataset were used for all three algorithms. The data were shuffled and randomly assigned into two subgroups based on the selected size of training subset (SEP parameter).

In order to ensure best performance of the classifiers, data were preprocessed in the following manner: the missing values were replaced with the median value of the variable across the subset, and all variables were subsequently normalized using the formula

$$z = \frac{x - u}{s}$$

where z is the normalized value, x is the current value, u is the mean value of the variable, and s is its standard deviation.

Computational Methods and Software

All experiments regarding machine learning were performed using Python platform v. 3.7.4. We used scikit-learn v.0.21.3 library in Python, for training logistic regression, MLP, and RF models. The matplotlib library for Python was employed to visualize results of the model performance. Calibration plots were created using Orange open-source software v. 3.24.

Logistic regression with iteratively reweighted least-squares optimization and 100 decision trees in the random forest classifier were employed.

Hyperparameters of multilayer perceptron were chosen automatically. All combinations of hyperparameters from predefined set of possible options were tested, and trained neural networks were compared in terms of their classification accuracy. It was shown that MLP provides an optimal performance with the following parameters: ReLU activation function $f(x) = \max(0,x)$ (Hahnioser et al. 2000), L-BFGS optimization (Nocedal and Wright 1999), and 1 hidden layer with 8 neurons in it. Training process was limited to 400 iterations.

Measurements of classification accuracy, mean absolute error (MAE), area under receiver operation curve (ROC), sensitivity, and specificity of all classifiers were used to estimate and compare their relative performance. As long as the process of the dataset division into training and testing subsets is random, the resulting parameters of classifiers slightly change in different experiments. Therefore, it was decided to consider performance metrics of classifiers as random and report the averaged values as a final result of analysis.

Let X_{ac}, X_{auc}, X_{mae}, X_{sen}, and X_{spec} be random values of accuracy, AUC, MAE, sensitivity, and specificity, respectively, for a given random training subset. Then, $\overline{X_{ac}}$, $\overline{X_{auc}}$, $\overline{X_{mae}}$, $\overline{X_{sen}}$, and $\overline{X_{spec}}$ are sample means for these values, and $S_{X_{ac}}$, $S_{X_{auc}}$, $S_{X_{mae}}$, $S_{X_{sen}}$, and $S_{X_{spec}}$ are sample standard deviations. In order to obtain means and standard deviations for classifiers parameters, we repeated the process of dataset subdivision and model training for 100 times.

Desired specificity and sensitivity of the models were obtained in the following manner: calibration curves were calculated, and the threshold of classification was adjusted for the highest possible sensitivity with reasonable decrease in specificity.

Study Participants and Experimental Groups

Participants for the further analysis were chosen based on the following criteria:

1. Fasting glucose should be measured at least twice during the period of examination.
2. At least 3 of 4 biomarkers controlled in this study, namely bilirubin, total cholesterol, alanine transaminase (ALT), and aspartate transaminase (AST), should be measured at least once.
3. Selected individual should have follow-up, namely two or more appointments during past 6 years.

After filtering out all individuals who did not meet these criteria, we included 2963 patients in our dataset for further analysis. 885 of them were diagnosed with type 2 diabetes mellitus.

We did not use anthropometric and clinical parameters such as BMI, waist circumference, and blood pressure, as these are measured manually and therefore might be unreliable.

Training and Testing Subset Size Selection

First, we determined the optimal size of training subset of our dataset. It had to be done in this particular case because of a relatively small size of the dataset, in order to achieve the best performance of models. These results are shown in Table 66.1.

It was determined that with this particular dataset, the best performance for all three classifiers was achieved with SEP parameter equal to 0.9.

Classification Performance and Model Comparison

Performance parameters of all three models are summarized in Fig. 66.1. One could observe that both random forest and MLP classifiers demonstrate better results compared to logistic regression. With the default value of classification threshold $p = 0.5$, classification accuracy of these models is in average 4% higher compared to LR, while sensitivity is almost 20% higher. However, specificity of both MLP and random forest was 3% lower than that of LR. Mean values of performance metrics of all three models are shown in Table 66.2 and in Fig. 66.2.

Overall, ANN displays better AUC (0.812 vs 0.76 and 0.802) and accuracy (0.764 vs 0.716 and 0.761) compared to other models.

Table 66.1 Performance of classifiers with different training subset size

	Artificial neural network			Logistic Regression			Random Forest		
Parameter	SEP = 0.75	SEP = 0.8	SEP = 0.9	SEP = 0.75	SEP = 0.8	SEP = 0.9	SEP = 0.75	SEP = 0.8	SEP = 0.9
MAE	0.31	0.32	0.30	0.36	0.36	0.36	0.32	0.32	0.31
AUC	0.81	0.80	0.81	0.76	0.76	0.73	0.80	0.79	0.81
Accuracy	0.77	0.78	0.77	0.71	0.73	0.72	0.77	0.76	0.78
Sensitivity	0.50	0.40	0.51	0.30	0.35	0.37	0.49	0.51	0.54
Specificity	0.88	0.93	0.87	0.90	0.90	0.86	0.89	0.86	0.88

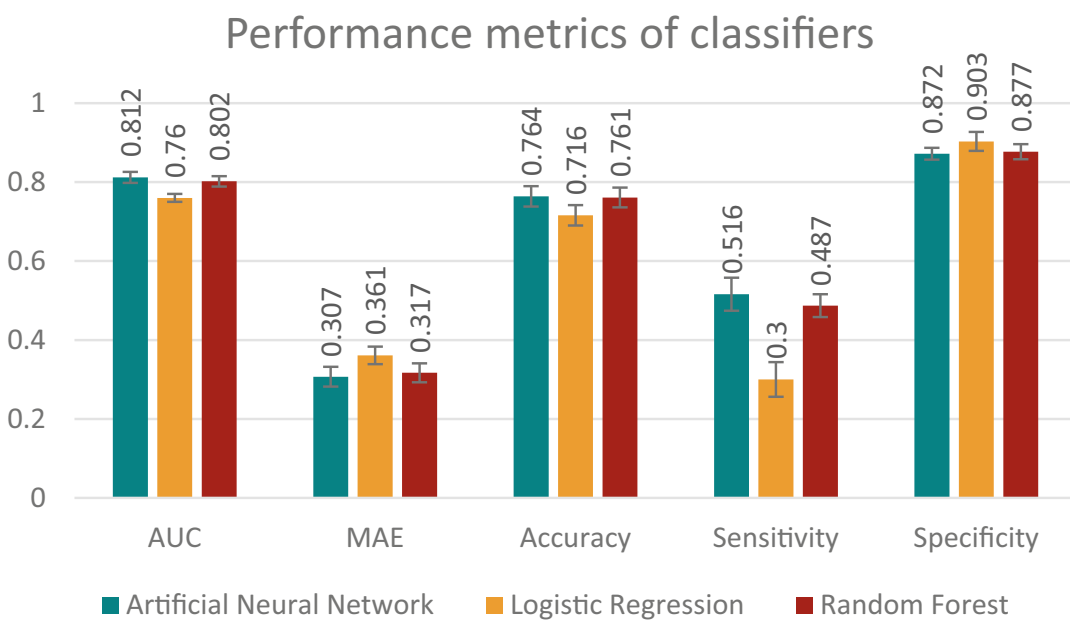

Fig. 66.1 Performance metrics of ANN, logistic regression, and random forest models. A—accuracy distributions, B—AUC distributions; C—sensitivity distributions; D—specificity distributions

Calibration Plots and Cut-Off Threshold Selection

In order to obtain the final model with the desired specificity and sensitivity, a calibration plot was built (see Fig. 66.3). As long as the main goal of the model is the prediction of the T2DM risk, it should detect as many cases of individuals at high risk of the disease as possible, therefore making sensitivity the highest priority.

Optimal probability threshold for clinical applications was found to be close to the value of 0.2, which allows one to achieve high sensitivity with reasonable decrease in specificity for all three models (see Table 66.3).

Probability of T2DM Development

In most regression-based models, age of a patient makes the greatest contribution to the probability of developing the disease. Figure 66.4 shows dependence of the probability to develop diabetes on the age of an individual. According to the published data and results observed in Fig. 66.4, males are more likely to develop T2DM compared to females, especially in the range from 25 to 50 years (Kautzky-Willer et al. 2016).

Comments

A large number of tools for assessing the risk of diabetes have already been developed. Some of them are designed as risk calculators that predict a risk of diabetes for various time periods. Most risk models rely on combination of both invasive biomarkers (levels of various metabolites in blood) and noninvasive anthropometric variables, such as height, weight, and wrist circumference, as well as personal data on the patient's lifestyle obtained via the questionnaire.

One can easily observe that in the vast majority of cases, the best predictors are age, body mass index, blood glucose and glycated hemoglobin levels. As a result of applying various methods of data analysis (often representing a classic logistic regression), models from reasonable to

Table 66.2 Performance metrics of classifiers

Parameter (mean ± SD)	Artificial neural network	Logistic regression	Random forest
AUC	0.812 ± 0.014	0.760 ± 0.010	0.802 ± 0.013
MAE	0.307 ± 0.025	0.361 ± 0.022	0.317 ± 0.024
Accuracy	0.764 ± 0.026	0.716 ± 0.026	0.761 ± 0.025
Sensitivity	0.516 ± 0.042	0.300 ± 0.044	0.487 ± 0.029
Specificity	0.872 ± 0.015	0.903 ± 0.024	0.877 ± 0.019

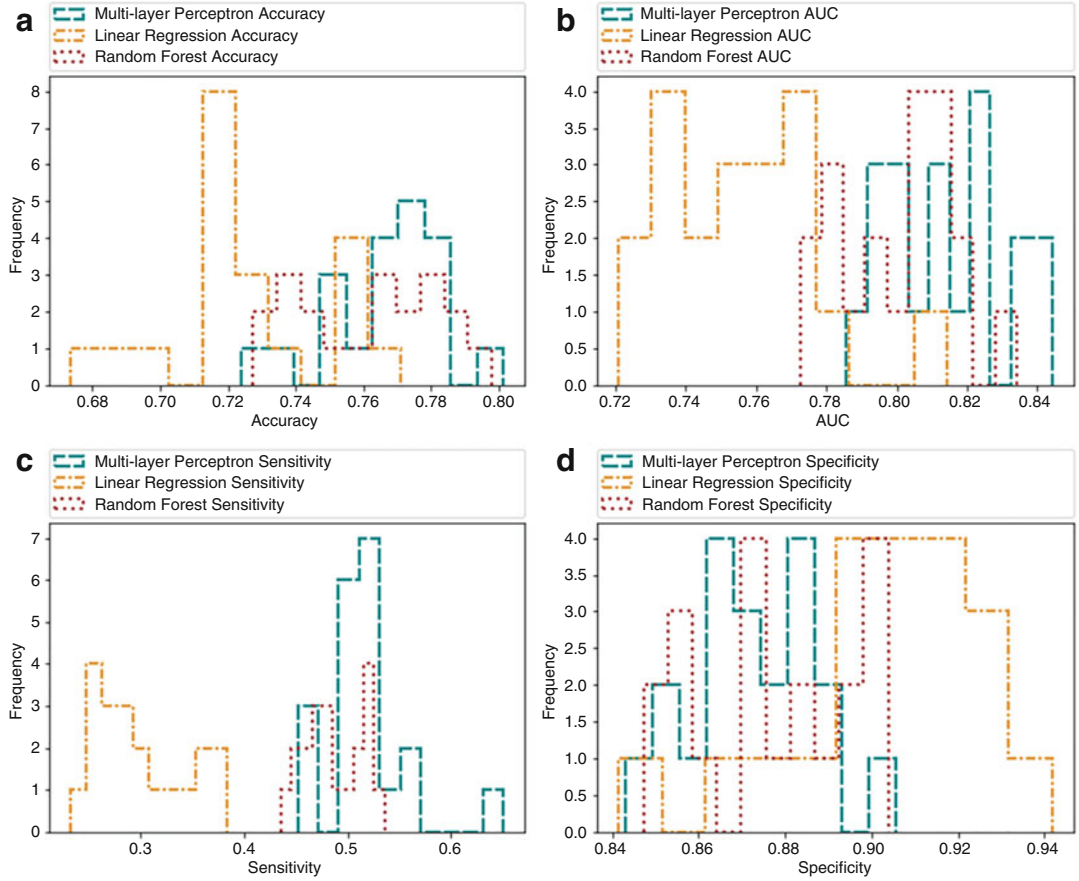

Fig. 66.2 Performance metrics of classifiers. Error bars indicate standard deviations

high values of accuracy, specificity, and sensitivity, with AUC of 0.8 and more were proposed.

Despite the fact that these results indicate a good predictive power of the model, from the point of view of statistics, in most cases, this approach is not entirely correct, since the diagnosis is made by the physician on the basis of the same biomarkers that are predictor variables in the model. In other words, a model uses these biomarkers to predict a response variable with a value, which had already been selected based on these predictors. This approach is similar to predicting a variable by the variable itself and therefore should be avoided if possible.

One way to resolve this problem is to search for new biomarkers, for example, using high-throughput platforms for analyzing "omics" data, or by using data mining in databases, which store EMRs. Several studies have shown the utility of deep learning for risk prediction of

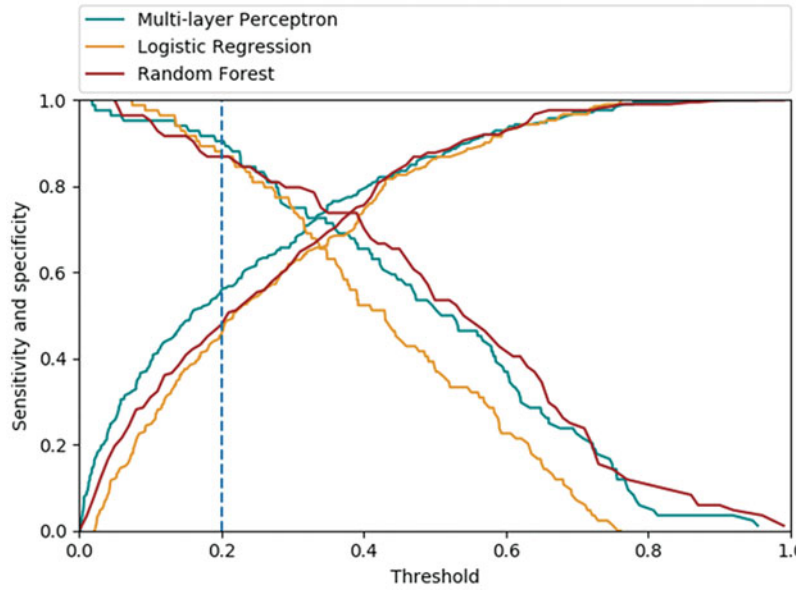

Fig. 66.3 Calibration plot for three models with sensitivity corresponding to curves falling from left to right, and specificity—to the rising curves

Table 66.3 Sensitivity/specificity of the models after threshold adjustment

Model	Sensitivity	Specificity
Logistic Regression	0.898	0.476
Artificial Neural Network	0.884	0.570
Random Forest	0.861	0.560

diabetes mellitus, based on both supervised and unsupervised processing of electronic medical records (Miotto et al. 2016; Bernardini et al. 2019; Nguyen et al. 2019; Spänig et al. 2019).

Another promising approach is to derive new types of biomarkers based on existing ones, for example, by calculating dynamic biomarkers, such as the rate of change of the biomarker over time. It was shown earlier that biomarker dynamics can significantly increase performance of a risk prediction model in terms of T2DM (Solodskikh et al. 2019), thus making them a promising tool in clinical practice.

One of the major drawbacks of existing approaches to diabetes risk assessment is the fact that the vast majority of measurements, which are stored in the electronic databases (employed for model training), are entered there manually. This makes such data less reliable compared to the data collected directly via program interfaces connected to a measurement instrument/device.

Conclusions

Introduction of EMR and EMR storage systems, e.g., Egton Medical Information Systems (EMIS Web) in the United Kingdom, or Veterans Health Information Systems and Technology Architecture (VistA), developed and implemented in Department of Veterans Affairs in the United States, resulted in accumulation of medical databases, which are accessible for both physicians and patients. More than 80 percent of hospitals in the U.S. claim that they have adopted some type of EMR management system. However, even within a hospital, the type of EMR data varies significantly. Types of EMR data used in hospitals include structured data (e.g., medication

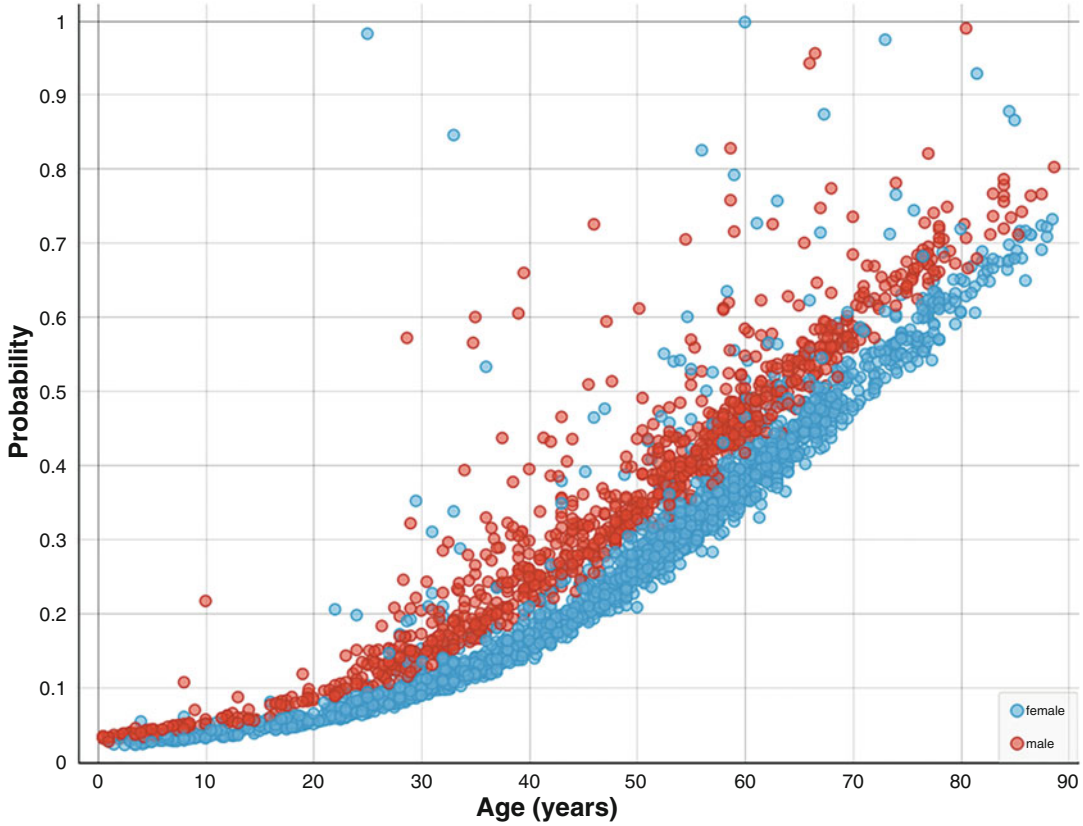

Fig. 66.4 Dependence of T2DM probability development on age, gender

information or results of measurements performed by various devices) and unstructured data (e.g., clinical notes).

Data stored in these databases can be potentially analyzed in order to obtain useful insights about certain relationships between measurement results and health conditions, drug intervention results and overall treatment outcomes, and prognosis. These analytical procedures can be performed in a background manner, using various unsupervised machine learning approaches.

Abstract

Polycystic ovary syndrome (PCOS) is a common endocrine disorder in women of reproductive age and is characterized by a combination of hyperandrogenism, ovulation dysfunction, and/or polycystic ovarian morphology. Low muscle mass relative to fat mass, described as "sarcopenic obesity," is a condition which leads to metabolic disorders to a greater degree than either sarcopenia or obesity alone. About 58% of women with PCOS have sarcopenic obesity; this may contribute the high degree of metabolic disorders (i.e., hyperglycemia, hyperinsulinemia, dyslipidemia). Diets designed to improve risk factors for cardio-metabolic disease (DASH, Mediterranean, Portfolio, low-glycemic index, low-carbohydrate diets), as well as supplements (vitamin D, omega-3 fatty acids, antioxidants, carnitine) have potential to be effective for women with PCOS. Low-moderate intensity aerobic training or high-intensity interval training combined with resistance training improves metabolic aberrations as well. Women with PCOS should be offered a wide variety of effective interventions to choose from since adherence to any one intervention tends to be low.

Muscle · Fat · Lipids · Glucose · Insulin · Androgens · Testosterone

General Features of Polycystic Ovary Syndrome

Approximately 18% of women worldwide suffer from polycystic ovary syndrome (PCOS), (Carmina and Lobo 1999); however, estimates vary with the definition and proper diagnosis of PCOS. Hyperandrogenism, ovulation dysfunction, and/or aberrant polycystic ovarian morphology are the cardinal features (Teede et al. 2018). Hyperandrogenism appears as hirsutism (unwanted or excessive hair growth) accompanied by elevation in total, free, and bioavailable testosterone, or free androgens (i.e., free androgen index) (Teede et al. 2018). Hirsutism is usually determined by the modified Ferriman-Gallwey Index. A score of $\geq$4–6 is considered diagnostic (Teede et al. 2018). The ovulation/ovulatory dysfunctions typically feature oligomenorrhea, whereas $\geq$20 follicles per ovary or mean ovarian volume $\geq$10 mL in the absence of corpora lutea, cysts, or dominant follicles characterize the polycystic ovaries (Teede et al. 2018).

8–46% in women with PCOS are affected by metabolic syndrome (Kazemi et al. 2019a). In our experience, compared to age-matched controls, patients had the greatest elevation of triglycerides (by 63%), followed by waist circumference (21%), reduced high-density lipoproteins (19%), elevated systolic blood pressure (5%) and glucose (4%) (Kazemi et al. 2019a). Other risk factors for diabetes or cardiovascular disease were also elevated. Elevated low-density lipoproteins (by 16%), total cholesterol to high-density lipoprotein ratio (by 31%), fasting insulin (by 122%), 2-hour oral glucose tolerance test glucose level (29%), and homeostatic model of insulin resistance (HOMA-IR) (elevated by 200%) were also documented, along with increased high-sensitivity C-reactive protein (by 413%), total testosterone (by 25%), whereas sex-hormone-binding globulin (SHBG) was reduced by 37% (Kazemi et al. 2019a). Pro-inflammatory status and hyperandrogenism in women with PCOS

promote atherosclerosis and endothelial dysfunction (Chiu et al. 2017).

Sarcopenic Obesity

Sarcopenic obesity signals low muscle mass (sarcopenia) combined with high-fat mass (obesity). Besides expected dyslipidemia, insulin resistance, diabetes, osteoarthritis, and depression, also mortality, reduced physical function, falls, and quality of life can be further impaired (Koliaki et al. 2019).

Defining features are low appendicular muscle mass relative to total body weight, two standard deviations below the age- and sex-matched mean of the population (McBreairty et al. 2019). In our experience, 53% of the women with PCOS had sarcopenic obesity (McBreairty et al. 2019). The percent appendicular skeletal muscle mass was negatively correlated with C-reactive protein ($r = -0.61$) and positively correlated to serum vitamin D ($r = 0.40$), suggesting that inflammation and low vitamin D could be relevant. Negative correlation with HOMA-IR ($r = -0.41$) and glycosylated hemoglobin ($r = -0.43$) further pointed toward the adverse effects of insulin resistance and poor glucoregulatory status. In a larger study, our observed incidence of sarcopenic obesity was slightly higher (i.e., 46/80 women or 58%) (Kazemi et al. 2019b), and appendicular skeletal muscle mass was positively associated with protein, monounsaturated fat, and omega-3 polyunsaturated fat intake, with potential implications for unique dietary recommendations in this setting.

Mechanisms for Sarcopenic Obesity

Women with PCOS have increased visceral adiposity (Kazemi et al. 2019b), a source of "adipokines" (i.e., leptin, adiponectin) and cytokines (Chilibeck et al. 2014). Elevated cytokines such as interleukin-6 (IL-6) and tumor necrosis factor-alpha (TNF-alpha) and leptin, along with reduced adiponectin (which tends to be anti-inflammatory) impact on muscle tissue. For example, leptin, IL-6, and TNF-alpha decrease the anabolic activity of insulin-like growth factor-1 (IGF-1), which is important for muscle growth and development (Koliaki et al. 2019). Inflammatory cytokines can directly increase protein degradation, leading to the loss of muscle mass (Reid and Li 2001). They also increase insulin resistance at muscle (Chilibeck et al. 2014), an anabolic and anti-catabolic hormone (Lee et al. 2015). Adiponectin improves insulin sensitivity (Chilibeck et al. 2014) potentially magnifying the negative muscular consequences. In women with PCOS, blood adiponectin levels are reduced by 40%, and this coincides with a 25% reduction in whole-body insulin sensitivity (Hansen et al. 2019).

Lipid Metabolism

Increased intra-muscular lipids are typical of obesity, associated with derivatives such as diacylglycerols and ceramides, which are considered to possess "lipotoxicity," increasing inflammation, and inducing insulin resistance (Hansen et al. 2019). Ceramides may cause mitochondrial dysfunction, leading to defects in the electron transport chain and increased oxidative stress. The oxidative stress leads to the degradation of muscular proteins (Kohara 2014). An increase in diacylglycerols and ceramides is associated with increased levels of myostatin (Consitt and Clark 2018) which diminishes satellite cell numbers and activation (Thornell 2011).

Satellite cells are stem cells associated with muscle that is important for repair of muscle damage and are incorporated into muscle fibers as new myonuclei when activated, leading to enhanced capacity for protein synthesis. Muscle tissue assessed from women with PCOS indicates an elevation of intramuscular triglycerides, diacylglycerol, and ceramide by 40%, 50%, and 300%, respectively. In addition, the regulation of pyruvate dehydrogenase, an enzyme important in mitochondrial metabolism of carbohydrates, was negatively affected, implying mitochondrial dysfunction (Hansen et al. 2019).

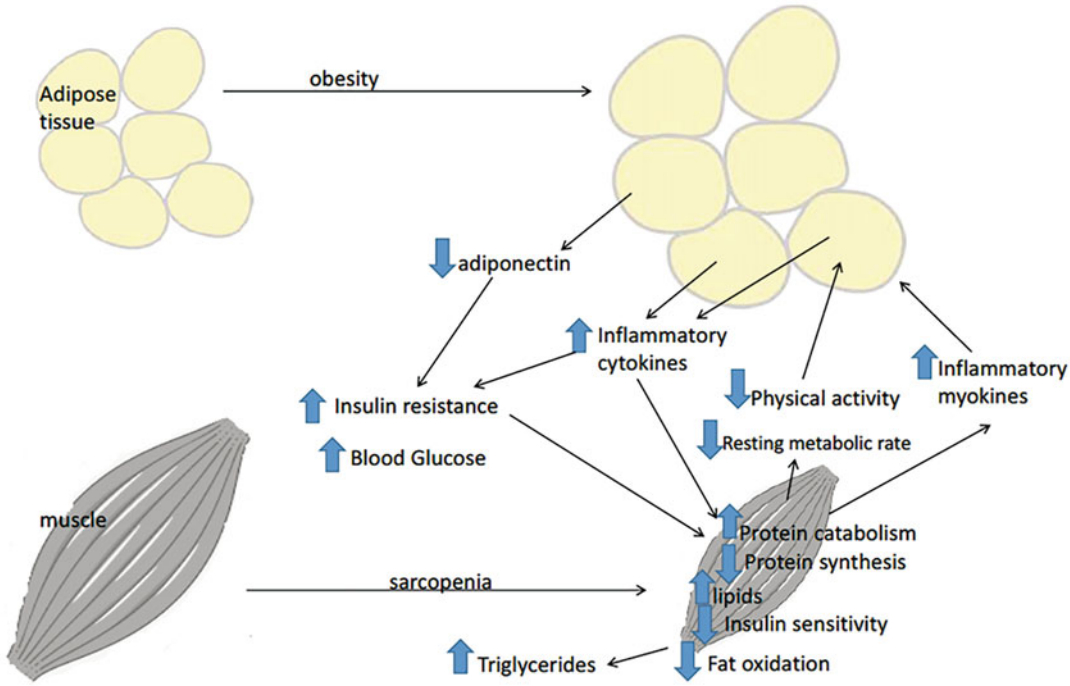

Fig. 67.1 Mechanisms and metabolic consequences of sarcopenic obesity

Myokines

The increased inflammation may result in the release of pro-inflammatory "myokines" from the muscle itself (Koliaki et al. 2019). These myokines may then circulate to adipose tissue, causing further inflammation in adipocytes, leading to a vicious cycle (Fig. 67.1).

Dietary Interventions: Vitamin D

In a previous review (Candow et al. 2012), we highlighted the anti-sarcopenic interest of vitamin D and omega-3 fatty acids, both of which reduce inflammation. In older adults, low vitamin D levels are associated with lower muscle mass, impaired strength, and reduced functional abilities (Visser et al. 2003; Snijder et al. 2006). There are receptors for vitamin D on muscle (Bischoff-Ferrari et al. 2004). Vitamin D has anti-inflammatory properties and decreases C-reactive protein, and several inflammatory cytokines (Schleithoff et al. 2006). In our previously alluded to study, vitamin D deficiency was frequent (41% in PCOS) and correlated with several indexes of obesity (McBreairty et al. 2019).

High-dose vitamin D supplementation (4000–8500 IU per day for 2–3 months) was followed by decreased testosterone levels, free androgen index, and androstenedione, and increased SHBG in women with PCOS, most of who presented with vitamin D deficiency (Jamilian et al. 2017a; Pal et al. 2012); increased menstrual cyclicity (Jafari-Sfidvajani et al. 2018) and reduced hirsutism scores (Jamilian et al. 2017a) were also observed. Improvements in metabolic profiles included increased antioxidant capacity and adiponectin levels, and reduced inflammation (i.e., C-reactive protein), fasting insulin, fasting glucose, HOMA-IR, glucose response to an oral glucose tolerance test, triglycerides, very low-density lipoproteins, low-density lipoproteins, total cholesterol, blood pressure, and alanine aminotransferase levels (Asemi et al. 2015; Dastorani et al. 2018; Jamilian et al. 2017a; Javed et al. 2019; Pal et al. 2012;

Seyyed Abootorabi et al. 2018; Trummer et al. 2019).

The latter improved liver enzyme could indicate reduced liver damage and possibly the alleviation of nonalcoholic fatty liver disease, which is common with obesity and in conditions such as PCOS (Javed et al. 2019).

We recommend that women with PCOS who have deficient vitamin D levels should be considered for high-dose vitamin D supplementation (i.e., 4000 to 8500 IU per day). Meta-analyses show that even with doses less than 4000 IU per day, it reduces inflammation, oxidative stress (Akbari et al. 2018), HOMA-IR (Łagowska et al. 2018), harmful lipids, testosterone levels, and hirsutism and improves menstrual regularity and follicular maturation (Shojaeian et al. 2019).

Omega-3 Fatty Acids

Omega-3 fatty acids (mostly from fish oils) compete with some of the same enzymes that are involved in the metabolism of omega-6 fatty acids, to produce eicosanoids which are less inflammatory (Calder and Grimble 2002). The end effect is that improving omega-3 to omega-6 ratio in the diet is likely to reduce inflammation. Omega-3 fatty acid intake is associated with enhanced strength and functional ability in older adults (Rodacki et al. 2012) and, therefore, has been promoted for preventing sarcopenia (Candow et al. 2012). Supplementation with 1.2 to 2.4 g/d omega-3 fatty acids derived from fish oil for 6–12 weeks in women with PCOS decreased free testosterone, luteinizing hormone to follicle-stimulating hormone ratio, hirsutism score, oxidative stress, C-reactive protein, fasting glucose, fasting insulin, and HOMA-IR, and increased adiponectin levels (Amini et al. 2018; Nadjarzadeh et al. 2015; Phelan et al. 2011; Rafraf et al. 2012). A longer supplementation intervention (i.e., 2 g/d for 6 months) was effective for reducing waist circumference, low-density lipoproteins, total cholesterol, and triglycerides, and increasing high-density lipoproteins and menstrual regularity (Khani et al. 2017).

Higher-dose supplementation (i.e., 4 g/d for 8 weeks) reduced liver fat, triglycerides, and systolic and diastolic blood pressure (Cussons et al. 2009). A less bioactive form of omega-3 fatty acid from flaxseed is also effective: Supplementation with 2 g/d for 12 weeks reduced fasting insulin, HOMA-IR, triglycerides, very low-density lipoprotein, and C-reactive protein, and increased peroxisome proliferator-activated receptor-gamma (PPAR-gamma) gene expression (i.e., mRNA) from blood mononuclear cells in women with PCOS (Mirmasoumi et al. 2018; Nasri et al. 2017). Peroxisome proliferator-activated receptor-gamma activation is important for improving glucose metabolism and reducing muscle insulin resistance (Janani and Ranjitha Kumari 2015). The most recent meta-analysis indicated that omega-3 supplementation in women with PCOS reduces HOMA-IR and harmful lipids and increases adiponectin levels (Yang et al. 2018). The only meta-analysis to assess hormone levels indicated a small effect for reducing testosterone levels, and that only longer-term studies (i.e., longer than 6 weeks) were effective for reducing DHEAS levels (Hajishafiee et al. 2016).

Antioxidant Supplementation

Sarcopenia may be linked to defects in the electron transport chain of mitochondria, which produces free radicals and oxidative damage to tissues (Johnston et al. 2008). Supplementation with antioxidants could alleviate inflammation associated with oxidative damage and its metabolic consequences. In a rodent model of PCOS, co-enzyme Q-10 supplementation reversed impaired mitochondrial function, reduced insulin resistance, decreased proteins related to apoptosis, and increased those with anti-apoptosis properties (Ding et al. 2019). In a clinical randomized series (Izadi et al. 2019), the combination of Coenzyme Q-10 and vitamin E reduced visceral adiposity, total cholesterol, low-density lipoproteins, and diastolic blood pressure, and increased high-density lipoproteins and SHBG. Fasting glucose and HOMA-IR were ameliorated

in patients managed with Coenzyme Q-10, whereas triglycerides diminished in all treatment groups.

Increased gene expression of PPAR-gamma, ovulation frequency, and pregnancy, along with attenuated gene expression for inflammatory cytokines, was documented in Coenzyme Q-10-treated cases (El Refaeey et al. 2014; Rahmani et al. 2018).

Selenium Supplementation

Selenium given in small amounts (200 μg/d for eight weeks) decreased dehydroepiandrosterone, and high-sensitivity C-reactive protein, and was beneficial for hirsutism, acne, and fertility rate (19% pregnancy vs. 3% in controls) (Razavi et al. 2016).

Chromium Picolinate

Chromium has long been associated with benefits in diabetes, and supplements in the form of chromium picolinate. Nevertheless, meta-analyses failed to confirm significant impact on insulin and other metabolic variables. Paradoxically, total and free testosterone became more elevated (Heshmati et al. 2018; Tang et al. 2018). Within such circumstances, there is doubt whether it could be recommended for PCOS.

Carnitine

Carnitine is an amino acid derivative that helps to shuttle fatty acids across the mitochondrial membrane so they can be oxidized. Supplementation of 200 mg/d carnitine for 12 weeks in women with PCOS was effective for reducing body weight, waist circumference, fasting glucose, fasting insulin, HOMA-IR, DHEAS, oxidative stress, and carotid intima-media thickness (Jamilian et al. 2017b; Samimi et al. 2016; Talari et al. 2019). Meta-analyses are not available yet.

Combinations of Nutritional Supplements

A combination of chromium picolinate (200 μg/d) and carnitine (1000 mg/d) for 12 weeks in women with PCOS reduced body weight, testosterone, C-reactive protein, markers of oxidative stress, hirsutism, fasting glucose, fasting insulin, triglycerides, low-density lipoproteins, and increased PPAR-gamma gene expression (Jamilian et al. 2019, 2020). Combining chromium picolinate, antioxidants (i.e., lycopene, n-acetylcysteine), and vitamins (i.e., vitamin D) for 12 weeks decreased body weight, improved menstrual cyclicity, and reduced acne and hirsutism in obese women with PCOS (Advani et al. 2020). Vitamin D in conjunction with omega-3 fatty acids for 12 weeks reduced total cholesterol, C-reactive protein, and enhanced antioxidant capacity (Jamilian et al. 2018). Also omega-3 fatty acids with vitamin E for 8–12 weeks improved antioxidant capacity, reduced C-reactive and carotid intima-media thickness (Sadeghi et al. 2019; Talari et al. 2018). Further studies on the impact on metabolic and reproductive phenotypes of PCOS would be advisable.

Dietary Approaches

Several diets such as the "dietary approaches to stop hypertension" (DASH), low glycemic index diets, low carbohydrate diets, Mediterranean Diet, and Portfolio Diet look effective for reducing risk factors for cardiovascular disease, occasionally encompassing women with PCOS.

DASH Diet

It emphasizes reduced sodium, saturated fat, refined grains and sweets, with more generous ingestion of potassium, calcium, and magnesium. Fruits, vegetables, low-fat dairy products, and moderate amounts of fish, poultry, whole grains, and nuts are recommended. Two to three months of the DASH diet for women with PCOS reduced

body weight, fat mass, waist circumference, and androstenedione levels while increasing SHBG (Asemi et al. 2014; Asemi and Esmaillzadeh 2015; Azadi-Yazdi et al. 2017; Foroozanfard et al. 2017). This alleviated oxidative stress and inflammation (i.e., C-reactive protein) and improved metabolic profile, as indicated by decreased fasting insulin, HOMA-IR, triglycerides, and very low lipoproteins (Asemi et al. 2014; Asemi and Esmaillzadeh 2015; Azadi-Yazdi et al. 2017; Foroozanfard et al. 2017).

Low-Glycemic Index Diets

The glycemic index (GI) of foods is determined by the 2-hour blood glucose response to 50 g available carbohydrate from a test food (Jenkins et al. 1981). Twelve weeks of a low GI diet in women with PCOS was effective for increasing insulin sensitivity and reducing HOMA-IR and C-reactive protein (Barr et al. 2013; Mehrabani et al. 2012), and after 12 months, menstrual cycles turned more regular (Marsh et al. 2010). We showed that 16 weeks of a pulse-based diet (composed of high-protein, high-fiber, low glycemic index legumes such as lentils, chickpeas, beans, and peas) reduced insulin response to an oral glucose tolerance test, low-density lipoproteins, total cholesterol/high-density lipoprotein ratio, and diastolic blood pressure, and increased high-density lipoprotein levels compared to a healthy diet designed for reducing lipids (the Therapeutic Lifestyle Changes diet) (Kazemi et al. 2018). A problem with many diets is long-term adherence. Indeed, in a 12-month follow-up after completion of our intervention, only HDL and total cholesterol/HDL improvements remained evident.

Low Carbohydrate Diets

They have reduced total fat, intra-abdominal fat, body weight, BMI, waist circumference, fasting glucose and insulin, HOMA-IR, total and free testosterone, and hirsutism, and preserved lean tissue mass loss in women with PCOS (Goss et al. 2014; Phy et al. 2015; Pohlmeier et al. 2014). The most recent meta-analysis on the topic indicated that low carbohydrate diets in women with PCOS are effective for reducing BMI, HOMA-IR, total cholesterol, and low-density lipoproteins (Zhang et al. 2019). More than four months were necessary for reducing testosterone and increasing SHBG. Diets lower in fat were best for improving hormone profiles and should be preferred.

The Mediterranean Diet and the Portfolio Diet

The lipid-lowering effect of these diets is comparable to that of certain pharmaceuticals (i.e., first-generation statins), without the side effects (Jenkins et al. 2003). A recent cross-sectional study indicated that women with PCOS consume smaller amounts of olive oil, legumes, fish, and nuts (Barrea et al. 2019). Fiber and magnesium are similarly scarce (Cutler et al. 2019). A randomized controlled study emphasizing increased intake of legumes (i.e., beans, lentils, chickpeas, peas) showed this diet was effective for reducing insulin levels during an oral glucose tolerance test, triglycerides, low-density lipoproteins, total cholesterol to high-density lipoprotein levels, and diastolic blood pressure, and increased high-density lipoproteins (Kazemi et al. 2018). Also walnuts decreased low-density lipoproteins, and glycosylated hemoglobin, and increased SHBG levels, whereas both walnuts and almonds increased adiponectin levels, and almonds reduced androgens in women with PCOS (Kalgaonkar et al. 2011).

The Portfolio diet includes viscous fibers, plant sterols, soy protein, and nuts, which could be useful for PCOS (Cutler et al. 2019; Kalgaonkar et al. 2011; Kazemi et al. 2018). An eight-week randomized controlled trial of a diet high in soy (i.e., 35% animal protein, 35% soy, 30% vegetable protein versus a diet of 70% animal protein and 30% vegetable protein) was effective for reducing BMI, glucose, total testosterone, insulin, insulin resistance, and

triglycerides in women with PCOS (Karamali et al. 2018). Yet at present, there are no interventions that have actually assessed the effectiveness of the Mediterranean or the Portfolio diet in women with PCOS.

Exercise

Exercise can target muscle and/or adipose tissue. Resistance (strength) training is best for increasing muscle mass, whereas aerobic training could reduce adipose tissue and change the adipokines released by adipose tissue (Chilibeck et al. 2014). Regarding aerobic exercise, there are traditional aerobic prescriptions (i.e., low- to moderate-intensity, long duration) and high-intensity interval training (high-intensity, shorter duration). There is interest in the latter form of exercise because it seems to be highly effective for inducing mitochondrial adaptations (Chilibeck et al. 1998).

Aerobic Training

This is the most common intervention for women with PCOS because of alleviation of metabolic and cardiovascular consequences of obesity. Simply encouraging women with PCOS to increase their step count by 1000 steps/day, or about 0.8 km/day walking over six months, significantly reduced inflammation by 13% as indicated by reduced interleukin-6 (IL-6) and C-reactive protein (Webb et al. 2018). Moderate-intensity aerobic training (i.e., 40–75% of peak heart rate, 60–70% of peak aerobic capacity) at three times per week for 30–60 min per session that involved walking, jogging, stationary cycling, or exercise on an elliptical trainer for 8–26 weeks reduced waist circumference, BMI, fat mass, ectopic fat in the lower leg, harmful lipids (i.e., triglycerides, cholesterol, low-density lipoproteins, very low-density lipoproteins), insulin resistance, fasting insulin, area under the insulin curve during oral glucose tolerance tests, systolic and diastolic blood pressure, intima-media thickness, testosterone, and number of ovarian follicles, and increased high-density lipoproteins, insulin sensitivity, flow-mediated dilation (indicating improved endothelial function), SHBG, and menstrual regularity (Costa et al. 2018; Orio et al. 2016; Sprung et al. 2013). Meta-analyses conclude that moderate-intensity aerobic exercise with a frequency of three times per week for a duration of at least 30 min/session and greater than or equal to three-month duration had favorable effects on waist circumference, body fat percentage, testosterone, SHBG, fasting glucose and insulin, HOMA-IR, blood lipids, systolic blood pressure, and C-reactive protein (Kite et al. 2019; Woodward et al. 2019), even though changes could be modest (Kite et al. 2019). Aerobic training interventions may, therefore, be best combined with other lifestyle interventions such as changes in diet (Kazemi et al. 2018).

High-Intensity Interval Training (HIIT)

HIIT is more effective than standard continuous moderate-intensity aerobic training for improving mitochondrial function, despite the fact that it is done for shorter durations and lower volume (Chilibeck et al. 1998). This is important considering that time commitment is often a major barrier to performing physical activity. Samadi et al. (2019) used a protocol where twelve weeks of aquatic HIIT involved 20 min of exercise three times per week. High-intensity interval training sessions involved 4 × 4 min bouts with 1-min rest between bouts; each bout involved 8 × 20 s "all out" intervals with 10 s rest between intervals. This form of HIIT reduced BMI, fat mass, HOMA-IR, hirsutism, and increased SHBG and menstrual cycle regularity.

Aktaş et al. (2019) compared HIIT to standard moderate-intensity aerobic training. Both programs involved 30 min of exercise done three times per week for 12 weeks. The HIIT sessions simply involved 2-min intervals of running alternated with 2 min of walking, whereas the standard aerobic program involved 30 min of moderate tempo running for 30 min. Body mass index decreased in both groups; however, only the HIIT increased adiponectin and high-density

lipoproteins and reduced insulin, triglycerides, total cholesterol, and low-density lipoproteins. Almenning et al. (2015) compared thrice-weekly HIIT to resistance training over 10 weeks. The HIIT involved twice a week training with 4 × 4 min exercise bouts at 90–95% maximal heart rate with each bout separated by 3 min moderate-intensity exercise at 70% maximal heart rate, and one session per week with 10 intervals of maximal exercise, with each interval separated by 1-min rest or low-intensity exercise. The mode of HIIT was on a treadmill, outdoor walking/running, or on a stationary bike depending on participants' preferences. The resistance training involved eight exercises done for 3 sets × 10 repetitions with 1-min rest between sets and resistance at 75% of 1RM, where 1RM is defined as the maximal strength or the maximal amount of weight that can be lifted once.

The resistance training was superior for increasing muscle mass and SHBG, and decreasing free androgen index, whereas the HIIT was superior for decreasing insulin, HOMA-IR, and DHEAS, and increasing high-density lipoproteins and flow-mediated dilation and therefore endothelial function. Both programs were effective for reducing percent body fat. Ideal results may be derived where HIIT training is combined with a resistance training program.

Resistance Training

It has the greatest potential for increasing muscle mass and, therefore, may be most effective for alleviating sarcopenia. One study indicated that 4 months of resistance training, done 3 times per week with 10 exercises induced favorable changes in body composition and strength, and reduced testosterone and fasting glucose levels, but had no effect on fasting insulin or HOMA-IR (Kogure et al. 2016, 2018). A small study randomized protocol of resistance training ($n = 7$) and controls ($n = 6$) revealed similar results (Vizza et al. 2016). While resistance training is effective for increasing muscle mass and physical function in women with PCOS, aerobic training may need to be added to achieve more marked improvements in metabolic measures. Turan et al. (2015) submitted women with PCOS to combined aerobic and resistance training. The duration of training was 8 weeks, 3 times per week. Compared to controls, the exercise group reduced waist circumference, diastolic blood pressure, low-density lipoproteins, total cholesterol, fasting insulin and glucose, HOMA-IR, and increased high-density lipoproteins and menstrual cycle regularity. A limitation of this study is that resistance training only or aerobic training only groups were not included; therefore, it is difficult to discern whether metabolic benefits were due to resistance training or aerobic programs.

A restricted diet, aerobic training, or the association of both were investigated in a cohort of PCOS. Exercise was superior for inducing changes in body composition. All groups showed metabolic and hormonal benefits, decreased waist circumference, and abdominal fat mass. The aerobic training group increased the number of ovulatory cycles compared to the diet-only group (Thomson et al. 2008, 2012). It appears diet and/or exercise are effective for inducing metabolic benefits; however, exercise interventions are best for improving body composition in women with PCOS.

Summary/Overall Recommendations

Dietary and exercise intervention studies in women with PCOS are characterized by low adherence rates; therefore, it would be practical to offer a variety of diet and exercise options so women can choose options they consider most enjoyable and feasible.

Contents

Abstract

Obesity contributes more to the mortality rates than malnourishment in countries with the majority of the world's population. First-line methods with lifestyle modifications may not be enough for the complete treatment of obesity, especially in genetic disorders. In the last two decades, several new therapies have emerged and many are still in development, to provide potential alternatives to currently available anti-obesity drugs. They belong to the class of centrally acting drugs, gut hormones, and incretin targets. Additionally, we have listed and described the status of novel anti-obesity agents targeting methionine

aminopeptidase 2 (MetAP2), lipase, triple monoamine reuptake, fibroblast growth factor 21, and anti-obesity vaccines. With an advancement in the development of these new drugs, anti-obesity drugs have the potential to provide better treatment opportunities and personalized care.

Keywords

Anti-obesity · Pharmacotherapy · Ghrelin · Vaccines · Neuropeptide Y · Mimetics · Leptin

Introduction

In 2010, obesity caused more than 3.4 million deaths, along with heavy loss of years of life and disability-adjusted life years/DALYs worldwide (Ng et al. 2014).

It is characterized by an increase in body fat content, when energy intake exceeds energy expenditure. Obesity has pernicious effects on nearly all the organ systems, which exacerbates the disease state and also increases the cost of care (Srivastava and Apovian 2018). Body mass index is widely used for diagnosis; however, this measurement does not differentiate between lean mass and fat mass and can thus be misleading (Table 68.1).

When WHO estimated a threefold increase in the worldwide prevalence of obesity between 1975 and 2016, it drew attention to lifestyle. Most of the world's population lives in countries where overweight and obesity kill more than underweight. Monitoring of diet and exercise are considered to be the first-line methods over drugs (WHO). However, these methods may not be enough. Prader-Willi syndrome (PWS) is an example of genetic obesity, with upper body fat accumulation, hypogonadism, and mental retardation. It is due to the loss of expression of genes from paternal inheritance on chromosome 15, deletion of chromosome 15q11-q13. Type II diabetes and thromboembolism are related concerns. Drugs that act on the actual body mechanisms (ghrelin) or on genes (melanocortin-4 receptor) are recommended (Duis et al. 2019).

Even alterations in the circadian cycle and nocturnal behavior (late awakening and late breakfast) can have an effect on the plasma glucose levels. Moreover, cardiovascular diseases, type II diabetes, and obesity are partially interdependent. Insulin is involved in promotion of lipolysis; therefore, decrease in insulin levels causes reduction in lipolysis. Thus, some of the target molecules in the pharmacological interventions are hormones and gut peptides, involved in long-term energy balance for, e.g., leptin and insulin, along with acute modulators like ghrelin, peptide YY (PYY), glucagon-like peptide 1 (GLP-1), and cholecystokinin (CCK) (Zhang et al. 2014).

Given that different types of obesity based on BMIs do not subject to the same risk of comorbidities (Table 68.1), there is a need for improved strategies for the identification of predictive biomarkers for these comorbidities (e.g., diabetes, hypertension, dyslipidemia, and cardiovascular disease). Likewise, effective preventive interventions with improved outcomes, by identifying what intervention is best suited for each individual (Zhang et al. 2014).

In this chapter, we will mainly focus on drugs in different stages of the research pipeline, which can be potential alternatives to currently available

Table 68.1 Classification of body weight in adults according to BMI (WHO)

Classification	BMI (kg/m^3)	Risk of obesity comorbidities
Underweight	<18.50	Low (however risk of other clinical problems is increased)
Normal range	18.50–24.99	Average
Overweight	25.00–29.99	Mild
Obese class I	30.00–34.99	Moderate
Obese class II	35.00–39.99	Severe
Obese class III	≥40.00	Very severe

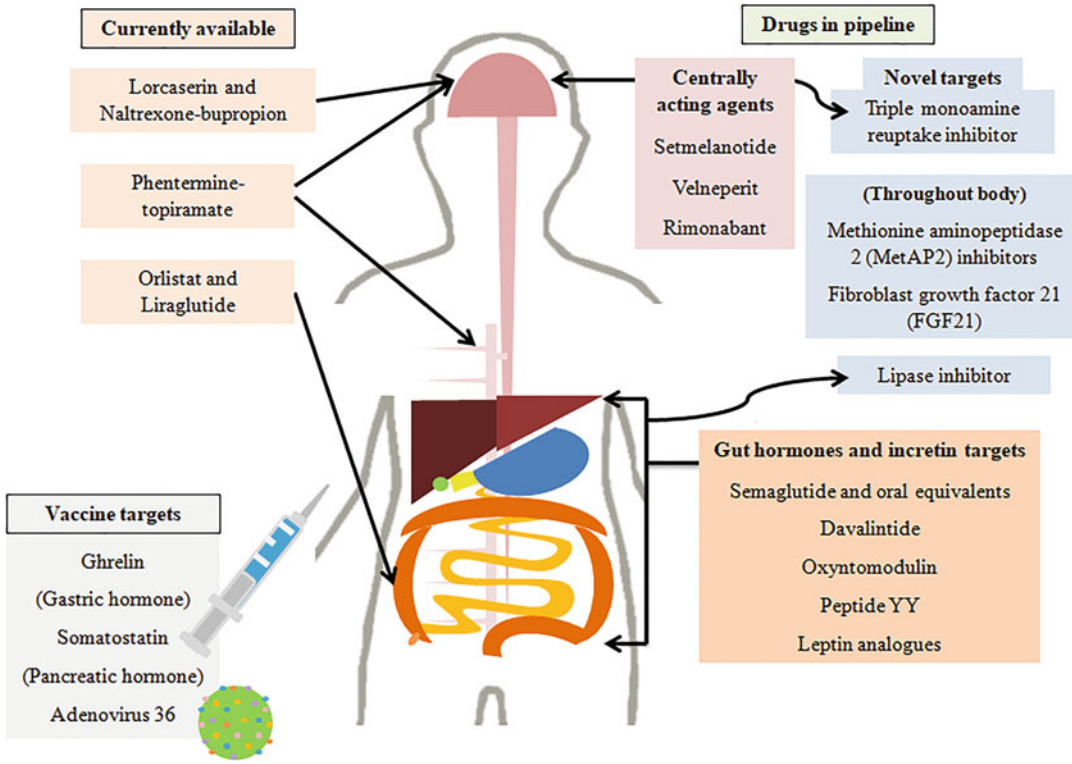

Fig. 68.1 Anti-obesity drugs, their targets, and locations

anti-obesity drugs (Fig. 68.1). The centrally acting drugs can be of potential use in the treatment of genetically acquired obesity. These drugs are known to mainly target receptors which influence the food intake and energy expenditure centrally. Novel anti-obesity targets mainly acting as inhibitors for methionine aminopeptidase 2 (MetAP2), lipase, and triple monoamine reuptake along with fibroblast growth factor 21 and anti-obesity vaccines which include ghrelin, somatostatin, and adenovirus 36 will also be addressed.

Current Drugs

There are currently five FDA-approved drugs used as prescription medications for weight loss namely Orlistat (Alli and Xenical), Lorcaserin (Belviq), Phentermine-topiramate (Qsymia), Naltrexone-bupropion (Contrave), and Liraglutide (Victoza) (Fig. 68.2). Given the magnitude of the obesity epidemic, they are considered as underutilized, in the USA and other countries. Table 68.2 compiles their information target sites, mechanism of action, dosage forms, and adverse effects.

Orlistat and liraglutide theoretically have high safety margin, as they have no central activity. Yet, there are indications that liver and kidney damage due to Orlistat along with faster multiplication of cancer cells and liraglutide 3.0 mg has been associated with gallstone disease and pancreatitis (Patel and Stanford 2018). Lorcaserin can induce depression and suicidal tendencies and can worsen preexisting depression. The rationale for a combination medication is that appetite regulation involves multiple pathways, so targeting different mechanisms simultaneously can have an additive effect on body weight. Another benefit is that the smaller dose of each medication reduces the risk of adverse effects.

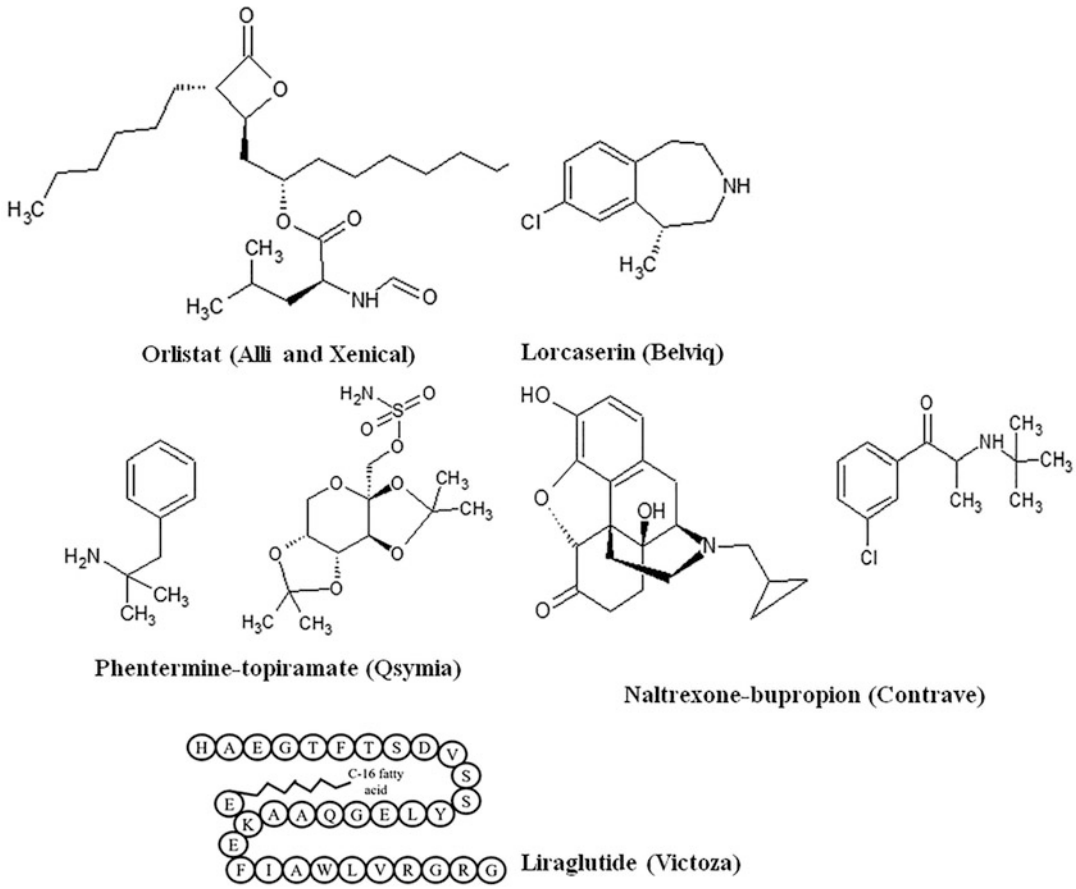

Fig. 68.2 Currently available FDA-approved prescription medications

Still naltrexone, an opioid receptor antagonist, can lead to drug abuse and dependency. Phentermine-topiramate can be used in combination therapy with other drugs as it is not likely to cause any clinically significant drug interactions.

Drugs in Pipeline

Centrally Acting Drugs

It has been found that food intake is controlled by receptors like melanocortin-4-receptor (MC4R), neuropeptide Y (NPY), and cannabinoid type-1 receptor (CB1R) which are present centrally, mainly in the hypothalamus. Drugs targeting these receptors are being researched. Some of these drugs have also shown positive results in clinical trials for the treatment of obesity that results from genetic disorders. However, since these drugs act centrally, their side effects can be more adverse compared to other anorectic drugs.

Melanocortin Receptor Agonist

The melanocortin-4-receptor (MC4R), which serves as a key regulator in the appetite controlling pathway within the hypothalamus, is a 332 amino acid GPCR (Garfield et al. 2015). When hunger signals are produced, they bind to their respective receptors and act on orexigenic neurons. This process leads to the release of melanocortin inverse agonist, agouti-related protein (AgRP). AgRP lowers the MC4R activation, thus inhibiting satiety signals and inducing the perception of hunger. The endogenous agonist

Table 68.2 Currently available FDA-approved anti-obesity medications

Drug, Class, Reference	Mechanism of action	Dosage form	Pharmacokinetics	Interactions	Most common adverse effects
Orlistat (Alli and Xenical) Lipase inhibitor Heck et al. (2000)	Inactivation of gastric and pancreatic lipase; different from other drugs as it does not target the feeding center but reduces fat absorption from food	Capsules (Alli—60 mg and Xenical—120 mg)	Half-life is 14–19 h. Two metabolites mainly M1 and M3 are excreted in bile having half-life of 2 h and 3 h, respectively; the drug undergoes extensive first pass metabolism.	Cyclosporine, warfarin, amiodarone, antiepileptic agents, and antiretroviral drugs. Malabsorption of fat-soluble vitamins (A, D, E, and K)	Abdominal discomfort, fecal incontinence, liquid stools, soft stools, and fecal urgency.
Lorcaserin (Belviq) Selective serotonin (5-HT_{2C}) agonist Brashier et al. (2014)	Stimulates the release of POMC from the arcuate nucleus which further causes the release of α-MSH which suppress the appetite	Tablet (10 mg or 20 mg)	Rapidly absorbed, delayed with fatty meals, peak concentration: 1.5–2 h; half-life: 11 h, distributed in the CNS, 70% plasma protein bound; metabolized in liver, major metabolite lorcaserin sulfamate, excretion mainly through urine (92%)	Risk of serotonin syndrome or neuroleptic malignant syndrome-like reactions with SSRIs, SNRIs, and MAOIs along with CYP450 2D6 inhibition; increase blood levels of drugs metabolized by this enzyme	Nausea, vomiting, constipation, diarrhea, fatigue, upper respiratory tract infection, urinary tract infections, back pain, headache, dizziness, and rash. Attention and memory deficit rare
Phentermine-topiramate (Qsymia) Adrenergic agonist/ neurostabilizer Shyh and Cheng-Lai (2014)	Phentermine is an agonist at TAAR1 receptor site that stimulates the release of norepinephrine and epinephrine. Topiramate modulates through GABA receptors, inhibiting carbonic anhydrase, antagonism of glutamate.	Capsule (3.75/23 mg, 7.5/46 mg, 11.25/69 mg, and 15.0/92 mg)	Phentermine undergoes p-hydroxylation on the aromatic ring and N-oxidation on the aliphatic side chain. 70–80% excreted in urine, half-life 20 hours. Topiramate does not undergo extensive metabolism, 70% excreted in urine; half-life: about 65 hrs	Topiramate may induce metabolism of ethinyl estradiol, thus decreasing contraceptive efficacy. Contraindications include pregnancy, glaucoma, hyperthyroidism, and MAOIs	Paresthesia, dizziness, dysgeusia, insomnia, constipation, and dry mouth. .
Naltrexone-bupropion (Contrave) Opioid receptor antagonist/ NDRI Saunders et al. (2018)	Acts on the arcuate nucleus of the hypothalamus where the firing rate of POMC neurons is increased and the mesolimbic dopamine reward	Tablet (8 mg or 90 mg)	It is metabolized in the liver and has a bioavailability of 5–40%, half-life: 4 hrs	It shows interactions with MAOIs opioids, disulfiram, and thioridazine	Nausea, constipation, headache, dizziness, insomnia, dry mouth, hallucinations, blurred vision, angioedema

	circuit is modulated.				
Liraglutide (Victoza) GLP-1 analog Bode (2012), Saunders et al. (2018)	It increases secretion of insulin from beta-cells, reduces postprandial glucagon secretion, delays gastric emptying, and improves the function of beta-cells.	Subcutaneous (dose increased 0.6 mg daily until 3 mg	Slowed absorption from the subcutis and decreased rate of elimination due to chemical difference from the endogenous peptide GLP-1 and protein binding leads to a longer half-life of approx. 13 h	Contraindicated in pregnancy or those with personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia syndrome type 2, with insulin or insulin secretagogues; risk of hypoglycemia.	Diarrhea, dyspepsia, abdominal pain, nausea, vomiting, constipation

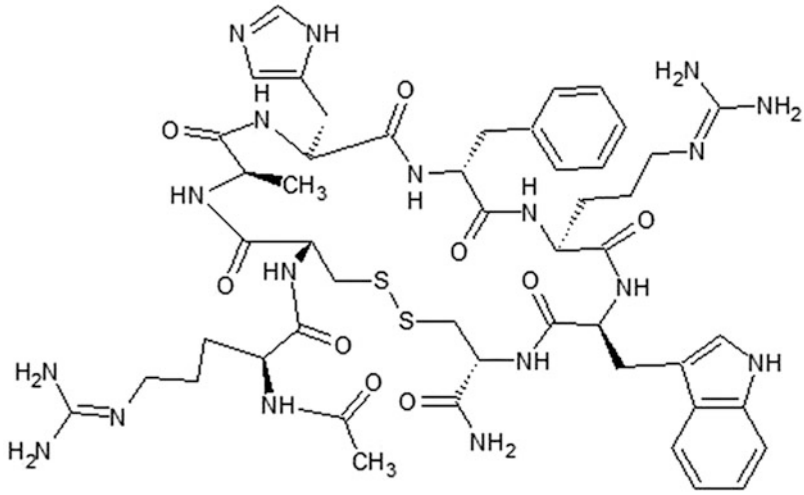

Fig. 68.3 Setmelanotide, an MC4R agonist

of MC4R is α-melanocortin-stimulating hormone (α-MSH) and is released when satiety signals bind to their respective receptors on anorexigenic neurons (Kim et al. 2011).

About 6–8% cases of obesity have been found to be a result of dysregulation or mutation of MC4R. Mutations can result in decreased affinity of endogenous agonist toward this receptor and decreased surface expression of the receptor or impaired signal transduction (Santini et al. 2009). Ser127Leu, Ser58Leu, Ile102Thr, and Gly252Ser are the four-point mutations that occur in MC4R and are known to affect the potency of this receptor (Roubert et al. 2010).

Setmelanotide

Setmelanotide, also known as RM-493 or BIM-22493, is a melanocortin-4-receptor (MC4R) agonist. It is a synthetic 8-amino acid cyclic peptide and has a molecular formula of $C_{49}H_{68}N_{18}O_9S_2$, with a molecular weight of 1117.3 Da (Fig. 68.3). Setmelanotide has a high

affinity toward human MC4R receptors (inhibitory constant $K_i = 2.1$ nmol/l) (Kievit et al. 2013).

Setmelanotide was studied for its action on normal MC4R (wild-type model) as well as on mutated MC4R. In the binding assays, setmelanotide showed 37-fold higher affinity than α-MSH (endogenous agonist). In the activation assays, it showed 20-fold more potency (Falls and Zhang 2018). In vivo studies were conducted on normal and diet-induced obese (DIO) mice. In normal mice, it reduced food intake and weight gain. In DIO mice, it reduced fatty liver disease and hyperinsulinemia (Roubert et al. 2010; Kumar et al. 2009). When setmelanotide was introduced in the wild-type model, it exhibited interactions with several residues that were known to be critical for α-MSH.

According to NMR and modeling studies, the endogenous agonist α-MSH binds to the receptor in a hairpin loop. The tetra peptide messaging sequence binds to the active site, and the rest of the peptide points out in the extracellular space. In contrast to α-MSH, setmelanotide is fully accommodated in the binding site, which is attributed to its better affinity and potency in the wild-type protein. The additional interactions of the amino acids present in setmelanotide are responsible for its accommodation in the binding site (Falls and Zhang 2018). When setmelanotide was introduced in the mutated model, it was observed that the mutated residues were not directly involved in the binding process. The mutated residues were found to be located in the proximity to those residues which are important in the MC4R activation by setmelanotide. However, in case of α-MSH, Ile102Thr and Ser127Leu are located in such a way that they can cause a shift of Glu100, Asp122, and Asp126, which are considered to be necessary for receptor activation.

Ser58Cys and Gly252Ser are located away from the binding site but are known to induce conformational changes, important for MC4R activation (Falls and Zhang 2018). Hence, setmelanotide due to its cyclic structure and extensive interactions has the ability to stabilize and activate the receptor even in the presence of polymorphisms. It can act as a positive allosteric modulator. Such properties of setmelanotide make it a non-traditional bitopic ligand. It has been termed as non-traditional because it can interact with two sites without requiring traditional linker and allosteric building blocks (Falls and Zhang 2018).

Setmelanotide has entered two phase III clinical trials in 2017. Indications were pro-opiomelanocortin (POMC) deficiency obesity and leptin receptor (LEPR) deficiency obesity. According to the manufacturer (Rhythm), both one-year-long trials met primary and secondary end points, with effects on weight loss, insatiable hunger, or hyperphagia (Globenewswire.com 2019).

Gut Hormones and Incretin Targets

Glucagon-Like Peptide-1 (GLP-1) Analogs: Semaglutide (Ozempic)

Glucagon-like peptide-1 (GLP-1), an incretin hormone, is secreted from L cells in the small intestine. Semaglutide is a GLP-1 receptor agonist, and it has more than two amino acids substitutions at position 8 (alanine to α amino butyric acid) and 34 (lysine to arginine) (Fig. 68.4). The substitution at eighth position provides resistance to DPP-4 (dipeptidyl-peptidase) degradation. The modification in the structure prolongs its half-life which in turn increases the efficacy of the drug (Christou et al. 2019).

It acts by releasing insulin from β pancreatic cells and reducing the production of glucagon from the α-pancreatic cells. It decreases both fasting and postprandial plasma glucose levels; therefore, it was approved in Dec 2017 for the treatment of Type-2 Diabetes Mellitus (T2DM). It also acts by promoting weight loss. Upon administration, it decreases the total energy intake followed by suppression of appetite and less food cravings for high-fat foods, along with better control of eating and meal portion size (Christou et al. 2019).

In the presence of GLP-1 agonist, the glucose activity is regulated by inhibiting the K^+ ATP channels. Further opening of voltage-dependant

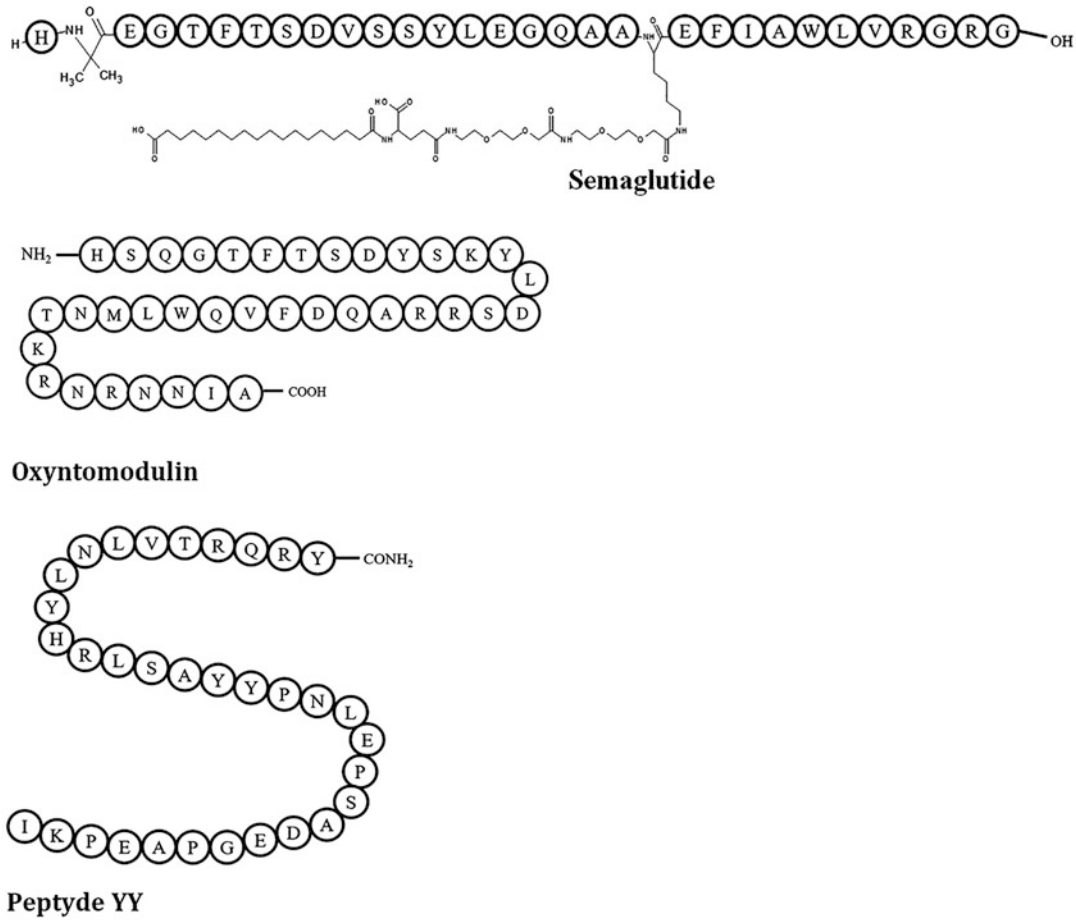

Fig. 68.4 Structure of Semaglutide and oxyntomodulin

calcium channels (VDCC) inhibits the K^+ channel repolarization. GLP-1 stimulates IP3 and ryanodine receptors (RYR) facilitating the influx of Ca^{++} ions, which further promote insulin secretion (Meloni et al. 2013). Semaglutide-induced weight loss was associated with a three-fold greater loss of mean fat over lean body mass (Blundell et al. 2017).

The half-life of the drug is 7 days (183 h), in case of normal kidney function, 201 h in moderate kidney dysfunction and 221 h in severe kidney failure. Catabolism mainly occurred through neutral endopeptidase (NEP), a membrane-bound enzyme located in the kidneys (Christou et al. 2019). Cholelithiasis is a side effect of semaglutide (Chamberlin and Dabbs 2019) (Fig. 68.4).

GLP-1 agonists are not advised as first-line treatment due to potential risk of thyroid carcinoma or multiple endocrine neoplasia nor in patients with a history of pancreatitis. Gastrointestinal adverse effects limit use in some patients. Patients having a history of diabetic retinopathy should be constantly monitored for disease progression.

Dual Action GLP-1/Glucagon Receptor Agonists

Oxyntomodulin

Oxyntomodulin (OXM) is a 37-amino acids peptide (Fig. 68.4) and influences energy intake. On central administration of oxyntomodulin, its

effects are canceled by exendin which is an antagonist of GLP-1 receptors (Baggio et al. 2004). The effects of oxyntomodulin also include decreased heart rate and energy expenditure. Similar effects were observed on activation of glucagon receptor (Sowden et al. 2007). These observations hence indicated that oxyntomodulin shows a dual action by acting as an agonist for both GLP-1 as well as glucagon receptor.

A phase 2b trial with an analog (OPK 88003) was finished in 2019 with obese diabetic patients. Weight loss, lipid profile, and HbA1c were more improved than with metformin. Further studies are expected (www.opko.com, 2019).

Peptide YY

Peptide YY (PYY) is a 36 amino acid peptide and is synthesized and discharged from specific endocrine cells called L cells, which are found essentially in the ileum. GLP-1, GLP-2, and oxyntomodulin are the co-secretions with PYY. $PYY_{1–36}$ and $PYY_{3–36}$ are the two forms of PYY, and $PYY_{3–36}$ is the most common form, which binds to Y2 receptor (Murphy and Bloom 2006). It acts through NPY receptors and reduces the secretion of gastric acid and GIT motility when the level increases during fasting and after feeding. One of the pathogenesis of obesity is known to be a decrease in PYY levels (Batterham et al. 2003). $PYY_{3–36}$ does not show any effect in Y2-deficient mouse, which is indicative of the fact that it shows its action through Y2 receptors (Batterham et al. 2003). A silent single nucleotide polymorphism (SNP), 585 T > C, is present on the Y2 receptors and was found to be associated with obesity. The frequency of 585 T > C was lower in obese men compared to the lean group (Lavebratt et al. 2006).

PYY Analogs

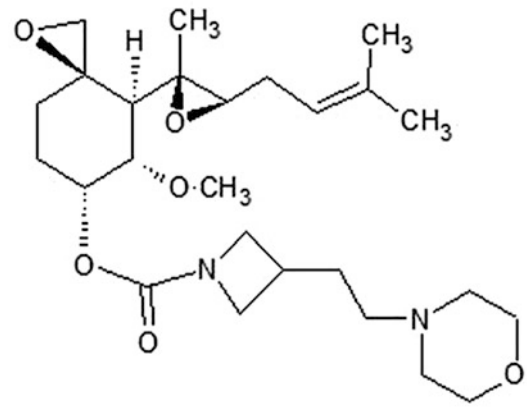
Native PYY has a short life; thus, several long-acting analogs are being developed. One of these, Y242, has demonstrated encouraging results in animal studies, with at least 72 hours action in rodents, after subcutaneous injection. Given the inhibition in food intake and significant weight loss associated with the product, toxicologic studies are going on, in anticipation of a human phase I trial (www.ukri.org 2019).

Novel Targets

Methionine Aminopeptidase 2 (MetAP2) Inhibitors: ZGN-1061

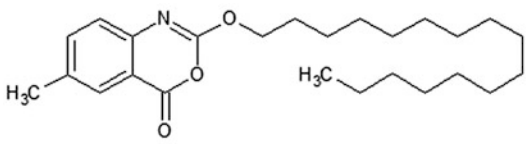
Methionine aminopeptidase 2 (MetAP2) is an enzyme responsible for the co-translational cleavage of N-terminal methionine, from a subset of newly made proteins important for a broad range of cellular functions, including metabolism, growth, and proliferation (Warder et al. 2008). It also binds to other important regulatory proteins such as extracellular signal-regulated kinase 1/2 (Erk 1/2) and elongation initiation factor 2 α (EIF2α) (Datta et al. 2004). Originally intended to be used in the treatment of cancer due to their anti-angiogenic property (Yeh et al. 2006), MetAP2 inhibitors were found to have marked anti-obesity effects in animal models and humans (Siddik et al. 2019).

This is a potent, selective, and covalent inhibitor of the MetAP2 enzyme that was developed to minimize endothelial cell exposure and exhibit an improved safety profile regarding platelet aggregation, neutrophil adhesion or NETs formation, clotting factor levels or function or blood clotting or clot lysis. After a 12-week treatment (Fig. 68.5) with 1.8 mg of ZGN-1061, subcutaneously injected every three days, part of a phase II clinical trial, body weight, and HbA1c favorably



ZGN- 1061

Fig. 68.5 Structures of the natural (Fumagillin) and synthetic (Beloranib and ZGN-1061) methionine aminopeptidase 2 (MetAP2) inhibitors



Cetilistat

Fig. 68.6 Cetilistat, a lipase inhibitor

responded in obese diabetic patients. Safety and tolerability were also encouraging, with no treatment-related serious adverse events and no cardiovascular (CV) safety signals observed. Additional studies are expected in the near future (Globenewswire 2019).

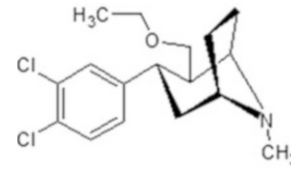
Lipase Inhibitor: Cetilistat

Cetilistat is a lipase inhibitor having the same pharmacological activity as orlistat and it inhibits the absorption of fat (Fig. 68.6). In phase II trial, there was an increase in fecal fat comparable to orlistat, and also, 11% of the subjects had oilier stools. It has less gastrointestinal complications than orlistat and is therefore more reliable (Hossain et al. 2019).

Triple Monoamine Reuptake Inhibitor: Tesofensine

Tesofensine (TE) inhibits appetite and stimulates thermogenesis. Devised for neurological diseases, weight loss was incidentally observed (Astrup et al. 2008b). Experimentally, it is associated with dopaminergic pathways in the brain (Hansen et al. 2013). A clinical trial confirmed weight loss (Astrup et al. 2008a); however, depending on the dose, major adverse effects were documented (Doggrell 2009; Astrup et al. 2008a). After a publication retraction (Retractionwatch 2013), further trials followed. Yet, long-term effects were not entirely satisfactory (Gilbert et al. 2012).

A new more successful trial was recently conducted, and the manufacturer intends to market the product in Mexico by 2020 (https://saniona.com 2019). Tesomet, which includes tesofensine and metoprolol, looks promising for Prader-Willi syndrome and other forms of obesity. Trials by the same manufacturer are going on (https://saniona.com 2019) (Fig. 68.7).



Tesofensine

Fig. 68.7 Tesofensine, a triple monoamine reuptake inhibitor

Fibroblast Growth: Factor 21

Fibroblast growth factor 21 (FGF21), analogously to other FGFs, stimulates cell growth and other functions in liver, adipose tissue, skeletal muscle, and pancreas (Giralt et al. 2015). Among other effects, glucose uptake, increased thermogenesis, and modulation of lipid metabolism experimentally occur (Cuevas-Ramos and Aguilar-Salinas 2016; Fisher and Maratos-Flier 2016; Domouzoglou and Maratos-Flier 2011; Badman et al. 2009).

Peroxisome-proliferator-activated receptor-α (PPARα) is involved in hepatic expression of FGF21 p (Inagaki et al. 2007; Lundåsen et al. 2007). Anti-inflammatory and anti-oxidative stress properties of FGF21 have been reported (Gómez-Sámano et al. 2017).

Preliminary observations in obese diabetics did not confirm clear benefits for either disease; however, lipid metabolism improved, along with markers of liver fibrosis. Steatohepatitis could therefore be a future target (Charles et al. 2019).

Anti-obesity Vaccines

Ghrelin

Under this section we will discuss the normal function of the target molecule and the results of

various studies on vaccines against these targets that have been carried out. Ghrelin is converted from the precursor proghrelin. As a major regulator of appetite, it is relevant for obesity and metabolic diseases. The x/A cells of the oxyntic glands in the gastric fundus are the main source, with minor contributions from pancreas, hypothalamus, and kidney glomeruli (Sakata et al. 2009; Kojima et al. 1999).

Ghrelin undergoes subsequent acylation to form acyl ghrelin (AG), with the help of ghrelin O-acyltransferase (GOAT), which occurs at the same gastrointestinal sites as ghrelin (stomach, pancreas, and gut) (Sakata et al. 2009; Yang et al. 2008; Gutierrez et al. 2008). In rodents, after ghrelin vaccines were applied, weight gain was inhibited along with less feed efficiency, whereas lean body mass was mostly conserved, a response consistent with diminished leptin. The ratio of brain/serum ghrelin signaled the anti-ghrelin effect (Zorrilla et al. 2006). Also in pigs, conjugated ghrelin combined with an adjuvant provided a successful vaccine, which induced mild anorexia and weight loss, with elevated growth hormone levels (Vizcarra et al. 2007).

Virus-like proteins (VLPs) are highly immunogenic viral proteins devoid of genetic material therefore safe and effective for vaccination studies (Lechner et al. 2002). Experimental combination with ghrelin confirmed weight loss; however, human trials were not successful (Vizcarra et al. 2007).

Somatostatin

Growth hormone (GH) and its effector insulin-like growth factor-I (IGF-I) stimulate positive nitrogen balance and tissue growth in most organs, whereas lipids tend to undergo catabolism. Deficiency has been deemed a cause of fat accumulation (Berryman and List 2017; Lewitt 2017). The aim of vaccination is to enhance GH and IGF-1. In rodents, weight loss was achieved; however, no human trials are available (Haffer 2012).

Adenovirus 36

Human adenovirus 36 (Ad36) is not uncommon, differentially affecting the obese (30%) and non-obese population (11%) in the USA (Atkinson et al. 2005), however, not in all countries (Abdel-Moniem et al. 2018). Experimentally, it induces fat accumulation; however, insulin sensitivity increases. In mice, vaccination followed by virus inoculation prevented weight gain and elevation of pro-inflammatory cytokines (Na and Nam 2014). Human experience is not available.

Conclusion

Currently, unaffordable drugs continue to be a challenge, and available pharmacotherapies are not efficient enough to overcome obesity. People with obesity and failing lifestyle therapies need to be escalated to the required pharmacological treatment, as bariatric surgery has strict criteria and is not appropriate for mass therapy.

The most promising of these are co-agonists for multiple gut hormones including glucagon, GLP-1, and GIP. They mainly affect food intake; hence, their analogs could prove to be a better line of therapy for obesity. Unlike other centrally acting agents, setmelanotide has shown comparatively less severe side effects, and therefore, it could have a future in the therapy of genetically acquired obesity.

Abstract

The melanocortin family of G-protein-coupled receptors is the main group of receptors to control appetite, energy homeostasis, and adipose tissue accumulation. In particular, the melanocortin-4 receptor (MC4R) is believed to have a central role in the management of food intake and energy expenditure. Mutations in this gene often lead to an increase in weight, therefore being considered the monogenic target for the treatment of obesity. Obesity is also often the cause of other onerous conditions, such as type 2 diabetes. Efforts to develop a novel pharmacotherapy for this condition have disclosed the complexity of physiological roles and activation mechanisms of this receptor. A promising drug is currently on clinical trials, but efforts to develop a more selective and potent compound have not ceased.

Keywords

Melanocortin receptor · Appetite hormones · Melanocortin pathways · Metanocortin agonists · Melanocortin diabetes

Incidence and Societal Burden of Obesity

The World Health Organization (WHO) data report that the state of being overweight and obese constitutes the fifth leading risk for global deaths. At least 2.8 million adults die each year as a result of being overweight or obese. In addition, 44% of the diabetes mellitus (DM) burden is attributed to excess weight. This increase in obesity rates is a great concern for governments worldwide, and it is also a huge economic burden for the society (De Carvalho et al. 2017; Leitner et al. 2017).

Obesity is defined by the WHO as abnormal or excessive fat accumulation that presents a risk to health. A person with a body mass index (BMI) of 30 or more is generally considered obese. Overweight and obese individuals are at greater risk for a number of chronic diseases, including cardiovascular diseases, type 2 diabetes mellitus, osteoarthritis, nonalcoholic fatty liver (NAFL) disease, respiratory complications, and certain forms of cancer. Cytokines, such as interleukin-6, resistin, and plasminogen activation inhibitor 1, derived from adipose tissue, have been implicated in the pathogenesis of several of the diseases mentioned (Ellacott et al. 2007; Makki et al. 2013). Therefore, when researching pharmacotherapies for this epidemic, the focus needs to expand beyond just weight loss and keep in mind all the other associated diseases (hyperglycemia, hyperlipidemia, and cardiovascular diseases). The healthcare system, the physicians, and the patients need to envisage obesity as being a chronic disease that will require a long-term treatment and follow-up. A reduction in bodyweight as low as 5–10% has a major impact in the levels of inflammation and pro-thrombotic markers, as well as chronic disease incidence (Guh et al. 2009).

Challenges in Pharmacological Management of Obesity

Currently, there are three main treatments for the management of obesity: behavioral modification, pharmacological therapy, and bariatric surgery. Despite being the most effective option, bariatric surgery is the least recommended due to the invasive nature of the procedure and the relative high costs associated with the surgery (Velazquez and Apovian 2018). Rather, behavioral modification is preferred as the first choice for therapeutic intervention. Even though different approaches are available, the success of the commonly applied medicinal or behavioral modifications methodologies is often transient, with most patients having regained the lost weight only two years after the treatment. To reduce the increasing incidence of obesity worldwide, new and more effective ways of controlling appetite and adipose tissue accumulation are, therefore, a pressing need.

Mammalian metabolism provides several protective mechanisms against weight loss (e.g., regulation of neuroendocrine hormones, leptin and

ghrelin) (Wren et al. 2001; Batterham et al. 2002; Cowley et al. 2001). In addition, energy expenditure is associated with increased sympathetic nervous system activity and increase of body temperature. Both responses present major challenges for the success and safety of pharmacological treatments, along with drug side effects.

Causes for obesity encompass primary causes derived from monogenic diseases and syndromes, and secondary ones that result from psychological, neurological, and drug-induced stress (Butler et al. 2000). Lifestyle adjustments are usually insufficient for the first category, whereas unhealthy habits and other environmental mechanisms are in principle amenable to behavior change (see Table 69.1).

Different pharmacological approaches for weight loss are available (Van Gaal and Dirinck 2016); however, undesired side effects have to be accounted for, besides the need for long-term safety and efficacy monitoring.

Melanocortin Receptors (MCRs)

These are a part of the G-protein-coupled membrane receptors (GPCRs), the largest protein superfamily in mammalian genomes. The MCRs cognate, physiological ligands are variants of melanocyte-stimulating hormone (MSH) and processed products of the proopiomelanocortin (POMC) gene. Following the discovery of these peptide hormones, denominated melanocortins, and identification of a cognate receptor (later determined to be the melanocortin-1 receptor, MC1R), Hruby and co-workers conducted comprehensive work in determining the physiological roles of this receptor (Sawyer et al. 1982; Castrucci et al. 1984; Haskell-Luevano et al. 1997). Subsequently, functional and structural diversity of the MCR family of receptors was revealed, including the four additional melanocortin receptors MC2R, MC3R, MC4R, and MC5R, as well as their distinct tissue

[b]Depression associated with overeating or binging

distributions and physiologic roles (Halem et al. 2008; Pantel et al. 2011). With respect to MC4R, this receptor was identified by northern blot analysis and its tissue distribution was characterized via *in situ* hybridization by Gantz et al. (1993). While several melanocortin agonists were developed initially, with some of them even completing clinical trials (as tanning agents), it was not until after the identification of the different melanocortin receptors that further testing for receptor selectivity took place (Sawyer et al. 1982; Castrucci et al. 1984; Hruby et al. 1995). This stimulated the development of specific agonists and investigations into possible applications for the previously developed MCR agonists.

Melanocortins and Feeding Behavior

In 1986, it was already suggested that melanocortin peptides inhibit food intake (Poggioli et al. 1986). Obesity was subsequently linked to disruption of the MC4R (Huszar et al. 1997). Mice with MC4R deficiency display elevated body fat tissue, hyperphagia, and hyperinsulinemia, and ectopic natural antagonists of the MC4R ligand are relevant in this context (Yeo et al. 2003). These findings were simultaneously corroborated in studies where MC4R mutations in mice resulted in a non-syndromic form of obesity (Vaisse et al. 1998). When increased the content of fat in a diet, wild-type mice tend to increase diet-induced thermogenesis and their physical activity and at the same time decrease the food intake in a few days, opposed to knockout mice that increase the food intake (Butler et al. 2000; Litt et al. 2017; Panaro and Cone 2013).

Heritability of fat mass ranges between 70–90% in monozygotic and 35–45% in dizygotic twins (Berrettini 2004; Maes et al. 1997). Not to exclude environmental factors, but when analyzed different humans with different ethnic backgrounds, the most prevalent single gene mutation that induces obesity is in MC4R (Yeo et al. 2003; Nogueiras et al. 2007; O'Rahilly et al. 2003). Over 1000 mutations are linked with adipose tissue and energy balance, encompassing different phenotypes (e.g. complete loss of receptor function to polymorphism, obesity, and even difficulty in gaining weight) (Santini et al. 2009); an MC4R website with this information has been compiled (Melanocortin 4 Receptor 2018).

Research on the other members of the melanocortin family describes the involvement of MC2 and MC3 receptors in the management of caloric intake and food consumption. MC2R, which is mainly located in the adrenal cortex (Table 69.2), is believed to be involved in the control of the glucocorticoids—so-called "stress hormones" that are responsible for helping the immune system, regulating the blood sugar level and help triggering nerve cell signaling in the brain (Webb and Clark 2010). Of the melanocortin receptors involved in weight regulation, MC3R remains the least characterized in terms of its physiological role(s).

Reports on knockout MC3R mice showed an increase in adiposity, which is believed to be

Table 69.2 Melanocortin Receptor Expression: The affinity of natural melanocortin ligands for their receptors, measured by radioligand binding, plus the distribution of melanocortin receptors in rodent tissues (inspired by (Millington 2006; Abdel-Malek 2001))

Ligand	Melanocortin receptor affinities	Melanocortin receptor expression
MC1R	αMSH >> ACTH, βMSH, γMSH	Melanocytes, macrophages, adipocytes, keratinocytes, fibroblasts
MC2R	ACTH	Adrenal gland, adipocytes
MC3R	γMSH > αMSH and βMSH	Brain, placenta, duodenum, pancreas, stomach
MC4R	βMSH > αMSH >>> γMSH	Brain, spinal cord, muscle
MC5R	as for MC1R, with lower affinity	Brain, sebaceous glands, adrenal, spleen, thymus, testis, ovary, muscle, adipocytes, mast cells

unrelated to the obesity phenotype of MC4R since investigations on the deletions of both MC3R and MC4R revealed an accumulative effect of adipose tissue. Contrary to what was observed for MC4R, MC3R knockout mice showed a susceptibility to weight loss, indicated by a decrease in lean mass (Huszar et al. 1997; Wang et al. 2000; Marks et al. 2006). Separate studies on MC3R suggest that this receptor has a meaningful role in energy homeostasis, immune response, and circadian rhythm (Leoni et al. 2008; Getting et al. 2008). Loss of MC3R has also been suggested to decrease the non-resting energy expenditure. Knockout MC3R mice exhibited a higher respiratory exchange ratio. On another report, it was shown that MC3R−/− mice become glucose intolerant, hyperglycemic, and hyper-insulinemic, despite normal response of the liver to an elevated insulin, indicating a unique diabetic phenotype (further reports on MC3R (Renquist et al. 2011; Begriche et al. 2009)). No obvious role for MC3R haploinsufficiency in human obesity has been elucidated so far (Girardet and Butler 2014).

Hormones and Biomolecules

The melanocortin pathway is highly relevant for CNS management of food intake. Two neuronal populations in the arcuate nucleus of the hypothalamus (ARH) are involved: those producing neuropeptides and those expressing the melanocortin-4 receptor. The anorexigenic POMC neurons release α-melanocyte-stimulating hormone (α-MSH) to stimulate MC4Rs, while the orexigenic agouti-related (AgRP) neurons release AgRP, with opposite properties. AgRP co-localizes with neuropeptide Y (NPY) (NPY/AgRP neurons) (Fig. 69.1) (Xiang et al. 2010;

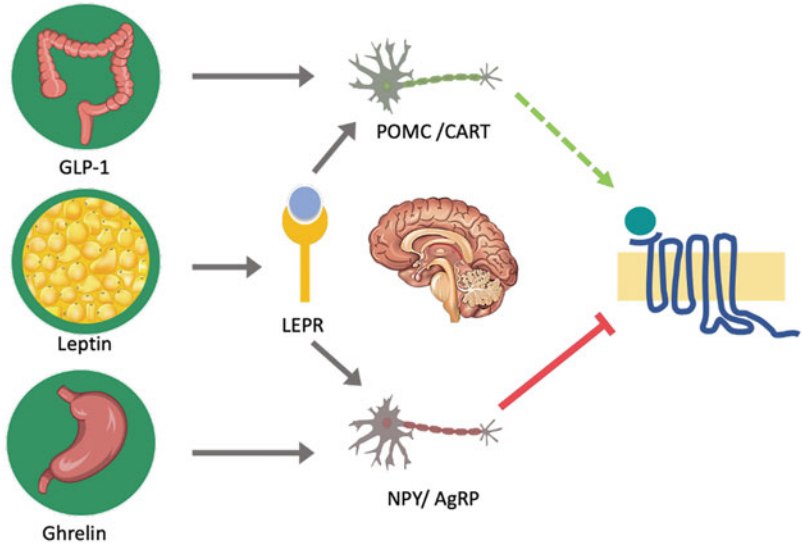

Fig. 69.1 Central regulation of appetite control and energy expenditure. Numerous peripheral signals, such as leptin, ghrelin, NPY, and glucagon-like peptide 1 (GLP-1), activate neurons in the ARH. Leptin is secreted by adipose tissue and stimulates leptin receptors (LEPR) in the arcuate nucleus. Thereby, POMC-expressing neurons are stimulated, promoting secretion of MSH. MSH triggers MC4R expressed in the paraventricular nucleus, regulating satiety, energy expenditure, blood pressure, and growth. In parallel, LEPR inhibits AgRP-expressing neurons, which are also localized in the ARH. AgRP has been suggested as an inverse agonist or antagonist at the MC4R (Kühnen et al. 2019)

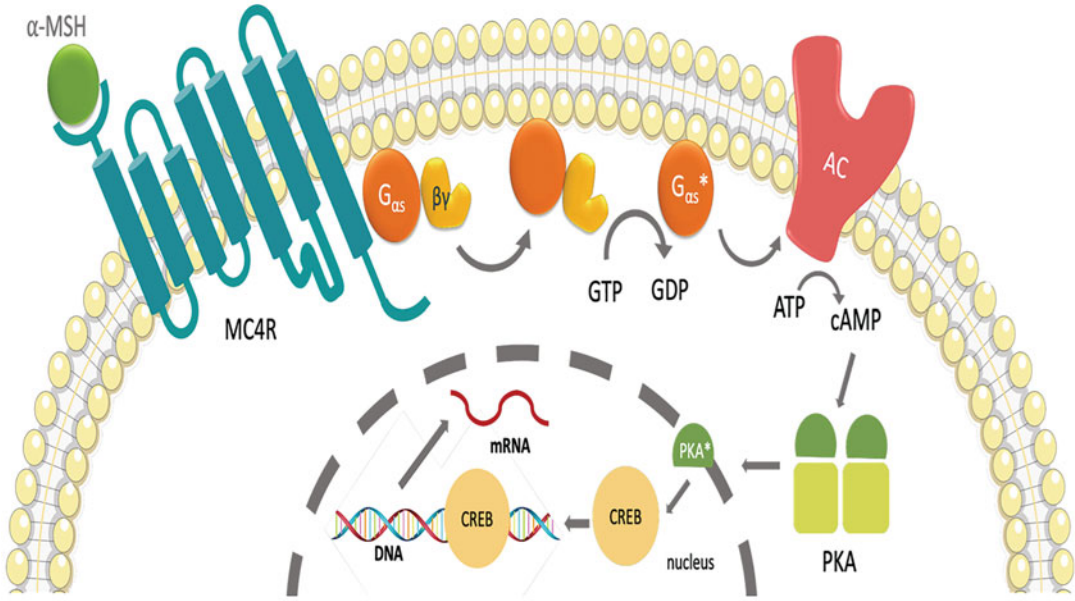

Fig. 69.2 Schematic representation of the GPCR G_s-mediated signaling cascade: Schematics for canonical cAMP signaling cascade as a mechanism for melanocortin-mediated regulation of gene expression. α-MSH stimulation of melanocortin receptors leads to activation of the α-subunit of the stimulatory heterotrimeric G-protein, $G_{\alpha s}$, and the subsequent activation of adenylyl cyclase (AC) enzymes, which convert ATP in cAMP. cAMP-mediated activation of protein kinase A (PKA) leads to the dissociation of the catalytic subunit of the PKA complex. Upon translocation of the active PKA catalytic subunit into the nucleus, PKA can phosphorylate the transcription factor CREB (cAMP Response Element-Binding Protein; CREB-P denoting the phosphorylated variant). When bound to an upstream consensus, DNA sequence called cAMP Response Elements (CREs) CREB-P can facilitate transcription of a gene by interaction with the core transcriptional machinery (adapted with permission from Gonçalves JPL, Palmer D, Meldal M, MC4R Agonists: Structural Overview on Antiobesity Therapeutics, https://doi.org/10.1016/j.tips.2018.01.004)

Millington 2007; Anderson et al. 2016; Williams and Elmquist 2012).

The most frequent genetic causes of severe human obesity are heterozygous mutations in the coding sequence of the serpentine melanocortin-4 receptor, which often causes total or partial loss of receptor function and ambiguous receptor activity (Farooqi et al. 2003); therefore, the MC4R system is often targeted for pharmacotherapy (Panaro and Cone 2013; Gonçalves et al. 2018). The natural regulating hormones (Table 69.2), such as the melanocyte-stimulating hormones, were the first studied. However, imbalance in MSH can result in hyperpigmentation and Addison's disease (Gonçalves et al. 2018; Tao 2010).

Signaling Pathways

Among the signaling pathways of melanocortins, the G-protein cascade deserves emphasis (Fig. 69.2) (Eves and Haycock 2010; Tao 2014). The bound receptor activates the alpha subunit of the G-protein complex, whereby effector enzymes release second messengers sequentially mobilizing effector proteins, including kinases, ion channels, and additional enzymes (Calebiro et al. 2009).

Despite the varied nature and function of GPCRs, only four G-protein paths have been assigned a nomenclature based on the subset of $G_{\beta\gamma}$ subunits activating the pathway: with the subsets being G_s (stimulatory), $G_{i/o}$ (inhibitory), $G_{q/11}$, and $G_{12/13}$. Of particular relevance to

MC4R is the G_s family, which is based on cAMP synthesis, conducts to both short- and long-term effectors (Hepler and Gilman 1992; Lalli and Sassone-Corsi 1994).

Protein kinases (PKA) are effectors relevant for ion channels, kinases, enzymes, and scaffolding/structural proteins, influencing transcription and other cell functions. cAMP response element-binding protein (CREB) and related proteins are involved in the transcription pathway (Imamura et al. 2017).

In addition to PKA isoforms, cyclic nucleotide-gated ion channels, such as Kv11.1, can modulate membrane polarity. Within such circumstances, cAMP electrically modulates sensitive cells. cAMP also binds strongly to guanine nucleotide exchange factors that facilitate the conversion of other small G-proteins, a class distinct from the receptor-coupled heterotrimeric G-proteins, to an activated GTP-bound state. Mesuring receptor activation through cAMP or some of its downstream signaling events is the most usual monotoring approach (Gonçalves et al. 2018).

Over the last 5 years, there have been an increasing number of reports confirming existence of different signaling cascades for MC4R activation (Tao 2014; Lotta et al. 2019; Yang and Tao 2017).

Interpretation of pharmacological studies can be biased when cell-specific effects on differential propagation of signaling responses are not taken into consideration. Some mutations causing gain of function are associated with protection from obesity (Lotta et al. 2019). Enhanced β-arrestin-mediated signaling rather than $G_s\alpha$ signaling was detected with some of such mutations. Natural variants of MC4R affecting signaling and the degree of β-arrestin recruitment to MC4R account for a large proportion of the variation in genetic association of these variants with obesity and diabetes risk.

In another study, seven human obesity phenotypes were associated as class V variants of the MC4R (Gillyard et al. 2019) providing evidence of other G-protein-dependent and G-protein-independent signaling cascades. The authors also underlined the impact of loss of β-MSH for the normal regulation of energy homeostasis, and advance a model where the recruitment of β-arrestin is a marker of normal MC4R function, in contrast to the results of Lotta *et al*. These results suggest a broader range of signaling responses than what it is known or assumed today.

MC4R exhibits a significant degree of constitutive activation of the $G_s\alpha$ signaling pathway, by the receptor's amino terminal domain, potentially inhibited by the melanocortin-2 receptor accessory protein (MRAP2), which also enhances response to α-MSH action (Anderson et al. 2016; Tao 2014; Srinivasan et al. 2004).

Like many other GPCRs, MCRs likely exist as a higher ordered multimers and particularly as dimers (Mondal et al. 2013; Piechowski et al. 2013). This has inspired the development of bivalent ligands that presumably can activate dimeric receptors and may yield improved agonists and antagonists (Fernandes et al. 2014; Lensing et al. 2016).

It is speculated that MC3R, MC4R, and MRAP2, all highly expressed in the hypothalamus, coordinate to regulate the energy homeostasis, yet further studies are necessary to develop successful pharmacologic interventions (Ghamari-Langroudi and Cone 2011).

Agonists with Potential Therapeutic Interest and Clinical Trials

As previously mentioned, MC4R is activated by POMC-derived peptides (Anderson et al. 2016). These peptide ligands derive from the proteolytic processing of POMC, including adenotropic hormone (ACTH) and the melanocortin-stimulating hormones beta (β-MSH) and gamma (γ-MSH). ACTH can be further processed to α-MSH which has a prominent role in the regulation of MC4R.

α-MSH is predicted to bind in a β-turn conformation, which presents the His-Phe-Arg-Trp motif for optimal binding with the receptor binding pocket, specifically with the transmembrane domains between TM2 and TM3 (Haskell-Luevano et al. 2001; Igel et al. 2017). This motif appears in several synthetic agonists. Cyclic

peptidomimetic structures have also been developed yielding a higher degree of potency, resembling the β-turn conformation of the natural agonist (α-MSH), providing a good fit in the receptor pocket. Despite having less potency, non-peptide agonists showed better selectivity, paving the way for additional molecular structures (Gonçalves et al. 2018).

Prior to 2012, few drugs had been approved by the Federal Drug Administration for obesity management. Often obesity was associated with an unhealthy lifestyle choice and not fully accepted as a disease. As the endogenous pathways governing these processes have been elucidated, obesity has been better established as a serious disorder and as such, pharmacotherapeutics have been accepted as a treatment approach with several more potential pharmacophores under evaluation in clinical trials. Currently, clinical trials evaluating Setmelanotide (RM-493 developed by Rhythm Pharma) are underway for the treatment of Leptin Receptor Deficiency Obesity, Pro-opiomelanocortin (POMC) Deficiency Obesity, Bardet-Biedl Syndrome, Alström Syndrome, and Smith-Magenis Syndrome. Unlike other drugs based on Melanotan-II, Setmelanotide does not increase blood pressure.

Some of the most promising structures for activation of MC4R developed over the last decade are summarized in Table 69.3.

Upon closer look at the most potent and selective candidates, it is possible to see the repetition of the motif, -His-D-phe-Arg-Trp-. Generally, the use of positively charged groups and three aromatic moieties, including the -His-D-phe-Arg-Trp- motif, are typical of synthetic MC4R agonists, in order to retain the core from the natural pharmacophore. In recent structures, however, more charged residues have been employed and have yielded enhanced selectivity, potency, and conformational preference.

Taking into account that MC4R also governs other body activities, namely sexual desire and neuropeptide regulation, any therapeutic targeted toward MC4R will need to find a way to minimize the activation of these additional pathways while maintaining robust activation of pathways shaping metabolism (Tao 2010).

Despite several efforts, there is still not a drug in the market targeting MC4R for the treatment of obesity. Nonetheless, advances in identifying optimal structural properties for ligands, paired with a deeper understanding of the signaling mechanisms that best shape desired physiological responses, promise to offer better MC4R-targeted therapeutics.

Diabetes as a Consequence of Obesity

Roughly 30% of overweight people have diabetes, whereas 85% of diabetics are overweight. In the USA, diabetes affects nearly 1 in 10 adults, with a majority (90%–95%) of the cases being type 2 diabetes (T2D). Diabetes induced by excess weight often requires lifelong chemical treatment, besides the possibility of cardiovascular complications, microvascular vision

impairments (glaucoma, retinopathia, cataracts), and kidney dysfunction, among others, justifying the investigation of MC4R and insulin resistance (De Carvalho et al. 2017; Chen et al. 2019).

Nucleotide polymorphisms near the MC4R gene have been strongly associated with T2D. There is robust epidemiological evidence that rs17782313 polymorphism is significantly associated with increasing risk of T2D (Xi et al. 2012). In mice with a homozygous $G_s\alpha$ deficiency in MC4R-expressing cells, impaired glucose tolerance and elevated insulin response were unearthed, suggesting that $G_s\alpha$ signaling in MC4R-expressing cells directly disturbs glucose tolerance and insulin sensitivity (Podyma et al. 2018; Al-Goblan et al. 2014).

Mice with POMC and MC4R deficiency released epinephrine and glucagon as response to hypoglycemia and glucopenia. In addition, diabetic mice showed decreased POMC and MC4R expression and a deficient counter regulatory response (Tooke et al. 2019) and this phenotype was not normalized with insulin treatment. On the other hand, when injected in the paraventricular hypothalamic nucleus with a MC4R agonist, the counter regulatory response was restored.

Perspectives

The melanocortin-4 receptor has a pivotal role in energy homeostasis and adipose tissue regulation. Nevertheless, this is a complex receptor class with diverse signaling cascades. There is not enough consensus about the role of certain proteins, such as β-arrestin, in the signaling mechanism. Understanding about GPCRs signaling pathways and specifically, how melanocortin receptors can be controlled are clear priorities, along with elucidation of the effects of mutations on MC2R and MC3R in the feeding behavior.

Melanotan-II and Bremelanotide did not survive clinical trials. Melanotan-II promoted intracellular synthesis of eumelanin in favor of pheomelanin which gave a darker skin pigmentation and also caused penile erection, while Bremelanotide is now being tested for the treatment of female sexual dysfunction. Currently, Setmelanotide is undergoing phase-III clinical trials.

New agonists with charged residues and aromatic moieties provided the most promising agonists, while non-peptide-derived candidates allowed for more selective ligands. Additionally, cyclic structures should be further considered because of the conformational preference for the receptor's binding site. Activation of the most appropriate signaling pathway for the physiologic effect should be highlighted, as biased agonists may offer the means for avoiding unwanted effects.

Supplementary evidence on the existence of multiple binding sites or receptor multimers is also needed, alongside with the receptor crystal structures.

Nanotechnology: Can It Be a Crusader in Diabesity?

70

Alexis Marie Speer and Mahua Choudhury

Contents

Abstract

Research in nanotechnology has been slowly expanding. It allows for expansion of work on a molecular scale. There has been success in targeting adipocytes, macrophages, fibroblasts, and vascular cells, which are related to diabetes and obesity pathophysiology. Development in nanosensors for usage in diabetic monitoring could provide better real-time monitoring and early detection of progression for patients, and this technology could help in earlier, life-saving intervention. In conclusion, nanotechnology could lead to the development of new treatments or novel prevention of diabesity in the near future.

Introduction

Current treatments for obesity and diabetes (diabesity) rely on lifestyle changes, surgery, and pharmacotherapy. There is an emphasis on diet modifications and increased exercise; yet, few American citizens have healthy nutrition or activity levels, with only 28% women and 20% men eating at least five servings of fruit and vegetables per day. Additionally, approximately 60% of adults are believed to not be engaged in sufficient levels of physical activity to provide health benefits. Due to low adherence to healthy living, there is a need to search for alternative therapy approaches to treat or prevent obesity, diabetes, and metabolic syndrome (Carbone et al. 2019).

Limitations of Current Pharmacological Therapies

Pharmaceuticals on the market for obesity treatments target weight management and progression prevention of its related diseases. These drugs work on the central nervous system (CNS) and gastrointestinal system (GI) to either suppress appetite, inhibit fat absorption, or increase energy expenditure and consist of both short-term and long-term therapies (Sibuyi et al. 2019). However, the effectiveness of obesity pharmaceutical treatments is questionable due to the side effects seen in these therapies. This has resulted in withdrawing patients from certain drugs and removal of others from the market due to their poor efficacy and nonspecificity. An example of this was the use of amphetamine analogs, sympathomimetics, and cannabinoid agents as anti-obesity therapies, where their side effects of cardiac valve defects, pulmonary hypertension, stroke, addiction liability, abuse potential, and psychotic behaviors resulted in withdrawal from the market (Sibuyi et al. 2019; Smith et al. 2020). Some agents used for anti-obesity purposes that remain on the market are Orlistat, a lipase inhibitor, and Liraglutide, a GLP-1 receptor agonist, as long-term treatment options [40]. Phentermine, diethylpropion, and benzphetamine are some examples of obesity short-term treatments [40]. Undesirable side effects of these medications that can lead to reduced efficacy and adherence include oily spotting, fecal urgency, pancreatitis, increased heart rate, fecal incontinence, insomnia, and restlessness. The side effects of Orlistat have caused a recommended limited use of not more than 2 years. Another shortcoming of current anti-obesity drugs is the failure to maintain a weight loss of over 10% in a year, with most FDA-approved drugs being discontinued due to the failure for patients to lose at least 5% of their body weight within 12 weeks of initiation of therapy (Smith et al. 2020; Dehdari and Dehdari 2019).

Diabetes Overview

Type 2 diabetes (T2D) has a variety of oral antidiabetic medication treatment options such as Metformin, Glinides, α-Glucosidase inhibitors, Thiazolidinediones, and Sulfonylureas, which carry a risk of side effects including hypoglycemia, β-cell death, pancreatitis, GI reactions, cardiovascular effects, and central nervous system effects (Smith et al. 2020; Vasan et al. 2018; Shi et al. 2010). T2D treatments usually begin as a monotherapy if nonpharmacological measures alone fail, followed by combination therapy if monotherapy proved to be insufficient (Veiseh et al. 2015).

Diabetes management can be complex and challenging. The goal of therapy is to prevent or delay further complications because of uncontrolled blood sugar levels, but the medication burden, monitoring schedules, and lifestyle change requirements make treatment plans strenuous. Adherence to oral antidiabetic medications ranges from 36% to 93% and to insulin approximately 60% (Dehdari and Dehdari 2019;

American Diabetes Association (ADA) 2019). Poor adherence could be contributed to many factors such as medication cost, medication regimen complexity, and side effects, as seen in studies linking low treatment adherence to oral antidiabetic medications and to the fear of side effects and to insulin, due to the injection itself and its storage being very difficult (Ash et al. 2019; Capoccia et al. 2016). Therefore, alternative therapies are warranted to prevent the diabesity epidemic.

Nanotechnology Promise

Scientists and engineers of varying backgrounds have discovered ways to manipulate materials down to the atomic level. Since these newer methods and technology involve working on such a minute scale, the terms 'nanotechnology,' 'nanoscale,' and 'nanoscience' have come into creation. Emerging fields involving nanotechnology hold promise of a wide range of biomedical applications including enhancing current treatment methods or creating new, more efficient therapies for many chronic disease states including diabetes and obesity (Sibuyi et al. 2019; Shi et al. 2010; Veiseh et al. 2015; Ash et al. 2019; Devadasu et al. 2013, 2017).

Pharmacological Applications

Potential nanotechnological impacts in treatments could be to improve drug encapsulation, protect the payload from degradation, improve solubility, and target specific disease areas (Ash et al. 2019; Devadasu et al. 2013, 2017). Nanodrugs and nanotechnology developments have been used in successful treatment and detection of chronic diseases and conditions (Sibuyi et al. 2019; Shi et al. 2010; Veiseh et al. 2015; Ash et al. 2019; Devadasu et al. 2013, 2017). Fields of interest encompass emesis, infectious diseases, autoimmune diseases, lipid regulation, immunosuppression, and especially cancer (Marta et al. 2016). Nanostructured contrast agents have been used in cases of cancer for targeted specificity and optimal sensitivity for diagnosis, using imaging techniques like optical imaging, radionuclide-based imaging, and computer tomography or magnetic resonance imaging (Shi et al. 2010; Devadasu et al. 2013; Marta et al. 2016).

Cancer, diabetes, and obesity can share a few characteristics such as hyperinsulinemia, hyperglycemia, inflammation, and compromised vascular system angiogenesis, suggesting the potential for nanomedicine to also work in cases of obesity and diabetes (Cui et al. 2015). Obesity and diabetes treatments have benefited thus far from strategies used in cancer treatment, and so there is promise that obesity treatments could benefit from nano-based antiangiogenic, antineoplastic, and transdermal therapies that have been originally used in cancer treatments (Sibuyi et al. 2019; Shi et al. 2010; Veiseh et al. 2015; Devadasu et al. 2013, 2017; Cui et al. 2015; Giovannucci et al. 2010; Lee et al. 2017; Sheng et al. 2014).

Defining 'Nanoscale'

The prefix 'micro-' originates from the Greek word *mikros* meaning "small" and is valued at 10^{-6} m. Here, on this scale, things begin to fall out of focus of the human eye. The diameter of a typical bacterium can range from 10^{-5} m to 10^{-6} m, the mean width of human hair is 8×10^{-6} m, and a nucleus of a typical eukaryotic cell is 7×10^{-6} m (Deza and Deza 2006).

The prefix 'nano-', from the Greek word *nannos*, means "dwarf". A nanometer is 10^{-9} m and can be used to refer to the size of molecules. The diameter of the DNA helix is 2×10^{-9} m, the diameter of known viruses range from 2×10^{-8} m and 8×10^{-7} m, and the limit of resolution of the light microscope is 2×10^{-7} m (Deza and Deza 2006). 'Nano' is used to indicate a scale at one-billionth of the *SI base units*, or the size in which nanotechnology functions, and operates (Allhoff et al. 2010).

Origins of Nanotechnology

One of the first traces of the concepts of nanotechnology is found in 1959 in a speech given by American physicist Richard Feynman. He discusses "*a field, in which little has been done, but in which an enormous amount can be done in principle.*" His talk, called "There's Plenty of Room at the Bottom," introduces how it could be possible to manipulate and control things on a small scale or more specifically on a *nanoscale*. Though not all concepts and ideas Feynman introduced in his speech were how the nanotechnological field expanded, he is still considered one of the many founders of nanotechnology (Allhoff et al. 2010).

The actual term 'nanotechnology' was not first coined, though, until 1974 by a professor of the Tokyo University of Science named Norio Taniguchi. Taniguchi' s paper "On the Basic Concept of 'Nano-Technology'" discusses the use of nanotechnology in semiconductor processes such as thin film deposition and ion beam milling (Taniguchi 1974).

Then, in 1987, American engineer K. Eric Drexler released his book "The Engines of Creation: The Coming Era of Nanotechnology," where he offers an introduction to the field of nanotechnology and where he sees the opportunities for the field to expand (Drexler 2000) (Fig. 70.1).

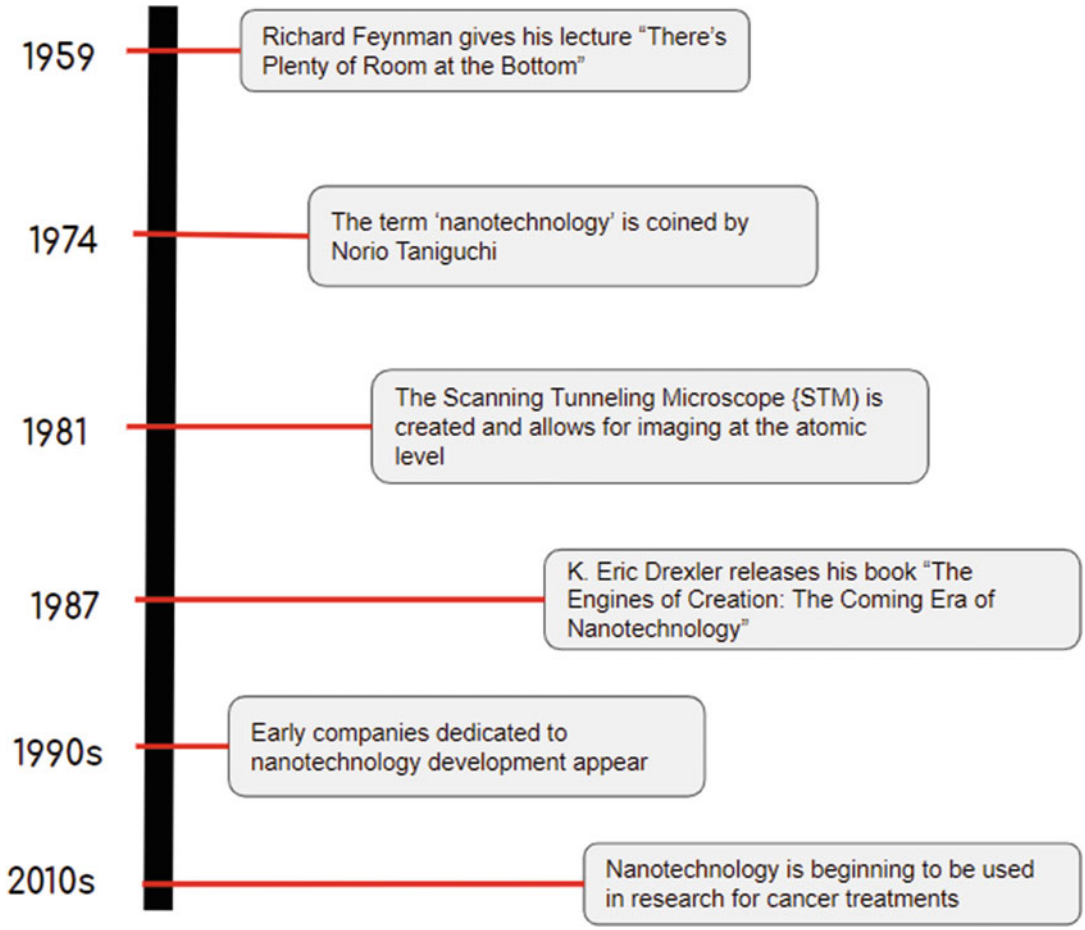

Fig. 70.1 A short preview timeline of the usage and development of nanotechnology

Nanotechnology Advances for the Treatment of Diabetes

Polymer therapeutics, micelles, liposomes, solid lipid nanoparticles, and nanoparticles of biodegradable polymers are examples of current nanotechnology-based insulin delivery methods that have caught many researcher's attention as a potential way to deliver noninvasively. There is also promise of prolonging insulin's duration of effect through nano-technological methods. Liposomal insulin has been tested in animals, and it has been tested orally. Compared to its free form, liposomal insulin has shown to be more bioavailable due to protecting insulin molecules from gastrointestinal degradation (Devadasu et al. 2013, 2017; Cui et al. 2015; Disanto et al. 2015; Liu et al. 2007).

Artificial Pancreas

The artificial pancreas is a closed loop delivery of insulin intended to provide constant measures of insulin throughout the day, triggering the release of insulin when sensors detect high glucose levels. This could offer a permanent solution for T1D patients or some cases of T2D. Setbacks of this development include the reliance on a sensor electrode that is capable of repeatedly measuring blood glucose along with the need to feed the information to a computer database that can activate the insulin release at a calculated amount based on the body's need (Cash and Clark 2010). An alternative to an artificial pancreas would involve prolonging the insulin delivery to the body's changing levels of glucose through the development of nanodrug delivery systems.

One such system is theorized to be composed of glucose-sensitive nanoparticles, which holds the possibility of releasing insulin in response to undesired high glucose levels (Rodbard 2016). Through this controlled release provided by nanoparticles, insulin's action could be extended, replacing the need for multiple injections (Cash and Clark 2010; Rodbard 2016; Wang and Lee 2015; Chen et al. 2017; Scognamiglio 2013; Rahiman 2012).

Biological Nanosensors and Diabetes Monitoring

Glucose monitoring devices have been developed through the usage of nanotechnology, which consist of a detector, a transducer, and a reporter that operate through the use of canulae or sensors placed under the skin, which monitor glucose multiple times throughout the day, with only needing a single insertion (Cash and Clark 2010; Rodbard 2016; Wang and Lee 2015; Chen et al. 2017). These devices hold the potential to provide real-time measurements of glucose levels in the blood or interstitial fluid, which can be more beneficial and accurate for diabetic patients, but there is room for improvement in the accuracy and specificity to properly achieve real-time detection, which can be offered through developments with nanotechnology (Cash and Clark 2010; Rodbard 2016; Wang and Lee 2015; Chen et al. 2017; Scognamiglio 2013; Rahiman 2012) (Fig. 70.2).

Current sensor devices used for diabetic monitoring also have limitations of surface area, catalytic activity, and size that can be addressed through the usage of nanotechnology, which could be a means to increase the surface area for the sensors and increase the catalytic activity of

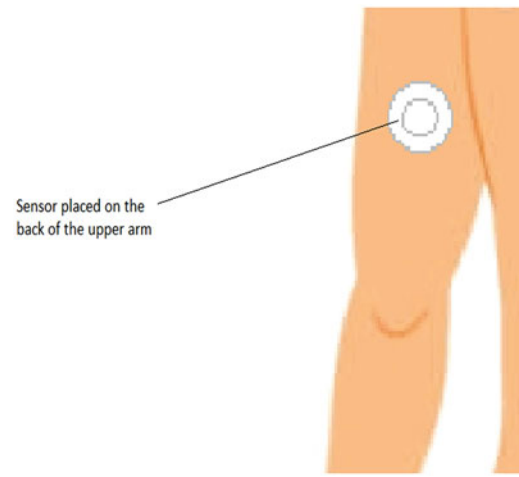

Fig. 70.2 Sensors are placed on areas of the back of the upper arms and the abdomen. These sensors measure interstitial glucose levels every few minutes throughout the day, providing continuous readings

the electrodes. Minimally invasive real-time glucose sensing electrochemical devices, intended to be a nanoscale implant under the skin, are being investigated [36]. Nanoparticle-based glucose sensors use enzymes such as glucose oxidase, or glucose binding proteins, and glucose binding small molecules as transducers. This enables a more convenient, precise, and rapid sensor method desired for the real-time measurements of glucose monitoring, by achieving larger signal enhancements and lower detection limits (Devadasu et al. 2017; Cao et al. 2016).

Smart Tattoos

There has also been development in using nanofibers as a means to provide noninvasive glucose readings in the form of smart tattoos, which are designed as skin implants that can provide continuous and reliable glucose monitoring for diabetic patients (Meetoo et al. 2019). Smart tattoos consist of biosensors made of nanofibers created primarily from electrospinning technology and alternating layer-by-layer deposition technique (Sibuyi et al. 2019; Shi et al. 2010; Veiseh et al. 2015; Devadasu et al. 2013; Cui et al. 2015; Giovannucci et al. 2010; Lee et al. 2017; Sheng et al. 2014). Usage of the layer-by-layer technique requires deposition of alternating layers of positively and negatively charged polymers, which results in a thin film with high activity. Six biolayers often achieve a thickness of 10 nm, implanted into the subcutaneous layer as seen in Fig. 70.3 (Meetoo et al. 2019).

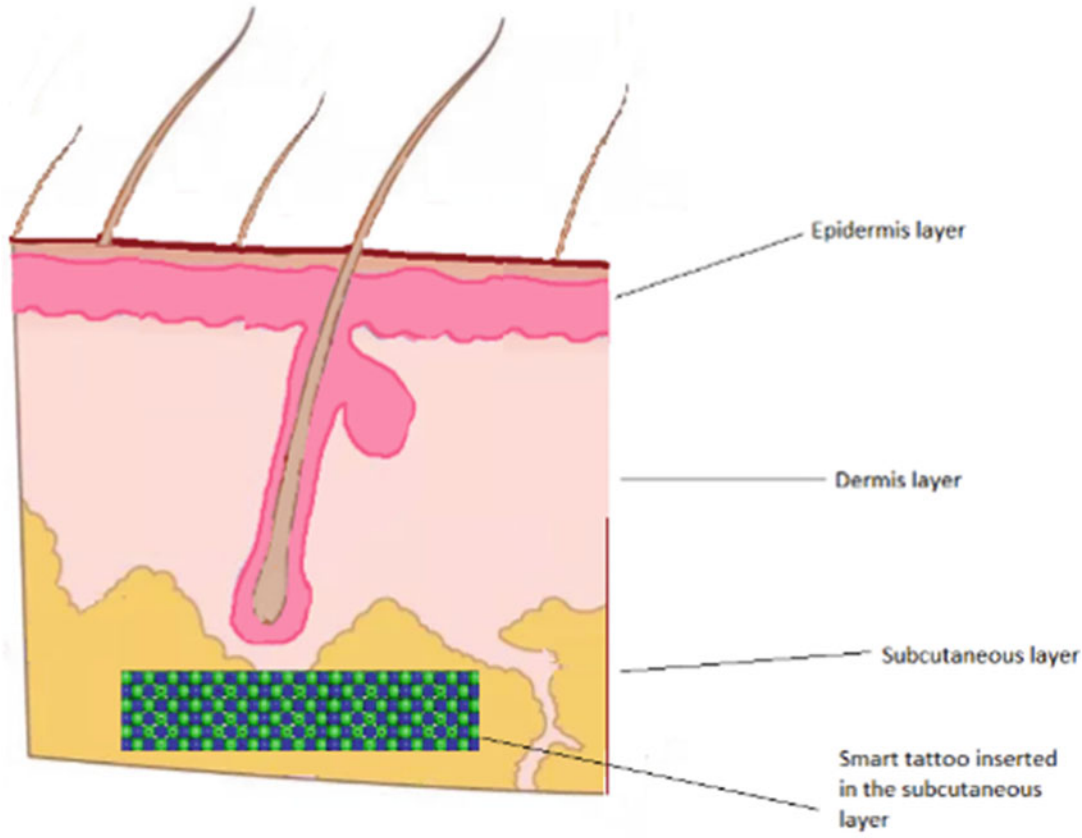

Fig. 70.3 Smart tattoos are inserted into the subcutaneous layer for glucose monitoring

Pancreatic Beta Cell Mass

Currently, the only way to measure β cell mass is by excising tissue samples from patients. A new development proposes a noninvasive method of quantifying β cell mass loss. This could be done by targeting β cells with superparamagnetic iron oxide nanoparticles, developed by the attachment of targeting moieties that can detect β cell mass noninvasively through magnetic resonance (Laurent et al. 2016). Using this method would allow for better monitoring of disease progression and can better prepare physicians for future treatment plans. For example, some medications have been known to exacerbate the death of β cells. Having the knowledge of the extent of death as a patient's disease state progresses could help signal to physicians when to change or avoid certain therapies.

Nanotechnology Targeted Treatment for Obesity

Interventions would target the various disordered molecules secreted or expressed by the cells that make up white adipose tissue (WAT), namely, adipocytes, macrophages, fibroblasts, and vascular cells. This could also potentially lead to further insight into the pathophysiology, prevention, and management of obesity and its comorbidities and provide improvement of the efficacy of existing therapies on and off the market (Sibuyi et al. 2019; Shi et al. 2010; Veiseh et al. 2015; Ash et al. 2019; Devadasu et al. 2013, 2017).

Inorganic nanoparticles could serve as a vector for delivery or as a treatment for obesity due to their physicochemical properties. Examples of inorganic nanoparticles include gold GNPs, iron oxide, mesoporous silica (MSNs), and calcium phosphate (Lee et al. 2017). Cerium oxide nanoparticles have been investigated, as they are linked to inhibiting adipogenesis through the reduction of mRNA transcription of obesogen genes and triglyceride accumulation. This process is expanding on the idea that oxidative stress contributes to the development of obesity, and so through the approach of inhibition, weight loss and a decrease in levels of insulin, leptin, glucose, and triglycerides in plasma have been demonstrated (Rocca et al. 2015).

Lipid Nanoparticles

Therapeutic characteristics are also present in lipid nanoparticles, which are biocompatible, form bilayers for encapsulation, and offer a method of fusion with the cell membrane for delivery (Zu et al. 2018). Lipid nanoparticles also allow for improved solubility due to their amphiphilic components. For instance, there have been investigations in using trans-resveratrol (R), an anti-obesity drug in development that induces browning in WAT. Figure 70.4 shows the theoretical process of how these nanocarriers assist in WAT browning.

Prohibitin (PHB)-targeted therapy (Veiseh et al. 2015) employing nanoparticles is also investigated. It is a 30-kDa protein that plays roles in cell proliferation, endothelial reticulum (ER) stress, transcription, apoptosis, and tumor suppression and is expressed in various compartments of the cell such as the mitochondria, nucleus, ER, the Golgi complex, and plasma membrane. PHB has been found in several reports to be overexpressed in obesity, cancer, and even in diabetes, suggesting a pleiotropic effector role in immunometabolism for these conditions (Cao et al. 2016).

Conclusion

In conclusion, nanotechnology provides healthcare professionals with the opportunity to provide a higher level of patient care by providing a wider range of treatment options that would resolve issues such as compliance. There is also a significant chance to halt progression of comorbidities seen with obesity and diabetes, as

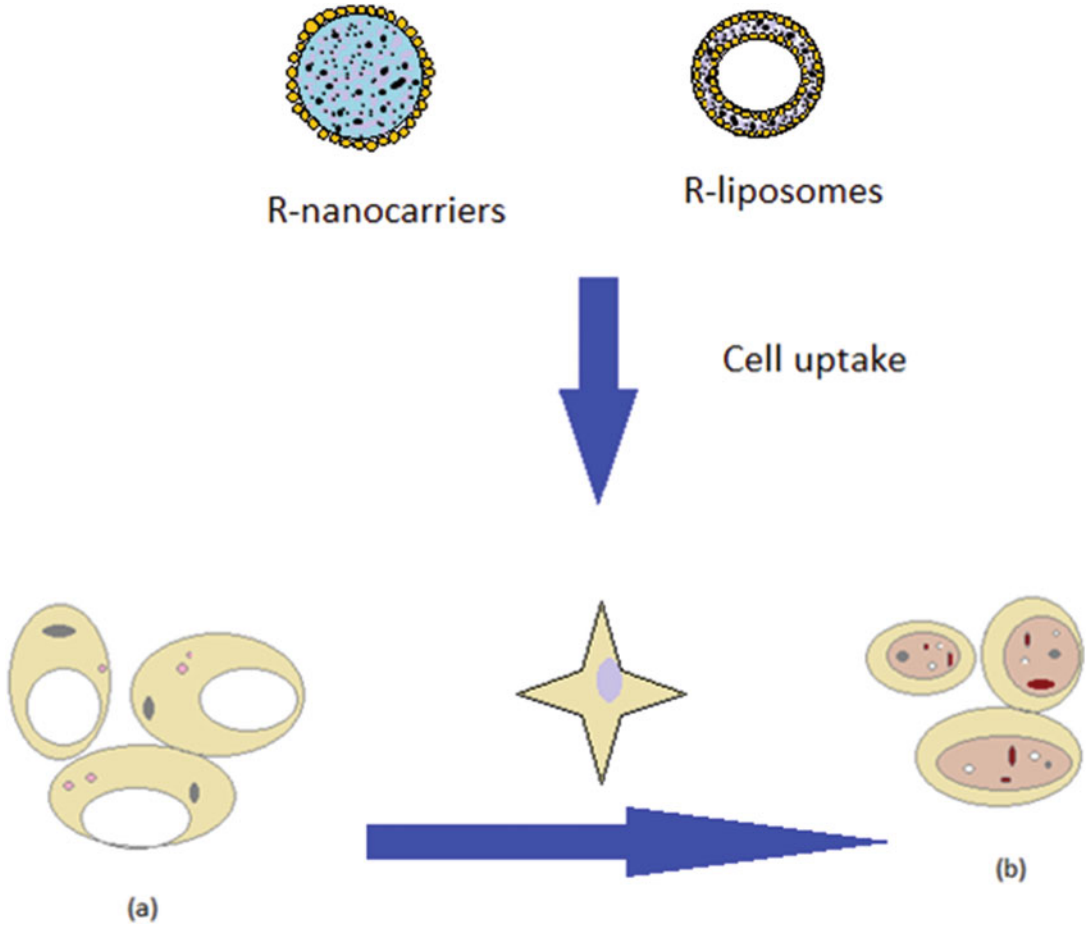

Fig. 70.4 Larger, white adipose tissue with noticeable single lipid droplet (**a**) is converted to smaller, brown adipose tissue with small lipid droplets and more mitochondria (**b**)

many researchers are looking to develop early detection techniques for these double epidemics .

Obesity Devices and Supplemental Material

Old and New Anti-obesity Devices for Medical, Surgical, and Endoscopical Use

71

Joel Faintuch and Salomao Faintuch

Contents

Abstract

The advent of surgical interventions in the 1950s to mechanically (and nonmechanically) prevent and treat obesity was received by certain health care professionals with shock, looking risky and disproportionate for an imbalance between calorie intake and expenditure. Newer anti-obesity devices run the gamut from merely curious to relative aggressive, sometimes reenacting a similar degree of surprise and disbelief. Nevertheless, they are not mere curiosities or experimental musings, but actual therapies are available for selected candidates. This chapter reviews a current sample of oral, intragastric, intrajejunal, and swallowable products, with the corresponding usage and contraindications.

Keywords

Dental wiring · Palate prosthesis · Intragastric devices · Temporary duodenojejunal bypass · Space-occupying swallowable capsule

Introduction

Anti-obesity devices seem to be as novel as the obesity epidemic itself, with a history of commercialized products spanning a couple of decades at most. Indeed, those in current use are mostly recent, given the shortcomings of historical models. Nevertheless, mechanical attempts to reverse overweight and obesity, or more precisely the ideas leading to the mental framework about how to accomplish it, have a long past.

Dental Wiring and Oral Intake Restriction

Few treatments seem as outlandish, or even cruel, as mechanical closing the mouth, in order to diminish food intake. No appliance ever became popular. In turn, the procedure was never entirely abominated. As officially approved devices or techniques are lacking, application is customized on a case-by-case basis. Yet, since the 1970s, reports keep appearing in the literature, even if in small numbers (Rodgers et al. 1977; Al-Dhubhani and Al-Tarawneh 2015).

Over 2400 years ago, Hippocrates already recommended jaw immobilization with gold wire (Ebooks 2019), although the indication was trauma, not adiposity. Only with the advent of modern orthodontics in the 1970s, based on brackets glued to the dental surface, easily and painlessly manipulated with elastic bands and other materials, were dentists attracted to the new possibility.

Candidates are morbidly obese subjects refractory to medical therapy, with concomitant surgical contraindications, or who abhor invasive operative or endoscopic interventions, yet are still willing to undergo much annoyance in order to improve body composition. Inconvenient the treatment unquestionably is, as it interferes not only with mastication but also with speech, jaw mobility, dental cleaning, and social life. Moreover eventual vomiting becomes risky and could lead to potentially fatal lung aspiration, even though no such cases have been registered so far (Al-Dhubhani and Al-Tarawneh 2015).

Regular visits to the dentist are mandatory, not only to prevent tooth and gum complications but also to unwire the brackets every 30 days and exercise the temporomandibular joints for a couple of days. And yes, the treatment cannot be indefinitely extended, with typical duration being around 6 months. Still, weight loss has been described as comparable to standard bariatric procedures, something potentially able to jumpstart more durable dieting and lifestyle changes (Rodgers et al. 1977; Al-Dhubhani and Al-Tarawneh 2015).

SMARTByte Palate Prosthesis Device

SMARTByte system (Sensor Monitored Alimentary Restriction Therapy) does not lock the teeth or close the mouth; however, its flattened palate cushion diminishes the volume of the oral cavity, so that smaller bites occur. The trick is accomplished by means of an intraoral tool, custom made to precisely fit the palate anatomy of the patient, so that it snuggly stays in place. It does not move nor is it swallowed, something that could otherwise precipitate choking. It is introduced and positioned by the patient himself or herself during mealtime, three times a day, being removed afterward. An embedded sensor documents compliance.

A pilot study with 76 adults, suffering from overweight or Class I obesity, was conducted during 16 weeks. Video lifestyle instruction was simultaneously provided. The protocol required at least 7 times/week use of the SmartByte, which would represent an average of one meal/day or more. At the end of the study, those who followed the protocol achieved 2.9% weight loss, contrasting with 1.5% reduction in noncompliers. One palate abrasion and two tongue lacerations were registered; however, they spontaneously resolved. The authors highlight that more frequent use than the minimum recommendation could be associated with 4% and even 5% weight reduction within a relatively short period, involving little risk (Ryan et al. 2017).

Intragastric Balloon

A well-established option for kick-starting weight loss, combined with lifestyle reeducation, or as preparation for future bariatric procedures in the high-risk super-super-obese, and its rationale are not as recent as usually believed. In the 1930s, gastrointestinal surgery was still infrequent and dangerous, as anesthesia, fluid and blood replacement as well as antimicrobials was rather primitive. Yet, emergencies such as gastrointestinal obstructions were already dealt with. Some surgeons were particularly impressed by gastric bezoars, rare and unexpected concretions formed by large amounts of swallowed hair or other nondigestible materials, often in compulsive patients with behavior disorders.

Such partially floating balls could become big enough, to intermittently impair food passage through the antrum and pylorus. Even if gastric obstruction was incomplete, vomiting, appetite reduction, and weight loss were prominent, as emphasized in surgical reports (DeBakey and Ochsner 1938). It was no coincidence that in the early 1980s, an "artificial bezoar" was nominally proposed for the handling of obesity (Nieben and Harboe 1982).

Of course, more than three decades later, materials, models, indications, and endoscopic introduction techniques are conspicuously more advanced. Currently available products are usually represented by a silicone 500 ml bag, which is endoscopically filled with saline after positioning, by means of a valve. A swallowable type also exists (Mion et al. 2013).

The swallowable device is smaller (250 ml), and covered with gelatin, for easier ingestion. It includes a thin catheter connecting the gelatin capsule to the exterior, for subsequent injection of gas. After gastric positioning is fluoroscopically confirmed, the balloon is insufflated with a special nitrogen gas mixture and the catheter is detached and removed, leaving the free-floating device in the stomach. Additional balloons (up to a total of three, amounting to 750 ml) can be swallowed in subsequent weeks, if weight loss is insufficient.

Another modality is the transpyloric shuttle device (Baronova 2019). Also much smaller than conventional gastric balloons, its main difference is a transpyloric extension till the first part of the duodenum. The purpose of this "tail" is to keep the balloon anchored in the prepyloric region, where it works as an intermittent embolus, blocking chyme passage into the intestine.

A controlled trial with 302 participants indicated substantially higher weight loss than in the sham control group, with good tolerance of the device. Of those who carried the shuttle, 66% achieved loss of 5% body weight or more (total reduction 9.3%), contrasting with just 30% exhibiting over 5% reduction among controls (total weight shift 2.8%). The product has an FDA initial approval.

Gastric balloons are temporary aids, as many other devices. After 6 or 12 months, depending on the model, they are removed. Their purpose is not to be a standalone therapy. Lifestyle interventions are mandatory, so that after loss of weight is jumpstarted, the patient will presumably comply with recommendations, adhering to a healthy diet and exercise.

Gastric Aspiration

Gastrointestinal fluid losses, as nowadays induced by gastric aspiration devices for weight-loss purposes, have a remote indirect early history. Sushruta, the author of a treatise on general and plastic surgery, lived in India around 600 BCE or 150 years before Hippocrates. He already reported some features of external gastrointestinal fistulas, indicating how important it was to repair the wound, with the help of suture materials such as tendon, hair, and silk (Saraf and Parihar 2006).

Of course, unplanned, spontaneous fistulas carry heavy morbidity and mortality, on account of unbridled dehydration, electrolyte imbalance, sepsis, tissue destruction, and malnutrition. Specifically, gastric fistulas are burdened by hypokalemic metabolic alkalosis, a condition that can lead to reduced muscle strength and nonperiodic paralysis, not unlike severe bulimia (Sung et al.

2015). The modern anti-obesity device bypasses those pitfalls by means of clean, aseptic, and titrated drainage of gastric juice, through an endoscopically introduced tube, connected to the abdominal wall.

Tube positioning is reminiscent of percutaneous endoscopic gastrostomy (PEG) placement. Indeed, a PEG tube could be used as well, although the purpose-built device is more efficient. Comparison of tube opening with bulimic episodes, during which certain patients forcefully eject their recent dietary intake by vomiting, is inevitable. However, these maneuvers are not associated with shame and guilt, analogous to other disordered eating behaviors, as they are medically directed and supervised.

The tube is conventionally opened three times a day, 20–30 min after meals, allowing food and fluid loss for about 10–15 min. The target is to remove 30% of ingested calories, thus inducing up to 20% BMI reduction in 12 months (Figs. 71.1, 71.2).

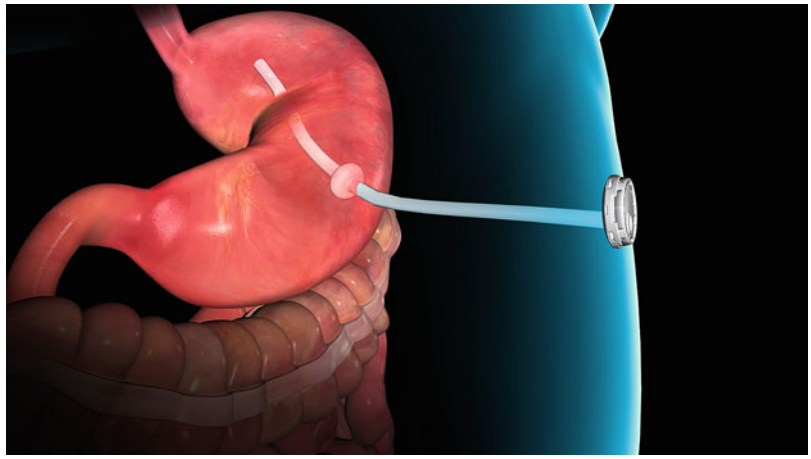

Fig. 71.1 Anatomic outline of the gastric drainage device. The tube can be accessed through an abdominal button, not unlike a percutaneous endoscopic gastrostomy (PEG). Reproduced by permission from Aspire Bariatrics.com

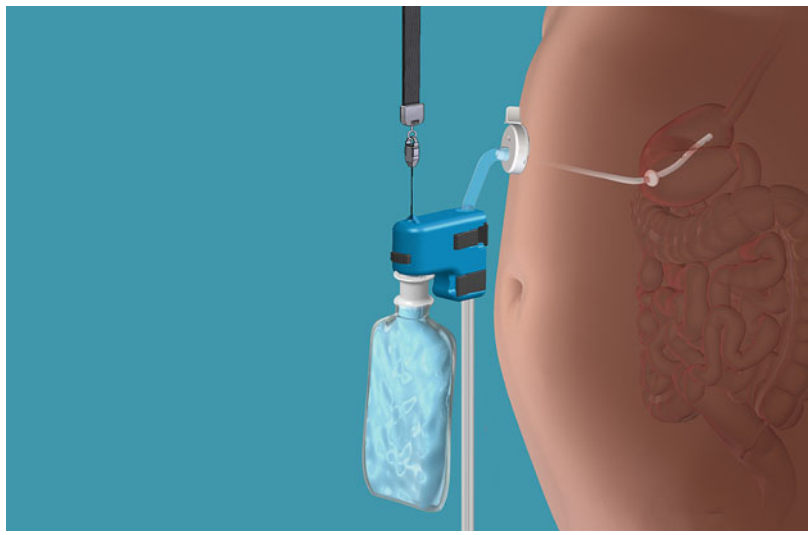

Fig. 71.2 The drainage reservoir is periodically connected to the intragastric tube, for postcibal partial evacuation of ingested foodstuffs. Reproduced by permission from Aspire Bariatrics.com

A 4-year trial has indicated safe and sustained weight loss for class II and III obesity patients (above 35.0 and 40.0 kg/m^2, respectively). There was no mortality, serious metabolic and electrolyte disorders did not occur, and tube removals as well as other complications were similarly uncommon (Thompson et al., 2019).

Nonsurgical Bypass of the Upper Gut

Operative jejunoileal bypass for obesity management was introduced by Payne and DeWind, in 1969. The roots of the malabsorptive procedure are more ancient, partly stemming from inadvertent gastroileal anastomosis in the management of peptic ulcers. As originally reported by Martin and Carroll in 1915 (Anonymous 1951), in the trying times of abdominal surgery in the early twentieth century, occasional surgeons catastrophically reconstructed the gastrointestinal continuity after Billroth II gastrectomy, using the terminal ileum instead of the first loop of jejunum. As both extremities of the small bowel are fixed, one to the colon, and the other by the ligament of Treitz, in a haste, an inexperienced surgeon can pull one instead of the other.

Such accident was followed by severe fecal loss of undigested food directly from the stomach, resulting in extreme undernutrition, requiring surgical correction. The Payne procedure was less radical, leaving 12 inches of functional ileum for a more reasonable degree of absorption. Still, the operation was virtually abandoned in the 1980s, in favor of similarly effective and better tolerated stomach-reducing alternatives.

An even more attenuated and safer alternative has now been devised, namely, the endoscopic temporary liner. The duodenojejunal bypass liner, as it is usually designated, is an impermeable, light and flexible plastic sleeve, endoscopically introduced via the stomach, so as to isolate food content from the surrounding mucosa. Digestion and absorption are consequently halted, until resumption some time later. Anchored at the pylorus by tiny hooks, and with a total length of 60 cm, it excludes the entire duodenum (roughly 30 cm), plus a couple of loops of upper jejunum. This provides a noninvasive gastrojejunal bypass, less aggressive than the alluded to inadvertent gastroileostomy. Standard implant duration is 12 months. Multicenter trials have pointed out not uncommon adverse effects, including hepatic abscess, eventually leading to early removal. Yet, results are encouraging, with significant weight loss and reduction of insulin consumption (Betzel et al. 2019). Weight loss is partially maintained 2 years after barrier explanation, however, not after 4 years (Betzel et al. 2019; van Rijn et al. 2019).

Plenity Capsule

A magic pill, which instantly fills the stomach with gases or liquids at mealtime and inhibits food ingestion, was probably one of the wildest dreams of early anti-obesity pioneers. Indeed, when one drinks highly carbonated sodas, and these have been in the market for a long time, the abdomen sometimes fills up to the point of discomfort. It is attributed to Joseph Priestley (1733–1804), the discoverer of oxygen, also the infusion of carbon dioxide from a beer vat into a bowl of water, thus generating a bubbly water drink. However, even in modern, highly carbonated soda, the impact on consumers is typically short lived, as it all vanishes with eructation and elimination of the fizz.

Plenity (Gelesis 2019) survives longer than an instant and represents more than hot air. This hydrophilic matrix of cross-linked cellulose and citric acid absorbs water in the stomach, converting into multiple tiny fragments of space-occupying gel, which generates satiety and inhibits food ingestion. After intestinal migration, it is partially digested and the remainder is eliminated, with virtually no systemic impact on the host, except for the intended one of appetite restriction and weight loss. In a randomized 24-week trial (GLOW protocol), 59% of the patients achieved weight loss of $\geq$5%, with tolerance comparable to placebo (Greenway et al. 2019). Prediabetics and drug-naive type 2 diabetics were even more benefited, with a six

times higher chance of responding with ≥10% weight loss.

Within such circumstances, Plenity is considered a device, not a drug, being theoretically exempt from the safety constrains of a pharmacologic agent. The FDA (USA) has approved it for overweight and obese adults with a BMI of 25–40 kg/m^2, in conjunction with diet and exercise. This is a first for the overweight population, as most devices are recommended for the higher strata of adiposity.

Final Considerations

Ingenuity has always been considered a virtue in medicine and even more so in surgical specialties. Especially at times of epidemics, wars, and other calamities, inventiveness has been a major route to make do in face of shortages and lack of resources. Nevertheless, it comes handy on a daily basis to every professional, even with the risk of being considered insane on account of his or her bold steps. Endoscopy provides stark examples. An important advance toward modern techniques occurred in 1868, when Adolph Kussmaul (1822–1902) used the abilities of a sword swallower to test and improve the apparatus he had developed, for in vivo viewing of the esophagus and stomach.

His highly successful career was enhanced, different from the earlier pioneer Philipp Bozzini (1773–1809), who created the *Lichtleiter* (light conductor), a smaller device that could be used for not so deep, however, still useful and effective endoscopic exploration, of such diverse sites as the upper and lower digestive system, nose, and ears, as well as urinary and genital tracts. He dedicated his life to the improvement of the instrument, aiming at its recognition and adoption by Austrian military hospitals. Due to intrigues, this never occurred. He died in poverty, and his three children were given over to friends.

Obesity and diabetes are not the only challenges in a world dilacerated by medical and social conflicts and inequalities. Yet, a dose of therapeutic ingenuity would be welcome, given the estimate that as little as 2% of obese patients are currently being managed by officially mandated lifestyle, pharmacologic or surgical interventions, and not more than 0.1% by available endoscopic alternatives (Kahan 2018).

Abstract

Gastroparesis is a symptomatic chronic clinical syndrome where there is delayed emptying of the stomach in the absence of mechanical obstruction. Typical symptoms of gastroparesis include early satiety, nausea and vomiting and it severely affects nutritional intake. For patients with diabetes, glycaemic control will be negatively impacted, with possible secondary effects on other organs that affect mortality rate. Conventional drug treatment and nutritional support fail some patients and new therapy options are required. High-frequency electrical stimulation is a treatment strategy that is employed in severe cases of gastroparesis. In this chapter, an overview of the electrophysiological slow waves is given, followed by emerging trends in novel electrical stimulation therapies in the stomach, with an emphasis on gastroparesis.

Keywords

Diabetic gastroparesis · Obesity control · Gastric pacing · Gastric slow waves · Low frequency stimulation · High frequency stimulation

Introduction

Electroceuticals are an all-encompassing term coined for bio-electrical medicine to influence and modify biological and physiological function. The use of exogenous electrical impulses is a type of electroceutical and has been extensively used in clinical electrocardiology, neurology and pain management to offer significant therapeutic benefit to patients with disordered electrical rhythms, such as atrial fibrillation and epilepsy (Cingolani et al. 2018; Frequin et al. 2020; Merin et al. 2009; Moreno-Duarte et al. 2014). Cardiac pacing has been used to treat arrhythmias in the heart, where the rhythm of the heart is fast, slow or irregular (Abrich et al. 2020; Dallaglio et al. 2020). Also, cardiac defibrillators are common in public places, which use high-energy impulses to restore the natural rhythm of the heart. More recently, electroceuticals have been used to alleviate or minimise chronic ailments (such as failed back surgery syndrome (Reverberi et al. 2013)), where previously pharmaceuticals were the primary treatment strategy. Furthermore, technological advances in real-time monitoring and miniaturisation of electrodes for brain surgery have advanced deep brain stimulation to be a viable treatment option for Parkinson's disease, epilepsy and tremors (Frequin et al. 2020). Studies have shown that implantable electroceutical devices both extend people lives and improve their quality of life (Marini et al. 2019; Merin et al. 2009).

The concept of applying electroceuticals to the stomach has been investigated by many researchers (Familoni et al. 1997b; Kelly and La Force 1972; O'Grady et al. 2010b). However, to date, its clinical use has been limited to a number of specialised centres (Abell et al. 2003, 2011; McCallum et al. 2011). For other regions of the gut, there is increasing use, such as stimulation of sacral nerves to control urinary and faecal incontinence (Rosen et al. 2001; Yamanishi et al. 2008), and stimulation of the lower oesophageal sphincter to increase resting lower oesophageal sphincter pressure to treat reflux disease (Soffer and Kim 2016). In this chapter, we will focus on the use of electrical stimulation targeted for functional gastric motility disorders such as gastroparesis, where there is an increasing level of research and clinical evidence to suggest that electroceuticals could provide therapeutic benefit. We will first introduce the gastric slow wave electrophysiological mechanisms and two types of gastric electroceutical approaches that have been used to alleviate symptoms and/or treat a gastric motility and emptying disorder known as gastroparesis.

Electrophysiology

ICC Regulation of Slow Waves

Gastric contractions are coordinated in part by bio-electrical slow waves (Huizinga and

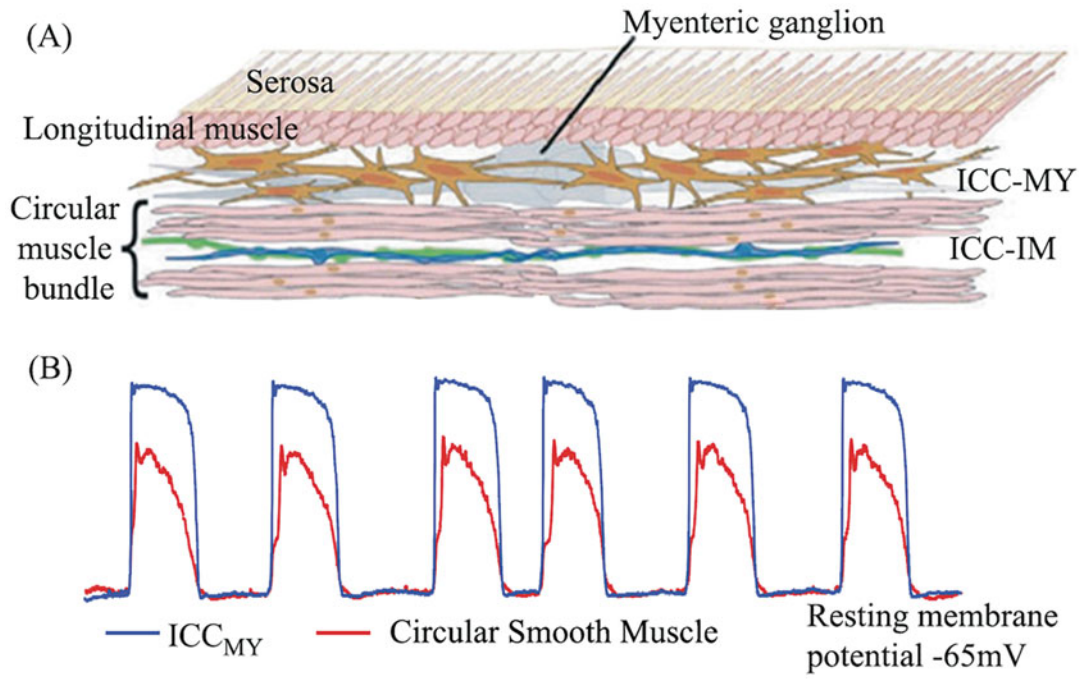

Fig. 72.1 Slow wave initiation in ICC and conduction pathway to smooth muscles. (**a**) Schematic of ICC and gastrointestinal smooth muscle architecture. ICC generates and propagates slow wave activity, which depolarises to the smooth muscles and initiates muscular contraction through Ca^{2+} channels in smooth muscles. (**b**) Shows a representative intracellular trace from ICC-MY and circular smooth muscle illustrating the action potential dynamics. Adapted from Hirst (2001) and Hirst and Edwards (2006)

Lammers 2009). Slow waves are generated and propagated through a network of interstitial cells of Cajal (ICC) present in the gastric musculature (Huizinga et al. 1995). A schematic architecture of the ICC networks and smooth muscles is shown in Fig. 72.1a. The ICC in the myenteric plexus (ICC-MY) is responsible for generating the slow wave action potential, which then passively conducts to the smooth muscle to induce slow wave tissue depolarisation (Farrugia 1999; Hirst and Edwards 2006). Intra-muscular ICC (ICC-IM), another class of ICC, lies within the circular muscle and is responsible for augmenting the action potential generated by ICC-MY to cause the L-type calcium channels in smooth muscles to open for induction of muscular contraction (Hirst 2001; Hirst and Edwards 2006). Figure 72.1b shows the time course of representative slow wave action potentials generated in the ICC-MY, which are then transduced to the neighbouring circular smooth muscles. However, as there is a decreasing intrinsic frequency across the stomach, the ICC with the highest frequency entrains the whole network (Hinder and Kelly 1977; Hirst and Edwards 2006).

Measurement of Slow Waves In Vivo

In vitro studies are attractive to investigate the cellular and ionic mechanisms and dynamics of slow wave action potential. However, findings from studies using excised tissue blocks are inherently different from in vivo whole organ studies due to the loss of communication in the enteric neural system and loss of intrinsic entrainment mechanism from neighbouring ICC, which are critical for normal function (Diamant and Bortoff 1969; Hinder and Kelly 1977; O'Grady et al. 2012b; Xue et al. 1995). Therefore, to get a physiologically realistic understanding of bio-electrical slow wave activity during normal

and abnormal function of the gut, organ level in vivo studies are required.

Traditionally, sparse recording sites were utilised in vivo to understand electrophysiological gastric slow wave activity, but they lacked spatio-temporal detail (O'Grady et al. 2018). Lammers et al. translated high-resolution (HR) mapping from the cardiac field to the gastrointestinal field (Lammers et al. 1993, 1996) and similar techniques were later adapted for use in human studies (Berry et al. 2016; O'Grady et al. 2010a). The application of HR mapping techniques in diseased cases, such as gastroparesis and chronic unexplained nausea and vomiting, has offered new insight into the dynamics of dysrhythmic slow wave propagation (See 'Gastroparesis' section for more details) (Angeli et al. 2015; O'Grady et al. 2012a).

With sparse recordings, typically 4 to 8 electrode sites are placed 1–3 cm apart either longitudinally or circumferentially (Alvarez and Mahoney 1922; Kelly et al. 1969), while with HR mapping, electrodes are densely spaced in a 2D configuration with inter-electrode distances of 1 to 7 mm. HR mapping allows for detailed tracking of spatial dynamics and these studies have provided a detailed understanding of the critical role that spatio-temporal slow wave dynamics play in health and disease (Lammers et al. 1993; O'Grady et al. 2018).

In the normal human stomach, the normal slow wave frequency is around 3 cycles per minute (cpm) and there are 3 or more concurrent wavefronts present at any one time (O'Grady et al. 2010a). The slow waves initiate in the mid- to upper-corpus region of the stomach on the greater curvature and propagates rapidly towards the lesser curvature and distally towards the antrum, in a ring formation (Kelly and Code 1971; Lammers et al. 2009; O'Grady et al. 2010a). Figure 72.2a shows an experimental recording of a slow wave propagation profile from a human stomach. The slow waves originate in the mid-upper corpus region of the stomach, where the signals are of a higher amplitude with faster propagation primarily in the circumferential direction (~0.6 mV, 8 mm/s). When the slow wave activity traverses the corpus-antrum border, there is an increase in slow wave amplitude and velocity as the propagation terminates at the pylorus (Berry et al. 2016) (Fig. 72.2b). This increase in slow wave activity is hypothesised to correlate with terminal antral contractions that aid in retropulsion of the food and allow recirculation and trituration (Berry et al. 2016).

Gastroparesis

Gastroparesis is defined as delayed gastric emptying in the absence of mechanical obstruction (Camilleri et al. 2013). Gastroparesis has a prevalence of 24.2 per 100,000 inhabitants and an incidence of 6.3 per 100,000 persons per year (Bharucha 2015; Rey et al. 2012). However, not everyone in the population undergoes a gastric emptying test, and regression models estimate the prevalence of gastroparesis at 1.8% of the population (Rey et al. 2012). The aetiology of gastroparesis is varied with around 36% of patients having an unidentified cause or idiopathic gastroparesis (Camilleri et al. 2013). Diabetes is the main cause and accounts for 29% of patients, followed by post-surgical causes, which account for 13% of patients (Camilleri et al. 2013). Other disorders such as Parkinson's, connective tissue disease and enteroviruses have also been identified as causes for gastroparesis (Camilleri 2007).

Diagnostic Scintigraphy

The conventional test for gastroparesis diagnosis is gastric emptying scintigraphy of a solid-phase meal (Camilleri et al. 2013). Diagnosis is confirmed if more than 10% of the meal remains in the stomach after 4 h, along with presentation of typical gastroparesis symptoms (Abell et al. 2008; Guo et al. 2001). The symptoms are multifactorial and include early satiety, post-prandial fullness, vomiting, nausea and epigastric and/or abdominal pain (Rey et al. 2012). It has a deleterious effect on acquiring adequate nutrition and impacts glycaemic control. It can induce secondary effects on other organs that reduce the quality of life and

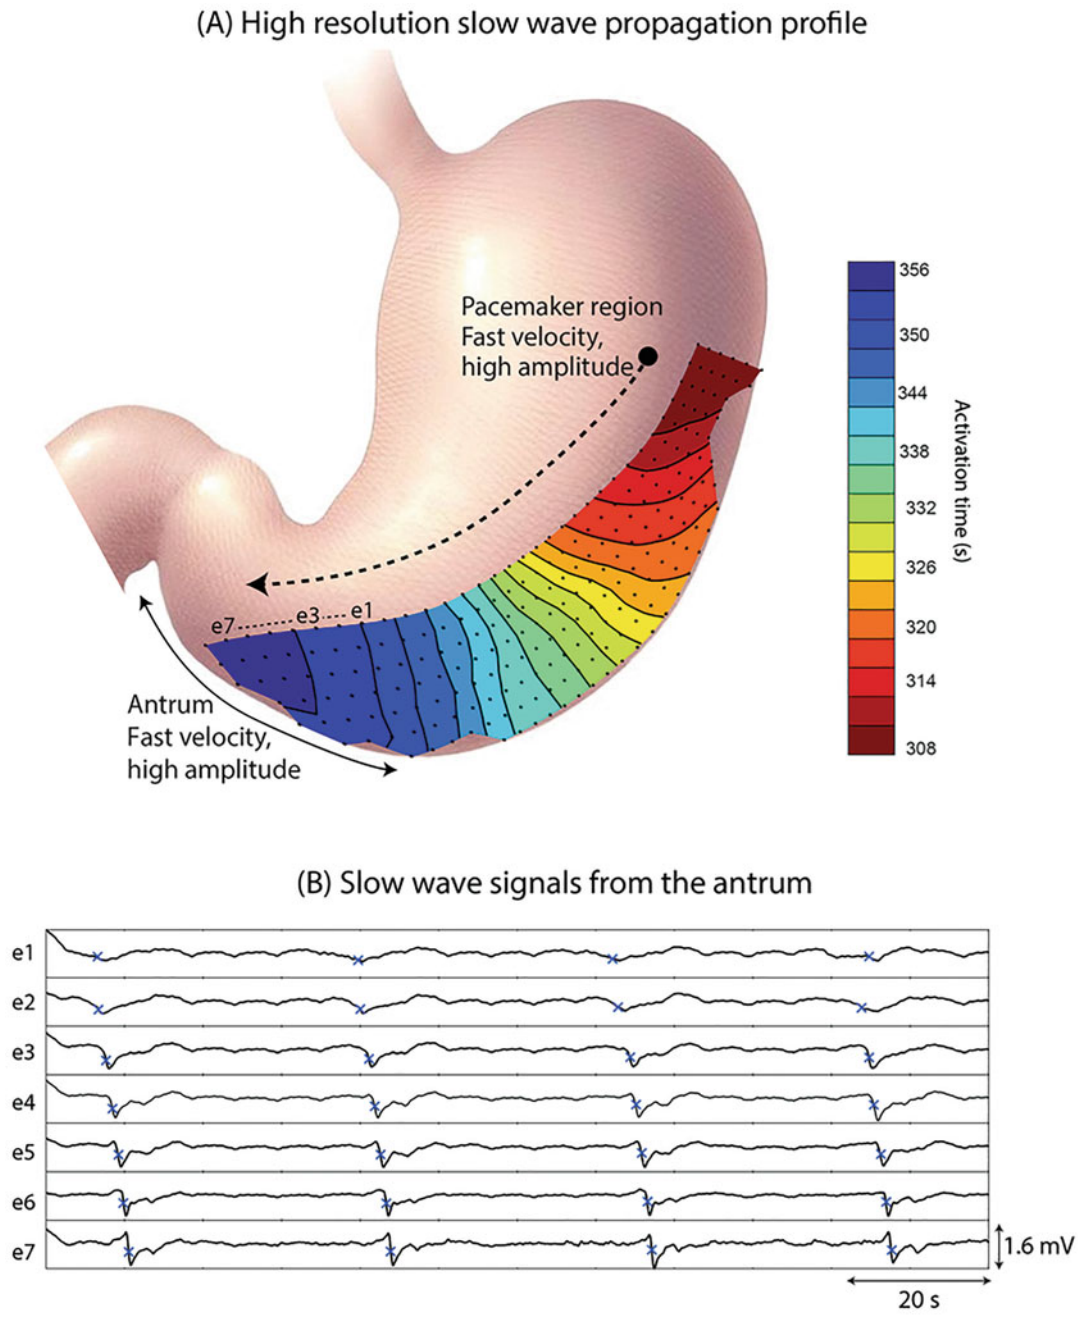

Fig. 72.2 Normal human gastric slow wave activity. (**a**) Shows an experimental recording of the slow wave conduction from the corpus to the antrum. The activation map is illustrated as an isochronal map, where the pacemaker initiates in the greater curvature of the mid-upper corpus and propagates towards the antrum. As the slow waves travel through the corpus and antrum border, the slow wave travels rapidly with increased amplitude. (**b**) Shows the recorded slow wave signals from the antrum, where the amplitude of slow waves is increasing from e1 to e7. The blue cross denotes the activation of the slow wave event

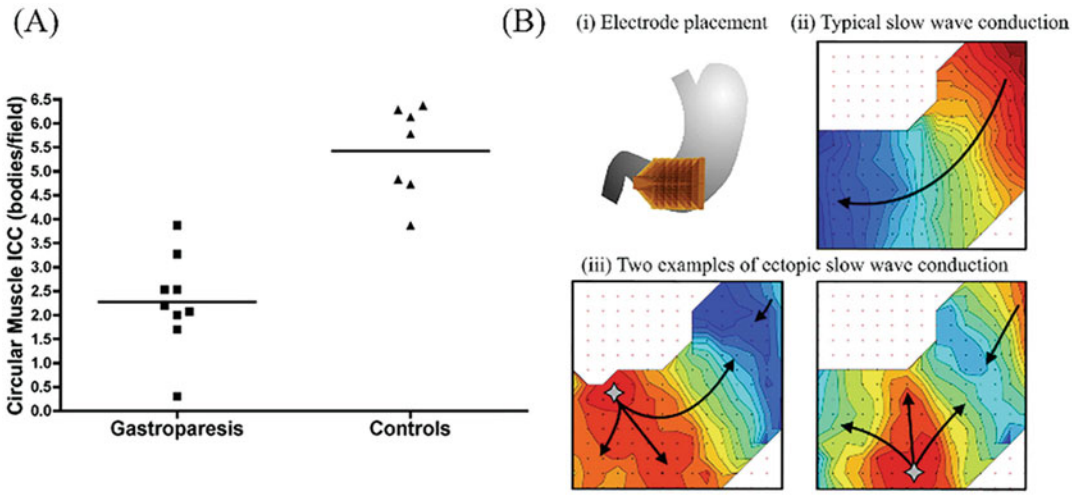

Fig. 72.3 (**a**) ICC count for gastroparetic patients and control subjects. (**b**) HR slow wave mapping in a gastroparetic patient. The placement of the HR electrode array on the distal stomach is shown in (**b**—i). A typical pattern of normal propagation is shown in (**b**—ii), and two examples of ectopic slow wave conduction were also recorded (**b**—iii). Reproduced from O'Grady et al. (2012a)

increase mortality in severe cases (Camilleri et al. 2013). The symptoms of gastroparesis overlap with other disorders such as functional dyspepsia and gastro-oesophageal reflux disease, making treatment stratification difficult for these patient groups.

Pathophysiology

The common denominator for gastroparesis is the loss and degradation of ICC (Farrugia 2008; Grover et al. 2011). Compared to control subjects, a study found significantly reduced levels of ICC in gastroparetic patients (Fig. 72.3a). Furthermore, HR mapping studies performed in patients with gastroparesis have revealed that these patients have abnormal patterns of slow wave propagation (O'Grady et al. 2012a). An example is shown in Fig. 72.3b, where in a gastroparetic patient, the slow wave ectopically activated in the distal corpus, propagating towards the proximal corpus, thus generating competing pacemakers. An important observation, however, was that despite the presence of abnormal patterns of activation, the frequency of slow wave was in the normal range of 3 cpm. Therefore, the use of spatio-temporal mapping and development of efficient analytical frameworks are pertinent to developing a better understanding of functional gastric disorders (Lammers et al. 1993; Paskaranandavadivel et al. 2017).

Differential Diagnosis

Similar patterns of dysrhythmic slow wave activity were also present in patients diagnosed with chronic unexplained nausea and vomiting (CUNV). CUNV patients suffer from the same symptoms as gastroparesis patients, but they have adequate gastric emptying, with less than 10% of food retained after 4 h. In these patients, a moderate ICC loss was observed (i.e. they had less ICC numbers than control subjects, but more than gastroparesis patients) (Angeli et al. 2015).

The ability to accurately quantify the structure of ICC networks has the potential to provide improved pathophysiological understanding (Krohn et al. 2017). Currently, histopathological classification and analysis of gastrointestinal tissue biopsies involve manual visual assessment of small tissues samples. This process is subjective and prone to bias (Grover et al. 2012; Knowles

et al. 2011). For example, as shown in Fig. 72.3a, in some control and gastroparesis subjects, 3–4 ICC bodies/field were observed, leading to uncertainties in classification when an intermediate level of ICC numbers was observed. More sophisticated techniques have been proposed where the spatial properties of the ICC networks are quantified by analysing the structure of the ICC network (Gao et al. 2013). Numerical metrics (e.g. ICC density, process thickness, whole size, etc.) were able to effectively differentiate between wild-type and 5-HT2B serotonin receptor knockout jejunal tissue samples that had compromised ICC networks. In addition, the functional properties of the ICC networks can also be quantified using biophysical simulations, to help distinguish between normal and ICC depleted tissue samples (Krohn et al. 2017; Sathar et al. 2015).

Management of gastroparesis begins by restoring hydration and nutrition, followed by prokinetics pain relief (Camilleri et al. 2013). It has been reported that around 30% of patients with gastroparesis will fail conservative pharmaceutical therapy. High-frequency gastric electrical stimulation, marketed as Enterra Therapy by Medtronic (Minneapolis, MN, USA), is another option which could be undertaken if patients have failed conservative treatment (Abell et al. 2002). Enterra Therapy was approved by the Food and Drug Administration (FDA) in 2000 as a humanitarian device exemption (HDE).

Low-frequency Pacing and High-Frequency Stimulation

There are two main classifications of electroceuticals in the stomach: (i) low-frequency (LF) pacing and (ii) high-frequency (HF) stimulation. With LF pacing, the frequency of the delivered impulses is typically within the physiological ranges of slow wave activity (generally on the order of 2–12 cpm), while with HF stimulation, the delivered impulses are significantly higher than the native slow wave frequency range. It is thought that HF stimulation affects the neural afferents in the vagus nerve, while LF pacing modulates the slow wave activity.

The impulse properties that could be applied are generally in three types of waveforms (i) monophasic, (ii) biphasic and (iii) modulated (Fig. 72.4). Monophasic and biphasic waveforms are typically used for pacing, while modulated monophasic impulses are used for HF stimulation. LF pacing can be classified as high-energy stimulation and HF stimulation as low-energy stimulation based primarily on the amplitude and width of the applied impulse.

Pacing

An overview of gastric pacing is given followed by recent advancements in HR mapping and closed loop systems, which are allowing renewed interest in the field.

In the early 1970s, gastric electrical stimulation studies were conducted in animals, where Kelly et al. were able to pace slow waves from 4.2 to 8 cpm and reverse spontaneous dysrhythmias (Kelly and La Force 1972; Kuramoto et al. 1979; Yamashita 1980). Canine trials may have shown increased emptying rates with pacing (Bellahsène et al. 1992), but when pacing was applied in human trials, it entrained slow waves but did not affect gastric emptying rates (Hocking et al. 1992). Early animal studies also showed that the antrum could be paced at higher frequencies than proximal regions of the stomach (Kelly 1974) and is likely due to a consequence of the intrinsic slow wave frequency gradient across the stomach. Gastric pacing is also likely to affect other gastrointestinal control mechanisms, rather than just myogenic. A canine study showed that long pulses reduced the fundic tone and increased the gastric volume with pacing protocols (Xing and Chen 2006).

A variety of pacing parameters have been applied to control gastric slow wave in animals and humans, as shown in Table 72.1. The seminal study by Kelly et al. applied a range of pulse widths and impulse frequencies from 2 to 12 cpm. They suggested that a pulse width of 500 ms at 4 mA was able to entrain slow wave

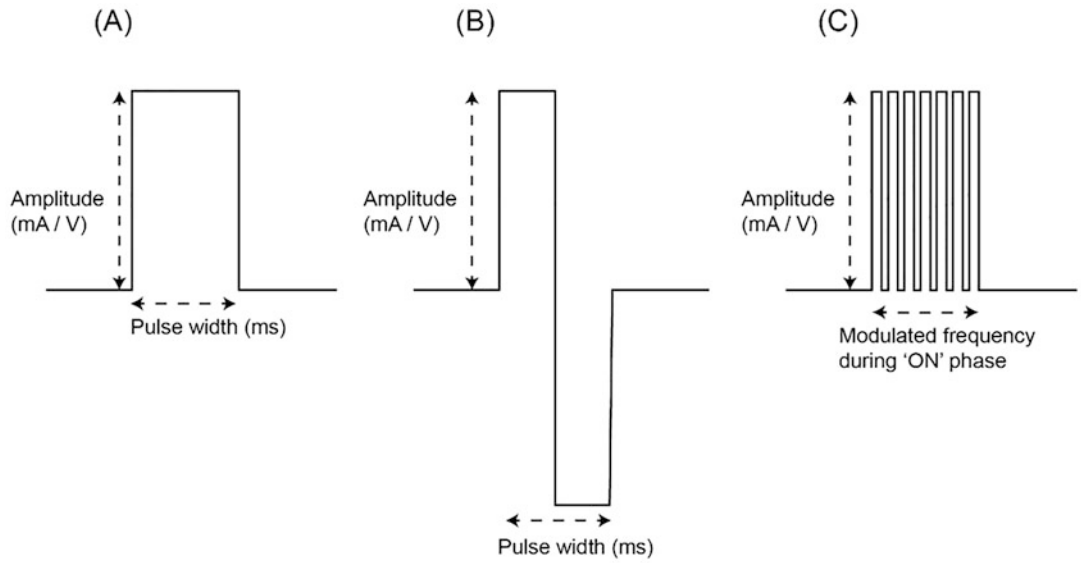

Fig. 72.4 Types of impulses for pacing and stimulation. (**a**) Shows a monophasic impulse, while (**b**) shows a biphasic impulse. Both (**a**) and (**b**) are typical waveforms used for slow wave pacing. (**c**) Shows a modulated impulse during the 'ON' phase, which is typically used for HF stimulation

Table 72.1 Impulse properties applied to control gastric slow waves

Article	Subject	Amplitude	Pulse width	Entrained frequency
Kelly and La Force (1972)	Dog	1–8 mA	100–200 ms	4–8 cpm
Lin et al. (1998) McCallum et al. (1998)	Human	1–4 mA	3–300 ms	4–12 cpm
O'Grady et al. (2010b)	Pig	2–4 mA	400 ms	3.2–3.52 cpm
Wang et al. (2018)	Pig	5–8 mA	500–900 ms	2.72–6 cpm
Alighaleh et al. (2019)	Pig	4 mA	400 ms	2–4.3 cpm

from a range of 4–8 cpm (Kelly and La Force 1972). Furthermore, they reported that a period of pacing interval shorter than 7.5 s (8 cpm) was unstable as it would initiate during the refractory period of slow waves. Consequent studies also varied the parameters but have found that slow waves cannot entrain beyond its physiological slow wave range (Alighaleh et al. 2019; Wang et al. 2018).

A significant long-term human pacing study was performed where pacing and the effects of slow waves were monitored over a 1-month period in gastroparetic subjects (McCallum et al. 1998). Slow wave entrainment was achieved in all subjects, where gastric retention reduced from 77% to 57% and induced symptom relief by 50%. The optimal pacing parameters were also investigated in human trials to apply appropriate impulses to modulate slow waves (Lin et al. 1998). The study showed that optimal pacing can be performed at 3.3 cpm at a current of 4 mA and pulse width of 300 ms, while decreasing the current to 1 mA reduces efficacy of successful entrainment by $50 \pm 11\%$ and decreasing the pulse width to 30 ms results in loss of slow wave entrainment (Lin et al. 1998).

Combining HR slow wave mapping with pacing allows a better understanding of spatio-temporal characteristics of the slow wave responses. The first HR pacing study was performed by Lammers et al. in an in vitro rabbit duodenum, illustrating that the site of slow wave initiation was likely 2 mm away from the electrodes (Lammers et al. 1993). These methods

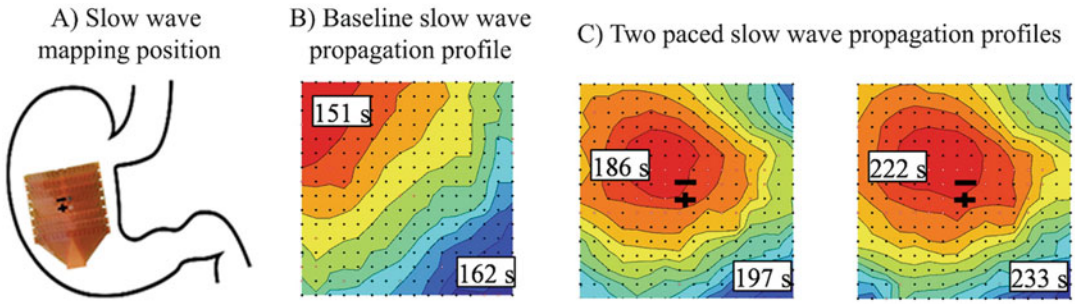

Fig. 72.5 Paced slow wave propagation. (**a**) Shows the area of the serosal region over which slow wave activity was mapped. (**b**) Shows the normal conduction profile, while (**c**) shows two slow wave propagation patterns due to the application of an impulse. The black plus and minus represent the positive and negative leads of the pacing leads

were also applied in an in vivo gastric pig model to reveal that pacing induces a new site of slow wave initiation around 8 mm away from the stimulus site (Alighaleh et al. 2019; O'Grady et al. 2010b). Figure 72.5 shows that the baseline slow wave propagation profile and the induction of a slow wave pacemaker activity near the pacing leads with the application of impulses. Future detailed analyses are required to characterise the regional variation of initiated slow wave activity to improve physiological understanding and clinical trials.

Despite successful trials, pacing has not yet been translated into clinical trials, in part due to high energy requirements, energy consumption in implants and electrode stability over time. Nonetheless, recent advances have shown that devices can be miniaturised and pacing long term is becoming a viable option. In particular, the use of application specific integrated circuits (ASICs) and wireless technologies for data communication and power transfer are being adopted for pacing applications and are improving the form factor and power utilisation (Ibrahim et al. 2015; Javan-Khoshkholgh et al. 2019a, b; Javan-Khoshkholgh and Farajidavar 2019; Paskaranandavadivel et al. 2015; Wang et al. 2018). The dimensions of one of the first reported portable gastric pacemakers were around 13 × 9 × 3 cm (Chen et al. 1995). This form factor has significantly shrunk in size to 3 × 2 × 0.5 cm (Javan-Khoshkholgh et al. 2019a, b). The combination of power efficient electronics and wireless power transfer has resulted in electroceutical devices that do not rely on batteries, circumventing a bottleneck in medical implants.

Gastric Pacing for Obesity Treatment

The concept of closed-loop pacing could further improve power consumption and enable further clinical interest in gastric slow wave pacing. The first reported use of closed-loop stimulation in the gut was in 1973, where stimulation was applied only if the upstroke of recorded bio-signals did not surpass a defined threshold (Sobakin and Shepelev 1973). In recent years, this concept has also been used for gastric stimulation to treat obesity. For obesity treatment, higher energy implantable stimulation devices are required where leads are placed in the fundus to detect food intake, after which stimulation is applied distally (Bohdjalian et al. 2006; Horbach et al. 2015). Meal intake is detected via a transient reduction in slow wave activity and rise in fundus impedance (Bohdjalian et al. 2006). The intrinsic slow wave frequency can also be directly used as an input to control the pacing stimulus. Recent hardware developments have allowed for recording and stimulation on a single module (Wang et al. 2018), while software developments have utilised hybrid automata methods to enable verifiable systems for real-time applications (Wang et al. 2019, 2020).

Table 72.2 High-frequency stimulation settings

Article	Subject	Amplitude	Pulse width	Modulated ON phase	Applied frequency
Bilgutay et al. (1963)	Human	1–10 mA	5 s	50 Hz	0.2–1 cpm
Familoni et al. (1997a)	Human	2 mA	300 μs	Nil	12 cpm
Song et al. (2006)	Dogs	5 mA	0.1, 0.3, 0.6 ms	14, 40 Hz	12 cpm

High Frequency Stimulation

The excessive energy requirements for long-term pacing motivated the use of HF stimulation, where lower energy impulses were applied at higher frequencies. The evolution of the HF stimulation is discussed along with emerging practice. Electrical stimulation in the gastrointestinal tract was initially trialled by Bilguaty et al. in 1963 to stimulate the stomach and intestine for the treatment of ileus (Bilgutay et al. 1963) (see Table 72.2 for stimulation setting used). However, following studies reported conflicting results and thus were not translated for further clinical use (Berger et al. 1966; Quast et al. 1965). About three decades later, Familoni et al. utilised HF stimulation, with shorter pulse widths of 0.3 ms applied at 0.6–6 times the intrinsic slow wave frequency in animals (Familoni et al. 1997a). They showed that a stimulation at 30 cpm, as compared to 3 cpm, elicited more mechanical activity, which was measured using a strain gauge on the serosal surface (Familoni et al. 1997a). A human case report was published by the same group where they performed HF stimulation on a gastroparetic patient at 12 cpm (pulse width: 300 μs; amplitude: 2 mA), and illustrated symptom relief and improvements in gastric emptying rates (Familoni et al. 1997b). For this subject, it was observed that the distal corpus and proximal antrum achieved the most effective stimulation response.

Consequent studies focussed closely in this range and utilised pulse width parameters from 0.1–0.6 μs at a modulated frequency of 14 Hz (Chen et al. 2003; Song et al. 2006). The mechanism of action for HF stimulation is not well understood but is likely to involve indirect neuromodulation of the parasympathetic nerves and/or ganglion, which is known to regulate gastric function. Early studies demonstrated that the HF stimulation did not affect gastric slow waves but caused a potent anti-emetic to the effects of vasopressin, which indicated that vagal pathways were being modulated (Chen et al. 2003; Song et al. 2006). HF stimulation has also been shown to modulate the thoracic spinal neurons, which are responsible for gastric distention (Qin et al. 2007). Results from position emission tomography of gastroparetic patients with HF stimulation indicated that there was an increase in the thalamus region of the brain (McCallum et al. 2010). Further studies in rats pinpointed that the increased neuronal activity from HF stimulation was from the paraventricular nucleus in the hypothalamus, which regulates food intake (Tang et al. 2006).

Human Trials

Two multi-centre human trials using HF stimulation (12 cpm, 5 mA and pulse width 0.3 ms, 14 Hz modulated impulse) were performed on refractory-diabetic or idiopathic gastroparetic subjects; GEMS (Gastric Electrical Mechanical Study) (Abell et al. 2002) and WAVESS (Worldwide Anti-Vomiting Electrical Stimulation Study) (Abell et al. 2003). Over 70% of subjects reported improvements in symptoms with reduced nausea and vomiting scores at 12 month follow-up and 73% of subjects experienced an improvement in the quality of life (Abell et al. 2003). Based on the WAVESS study, Enterra Therapy system was approved for use under the HDE by the FDA.

The Enterra Therapy system consists of an implantable pulse generator, a pair of leads and a programming system. A radio-telemetry link from the programming system to the pulse

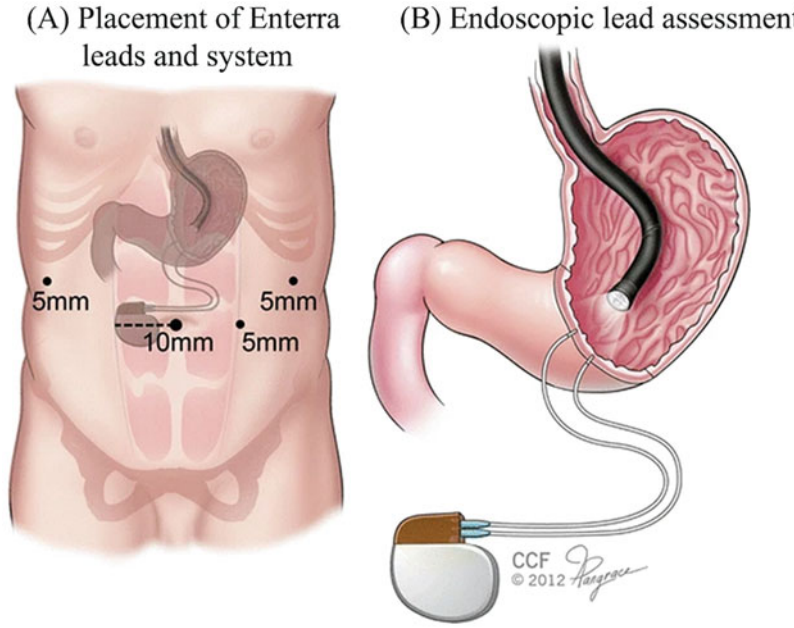

Fig. 72.6 Placement of Enterra system and verification of stimulation leads via the lumen wall. (**a**) Shows the position of where the leads are placed in the stomach guided via four laparoscopic ports. (**b**) Shows the use of endoscopy to assess that the leads are at the right position in the stomach as visualised from the lumen wall. Reproduced with permission from Timratana et al. (2013)

generator controls the applied stimulation protocols. The pair of leads is surgically placed in the serosa-muscular layer of the gastric wall, around 10 cm proximal from the pylorus (Fig. 72.6a), and connected to the implantable pulse generator. The placement of leads is visually assessed endoscopically to ensure that it has not penetrated the lumen wall and is at the right position in the stomach (Fig. 72.6b). A subcutaneous pocket is made for the pulse generator to be implanted in the body. The pulse generator has been estimated to have a battery life of 5 to 10 years, dependent on the stimulation parameters (Medtronic 2020).

There have been a number of studies with varying study design and quality to assess the efficacy of HF stimulation for gastroparesis. One meta-analysis, which included open-labelled studies, reported that the total symptom severity score (TSS) significantly decreased by a mean difference of 6.52 (O'Grady et al. 2009). However, a recent meta-analysis revealed that the TSS score did not differ in randomly allocated design groups (TSS difference of 0.17, $P = 0.15$), but there was a significant decrease in TSS in open-label studies (TSS difference of 2.68, $P < 0.001$) (Levinthal and Bielefeldt 2017). Therefore, there is a significant need for randomised double blind, cross-over, placebo-controlled studies to ascertain efficacy of HF stimulation. According to the American Gastroenterological Association, HF stimulation has moderate level of evidence for use (Camilleri et al. 2013; Levinthal and Bielefeldt 2017). A recent randomised cross-over trial reported that although HF stimulation did not increase the quality of life or rate of gastric emptying, it reduced the frequency of refractory vomiting in both patients with and without diabetes (Ducrotte et al. 2020).

Clinical Protocols

Typically for Enterra system, HF stimulators are implanted permanently, after which the clinician might optimise stimulation parameters. Another approach that is adopted by some centres is to perform temporary stimulation, which can allow for better patient selection and optimisation of stimulation location (mid-corpus vs antrum) and parameters (Abell et al. 2011; Ayinala et al. 2005; Corvinus et al. 2018). This is a similar approach

to what is undertaken for sacral nerve stimulator implantation for faecal incontinence where a testing phase is standard (Dudding et al. 2011). Corvinus et al. used a standard gastroparesis symptom index, before and after temporary stimulation to assess proceeding to permanent implantation (Corvinus et al. 2018). A 50% decrease in symptom index was considered as the threshold to continue to permanent implantation and illustrated economic benefit from a case series. The temporary stimulation leads were inserted laparoscopically and subsequent surgery was required for permanent lead and device implantation (Corvinus et al. 2018). This approach may lead to extended hospital stays and increases likelihood of infection.

Another approach for temporary stimulation is to place the stimulation leads mucosally via endoscopy (Abell et al. 2011). Here, the stimulation leads, which are extending from the nasal cavity, are connected to the pulse generator secured in an external pouch. Abell et al. illustrated that temporary stimulation can predict the outcomes of permanent HF stimulation, and reported that baseline symptom status and mucosal slow waves should be taken into account prior to permanent implantation (Abell et al. 2011). Recent advances in recording methods have allowed mucosal slow wave recordings to be obtained simultaneously along-side the temporary stimulation process (typically 5 days) and could be integrated alongside patient symptoms for future optimisation of stimulation settings (Paskaranandavadivel et al. 2019).

Future Outlook

Detailed comparative HF stimulation and LF pacing studies are required to illustrate efficacies of each method. To date, the only trial was conducted by Sobocki et al. where they showed that both LF and HF stimulation provided improvements to subjects with symptom score and gastric retention rates (Sobocki et al. 2003). Applying pacing and HF stimulation in tandem has been hypothesised to yield superior performance (Song et al. 2008). It is thought that using this approach, HF stimulation could provide relief from symptoms, while pacing could improve emptying rates; but to date, this has only been performed in an animal study (Song et al. 2008). The use of multi-channel stimulation should also be further explored, as it has been indicated that about 1% of energy of the single channel protocol is required to modulate slow waves for gastric emptying (Chen et al. 2005).

There are possible neuromodulation applications to obesity and gastrointestinal disorders such as ileus, irritable bowel syndrome and abdominal pain (Kovacic et al. 2017; Lin and McCallum 2015; Liu et al. 2006; Zhang et al. 2014). In particular, efforts are underway to translate HF stimulation to treat obesity by using a modified set of stimulation parameters (Cigaina 2002), but a recent clinical trial did not show significant improvements (Shikora et al. 2009). The use of stimulation has been highly successful in the treatment of gastroesophageal reflux disease (GERD) (Soffer and Kim 2016). The use of percutaneous electrical nerve field stimulation (PENFS) in the external ear can modulate pain pathways and a recent randomised double-blind, sham-controlled study has shown sustained efficacy in pain reduction (Kovacic et al. 2017).

Joel Faintuch and Jacob J. Faintuch

Abstract

The internet has become such an omnipresent service, which, in the view of many, has already upgraded from slave to master and quite a tyrannical one. Whatever the feelings, scientific information would not flow worldwide without the tool, in such unlimited amounts. Just as an example, gene sequencing and metabolomics as well as the related precision medicine approach as now envisaged would be inconceivable. Each omics analysis and clinical correlation would be labor intensive and take weeks to be conducted, instead of minutes or seconds and rather negligible expenditures, without internet-available search engines and reference libraries. The same applies for large biobank screening and biostatistical interventions, for both clinical and research purposes. This chapter has listed a large choice of useful obesity, bariatric, type 1 and 2 diabetes sites, as well as general internet sources, most of them costless, geared at the needs of office or bedside assistance, laboratory investigation, and educational or public health initiatives.

Keywords

Diabetes sites · Obesity sites · Bariatric sites · Trial database sites · Endoscopic intervention sites

Correction to: Obesity and Diabetes

Joel Faintuch and Salomão Faintuch

Correction to:
J. Faintuch and S. Faintuch (eds.), *Obesity and Diabetes*,
https://doi.org/10.1007/978-3-030-53370-0

The book was inadvertently published without the co-author names Yue Liao and Michelle R. Jospe. This has been corrected now.

In addition to this, the new co-author "Sandra Vazquez-Diaz" was included in Chapter 27.

The updated versions of the chapters can be found at
https://doi.org/10.1007/978-3-030-53370-0_27
https://doi.org/10.1007/978-3-030-53370-0_43

J. Faintuch and S. Faintuch (eds.), *Obesity and Diabetes*, https://doi.org/10.1007/978-3-030-53370-0_74

Glossary[1]

Diabetes Glossary

A1C (HbA1C) Glycosylated hemoglobin concentration reflects blood glucose over the past 2 to 3 months. There are cut-off points for prediabetes and diabetes.

Acanthosis nigricans Dark skin patches in armpits, groin and neck. Not uncommon in diabetics, can be associated with insulin resistance.

Acarbose See Alpha glucosidase inhibitors.

Alpha glucosidade inhibitors Oral antidiabetic drugs which inhibit an intestinal enzyme responsible for carbohydrate digestion. Less glucose is produced and absorbed, benefiting the disease. Clinical efficacy is nor remarkable, and gastrointestinal side effects can occur. Acarbose and miglitol are best known examples.

Artificial pancreas Any system or device that simultaneously monitors blood glucose, and pumps into the organism appropriate amounts of insulin. The aim is to mimick pancreatic function and improve quality of life, mostly in type 1 diabetes, however also in severe forms of type 2 diabetes.

Beta cells One type of cells present in pancreatic islets of Langerhans. They are responsible for the synthesis of insulin.

Biguanides Oral antidiabetic drugs with actions on liver and muscle glucose metabolism, as well as possible indirect incretin properties, via modulation of bile acid resorption. The principal representative is Metformin.

Body mass index (BMI) The ratio between body weight (in kilograms), and the square of the height (in meters). Used for both adults and children to diagnose obesity, Normal range is 18.5–24.9 kg/m^2, whereas values up to 29.9 signal overweight, and above that, obesity.

Canaglifozin See Glifozins

DPP4 Inhibitors These antidiabetic drugs inhibit the enzyme dipeptidyl peptidase 4 (DPP 4), responsible for degradation of GLP-1 (Glucagon like peptide 1), a major endogenous incretin. As a consequence, endogenous insulin production is enhanced. See also Gliptins.

Dapaglifozin See Glifozins.

Diabetic ketoacidosis See Ketoacidosis.

Diabetic Retinopathy See Retinopathy.

Dulaglutide See Glucagon-like peptide 1 receptor agonists.

Empaglifozin See Glifozins.

Exenatide See Glucagon-like peptide 1 receptor agonists.

Fasting blood glucose The most widely used test for diabetes screening and monitoring. Can be performed in the laboratory, or at home, with paper strips or electronic devices.

Gastroparesis A gastric neuromuscular complication mostly seen after many years of type 2 diabetes. The stomach and small bowel nerves become dysfunctional, resulting in disordered peristalsis, poor gastric and/or intestinal emptying, nausea, vomiting, and weight loss.

Gestational diabetes Diabetes that is precipitated by pregnancy. Both early and late modalities are recognized. Spontaneous

[1] This Glossary was compiled by Joel Faintuch and Jacob J. Faintuch.

J. Faintuch and S. Faintuch (eds.), *Obesity and Diabetes*, https://doi.org/10.1007/978-3-030-53370-0

cure after delivery is common, however type 2 diabetes may subsequently ensue.

Ghrelin A major appetite hormone, produced mostly at the gastric fundus. Diminishes after bariatric operations which remove the fundus, such as gastric bypass and vertical gastroplasty, thus contributing to the favorable weight loss curve. Long term recovery after bariatric intervention is reported.

GLP1-RA See Glucagon-like peptide 1 receptor agonists.

Glifozins Oral antidiabetic drugs, inhibiting glucose reabsorption in the kidney tubuli. Canagliflozin, dapagliflozin, and empagliflozin belong to this family.

Glimepiride See Sulfonylureas.

Glipizide See Sulfonylureas.

Gliptins Oral antidiabetic drugs (See DPP 4 inhibitors). Alogliptin, linagliptin, saxagliptin, and sitagliptin are available in the market.

Glitazones See Tiazolidinediones.

Glucagon A glucose-elevating hormone secreted by alpha cells of the islets of Langerhans. Together with insulin, it is a key regulator of glucose homeostasis. Intranasal glucagon can be used for emergency therapy of hypoglycemia.

Glucagon-like peptide 1 receptor agonists A recent family of antidiabetic, and antiobesity injectable drugs, with strong incretin properties (incretin mimetics). Principal agents are Exenatide, Semaglutide, Dulaglutide and Liraglutide.

Glucose homeostasis The association of biochemical reactions, metabolic pathways, regulatory molecules and feed-back mechanisms, responsible for assuring stable glucose concentrations along the 24 h. It is conjectured that the aim is to provide a steady flux of glucose to the brain, despite fluctuations resulting from such potentially disruptive phenomenons as meal ingestion, physical exercise, fasting periods, and night sleep. Diabetes does impact glucose homeostasis.

Glyburide See Sulfonylureas.

Glycemic index (GI) A measure of the ability of ingested foods to raise blood glucose levels. Foods with high GI, such as white bread or ordinary rice, tend to be associated with obesity and diabetes. The opposite should occur with whole grain, fiber rich products, considered more desirable in these contexts.

Hypoglycemia Blood glucose concentration below 80 mg/dl. It is typically associated with excessive insulin or insulin secretagogue administration, or insufficient food intake. It becomes a life-threatening condition below 50 mg/dl, requiring immediate glucose replenishment, via sugar rich food (if the patient is conscious), intravenous glucose, or nasal glucagon powder.

Incretins Hormones (endogenous or exogenous) as well as synthetic pharmacological agents, with the ability of enhancing beta-cell mass and function, or inhibiting their apoptosis, thus improving glucose homeostasis. Principal physiological incretins are GLP-1 (glucagons like peptide 1), and GIP (glucose dependent insulinotropic polypeptide).

Induced pluripotent stem cells Adult cells from skin and other sources. After laboratory processing, they can become pluripotent, mimicking embryonic stem cells. See also Stem cells.

Insulin The most important hormone produced by the endocrine pancreas, and also the crucial molecule of glucose homeostasis, along with glucagon. It is lacking or inefficient in all types of diabetes. See also Beta cells, and Glucose homeostasis.

Insulin resistance Any condition that hampers response to insulin, resulting in impaired cell entrance and metabolization of glucose. One of the first derangements in severe obesity and type 2 diabetes. During many years it was a synonym for prediabetes. See also Prediabetes.

Ketones/Ketone bodies See ketoacidosis.

Ketoacidosis A condition that signals serious decompensation of diabetes, either type 1 or 2. Lack of sufficient insulin, be it endogenous (synthesized by the pancreas) or exogenous (pharmacologically administered), leads to high glucose concentration in the blood, along with accumulation of endogenous

acids, and small molecules called ketone bodies. It can result in coma and death, and requires emergency treatment.

LADA See Latent Autoimmune Diabetes in Adults.

Latent Autoimmune Diabetes in Adults A modality of autoimmune diabetes, exhibiting islet autoantibodies. Beta-cell destruction tends to be slower than in typical autoimmune disease. Despite the name, it is not uncommon in children and adolescents, as well as in adults with type 2 diabetes.

Liraglutide See Glucagon-like peptide 1 receptor agonists.

Maturity Onset Diabetes of the Young An uncommon familial form of diabetes, with features of both type 1 and 2 of the disease. The most common involved gene is HNF1-alpha, and onset is usually in adolescence. It may be insulin-dependent or not, and association with obesity is not obligatory. See also Type 2 diabetes of children and adolescents.

Mediterranean-type diet A popular diet for metabolic diseases, and prevention of cardiovascular troubles. It is rich in fruits, vegetables, nuts, grains and omega-9 fatty acid (olive oil).

Meglitinides Short-action oral insulin secretagogues, used in type 2 diabetes therapy. Examples are Nateglinide and Repaglinide.

Mesenchymal stem cells Mostly collected from adipose tissue. Analogously to other stem cells, they can differentiate into several types of cells. See also Stem cells.

Metabolic syndrome The association of abdominal obesity, arterial hypertension, dyslipidemia, and glucose intolerance. Other derangements are sometimes included in the cluster, and diagnostic criteria vary. Typically linked to fatty liver disease, diabetes, and cardiovascular complications.

Metformin See Biguanides.

Miglitol See Alpha glucosidase inhibitors.

MODY See Maturity Onset Diabetes of the Young.

Nateglinide See Meglitinides.

Pioglitazone See Thiazolidinediones.

Prediabetes Impaired fasting blood glucose, or glucose tolerance test. Increases risk for type 2 diabetes, as well as for cardiovascular complications. Formerly known as insulin resistance.

Repaglinide See Meglitinides.

Retinopathy A serious ophtalmological complication of diabetes, especially in the elderly, however also affecting children and young adults. It can progress from blorred vision to total blindness. Requires periodic ophtalmological evaluations for early diagnosis and treatment.

Rosiglitazone See Thiazolidinediones.

Semaglutide See Glucagon-like peptide 1 receptor agonists.

SGLT2 inhibitors See Glifozins.

Sodium glucose co-transporter 2 inhibitors See Glifozins.

Stem cell A pluripotent cell able to differentiate into different tissues, given the right stimulation. This includes cells of pancreatic islets of Langerhans, or more specifically, insulin-secreting beta cells, rendering them attractive for cell therapy of type 1 diabetes. Embryonic stem cells can be collected from cord blood, whereas adult stem cells are often harvested in blood, bone marrow, or muscle tissue.

Sulfonylureas Oral antidiabetic drugs which stimulate insulin secretion. Hypoglycemia can be a side effect. Glimepiride, glipizide, and glyburide are better tolerated, second generation products.

Thiazolidinediones Oral antidiabetic drugs which are not insulin secretagogues, however improve insulin sensitivity. Examples are troglitazone, pioglitazone and rosiglitazone.

Trans fats An ubiquitous type of fatty acids, found in nature only in small concentrations, in meats and dairy products. Significant amounts in dozens of industrialized or processed foods, such as cakes, cookies, margarines, ice cream, fried potatoes, snacks, and fast food. Formed by hydrogenation of preexistent unsaturated fatty acids. They raise

LDL cholesterol and diminish HDL cholesterol, a double jeopardy for lipid blood profile, and should be strictly avoided.

Troglitazone See Thiazolidinediones.

Type 1 Diabetes Previously known as juvenile diabetes, onset is more common at early age, however it affects adults and elderly as well. Beta cell destruction is the rule, and insulin therapy is almost always required.

Type 2 diabetes By far the most common form of the disease. Previously known as maturity onset diabetes, it progressively affects young people as well, on account of obesity and metabolic syndrome prevalence at young age. Confusion should be avoided with Maturity onset diabetes of the young, a hereditary modality.

TZD See Thiazolidinediones.

Obesity and Bariatric Surgery Glossary (See also Diabetes Glossary)

Anthropometric evaluation Measurement of external variables such as weight, height, and waist circumference, in order to gain insight about nutritional and metabolic status. Routinely conducted in both adult and pediatric patients, even though variables are not always the same.

Body mass index (BMI) The ratio between body weight (in kilograms), and the square of the height (in meters). Used for both adults and children to diagnose obesity, Normal range is 18.5–24.9 kg/m^2, whereas values up to 29.9 signal overweight, and above that, obesity.

Calorie dense foods Foods, snacks and drinks rich in simple carbohydrates and fats. They can be highly processed, with elimination of useful nutrients, or just overcaloric. They tend to precipitate obesity.

DALY See Disability adjusted life year.

Disability adjusted life years A modern concept to estimate the burden of chronic diseases, like obesity and diabetes. It basically multiplies the number of years the individual is expected to suffer from disability, by a coefficient related to its severity.

Duodenal switch See Biliopancreatic diversion.

Duodeno-jejunal bypass barrier An endoscopic modality of bariatric/metabolic treatment for obesity and diabetes. A long flexible implant (sleeve or liner) is anchored at the pylorus, and positioned inside the duodenum and part of the jejunum. The aim is to produce limited malabsorption, preventing contact of the food bolus with the lined mucosa. Usually limited for 6 months utilization only.

Duodeno-jejunal bypass liner See Duodeno-jejunal bypass barrier.

Endoluminal bariatric techniques See Duodeno-jejunal bypass barrier, see Endoscopic sleeve gastrectomy.

Endoscopic sleeve gastroplasty An endoscopic procedure that mimicks classic sleeve gastrectomy. A suturing device applied to the gastric mucosa, without puncturing the gastric wall, creates a series of internal folds or plications, which substantially reduce stomach capacity.

Epigenome Assembly or set of chemical changes of DNA which regulate gene expression and consequently phenotype (disease). Even though they are environmental, not primarily inherited, they can eventually be passed down to future generations by epigenetic inheritance.

Fish oil A popular designation for omega-three-fatty-acids rich seafood. Best sources are salmon, menhaden, mackerel, herring, sardines, cod liver oil, and krill. Consumption is not associated with elevated cardiovascular risk, however purported protective actions in adults are still debated. Supplementation is recommended for infants (central nervous system development).

Gastric balloon A soft, fluid-filled balloon that is positioned in the stomach. By occupying space, it prevents overeating and promotes early satiety. It is usually introduced via endoscope, however a model than can be swallowed is aleady available. Recommendations are for use up to 6 months.

Gastric Banding A bariatric operation which reduces food intake (restrictive procedure),

by means of a silicone band placed around the stomach, a few centimeters below the esophagogastric junction. Very popular during decades in some parts of the world, it is being progressively abandoned, due to unreliable long term results.

Gastric Bypass One of the most popular bariatric interventions. It markedly reduces gastric volume to just a small pouch (restrictive feature), at the same time shunting food down to the small bowel (malabsorptive characteristic). Also known as Roux-en-Y gastric bypass.

Genome The entire complement of genetic material, in a human or animal sample.

Genotype The entire set of genes and their characteristics, which determine the structure and function of an organism.

High-density lipoprotein/High density cholesterol (HDL) A fraction of plasma cholesterol that is associated with improved cardiovascular prognosis. Also known as "good cholesterol".

Highly processed foods Those that undergo multiple industrialization steps, typically removing useful nutrients such as fibre, vitamins and minerals. Sugar, fat and salt are often added as well. They tend to precipitate obesity. See also Calorie dense foods.

Intragastric balloon See Gastric balloon.

Leptin A central hormone for appetite and obesity. Manufactures by adipose cells as well as other sources, it inhibits appetite at high concentrations, thus preventive excessive fat accumulation. In obese humans, leptin administration doesn't lead to weight loss, suggesting decreased sensitivity.

Low-density lipoprotein/Low density cholesterol (LDL) The main fraction of plasma cholesterol that is associated with elevated cardiovascular risk. Also known as "bad cholesterol".

Metabolic syndrome The association of abdominal obesity, arterial hypertension, dyslipidemia, and glucose intolerance. Other derangements are sometimes included in the cluster, and diagnostic criteria vary. Typically linked to fatty liver disease, diabetes, and cardiovascular complications.

Monogenetic A disease or trait that is triggered by a single, well-known gene. A few uncommon modalities of obesity and diabetes are monogenetic.

Monounsaturated fatty acid Mainly consumed as olive oil, it is one of the pillars of the Mediterranean diet. Also present in canola oil, avocados and other sources.

Morbid Obesity A Body Mass Index of 40 kg/m^2 or greater. Also known as Class III obesity. The concept is intimately associated with indication for bariatric surgery, even though a BMI of 35 kg/m^2 with comorbidities, or in certain countries <35 kg/m^2, can be a legitimate indication as well.

Nutrient dense foods and drinks Usually designates natural foods, with a useful composition. Contrasts with Highly processed foods or Calorie dense foods.

Obstructive sleep apnea See Sleep apnea.

Omega-nine fatty acids See Monounsaturated fatty acids.

Omega-six fatty acids See Vegetable oils, See Polyunsaturated fatty acids.

Omega-three fatty acids See Fish oil, See Polyunsaturated fatty acids.

Phenotype Physical and metabolic makeup of an organism, which is controlled by genes. Can be divided in conventional (external appearance) and deep phenotype (proteins, enzymes, metabolites), as identified by biochemical and metabolomics studies. See also Genotype.

Polygenetic Disease or trait related to the interaction of many genes. Most types of obesity and diabetes undergo polygenetic influences.

Polyunsaturated fatty acids Type of fat which is chemically unsaturated, with multiple double or triple bonds. Typically liquid at room temperature, they comprise omega-6 fatty acids (soybean oil, corn oil, safflower oil and some other vegetable oils) as well as omega3 fatty acids (basically fish oil, however also flaxseed oil, canola oil and soybean oil).

Roux-en-Y gastric bypass See Gastric bypass.

Satiety The sensation of a fed state. It is mediated by hormones like ghrelin, leptin, PYY and other appetite regulating biomolecules. Derangements in obese subjects have been reported.

Saturated fatty acids Type of fat that is chemically saturated, or that has been saturated by industrial hydrogenation. Typically solid at room temperature. Representative examples are milk fats, other animal fats (lard, chicken fat), coconut and palm oil, any hydrogenated vegetable fat (margarine, mayonnaise, cookies).

Sedentarism A lifestyle modality featuring little or no physical activity or exercise. It is associated with watching television and other screens. A serious predisposing factor for obesity, in both children and adults.

Scopinaro's operation See Biliopancreatic diversion.

Sleep apnea A respiratory complication of severe obesity. It can be associated with cardiovascular complications, including hypertension, coronary heart disease, arrhythmia, and heart failure. Response to bariatric weight loss is usually favorable.

Sleeve gastrectomy One of the most popular bariatric interventions. Originally part of the biliopancreatic diversion, it is performed as a standalone procedure. The stomach is divided along the smaller curvature, creating a long and narrow channel, which inhibits large meals (restrictive modality).

Subcutaneous fat The most important fat depot, with over 95% of total body fat. Has much less implications regarding cardiovascular risk than visceral fat. Increased thigh fat in postmenopausal women is indeed associated with less myocardial infarction and stroke.

Vertical gastroplasty The vertical banded gastroplasty was a purely restrictive operation, which partially divided the stomach, creating a small vertical pouch. This intervention has been nearly completely abandoned. See also Sleeve gastrectomy.

Visceral fat Body fat that accumulates inside the abdominal cavity, mostly on the greater omentum, and around viscera. A metabolically active fat compartment associated with inflammation, hormone and coagulation factor production, and cardiovascular complications. See also Waist circumference.

Waist circumference A surrogate (anthropometric) measurement of visceral fat. Associated with metabolic syndrome and cardiovascular complications.

Wild type The genotype or phenotype of an experimental animal that is found in nature. Non genetically manipulated.
