## Foreword of the First Edition

Regulatory toxicology requires knowledge of aspects related to a number of disciplines of natural and social sciences, including chemistry, biology, bioinformatics, toxicology, epidemiology, exposure assessment and nutrition, as well as sociology, psychology and communication, to name a few. It builds a bridge between science and decision-making. In fact, risk analysis, the centrepiece of regulatory toxicology, is often seen as an art, in addition to its being a science. This explains why standard textbooks on regulatory toxicology are rare.

Ten years after the publication of the first standard work on regulatory toxicology in German, an updated, expanded version is now at hand in English language. This major publication addresses questions covering various aspects of risk assessment and risk management in general, paying attention to a number of fields including health protection, occupational health, environmental health and consumer protection. Basic principles are outlined, new developments described, and scientific, social and philosophical questions discussed at length. In times of an increased understanding that risk assessment and management need to be conducted in full transparency and with full involvement of all stakeholders, issues of risk perception and risk communication are addressed.

This breadth of information, complemented by a listing of the newest guidance values, makes this book a standard reference to those involved in the field of regulatory toxicology. It is of interest to risk scientists of various backgrounds, to policymakers and their advisors, and also to informed consumers.

A welcome and timely publication, indeed.

WHO, Geneva, Switzerland  
IUTOX-president, Aarhus, Denmark

## Preface

Based on the success of the first edition (2014) of the book *Regulatory Toxicology*, the editors decided to compile a second edition. Though the basics of toxicological risk assessment and risk management experienced only moderate changes, the methods to study and evaluate adverse chemico-biological interactions were further refined in the years since the first edition, not least due to numerous novel in vitro test systems. Moreover, we experienced a decade of many advances in the consolidation of rules and guidelines on national and international levels.

The chapters of the first edition were updated for this second edition. Moreover, many new chapters were included, dealing with novel developments, such as regulations of nanoparticles, designer drugs, tattoos, biopharmaceuticals and gene therapy. The chapters were written by experts for all those who are involved in toxicological data generation and decision-making in institutions of pure and applied regulatory toxicology.

In summary, this handbook deals comprehensively with the management of chemical hazards and risks in regulatory toxicology, with a focus on test systems and their interpretation, and the concepts used to estimate acute and chronic toxicity to humans and the environment. Such information supports the work of those involved in risk assessment in academia, industry, government or related agencies. It also serves the superior aim of contributing to the protection of human health, clean environments, and a sustainable development on earth.

The editors have sought to bring consistency to the diversity of approaches and of opinions concerning toxicological risk assessment. Guideline values, regulations and data may change with time and among jurisdictions. However the basic principles and approaches discussed in this handbook will continue to provide a stable basis for future decision finding. Opinions expressed are those of the individual authors and do not necessarily represent the views of their institutions.

September 2021

Franz-Xaver Reichl  
Michael Schwenk

---

## Acknowledgments

The editors wish to thank all authors for their valuable contributions to this edition of *Regulatory Toxicology*. They also thank Kerstin Beckert and Barbara Wolf from the Editorial team of Springer for the excellent cooperation.

# Contents

## Volume 1

<b>Part I The “Modus Operandi” of Regulatory Toxicology</b> .....	<b>1</b>
<b>1 Aims and Mission of Regulatory Toxicology</b> .....	<b>3</b>
Helmut Greim	
<b>2 Working Areas of Regulatory Toxicology</b> .....	<b>23</b>
Michael Schwenk and H. Paul A. Illing	
<b>3 National and International Collaboration in Regulatory Toxicology</b> .....	<b>35</b>
Alfonso Lampen and Klaus E. Appel	
<b>4 The Regulatory Process in Toxicology</b> .....	<b>51</b>
Dietrich Henschler and Wolfgang Dekant	
<b>5 Quality Assurance in Toxicology</b> .....	<b>59</b>
Klaus-Michael Wollin, Stephen Harston, and Werner Lilienblum	
<b>6 Toxicological Risk Assessment</b> .....	<b>69</b>
Maged Younes and Nikolaos Georgiadis	
<b>Part II Tests and Methods</b> .....	<b>81</b>
<b>7 Monoclonal Antibodies: Discovery and Protein Engineering</b> .....	<b>83</b>
Wibke Lembke and Mathias Locher	
<b>8 Characterization of Physicochemical Parameters in Toxicology</b> .....	<b>99</b>
Mathias Locher	
<b>9 Examination of Acute and Repeated-Dose Toxicity</b> .....	<b>107</b>
Volker Mostert, Karl Georg Heimann, and Kevin Doughty	
<b>10 Examination of Organ Toxicity</b> .....	<b>117</b>
Wolfgang Kaufmann and Matt C. Jacobsen	

---

<b>11</b>	<b>Specific Toxicity Tests for Neurotoxicity, Immunotoxicity, Allergy, Irritation, Reprotoxicity, and Carcinogenicity</b> .....	129
	Eckhard von Keutz	
<b>12</b>	<b>Toxicity Testing In Vitro: Regulatory Aspects</b> .....	139
	Eckhard von Keutz	
<b>13</b>	<b>Integration of Advanced Technologies into Regulatory Toxicology</b> .....	149
	Horst Spielmann and Helena Kandarova	
<b>14</b>	<b>Computer-Based Prediction Models in Regulatory Toxicology</b> ...	163
	Thomas Steger-Hartmann and Scott Boyer	
<b>15</b>	<b>Metabolism Investigations in Drug Development</b> .....	177
	Jens Riedel and Alain Krick	
<b>16</b>	<b>Toxicokinetic Tests</b> .....	189
	Jürgen Pauluhn	
<b>17</b>	<b>Toxicodynamic Tests</b> .....	215
	Alexander Cartus and Dieter Schrenk	
<b>18</b>	<b>Omics in Toxicology</b> .....	231

## About the Editors

### **Franz-Xaver Reichl**

Department of Operative/Restorative Dentistry  
Periodontology and Pedodontics  
LMU, Munich, Germany

Walther-Straub-Institute of Pharmacology  
and Toxicology  
LMU, Munich, Germany

Franz-Xaver Reichl studied microbiology and medicine in Munich, Germany. He then qualified as a toxicologist/pharmacologist and works at the Ludwig Maximilians University of Munich (LMU) as a dental-toxicologist at the Dental Clinic and at the Walther-Straub-Institute of Pharmacology and Toxicology at the LMU. His research is mainly related to molecular, cellular, and analytical (dental) toxicology and toxicity. F.X. Reichl consulted health agencies in toxicological risk management and is member of toxicological/pharmacological committees. He is head of the “International Advisory Board for the Biocompatibility/Toxicology of Dental Materials” at the LMU and is “Officer for Biosafety of Bacteria and Viruses” at the LMU Munich.

### **Michael Schwenk**

Medizinische Hochschule Hannover  
Center of Pharmacology and Toxicology  
Hannover, Germany

Michael Schwenk studied biochemistry and medicine in Tübingen, Germany, and thereafter specialized in pharmacology, toxicology, and nutritional and environmental medicine. He was appointed professor in Pharmacology and Toxicology in 1987. He worked in

universities, basic research institutions, pharmaceutical industry, and a state health agency.

He created and headed the Regulatory Toxicology Study Group of the German Society of Toxicology, consulted health agencies in toxicological risk management, and was secretary of the IUPAC Division Chemistry and Human Health.

His research areas include membrane transport of xenobiotics, drug-biomolecule interactions, drug metabolism, cytotoxicity, phase I clinical studies, human biomonitoring, and risk assessment.

**Abstract**

The aim of regulatory toxicology is to control production, use, and deposition of dangerous materials to prevent adverse effects on human health and the environment. This requires sufficient information on the hazardous properties of a chemical compound, their relevance to man, and of human and environmental exposure, which is a prerequisite for appropriate risk assessment and the decision whether regulatory consequences are warranted. The three elements of risk assessment of chemical substances are hazard identification, evaluation of dose–response relationship, and exposure assessment. The risk assessment process requires differentiation between reversible and irreversible effects, that is, identification of a “no observed adverse effect level” (NOAEL) and/or a “lowest observed adverse effect level” (LOAEL) for the most critical effect of the substance, or, in case of irreversibility, estimation of the risk at a certain exposure. Up to now, the risk of genotoxic carcinogens at a certain exposure concentration is estimated by linear extrapolation of the dose–response curve. Further, to set priorities the margin of exposure (MOE) or margin of safety (MOS) can be calculated by comparing the NOAEL with the human exposure. Additional information for the evaluation of the human relevance of experimental data are available from toxicokinetics or the mode and/or mechanism of action. In the evaluation of the existing data base, setting limit values like “acceptable daily intake” (ADI) or “derived no effect levels” (DNELs) or implementing risk management measures, the uncertainties of the database have to be described and taken into consideration. Another challenge is the evaluation and regulation of mixtures, which needs to take into account concentrations and mode of action of the individual components. The systems for classification of carcinogens used by various national and international institutions are summarized. The use of the so-called precautionary principle and of the “Threshold of Toxicological Concern” (TTC) concept for risk assessment purposes is explained. In addition, the regulations for specific chemical classes like drugs or pesticides are completed by a short description of the European Union Registration, Evaluation, Authorisation and Restriction of Chemicals (EU REACH) regulation for chemical substances.

**Introduction**

Regulatory toxicology uses the information on hazard and risks of human and environmental exposure of agents for their regulation. This requires understanding of the relevant regulations in this area as well as a basic understanding of the principles of toxicology. The latter is of specific importance because regulations are based on precise

numbers like the ADI (acceptable daily intake) or cut-off levels for the labeling of hazardous chemicals, whereas toxicology as a biological and experimental discipline does not provide such precise data. A NOAEL (No Observed Adverse Effect Level) is a number obtained from animal experiments using different doses. Its preciseness depends on the number of animals used at each dose and the difference to the LOAEL (Lowest Observed Adverse Effect Level). Depending on the dose intervals it might be 2- or 10-fold. Thus, expert judgment is required to correctly interpret the reliability of the data on which the ADI value is based and to decide on the need of regulatory consequences if the ADI is exceeded. Moreover, as implied by REACH regulations the socioeconomic consequences including the availability of alternatives and their own hazardous properties need to be considered. Although there are guidelines and regulations for almost all aspects of risk assessment, risk management, and regulations, it is the quality of hazard identification and risk assessment for human and the environmental exposure that determines the regulatory consequences. Consequently toxicology has to provide sufficiently defensible data for hazard identification and risk assessment and provide information, which are applicable for regulations as decided by the risk manager. On the other side the risk managers have to understand uncertainties of the risk assessment process and that a slight exceedance of an ADI or the risk control ratio (RCR) of 1 does not per se pose a nontolerable risk.

Since toxicology is the basis of all regulations to protect human health, a profound understanding of toxicology is essential for regulatory toxicology (c.f. Greim and Snyder 2019).

When a substance produces toxic alterations at a low dose, it is said to have a high potency. The type and extent of adverse effect is associated with duration and route of exposure (oral, inhalative, dermal) and the toxicokinetic behavior. Susceptible persons or groups may react already at lower dose than the general population. To characterize the risk of a given or potential exposure the adverse effects of chemicals have to be understood, and by evaluating the dose response to identify at what exposure a chemical will produce adverse effects.

It is obvious from this that risk characterization comprises three elements:

- Hazard identification, that is, a description of the agent's toxic potential
- Evaluation of the dose–response, including information on the concentration above which the agent induces toxic effects to identify the NOAEL
- Exposure assessment to understand the concentration of the agent in the relevant medium, time, and routes of human exposure

---

## Components of Risk Assessment

### Hazard Identification

Chemicals induce local and/or systemic effects such as embryotoxicity, hepatotoxicity, and neurotoxicity after absorption from the gastrointestinal tract, through the skin or via the lungs.

Depending on exposure concentration and time of exposure acute or chronic effects may result. Acute intoxication usually occurs in response to large doses of the parent compound less due to its metabolites. Acids or bases are directly acting agents which cause local irritation or corrosion at the site of exposure, such as the nasal and ocular surfaces, the respiratory tract, mouth, esophagus, or skin.

Highly lipophilic substances, such as 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) accumulate in tissues especially in body fat because they are lipophilic and are not well metabolized. In humans the half-life of excretion of TCDD is about 8 years. To insure safe use by the consumers or the specific conditions in the workplace the toxicological profiles of each chemical need to be evaluated. Such evaluation may take different forms for new and existing chemicals. In the case of newly developed drugs, pesticides, or new chemicals a stepwise procedure is used starting from simple in vitro and in vivo short-term tests. Depending on the hazardous potential of the agent, studies are extended to evaluate long-term effects by repeated dose studies, toxicokinetics, and toxic mode of action. For existing chemicals the available information is collected and a risk assessment based on exposure data, knowledge of the dose-response relationship, and the mode of action can be performed or in case of data gaps additional experiments requested.

Reactivity, solubility, and metabolism of the chemical or its metabolites determines the target organ of the critical effects. Histopathological and biochemical changes have been the major parameters used to detect organ toxicity. Increasing availability of sensitive methods in analytical chemistry and molecular-biological approaches including toxicokinetics and the various “omics” has significantly improved the understanding of the mechanisms by which cellular and subcellular functions are impaired and how the cells are responding to toxic insults. This results in a better understanding of toxic mechanisms, species differences, and the consequences of exposures at high and low concentrations over different times.

## **Dose-Response and Toxic Potency**

According to the general principle of toxicology as expressed by Paracelsus (1493–1541): “In all things there is a poison, and there is nothing without a poison. It depends only upon the dose whether a poison is poison or not” or in short “the dose makes the poison.” The consequences of human or environmental exposures depend on the amount and duration to which these individuals or populations are exposed. This paradigm anticipated today’s threshold concept which can be assessed in studies on dose-response relationships.

Animal or human exposure is usually defined as the dose, for example, in mg of the chemical/kg body weight/day. This daily dose may result from oral, inhalation, or dermal exposure or as a sum thereof. The external dose leads to a specific internal dose, which depends on the amount absorbed via the different routes. Absorption rates via the different routes can vary significantly, although oral and inhalation exposure usually lead to the highest internal dose. For example, about 50% of cadmium in tobacco smoke is absorbed in the lung, whereas cadmium absorption from the

**Fig. 1** Dose–response curve showing the dose on the X-axis and % response (Effect) on the Y-axis. The figure illustrates the location of regulatory values such as the NOEL (NOAEL), occupational exposure levels (OELs), or environmental standards such as acceptable daily intake (ADI). Note that a doubling of dose in the lower or upper part of the S-shaped curve results in small increases in effects, whereas they are much more prominent in the steep part

gastrointestinal tract is about 10%. Ultimately, it is the dose which reaches the cellular target over a given time period that results in the toxicological response. No toxic effects will be seen at doses up to the NOAEL, which is the starting point to derive values of acceptable exposures for consumers (acceptable daily intake (ADI)) or at the workplace (occupational exposure limits (OELs)). The dose–response curve may be expressed using a variety of mathematical formulas. Using the linear form of the dose–response relationship the curve is sigmoidal in shape and varies in slope from chemical to chemical. Thus, if the curve is shallow a doubling of the dose results in a small increase of effects, whereas effects increase severalfold when the slope is steep (see Fig. 1). The dose is plotted on the abscissa (X axis). The position of the sigmoidal part of the curve above the x-axis provides information about the toxic potency of a substance.

## Exposure Assessment

According to the Paracelsian admonition exposure assessment or prediction of exposure is an ultimate requirement for risk assessment and to decide on the need for regulations.

Exposure defines the amount of a chemical to which a population or individuals are exposed via inhalation, oral, and dermal routes and is commonly defined by mg of the chemical/kg body weight per day.

Since occupational exposure is regular and repetitive it can easily be measured in the air of the workplace and/or by use of personal monitoring equipment; exposure of general population is more difficult to assess. It usually is a combination of the presence of the compounds in indoor/outdoor air, drinking water, food, or use of products that contain the chemical. Moreover, frequency, duration and site of exposure, concentration, and weight of substance in the products need to be

considered. Children represent a special case of exposure. They may be exposed to chemicals that are released from toys during mouthing, via skin contact or uptake of contaminated dust/soil by hand-to-mouth behavior. Exposure scenarios that estimate and quantify the frequency of contact, ingested amounts, solubilization, and the extent of absorption will help to model and roughly estimate the combined uptake from various sources.

Absorption through the skin will also influence the body burden of the chemical. Use of these parameters to assess exposure is plagued by many uncertainties, which often lead to overestimation of the actual exposure, because external exposure may not necessarily correlate with internal exposure. Biomonitoring of the compound or its reaction products in the exposed individuals provides the most reliable estimate of internal exposure. However, dose–response curves usually provide a correlation between external dose and effects. Therefore, risk assessment of an internal exposure either requires knowledge of the dose–response of internal exposure versus adverse effects or information to which extent external and internal doses correlate. The estimation of exposure is more complicated when mixtures of chemicals are the source of exposure.

Ultimately, it is the dose that reaches the cellular target over a given time period that results in the toxicological response. Thus, the toxic potency of a chemical is the product of the interrelated external, internal, and target doses, which results from the multiple pathways and routes of exposure to a single chemical (aggregate exposure). In the case of existing chemicals an appropriately designed program to measure the chemical in the different media will provide the necessary information.

The measurement of external dose is either done on collected samples, such as food samples or by direct measurement, that is, in air. When collected samples are used representative sampling and appropriate storage conditions as well as accurate and reproducible measurement techniques are essential. This also applies to biomonitoring programs.

Exposure data are not fully known for many chemicals, and exposure-modeling is therefore an important tool.

The Technical Guidance Document on Risk Assessment Part I (European Chemicals Agency (ECHA) 2003) of the European Commission lists the following core principles for human exposure assessment for new substances, existing substances, and biocides:

- Exposure assessments should be based upon sound scientific methodologies. The basis for conclusions and assumptions should be made clear and be supportable and any arguments developed in a transparent manner.
- The exposure assessment should describe the exposure scenarios of key populations undertaking defined activities. Such scenarios that are representative of the exposure of a particular (sub) population should, where possible, be described using both reasonable worst-case and typical exposures. The reasonable worst-case prediction should also consider upper estimates of the extreme use and reasonably foreseeable other uses. However, the exposure estimate should not be grossly exaggerated as a result of using maximum values that are correlated with each other. Exposure as a result of accidents or from abuse shall not be addressed.

- Actual exposure measurements, provided they are reliable and representative for the scenario under scrutiny, are preferred to estimates of exposure derived from either analogous data or from the use of exposure models.
- Exposure estimates should be developed by collecting all necessary information (including that obtained from analogous situations or from models); evaluating the information (in terms of its quality, reliability, etc.); thus enabling reasoned estimates of exposure to be derived. These estimates should preferably be supported by a description of any uncertainties relevant to the estimate.
- In carrying out the exposure assessment the risk reduction/control measures that are already in place should be taken into account. Consideration should be given to the possibility that, for one or more of the defined populations, risk reduction/control measures that are required or appropriate in one use scenario may not be required or appropriate in another (i.e., there might be subpopulations legitimately using different patterns of control which could lead to different exposure levels).

**Exposure-biomonitoring** provides direct information about the internal exposure of organs. It allows to measure or estimate:

- The aggregate exposure that reflects the quantity of a substance that has entered the organism via all routes.
- Its biotransformation and biological half-life and the estimated total body burden at the time of measurement.
- The exposure of target organ to the original substance and its metabolites.
- Exposure-biomonitoring is an important diagnostic tool that allows to estimate whether a chemical exposure via the air, food, or contaminated house dust causes increase of the internal body load, as compared to populations that are not specifically exposed.

**Effect-biomonitoring** is a diagnostic tool that investigates substance-induced changes of enzyme activities or other molecular and cellular parameters.

---

## Risk Assessment

Advanced methods of sample preparation and chemical analysis are available that can detect extremely small substance levels in environmental media and biological tissues. When a chemical is found, this alone does not mean that it is accompanied with a toxic response of an exposed individual. According to the Paracelsus paradigm, dose is an essential parameter that determines toxic response. Only when the NOAEL is exceeded, an effect can be expected.

It is essential to differentiate between effects that are reversible and others that may be irreversible and associated with chronic disorders. Substances that induce reversible effects have a segment in the lower dose range of their dose–response plots, below which no adverse effect can be observed. The discrimination point is the NOAEL. The first dose that elicits an adverse effect is the LOAEL. When using the terms NOAEL and LOAEL, an analysis should be made, whether the observed

response is a physiological adaptation or an adverse effect. It is to be noted that threshold is not the equivalent of an NOAEL, since it describes a concentration or exposure where the slope of the dose–response curve changes.

If damage is not repaired and/or eliminated, the effect persists, may accumulate upon repeated exposure, and becomes irreversible. Reversibility depends on the regenerative and repair capacity of cells, subcellular structures, and macromolecules during and after exposure. Epithelial cells of the intestinal tract or the liver have a high regenerating capacity and rapidly replace damaged cells by increased cell replication. The highly specialized cells of the nervous system have lost this capacity during natal and post-natal development. Consequently damaged cells are not or slowly replaced, at least in the adult.

For chemicals that induce reversible effects the NOAEL of the most sensitive endpoint is determined and compared with the human exposure to describe the margin of exposure (MOE) (or margin of safety (MOS)). If the NOAEL is derived from animal experiments, an MOE of 100 or greater is desirable, which comprises a factor of 10 for interspecies differences and another factor 10 for intraspecies differences. An MOE of at least 10 is sufficient if the NOEL is derived from human data.

The covalent binding of genotoxic mutagens and carcinogens to DNA is considered an irreversible event despite the availability of repair processes. However, there is increasing knowledge about DNA-repair mechanisms, the role of tumor-suppressor genes, apoptosis, and the level of background mutation rates, so that the assumption that even genotoxic effects exhibit a threshold becomes increasingly plausible (see Greim and Albertini 2015). So far the general agreement remains that the potency of genotoxic carcinogens increases with increasing dose without a NOAEL.

To determine the potency of genotoxic carcinogens and cancer risk at a given exposure, a linear or sublinear extrapolation from the high dose effects observed in animals to the usually lower human exposure is requested by regulatory agencies. The European Food and Safety Authority (EFSA) recommends to avoid this extrapolation because of the inherent uncertainties. Instead, the MOE between a benchmark dose, or the T25 calculated from a carcinogenicity study in animals and human exposure, should be determined. An MOE of 10,000 and more is of minor concern. The advantage is that neither a debatable extrapolation from high to low doses needs to be performed nor are hypothetical cancer cases calculated.

---

## **Requirements for Toxicological Hazard Identification and Risk Assessment**

The identification of hazardous properties of a chemical includes the following studies:

- Acute, subchronic, and chronic toxicity (oral, inhalation, dermal)
- Genotoxicity (in vitro and in vivo methods)
- Carcinogenicity (lifetime studies)
- Irritation (skin, mucous membranes, eye) and phototoxicity

- Sensitization and photosensitization
- Reproductive and developmental toxicity
- Toxicokinetics
- Mode and mechanism of action
- Other aspects such as neurotoxicity and immunotoxicity

Wherever adequate, dose–response relationships, presence of thresholds, NOAEL, LOAEL, and maximal tolerated dose (MTD) should be studied. Guidelines are available for many test systems and assays (Organization for Economic Cooperation and Development (OECD) Guidelines). For existing chemicals a broad database is generally available and published by various organizations (see Table 1). The test systems have been continuously refined and improved in the past decades and it can be expected that additional novel test procedures will be developed in the future (c.f. Greim and Snyder 2019).

## Acute Toxicity, Subchronic Toxicity, and Chronic Toxicity

**Acute toxicity studies** are performed in rodents. They employ a range of doses including the estimated lethal dose. Acute and delayed effects are observed during 2 weeks, and the acutely lethal dose is determined.

In **repeated dose (subacute) studies** the chemical is administered to rodents daily for several weeks or months. In special cases larger species such as dogs, and in the case of new drugs, monkeys or apes may be employed. Possible toxic effects, for example, with regard to animal behavior, body weight, or common diagnostic parameters, are documented. At the end, the animals are sacrificed to examine organs for pathological and histopathologic alterations.

**Chronic studies** are characterized by repeated dosing of animals, in general rodents, for months up to a lifetime. They investigate possible effects of long-term exposure. A major goal of lifetime studies is the detection of possible carcinogenic effects.

There is an ongoing tendency to replace animal studies by *in vitro* studies and *in silico* prediction of structure–activity relationships. They are novel developments and contribute to reduction of cost as well as animal protection. At present, the information, deduced from these types of replacement studies, is restricted to selected endpoints. They cannot reflect the complex network and interactions of organs, hormones, transmitters, neurons, etc. and so it is presently not possible to fully replace *in vivo* methods.

Nevertheless, some *in vitro* systems can be used to estimate aspects of dose–response relationship and may contribute to toxicokinetic modeling and prediction of dose-dependent effects in the specific target. Test systems with a drug-metabolizing function may detect relevant biotransformation products and reactive intermediates. Nevertheless, this does not necessarily reflect the situation in the living organism. In fact, assessment of all relevant endpoints, their dose dependency, thresholds, and NOAELs can only be finally assessed in the intact animal. When such information is unavailable hazard identification is incomplete. Consequently the basis for appropriate risk assessment of human exposure is missing.

## Genotoxicity

Substance-induced damage of DNA is usually detected by bacterial mutagenicity assays in the absence and presence of drug metabolizing enzymes as well as by an *in vitro* cytogenetic assay. This is supplemented by the mouse bone marrow micronucleus test that detects chromosomal abnormalities. When these tests show genotoxic potential a chemical substance is usually not further developed, unless for specific applications (e.g., chemotherapeutics). When there is unclear evidence for genotoxicity, carcinogenicity studies in the further characterization of the substance will provide further information.

## Carcinogenicity

Carcinogenicity studies have a similar design as studies on chronic toxicity. Three or more doses in the range of the maximum tolerated dose are administered to animals (50 animals per sex and dose) with the aim to detect possible increases over the natural tumor incidence. Rats and mice have several advantages for such studies:

They have a lifespan of only 2 years, during which they develop from young to aged animals. There is plenty information about their physiology, pathology, and susceptibility to chemical tumor induction and promotion. Databases on spontaneous tumor incidences for many strains and their tissues exist. The incidence of spontaneous and substance-induced tumors tends to increase in older animals.

When interpreting results of tumor incidence, it must be considered that non-carcinogenic chronic toxic effects may have influenced the study outcome. For example, very high doses may result in insufficient detoxification of the test substance, decreased intracellular GSH levels, or overwhelmed DNA repair. Some forms of tumors such as the  $\alpha$ -urinary globulin-induced kidney tumors of the male rat are species-specific. Their occurrence will hardly be relevant for humans. Also rodents are more sensitive to peroxisome proliferators. Results of carcinogenicity studies must be evaluated by experienced experts. They will take into account their experience about the pattern of toxic changes and possible underlying mechanisms to identify a substance as a carcinogen.

## **Irritation and Phototoxicity**

Dermal irritation of substances is studied in animals and humans. It is common to use a single occluded patch. Substances having significant light absorption in the ultraviolet range (290–400 nm) carry a risk of phototoxicity and photoallergic reactions. Here, a substance-treated patch site is irradiated either immediately or after patch removal. In vitro assays for phototoxicity include the test for uptake of Neutral Red by 3 T3 cells. In the case of negative results, further testing in the living organism may not be necessary.

## **Sensitization**

To study immunological sensitization, the Buehler skin test in guinea pigs and the local lymph node assay (LLNA) in mice are performed in animals, but novel tests such as human skin cultures are in development. The LLNA has been reported to correlate closely with the results gained by repeat patch testing in humans. In cases, where animal data indicate a potential for contact sensitization, human skin sensitizing testing is conducted, usually by a human repeated-insult patch test (HRIPT). If possible, the formation of specific antibodies in the course of substance exposure should be monitored.

## **Toxicity for Reproduction and Development**

Such studies aim at detecting substance-induced changes of reproductive function of the parents, fetotoxic, teratological, or development-disturbing effects on the fetus and possible effects on the second generation.

## Toxicokinetics

A chemical may enter the body via the gastrointestinal tract, the lung, or the skin. The amount absorbed depends on the concentration in the different media like food, air, on physical-chemical parameters such as solubility in water and fat, stability, and the route of exposure. Toxicokinetics describe absorption, distribution, metabolism and elimination (ADME) of a chemical in humans, or experimental animals. Of specific importance for interpretation of animal studies and for extrapolation between species is the comparative information on the exposure and the dose that reaches the critical target.

Upon inhalation or skin penetration the compound directly enters the cardiovascular system and distributes into the organs. When absorbed from the gastrointestinal tract the chemical enters the liver via the portal vein and to a much less extent is taken up directly into the cardiovascular system. The epithelial cells of the gut wall and the liver present a large capacity for metabolizing chemicals so that a compound may be extensively metabolized by this **“first pass effect”** before entering the (cardiovascular) systemic circulation. Larger molecules, for example, the glucuronosyl-conjugates can be excreted via the biliary system into the duodenum where the conjugates may be hydrolyzed so that the original compound is reabsorbed and reenters the liver. This process is defined as **enterohepatic circulation**. Inhalation or dermal exposure to a chemical, intravenous, or intraperitoneal injection may result in different effects than after oral exposure because of the “first pass effect.”

After entering the cardiovascular system the chemical or its metabolites distribute to the organs where they can accumulate in organs such as fat or bones, or are further metabolized. Reactive metabolites will interact with tissue components and may induce cellular damage. This “tissue dose,” that is, the concentration of a chemical or its metabolite at the critical target over a given time, is an important factor that helps to understand the correlation between internal exposure and external (environmental) exposure in relation to toxicity. By comparing tissue doses in different species at similar exposures also helps to understand species differences in the sensitivity to chemicals, as well as interindividual variations.

The chemical or its more water-soluble metabolites are primarily excreted via the kidneys or the biliary system. Volatile compounds may be exhaled. The great variety of processes observed during absorption, metabolism, distribution, and excretion cannot be predicted by modeling or by *in vitro* experiments without confirmatory data from animals and man.

## Mode and/or Mechanism of Action

There are many mechanisms by which chemicals or other stressors like heat or radiation can lead to toxicity. Knowledge of the modes or mechanisms by which a chemical induces toxicity are essential to understand species specificities, species differences, sensitive populations, or the interpretation of data regarding threshold or non-threshold effects. They also help to evaluate the relevance of the toxic effects to

humans when the data are derived from experimental animals. Whereas toxic mechanism is often not known in detail, modes of action, which can be described in a less restrictive manner, are helpful in the risk assessment process as well. Generally toxic mechanisms or modes of action are differentiated as follows:

**Physiological changes** are modifications to the physiology and/or response of cells, tissues, and organs. These include mitogenesis, compensatory cell division, escape from apoptosis and/or senescence, inflammation, hyperplasia, metaplasia and/or preneoplasia, angiogenesis, alterations in cellular adhesion, changes in steroidal estrogens and/or androgens, and changes in immune surveillance.

**Functional changes** include alterations in cellular signaling pathways that manage critical cellular processes such as modified activities for enzymes involved in the metabolism of chemicals such as dose-dependent alterations in phase I and phase II enzyme activities, depletion of cofactors and their regenerative capacity, alterations in the expression of genes that regulate key functions of the cell, for example, DNA repair, cell cycle progression, post-translational modifications of proteins, regulatory factors that determine rate of apoptosis, secretion of factors related to the stimulation of DNA replication and transcription or gap-junction-mediated intercellular communication.

**Molecular changes** include reversibility or irreversibility of changes in cellular structures at the molecular level, including genotoxicity. These may be formation of DNA adducts and DNA strand breaks, mutations in genes, chromosomal aberrations, aneuploidy, and changes in DNA methylation patterns.

Mechanistic information is most relevant for the evaluation, classification, and regulation of all hazardous and at a given exposure to risky chemicals including carcinogens. For example, if the carcinogenic effect is induced by a specific mechanism that does not involve direct genotoxicity, such as hormonal deregulation, immune suppression, cytotoxicity, the detailed search for the underlying mode of action may allow identification of a NOAEL. This is also applicable for inert materials, such as poorly soluble fibers, dusts, and particles, which induce persistent inflammatory reactions as a result of their long-term physical presence that ultimately lead to cancer.

---

## Evaluation of Uncertainties

When discussing regulations of specific chemicals, one has to be aware that the data used to set a DNEL or to determine the carcinogenic risk of the exposure to a certain chemical always include uncertainties, with the consequence that the risk of a certain exposure may be over- or underestimated. For example, the NOAEL may not be a real NOAEL for statistical reasons in that too few animals have been used in the specific experiment. Or the NOAEL is rather conservative because the next higher dose, which determines the LOAEL of a weak adverse effect, is 10-fold higher. Usually this uncertainty is covered by deliberately applying assessment factors that build in a margin of error so as to be protective of the population from risks. In case

of DNELs the uncertainty factor of 100 covers the uncertainties of inter- and intraindividual differences unless toxicodynamic and/or toxicokinetic information allows its reduction. Whereas the experts who have performed the risk assessment are usually aware of uncertainties, the risk manager tends to use the numbers as such, with the consequence that any exposure even slightly higher than the DNEL is not considered to be acceptable.

Acknowledging these uncertainties with data the distribution of uncertainties may be defined by statistical approaches to characterize and weight the different assumptions from various components (including dose–response, emissions, concentrations, exposure, valuation). This will improve understanding of the reliability of the available information, how risk may vary in a population, and thereby allowing better mean estimates of risk and of the magnitude of risk for different individuals.

There is an ongoing discussion about the risk of chemicals in toys, which can be mouthed by children. Obviously, the resulting exposure is determined by the migration rates of the chemical from the material and the daily mouthing time. Since there is no standard procedure to determine migration rates and the data on mouthing time published in the scientific literature differ by a factor of almost 10, the database for regulatory consequences is rather uncertain. This is why the Scientific Committee on Toxicology, Ecotoxicology and the Environment in its opinion on diethyl-hexylphthalate in teething rings only concluded that the resulting exposure is only about 20-fold below the NOAEL instead of the usually applied factor of 100. Based on this information the European Commission restricted the use of diethyl-hexylphthalate in teething rings **and** in all toys which can be mouthed by children. With this the Commission applied the precautionary principle, because such toys usually contain lower concentrations of diethyl-hexylphthalate and mouthing times will be less than for teething rings.

Methods for the evaluation of unquantified uncertainties are described by EFSA (2006) and ECHA (2003).

---

## Evaluation of Mixtures

Humans and their environments are exposed to a wide variety of substances. The potential adverse effects of the interactions between those substances when present simultaneously in a mixture have been analyzed in several reviews and documentations. Most recently the available scientific literature has been analyzed by the nonfood scientific committees of the European Commission. The following conclusion have been reached (see SCCS/SCHER/SCENIHR (2012a)):

1. Under certain conditions, chemicals will act jointly in a way that the overall level of toxicity is affected.
2. Chemicals with common modes of action will act jointly to produce combination effects that are larger than the effects of each mixture component applied singly. These effects can be described by dose/concentration addition.
3. For chemicals with different modes of action (independently acting), no robust evidence is available that exposure to a mixture of such substances is of health or

environmental concern if the individual chemicals are present at or below their zero effect levels.

4. Interactions (including antagonism, potentiation, and synergies) usually occur at medium or high dose levels (relative to the lowest effect levels). At low exposure levels, they are either unlikely to occur or are toxicologically insignificant.
5. In view of the almost infinite number of possible combinations of chemicals to which humans and environmental species are exposed, some form of initial filter to allow a focus on mixtures of potential concern is necessary. Several criteria for such screening are offered.
6. With regard to the assessment of chemical mixtures, a major knowledge gap at the present time is the lack of exposure information and the rather limited number of chemicals for which there is sufficient information on their mode of action. Currently, there is neither an agreed inventory of mode of actions nor a defined set of criteria how to characterize or predict a mode of action for data-poor chemicals.
7. If no mode of action information is available, the dose/concentration addition method should be preferred over the independent action approach. Prediction of possible interaction requires expert judgment and hence needs to be considered on a case-by-case basis.

---

## Classification of Carcinogens

The systems for classification of carcinogens used by various national or international institutions were developed in the 1970s. Classification is based on qualitative criteria, and reflects essentially the weight of evidence available from animal studies and epidemiology. Classification is usually based on the certainty with which a carcinogenic potential for a chemical can be established. Generally three categories, the definitions of which slightly differ, are used.

- Human Carcinogens
- Animal Carcinogens, reasonably anticipated to be human carcinogens
- Not classifiable because of inadequate data

For classification, mode of action and potency of a compound are either not taken into account or at best is used as supporting arguments. The advancing knowledge of reaction mechanisms and the different potencies of carcinogens may lead to a reevaluation of the traditional concepts.

The International Agency for Research of Cancer (IARC) and the OECD propose to use data on the carcinogenic mechanism and potency in decision-making. The SCOEL (Scientific Committee for Occupational Exposure Limits, now part of ECHA) of the General Directorate Employment of the European Union applied information on carcinogenic mechanisms and potency as criteria for a revised classification. The US Environmental Protection Agency (EPA) and a committee of the German Research Foundation (Deutsche Forschungsgemeinschaft) recommended consideration of mode

of action and have published modified concepts for classification. These activities in part originate from the recognition that one can distinguish between mechanisms of carcinogenicity caused by non-genotoxic and genotoxic carcinogens. Thus, it is possible to identify a NOAEL for non-genotoxic carcinogens, provided there is sufficient information on the primarily non-genotoxic mechanism. The American Conference of Governmental Industrial Hygienists (ACGIH) uses a concept, which considers carcinogenic potency for classification since 1995.

As indicated above the REACH uses the C&L criteria of the Globally Harmonised System (GHS), which is exclusively hazard based. This leads to classification of CMR (carcinogenic, mutagenic, reproductive) compounds without considering whether the test conditions of the animal experiments are relevant for humans or whether there is human exposure which may result in a risk. Since classification in CMR Categories 1A or 1B has consequences for consumer exposure, this may lead to scientifically non-justified restrictions. Although industry can submit a proposal for authorization the severe consequences of a toxicologically and socioeconomically not justified C&L can be avoided if the C&L process would become risk based.

---

## The Precautionary Principle

According to Article 191 of the Treaty on the Functioning of the European Union (EU) the precautionary principle aims to assure a higher level of environmental protection through preventative decision-taking in the case of risk. However, in practice, the scope of this principle is far wider and also covers consumer policy, European legislation concerning food and human, animal, and plant health. It is a measure to enable rapid response in the case of a possible danger to human, animal, or plant health, or to protect the environment. In particular, where scientific data do not permit a complete evaluation of the risk, this principle may, for example, be used to stop distribution or order withdrawal from the market of products likely to be hazardous.

Since this description allows various interpretations, a more precise definition is given in the Communication from the Commission of February 2, 2000, on the precautionary principle. There it is outlined that the precautionary principle may be invoked when a phenomenon, product, or process may have a dangerous effect, identified by a scientific and objective evaluation, if this evaluation does not allow the risk to be determined with sufficient certainty. The Commission specifically stresses that the precautionary principle may only be invoked in the event of a potential risk and that it can never justify arbitrary decisions. To allow its application three preliminary conditions should be met:

- The fullest possible scientific evaluation, the determination, as far as possible, of the degree of scientific uncertainty
- A risk evaluation and an evaluation of the potential consequences of inaction
- The participation of all interested parties in the study of precautionary measures, once the results of the scientific evaluation and/or the risk evaluation are available

In addition, the following general principles of risk management remain applicable when the precautionary principle is invoked:

- Proportionality between the measures taken and the chosen level of protection
- Nondiscrimination in application of the measures
- Consistency of the measures with similar measures already taken in similar situations or using similar approaches
- Examination of the benefits and costs of action or lack of action
- Review of the measures in the light of scientific developments

Other states use slightly different definitions. For example, the Canada definition is as follows:

The precautionary principle is an approach to risk management that has been developed in circumstances of scientific uncertainty, reflecting the need to take prudent action in the face of potentially serious risk without having to await the completion of further scientific research.

Canada refers to the definition of the Precautionary Principle of the Rio Conference on Environment and Development (Principle #15 of the June 1992, Declaration), which reads:

In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation.

Although these definitions seem to be contradictive they generally indicate that the precautionary principle should be applied in cases of potentially *serious* risks without having to wait for a complete risk assessment. This implies that the principle is only applicable in case of a severe risk in case it cannot be sufficiently defined at present.

---

## The TTC Concept

The Threshold of Toxicological Concern (TTC) is a concept to establish a level of exposure for chemicals, regardless their chemical-specific toxicity data, below which there is no appreciable risk to human health. The concept is based on knowledge of the chemical structure to evaluate structural alerts, the amount of a specific chemical in a product, and the daily human exposure. So far the TTC concept is applied for chemicals in food. It is defined as a nominal oral dose which poses no or negligible risk to human health after a daily lifetime exposure. At a mean dietary intake below the level of the TTC, toxicology safety testing is not necessary or warranted. By that the TTC concept can contribute to a reduction in the use of animals for safety tests. The TTC concept may also represent an appropriate tool to evaluate or prioritize the need for toxicological testing. There is ongoing discussion on its general applicability

for safety assessment of substances that are present at low levels in consumer products such as cosmetics or for impurities or degradation products. For the recent evaluation of the general applicability of the TTC concept by the nonfood Scientific Committees of the European Commission, see SCCS/SCHER/SCENIHR (2012b).

---

## Regulations for Specific Chemical Classes

Jurisdictions and regulatory agencies around the world have established a variety of guidelines for risk assessment and permissible exposure standards for chemicals in the workplace, the home, and the general environment. Regulatory decision-making depends upon the estimation of health risks from chemical exposure.

Health risks of chemicals designed for specific applications, for example, consumer products, drugs, or pesticides, must be assessed when people are exposed in the many types of environment in which people can be found. Therefore all elements of risk assessment, for example, hazard identification, dose response, exposure, and the risk, have to be thoroughly evaluated.

Data requirements for **new and existing chemicals** usually depend on annual production rate and the extent of human exposure. When there is considerable exposure, regulatory requirements demand an extensive toxicological evaluation of the potential adverse effects of the specific chemical and the likelihood of their expression under the conditions of use or exposure and the definition of the MOE or the health risk under defined conditions of exposure.

For **drugs** special emphasis must be placed on efficacy, therapeutic index, potential side effects, and the effects of over-dosage.

For **pesticides** the relative impacts of the chemical on the target versus on people is a critical requirement. Thus, the NOEL for people must be established, and an ADI must be determined because of the possibility of contamination of food and other consumer products with the pesticide, and the margin of safety needs to be established.

Exposures to **chemicals at the workplace** is, accordingly to law, controlled by the Occupational Safety and Health Administration (OSHA) in the United States and by the Chemicals Law Act (1992) in Europe. Various governmental and non-governmental institutions are involved in setting occupational exposure standards. Since the institutions publish the complete toxicologically relevant information and a justification for the proposed limit value, these documentations are valuable sources for the toxicological database of the compounds.

Table 1 provides references to institutions that publish documents on the toxicological data of chemicals.

---

## REACH

In 1992 the European Commission estimated that about 100,000 chemicals are in use. They are produced in quantities ranging from less than one ton to several million tons produced per year. Except drugs and pesticides, data requirement for existing or new chemicals has not been regulated. Although it is the responsibility of the

producer and downstream user to release safe products, there are high volume products with a relatively small database. Several programs have been launched to obtain knowledge at least for compounds with high annual production rates. In the US EPA has initiated a HVP program. In an international cooperation the OECD has launched the ICCA program, which evaluates and documents the available information on environmental and human health hazards and risks for about 1000 chemicals. In Europe, Risk Assessment Reports under the Existing Chemical Program of about 150 compounds are being produced.

REACH (Registration, Evaluation and Authorization of Chemicals) of the European Union is to identify substances with hazardous properties and to evaluate the risks of human and environmental exposure. The regulation became effective by 2008. It is the responsibility of the producer or downstream user to provide the necessary information to the European Chemical Agency (ECHA [2017a](#)). The extent of toxicological information largely depends on the annual production rate of a chemical. As long as there is no indication of a specific risk the chemicals will be registered for the intended use. Special attention will be paid to CMR compounds as well as to chemicals, which show bioaccumulation, persistence, and toxicity (BPT compounds) in the environment. According to the regulation the extent of information to be submitted depends on the amount produced or imported annually and requirements are highest for compounds of >1000 t/a, less for <100 t/a and lowest for 10–100 t/a chemicals.

Member states, producers, or downstream users can propose classification and labeling of chemicals and restrictions and the proposals are evaluated by the Risk Assessment Committee (RAC) of ECHA. The consequence of a CMR classification in Category 1A or 1B is a ban for consumer exposure. In such cases industry can apply for authorization for a specific use by providing evidence; there are no alternatives and the risk of consumer exposure is low. Proposals for restrictions also need to demonstrate that there are no less toxic and economically acceptable alternatives and in case the chemical is further used that the risk for consumers is not tolerable. Both the proposals for authorizations and restrictions are evaluated by the Risk Assessment Committee (RAC) and the Socio-Economic Committee (SEAC) of ECHA. The latter committee performs a cost benefit analysis for the restriction or authorization of the chemical and the alternatives.

---

## Summary

The aim of Regulatory Toxicology is to control production, use, and deposition of dangerous materials in order to prevent adverse effects on human health and the environment. This requires sufficient information on the hazardous properties of a compound, their relevance to man and of human and environmental exposure, which is a prerequisite for appropriate risk assessment and the decision whether regulatory consequences are warranted.

There is an array of testing procedures to determine the hazardous properties such as acute, subchronic, and chronic toxicity, irritation and phototoxicity, sensitization and photosensitization, genotoxicity, carcinogenicity, or toxicity to reproduction. Information on the toxicokinetics and mechanisms of the toxic effects improve the

relevance of the findings for man. More recent methodologies like toxicogenomics, or high-throughput testing of agents for a single end-point, will become increasingly available and may improve hazard identification and aid in the identification of common mechanisms of multiple agents.

The public and the scientific community expect that Regulatory Toxicology is science based and that the proposed regulations rely on an appropriate evaluation of the intrinsic properties of an agent (hazard identification) and of the risk of a defined human and environmental exposure. Thus, the prerequisite of Regulatory Toxicology is an understanding of the principles of toxicology, the uncertainties of hazard assessment, and risk assessment and by that identification of adverse and no adverse effect levels and exposure assessment. The precautionary principle should be applied only in case of insufficient information for a final regulatory decision, not to justify elimination of exposure to any non-wanted chemicals. The TTC concept is a nominal oral dose which poses no or negligible risk to human health after a daily lifetime exposure. At such low exposures no hazard identification is considered to be necessary.

In general any regulatory decisions need to be based on an appropriate risk assessment of the possible human or environmental exposure. This can be retrospective in case of existing chemicals or prospective for newly developed compounds. According to REACH restrictions and authorizations also require a socioeconomic evaluation before the final decision.

## Abstract

As in other technical fields, there is increasing diversification in the toxicological risk assessments undertaken by, or on behalf of, regulatory agencies. This is reflected in the many ways in which regulatory toxicology (health and environmental risk assessment) work areas can be divided. These include by end use, by institution,

by chemical properties, and by working methods. Although coordination is essential, different institutions sometimes make regulatory decisions independently of one another. Consistency of decision involves harmonizing; thus, cross-border cooperation of toxicologists and other regulatory affairs specialists is essential.

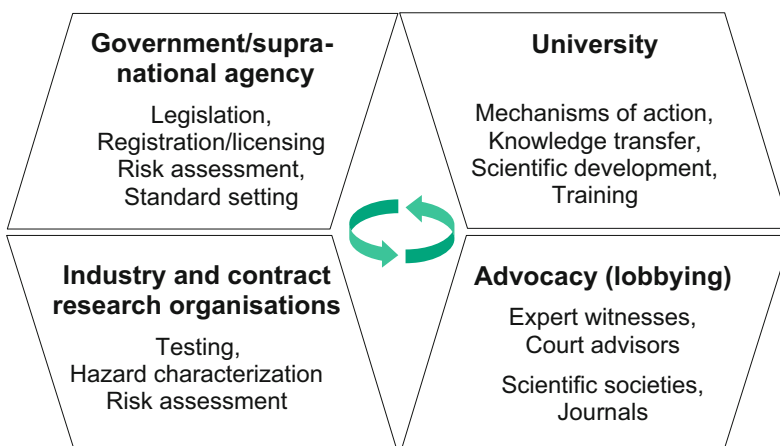

### Keywords

Discipline · Agency · Authorities · Industry · University · Toxicology

## Introduction

Regulatory toxicologists do not operate in a vacuum. There is an objective, and there are societal, legal, and philosophical contexts that underlie the scientific decision-making processes of regulatory toxicology. Setting these contexts involves other professionals and nonprofessional groups, such as citizen action committees, lobbying groups, trade associations, and legislators (politicians and lawyers). Understanding and explaining these contexts and how they operate is the role of psychologists and sociologists. Further information on this aspect of regulatory toxicology is beyond the scope of this chapter but can be found in, for example, Illing and Marrs (2009) and Illing (2009).

The expertise for undertaking regulatory risk assessments comes from toxicologists, epidemiologists, exposure specialists, and, in some cases, economists concerned with risk–benefit assessments. These may be found working in government authorities, industry, contract research organizations, and academia (Fig. 1). Each of these institutions has extended international communications networks (both to regional, e.g., European, and international [UN and OECD] bodies). Despite some competition, there is also a constructive cooperation between the institutions.

**Fig. 1** Institutions

## Authorities

Toxicologists (including clinical toxicologists) and other related specialists such as epidemiologists, occupational hygienists, exposure specialists, and policy makers in government (and supranational) agencies advise the authorities on various levels such as local administrations, ministries, and the government. Toxicologists are involved in the generation and monitoring of test method standards, audit procedures, and standards, registrations, and licensing procedures. Since they have to consider long-term unwanted aspects on the population and environment, they largely work on the basis of conservative risk assessments and, when dealing with environmental issues, the “precautionary principle.” They use their toxicological and ecotoxicological expertise to estimate specific risks (in a risk assessment), and when the risk is not sufficiently low to constitute an acceptable risk, they may then join with others in undertaking a risk–benefit analysis in order to determine a “tolerable risk” based on trading the usefulness of a substance with the necessity of protection.

While it may be developed by individual scientists and regulatory specialists, acceptance of the relevant conceptual underpinning for this work is usually very slow and obtained via authoritative national and international bodies. Test methods and audit systems (“Good Laboratory/Clinical/Manufacturing Practice guidelines”) are also developed through authoritative international bodies. Of particular importance are the OECD (Organisation for Economic Co-operation and Development), the ICH (International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use), the EU Scientific Committees, and academic bodies such as the US National Academy of Sciences, the UK Royal Society, and the DFG (Deutsche Forschungsgemeinschaft). The regulation of different sectors may be (a) by sector defined by end use, e.g., pharmaceuticals, veterinary medicines, medical devices, food (including additives and contaminants), animal feed, plant protection products, and biocides, and (b) by environmental compartment – water quality; indoor, outdoor, or workplace air quality; and soil contamination. These sectors can involve different agencies, and the agencies may be largely independent of each other though they are cooperating at UN and international levels (Fig. 2). However, there are overlaps, for example, between automobile exhausts and urban air pollution. In general, good networking is required to allow for better harmonization.

## Industry

Toxicologists and regulatory affairs specialists in industry have the responsibility to ensure that products placed on the market have a satisfactory risk/benefit ratio. This is of particular interest for quality conscious companies. Toxicologists in industry may commission contract research organizations (CROs) to undertake standard tests to protocols described by the authorities, or they may undertake testing “in house.” Studies for regulatory purposes rely largely on internationally

<b>Authority</b>	<b>Toxicological Responsibility</b>
US EPA / EU National Authorities <b>WHO</b>	Toxicology of drinking water
EMA (EU) / FDA (US), <b>ICH</b>	Pharmaceutical toxicology
Individual national or sub-national investigators (e.g. Police), <b>UNODC</b>	Forensic toxicology

US OSHA / EU National bodies, <b>ILO</b>	Workplace toxicology
US FDA and Dept Agric / EU EFSA, <b>FAO</b>	Food toxicology

**Fig. 2** Examples of toxicology-associated agencies and their fields in the USA, EU, and under international umbrella (blue color)

standardized protocols for determining the toxic potential of individual substances. These studies usually seek to identify pathological and clinical–chemical endpoints and a dose–response in animals. Investigative studies using structure–activity relationships and/or in vitro methods are increasingly important when seeking to better understand the potential toxicity. These results form the basis for the initial hazard assessment for a newly developed chemical. Exposure assessment is also conducted to see if there is a sufficient margin of exposure for the intended use. If specific risks have to be further clarified, additional experimental work related to, for example, toxicokinetics and mechanisms of action may be performed. Such nonstandard tests often require very specific methodologies and may be performed in cooperation with partners from universities or from contract research institutions. Where possible, the standardized regulatory testing is subjected to an audit process, Good Laboratory Practice, supervised by the relevant national authorities. The tests are conducted to standardized protocols, and the results evaluated using standard procedures. When dealing with products intended for human use, studies may also be conducted in volunteers, in which case they are subject to clearance by appropriate ethics committees and Good Clinical Practice. This is the main information source for the authorities, who make a regulatory decision about the registration and categorization of the compound.

Once a substance has been placed on the market, either for a specific use or more generally, there is a need for monitoring for unidentified toxic effects (“unknown unknowns”). For drugs this is called “pharmacovigilance.” Through this process, it is possible to check if the risk management procedures (either for the specific chemical or use or more generally) are adequate or, if not, to reassess and reevaluate the risks.

## **Universities and Other Basic Research Institutions**

Toxicologists at university and in basic research mainly aim at understanding toxicological mechanisms at the cellular level. They often use investigation techniques which are not subject to standardization but provide new methodological approaches and scientific knowledge. In this context, they develop novel methods that better predict toxic effects. Epidemiologists and experts in exposure modeling and measurement also contribute to the sciences underpinning risk analysis. All of these specialists must encourage cooperation with neighboring scientific disciplines and networking with regional and national partners. They often act as experts in regulatory committees. Finally, they play a central role in the education of young academics.

When there is a need for risk–benefit analysis, there is a need to environmental economists. Integrating their role with that of the other participants in the risk (or risk–benefit) evaluation is still at an early stage, and there is therefore much scope for academic research in this field.

Of increasing importance is the need for an understanding of the psychological and sociological aspects of the process of risk analysis (risk assessment and risk management) and of how the public perceives risks. It is essential that the public (as a whole) has confidence in the regulators, and a key need is an understanding of how public and regulatory understanding can be merged. Psychologists and sociologists working on aspects of risk perception offer insights into this process, and their contribution should not be disregarded.

## **Contract Research Organizations**

CROs are often specialists in specific tests or evaluations, in which they are highly experienced. In these niches, they are likely to be more efficient and more economical than other institutions.

## **Advocacy (Lobbying)**

Advocacy groups (such as Greenpeace, Friends of the Earth, anti-vivisectionists, trade associations) are essentially aimed at trying to persuade regulators, either directly or through persuading public opinion, that their views concerning issues should be preferred in place of those accepted by or about to be accepted by the regulator.

## **Expert Witness/Court and Public Inquiry Advisor Work**

Generally, this work is carried out by the individual rather than by a type of institution. The focus of this type of specialist is in defined problem fields, such as

advising in litigation or in criminal prosecutions concerning causes of damage or in public inquiries into incidents/accidents. The expert witness prepares expert statements containing toxicity profiles set against information on specific incidents (and the requirements of the legislation) in order to indicate to the parties and, if it comes to Court, the Court the relevant facts and their implications. The public inquiry expert advisor advises the presiding officer (usually a judge) on the scientific facts and their implications for the inquiry.

---

## Scientific Societies and Journals

The toxicological scientific societies are self-administered organizations of toxicologists from the different working areas. They have the main aim to promote the toxicological sciences. Scientific questions concerning how toxic agents work are traditionally the main focus of these societies.

Risk is a statistical concept that relies on toxicological data to define the hazard on the one hand and statistics (probability) to define the likelihood of the event occurring or of the exposure resulting in harm. Traditionally, scientists in universities and university-associated research units are research-oriented and not much interested in the principles and issues associated with the risk evaluation part of the regulatory process. These issues involve nonscientific aspects of risk (such as attitudes to risk and risk perception), and nonscientific aspects may prevail.

As a political process is involved, there is room for contributions from the social sciences (sociological and psychological aspects of risk, notably the influence of risk perception on risk evaluation). The ability to obtain a compromise may have a greater role in toxic risk regulation than scientific exactness. Hence, the ability to influence regulatory decisions is becoming increasingly important as an activity in which chemical and toxicological societies participate. It also provides a platform for the participation of science in international regulatory spheres and sometimes opens the door to highly interesting new ideas for research.

So it is not surprising that many scientific societies are increasingly engaging in issues of regulatory toxicology at the national and international level. They provide a forum in which basic scientists, risk analysts, and toxicologists can freely exchange ideas, without the restrictions, which they might have within their institution.

As a consequence of the recognition of this wider role for experts in regulatory toxicology, risk assessment and risk evaluation are increasingly important parts of the training of toxicologists. This is being encouraged by the scientific societies. In parallel, articles on topics involving regulatory toxicology are increasingly found in the scientific journals. This trend has been early recognized and promoted by the "International Society of Regulatory Toxicology and Pharmacology" and its journal and the foundation and development of journals in the field of risk analysis that accept articles on toxicological aspects of risk analysis.

---

## Chemical Properties

The chemist is usually most interested in the chemical properties of a substance and will therefore find it logical to classify toxic substances according to their chemical properties. Thus, one can distinguish between the regulation of inorganic chemicals (e.g., metal toxicology), organic chemicals (many industrial chemicals), natural products (e.g., toxins), and genetically engineered products (these are a subgroup of organic molecules, usually of high complexity). A more far-reaching differentiation can be based on functional groups (nitrosamine regulation) or a chemical moiety (“dioxin” regulation). Finally, it may be crucial for the toxicological assessment whether one deals with a pure substance or a mixture (combination effects such as inhibition or synergism) and whether these are dissolved or in particulate form (e.g., dust, fine dust, nanoparticles).

The effect researcher, who may typically be a biologist or physician, is more interested in biological and medical effects. He/she accordingly arranges groups of substances with the same effect, such as allergens, irritants, initiators, promoters, endocrine disruptors, cytochrome P450 inducers, and neurotoxic or hepatotoxic substances.

The attention of toxicologists in the event of toxicological emergencies is focused on the harmful effects and the causing substances (e.g., dioxins after the accident at Seveso, fatalities after intake of novel psychoactive substances).

The legislation concerning prevention and control of accidents and emergencies may be included in the regulations concerning specified areas of use or, especially in the case of industrial processes, may be based on the scale of the potential consequence.

---

## Regulated Areas and Legislature

It is not unusual that different levels of protection are defined for different purposes. The two principal criteria are the “broadly acceptable” criterion and the “intolerable” criterion. There may be a range of circumstances between these two criteria where a risk–benefit analysis indicates that a risk is “tolerable.” Thus, for a pharmaceutical with a high positive effect (e.g., a “lifesaving” drug), it may be acceptable to take into account a certain level of unwanted effects that would be unacceptable for a treatment for a minor effect such as headache. This means that a risk–benefit analysis is applied. In the case of regulation of persistent environmental pollutants (e.g., dioxins) in the human body, one has to accept that it will take years before reduction measures, such as minimization of exposure, achieve visible success. These are circumstances where it might be appropriate to apply the “precautionary principle” and minimize exposure.

## Regulations According to Application Area

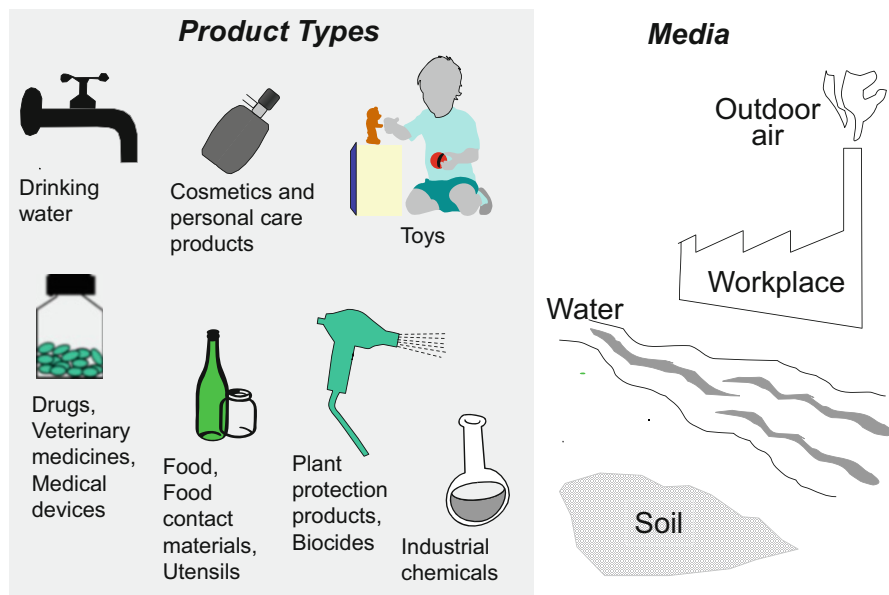

When manufacturing and marketing a chemical, there is a clearly identifiable manufacturer/supplier. Both incidental worker exposure and release to the environment during manufacture can be regulated, as can the approach to dealing with major accidental releases. Product safety regulations are made according to the use to which the substance is put, with a reserve scheme for those chemicals and uses not subject to more specific legislation. Regulated uses include pharmaceuticals, cosmetics, biocides, flame retardants, food additives, industrial chemicals, radiochemicals, solvents, or chemical weapons. Regulations concerned with ambient media are more difficult to enforce as there may be no clearly identifiable source and/or they have no identifiable supplier. They are regulated by medium (air, water, soil) where it occurs.

### Ambient Media

Among the regulated media are water, soil, ambient air, indoor air, workplace, food, consumer products, and human body fluids. The example of “water” can demonstrate, in how many subareas regulations of chemicals are effective: drinking water, mineral water, bottled water, water for baby food, water for injection, pool water, river water, bathing water, wastewater, surface water, groundwater, etc., each having a larger number of country-specific sub-rules. A clear demarcation between regulated uses and regulated media is not always possible.

### Understanding Regulations

There exist detailed technical specifications, guidelines, and limit values associated with the control of toxic chemicals (Fig. 3). The relevant laws and regulations usually describe the levels of protection required and provide guidance on the technical rules and procedures that were applied in order to generate a guideline or a limit value. Knowledge about the background of the respective regulations and about the state of discussion among experts in the relevant area is a prerequisite for appropriate work by the regulatory toxicologists. Regulations are often updated in order to take into account new developments and insights to protect the population and environment. Much of this work is becoming international in nature. For an individual toxicologist, it is no longer possible to keep an overview of the entire width of all areas either nationally or internationally. Therefore, a division of labor is essential. But it is just as important to have an exchange between the fields and to encourage harmonization, provided that it does not impose a “drag” on the implementation of new procedures.

**Fig. 3** Regulated products and media (examples)

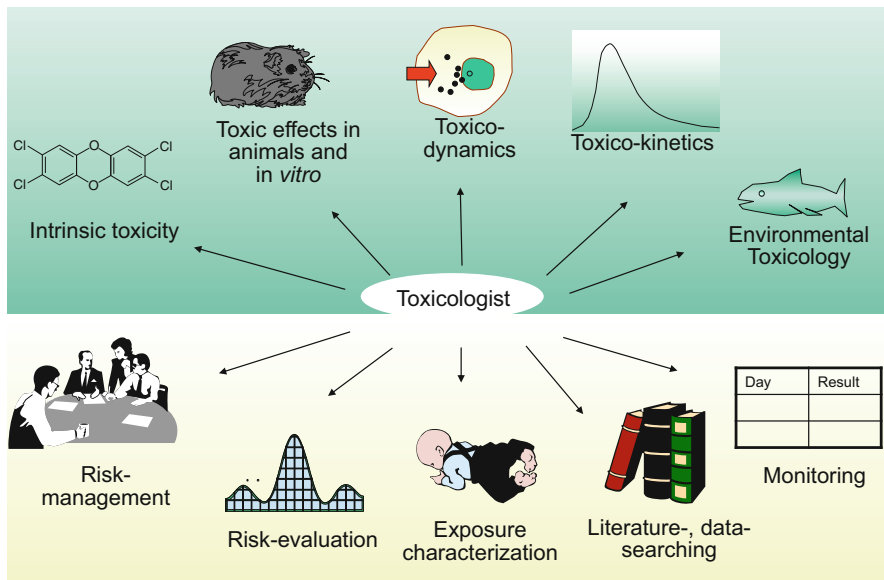

## Alarm Systems

There are three types of risk: “known knowns” (identifiable and quantifiable risks), “known unknowns” (identifiable but unquantifiable risks), and “unknown unknowns” (risks which have not yet been identified). Even a good regulation for the protection of workers, consumers, and the public and good management systems may not completely exclude the possibility of a toxicological accident or an unforeseen situation. This is, for example, the case, when an unforeseen rare immunological sensitivity is triggered by a compound in few individuals or when a substance is applied the wrong way. To detect such incidents, many countries have a monitoring requirement. For medicines, one such scheme is known as “pharmacovigilance,” and physicians are expected to report suspicions of “side effects.” The collected information is analyzed by toxicologists, who thus gain insight into the role of specific substances in incidents and can change the risk management measures (greater supervision, e.g., by restricting prescribers and outlets, improved regulation).

## Working Methods

Based on toxicological data, the regulatory toxicologist considers the safety requirements for the particular use and then estimates under what conditions and to what extent the population, including predefined groups at extra risk, may be exposed to a substance,

**Fig. 4** Work areas in regulatory toxicology

ideally without incurring any ill health. For this task, he/she requires special knowledge and experience in the interpretation of toxicological findings, the regulatory standards, the legal framework, and the implementation process. Specifically, in-depth knowledge of the common working methods, shown in the figure, is required (Fig. 4).

In addition to that methodological experience, the regulatory toxicologist should have some technical creativity that helps to find acceptable solutions for unsolvable problems and should exhibit a high communicative competence. The latter is required, because the regulatory toxicologist must sometimes explain unpleasant findings or defend unpopular decisions in his institution or in public. In conflict situations, he must be able to defend the ethics of toxicology, explain safety standards, and discuss technical feasibility.

As in all professions, there is a hierarchy concerning the professional status of toxicologists. The experimental toxicologist can publish in esteemed journals and thus contribute to global knowledge and ensure its status among peers. The regulatory toxicologist will remain more anonymous, since his written work will normally be used by commissions, who will incorporate it in statements or in laws. This gives little scientific credit but a great deal of satisfaction due to the practical importance of his/her work.

## Abstract

Achieving the world's social and economic objectives is not possible without the use of significant quantities of chemicals, including industrial chemicals, pesticides, and pharmaceuticals. Comprehensive and cost-effective use of these substances while maintaining high health and safety standards is, in principle, possible and has been shown in a number of cases. However, it is still a long way until these standards are implemented worldwide following the principles of sustainable development with the goal of a better quality of life of all people. A number of international bodies and authorities promote the sound management of chemicals at national and international level, some of which are described in this chapter.

## Global Chemical Production

Production, trade, and consumption of chemicals are of enormous economic importance. According to the chemical industry chemicals valued at € 3347 billion were produced worldwide in 2018 (Cefic Chemdata International 2019). Since 2009, China is the world's largest chemical producer contributing 35.8% of global chemical sales in 2018. Europe (EU) is the second largest chemicals producer in the world (€ 565 billion). Although 80% of all chemicals are produced in only 16 countries, chemicals are used in all countries worldwide. Economic indicators point to a significant increase in chemical production and use in the decades to come. The BRIC countries (Brazil, Russia, India, and China) accounted for 42.8% of global chemical sales in 2018. Most of this production is still expected to take place in OECD (Organisation for Economic Co-operation and Development) countries. However, a shift to developing countries takes place in parallel.

Today, approximately 100,000 chemicals are available on the market, and many new substances are added each year. In addition, thousands of chemicals of natural origin exist. Taking into account that people can potentially come into contact with all of these chemicals, the resulting need for information concerning related health and environmental risks is enormous. Considering costs and time necessary to collect relevant toxicological information, it is only normal that the international community shares the task of data collection, especially since no country alone would probably be able, to cope with this challenge alone.

---

## **Milestones in International Chemical Safety**

Chemical safety dates back to the beginning of the twentieth century. At the time, few chemicals of known risks were regulated, for example, international recommendations existed concerning the safe handling of white phosphorus in the production of matches. In fact, little to nothing was known about the risks of the majority of the chemicals produced and used at that time, and accordingly, these chemicals were not regulated. It was only decades later that industrialized countries began evaluating and classifying some chemicals in order to inform the process of establishing safety measures. In addition, countries started to evaluate not only the risks associated with the acute health effects but also chronic, genetic, environmental, and other effects that may be caused by handling the chemicals (Somogyi et al. 1999).

## **International Program on Chemical Safety (IPCS)**

In 1972, the United Nations Conference on the Human Environment was held in Stockholm, Sweden. At this conference, among other things, countries asked for an international chemicals safety program to serve as an early warning system to prevent disease burden associated with chemicals by undertaking risk evaluations of chemicals by applying internationally harmonized methodologies. As a result of the Stockholm Conference, the IPCS was established in 1980. IPCS is a joint venture of the UNEP, ILO, and WHO. The overall objectives of the IPCS are to establish the scientific basis for assessment of the risk to human health and the environment from exposure to chemicals, through international peer-review processes, as a prerequisite for the promotion of chemical safety, and to provide technical assistance in strengthening national capacities for the sound management of chemicals.

## **United Nations Conference for Environment and Development (UNCED)**

In 1992, UNCED introduced sustainable development as the guiding principle of national and international environmental policy (United Nations 1992). The principles for effective international chemical safety and the sound management of

chemicals were presented in Chapter 19 of Agenda 21, the program of action for the twenty-first century, adopted by more than 170 countries. Chapter 19 contains objectives for the environmentally sound management of toxic chemicals including the prevention of illegal international traffic in toxic and dangerous products. The program areas for chemical safety in Chapter 19 of Agenda 21 include (i) international assessment of chemical risks, (ii) harmonization of classification and labeling of chemicals, (iii) information exchange on toxic chemicals and chemical risks, (iv) establishment of risk reduction programs, (v) strengthening of national capabilities and capacities for management of chemicals, and (vi) prevention of illegal international traffic in toxic and dangerous products.

### **International Forum on Chemical Safety (IFCS)**

In 1994, the IFCS was established in response to the request by governments at UNCED. IFCS provided an open, transparent, and inclusive forum for discussing issues of common interest and also new and emerging issues in the area of sound management for governments, intergovernmental organizations, and non-governmental organizations, including from the private sector. The IFCS facilitated consensus building on issues and actions addressing chemicals safety and adopted recommendations for governments and intergovernmental organizations, including the Bahia Declaration on chemical safety in 2000. By its efforts, IFCS made an important contribution to the implementation of the Strategic Approach to International Chemicals Management (SAICM). With the adoption of SAICM, the existing of IFCS has practically ended (see below).

### **Interorganization Program for the Sound Management of Chemicals (IOMC)**

The IOMC was established in 1995 following recommendations made by UNCED in 1992. IOMC's role is to promote coordination of policies and activities of chemical programs of international organizations, pursued jointly or separately, to achieve the sound management of chemicals in relation to human health and the environment. FAO, ILO, UNEP, UNIDO, WHO, and OECD initially signed a Memorandum of Understanding; UNITAR joined the IOMC in 1997, the World Bank in 2010, and UNDP in 2012. The IOMC works on subjects related to those elaborated in Chapter 19 of Agenda 21 (see above) and now covered by the SAICM (Strategic Approach to International Chemicals Management) Global Plan of Action (see below).

### **World Summit on Sustainable Development (WSSD)**

The WSSD in Johannesburg, South Africa, was held 10 years after the UNCED Conference in Rio de Janeiro and 30 years after the first United Nations Conference on the Human Environment in Stockholm Environmental Conference. Chapter 22 of

the action plan adopted in Johannesburg is addressing chemical safety renewing the commitments of Agenda 21 of UNCED for the environmentally sound use of chemicals for the purpose of sustainable development, as well as the protection of human health and the environment. WSSD targeted that by 2020, chemicals are used and produced in ways that minimize significant adverse effects on human health and the environment, taking into account the precautionary principle.

### **The Strategic Approach to International Chemicals Management (SAICM)**

SAICM is a policy framework to promote chemical safety around the world. SAICM has as its overall objective the achievement of the sound management of chemicals throughout their life cycle so that, by 2020 meeting the WSSD goal (see above), chemicals are produced and used in ways that minimize significant adverse impacts on human health and the environment.

SAICM is distinguished by its comprehensive scope: ambitious “2020” goal for sound chemicals management, multi-stakeholder and multi-sectoral character, endorsement at the highest political levels, emphasis on chemical safety as a sustainable issue, provision for resource mobilization, and formal endorsement or recognition by the governing bodies of key intergovernmental organizations. SAICM comprises the Dubai Declaration on International Chemicals Management, expressing high-level political commitment to SAICM, and an Overarching Policy Strategy which sets out its scope, needs, objectives, financial considerations underlying principles, and approaches and implementation and review arrangements. Objectives are grouped under five themes: risk reduction, knowledge and information, governance, capacity building and technical cooperation, and illegal international traffic. The Declaration and Strategy are accompanied by a Global Plan of Action that serves as a working tool and guidance document to support implementation of SAICM and other relevant international instruments and initiatives. Activities in the plan are to be implemented, as appropriate, by stakeholders, according to their applicability.

---

### **International Agreements**

Intense debates in the 1980s and 1990s led to the beginning of the adoption of a number of important conventions related to chemical safety.

#### **Rotterdam Convention: Convention on the Prior Informed Consent Procedure for Certain Hazardous Chemicals and Pesticides in International Trade**

The Rotterdam Convention prevents unwanted trade of chemicals through the application of the legally binding prior informed consent (PIC) procedure. PIC regulates the exchange of information and the shared responsibility of export and

import country in the international trade of certain hazardous chemicals in order to protect human health and the environment from potential harm. The convention deals with chemicals that are banned or severely restricted in some countries (particularly in industrialized regions) but that are still exported to other countries (particularly in developing regions).

### **Stockholm Convention: Convention on Persistent Organic Pollutants (POPs)**

The Stockholm Convention is a global treaty to protect human health and the environment from highly dangerous, long-lasting chemicals by restricting and ultimately eliminating their production, use, trade, release, and storage. Twenty-one compounds are covered by the convention, including pesticides, industrial chemicals, and unwanted combustion by-products. Once released into the environment, POPs remain intact for exceptionally long periods of time (many years), become widely distributed throughout the environment as a result of natural processes involving soil, water, and, most notably, air. POPs are found at higher levels in the food chain, they accumulate in the fatty tissue of living organisms including humans, and are toxic to both humans and wildlife.

### **Basel Convention: Convention on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal**

The Basel Convention was adopted in 1989 to protect human health and the environment against the adverse effects resulting from the generation, management, transboundary movements, and disposal of hazardous and other wastes. It was created as a result of tighter environmental regulations in industrial countries in the 1980s which had led to the trade of toxic waste from developed to developing countries where the wastes were dumped indiscriminately, spilled accidentally, or managed improperly, causing severe health and environmental problems.

The convention regulates the transboundary movements of hazardous and other wastes and obliges its countries to ensure that these wastes are managed and disposed of in an environmentally sound manner. Countries are also required to minimize transboundary movements to the extent consistent with the environmentally sound and efficient management of such wastes and treating and disposing of wastes as close as possible to their place of generation. The export of hazardous waste to non-contracting countries is prohibited and permitted only in exceptional circumstances. The export to the Antarctic is generally prohibited.

### **Minamata Convention on Mercury**

The Minamata Convention on Mercury was named after a city in Japan where serious health damage occurred as a result of mercury pollution. Adopted in January

2013, the convention provides controls and reductions across a range of products, processes, and industries where mercury is used, released, or emitted. These range from medical equipment such as thermometers and energy-saving light bulbs to mercury-emitting activities such as mining, cement, and energy production. Governments have agreed on a range of mercury-containing products to be banned by 2020. In addition, governments agreed to draw up strategies to reduce the amount of mercury used by small-scale miners. Furthermore, the treaty aims at controlling mercury emissions and releases from, for example, coal-fired power stations, industrial boilers, smelters, waste incineration, and cement clinker facilities.

### **ILO Convention Concerning Safety in the Use of Chemicals at Work**

The chemicals convention of the International Labor Organization (ILO) from 1990 and its accompanying recommendation aim to improve safety and health in the use of chemicals at work, which includes the production, the handling, the storage, and the transport of chemicals as well as the disposal and treatment of waste chemicals, the release of chemicals resulting from work activities, and the maintenance, repair, and cleaning of equipment and containers of chemicals. In addition, it allocates specific responsibilities to suppliers and exporting states.

### **Chemicals Weapons Convention (CWC): Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and on Their Destruction**

This agreement of 1993 aims to eliminate an entire category of weapons of mass destruction by prohibiting the development, production, acquisition, stockpiling, retention, transfer, or use of chemical weapons by countries. Countries have agreed to chemically disarm by destroying any stockpiles of chemical weapons they may hold and any facilities which produced them, as well as any chemical weapons they abandoned on the territory of other countries in the past. A unique feature of the CWC is its incorporation of the “challenge inspection,” whereby any state party in doubt about another state party’s compliance can request to send an inspection team.

### **Vienna Convention for the Protection of the Ozone Layer and Montreal Protocol on Substances That Deplete the Ozone Layer**

The Vienna Convention (1985) and the Montreal Protocol (1987) aim to protect environment and thus human health against detrimental effects of human activity which change or could change the ozone layer. Concrete objectives set out in the Vienna Convention are specified in the Montreal Protocol which is to eliminate the production and use of almost 100 substances that damage the ozone layer, including freons and halons and the production and use of methyl bromide. Substances that are

very stable in the atmosphere allowing them to reach and destroy the ozone layer which protects the Earth from the UV radiation.

---

## **International Organizations**

### **World Health Organization (WHO)**

Through the International Program on Chemical Safety (IPCS), WHO works to establish the scientific basis for the sound management of chemicals and to strengthen national capabilities and capacities for chemical safety. Main activity areas include the evaluation of priority chemicals and risk assessment, the prevention and treatment of poisonings, and the health aspects of chemical incidents and emergencies. Jointly with FAO, WHO provides the Secretariat of the Joint FAO/WHO expert meeting on pesticide residues (JMPR) and the Joint FAO/WHO Expert Committee for food additives, veterinary drugs, and contaminants. The International Agency for Research on Cancer (IARC) of WHO evaluates the cancer risks of chemicals which are published in the IARC Monographs.

### **United Nations Environment Program (UNEP)**

UNEP provides leadership and encourages partnership in caring for the environment by inspiring, informing, and enabling nations and peoples to improve their quality of life without compromising that of future generations. The UNEP Chemicals program is the focal point of UNEP activities on chemicals and provides assistance to countries in risk assessment and reduction of hazardous substances. In addition, UNEP is providing the secretariats for SAICM, the Basel and Stockholm Conventions, as well as the Rotterdam Convention jointly with FAO (see above).

### **Food and Agriculture Organization of the United Nations (FAO)**

FAO was founded to improve the food situation and to increase agricultural productivity. Chemical safety at FAO is focusing on plant protection products and chemicals in food. FAO has developed an international code of conduct on the distribution and use of pesticides. Other activities are dealing with the disposal of obsolete and unwanted pesticides, particularly in Africa. Together with the UNEP, FAO provides the Secretariat for the Rotterdam Convention and, together with the WHO, the Secretariats for JMPR and JECFA (WHO see also).

### **International Labor Organization (ILO)**

Chemical safety forms part of ILO's mandate to improve occupational safety and health. In addition the Chemicals Convention mentioned above, ILO Conventions

and recommendations in the field of chemical safety are dealing, for example, with the prevention of major industrial accidents, asbestos, the working environment (air pollution, noise, and vibration), and occupational cancer. ILO's main areas of activity are the development and implementation of their conventions and recommendations, including the development, promotion, and distribution of guidelines and technical standards.

### **United Nations Industrial Development Organization (UNIDO)**

UNIDO promotes and accelerates sustainable industrial development in developing countries and in countries with economies in transition. UNIDO promotes the development of Clean Production Centers and develops and promotes risk minimization strategies for the production of agricultural chemicals as well as the transfer of safe and environmentally friendly technologies and industrial processes.

### **Organization for Economic Cooperation and Development (OECD)**

OECD is a non-UN international governmental organization to promote policies to improve the economic and social well-being of people around the world. The OECD provides a forum in which governments can work together to share experiences and seek solutions to common issues. Chemical safety activities aim to identify, prevent, and mitigate chemical-related environmental and health risks, to prevent unnecessary trade barriers, to optimize national resources for chemical safety, as well as to integrate economics and chemical safety policy. OECD programs are dealing with chemicals safety issues, including the testing and test guidelines and assessment of chemicals, good laboratory practice and compliance monitoring, pesticides, pollutant release and transfer register (PRTR), risk management and chemical accidents, emission scenarios, and harmonization of regulatory oversight in biotechnology. If national approaches to chemical regulation are harmonized, industry is not faced with a plethora of conflicting or duplicative requirements, governments are provided with a common basis for working with each other, and non-tariff barriers to trade are reduced. The principal tools for harmonization are a set of OECD Council Decisions which make up the OECD Mutual Acceptance of Data (MAD) system, including its OECD Guidelines for the Testing of Chemicals and OECD Principles of Good Laboratory Practice (GLP; OECD 2020).

### **World Bank**

In its environmental strategy, the World Bank lays out its ambition to support “green, clean, resilient” paths for developing countries, as they pursue poverty reduction and development in an increasingly fragile environment. The environment strategy recognizes that while there has been notable progress in reducing global poverty, there has been significantly less progress in managing the environment sustainably,

and while developing countries will still need rapid growth to reduce poverty over the next decade, the global environment has reached a critical state that could undermine livelihoods, productivity, and global stability. World Bank's objectives in the environment strategy are to improve the quality of life in countries and to protect people's health from environmental risks and pollution to reduce the disease burden. Among others, particular emphasis is given in the strategy to reduction of exposure to toxic substances.

## **United Nations Development Program (UNDP)**

UNDP promotes the sound management of chemicals and waste as an important aspect of their work to reduce global poverty and achieve the Millennium Development Goals (MDGs). UNDP addresses unsustainable management approaches, as well as unsustainable consumption and production patterns, including poor design and material choices. These issues are considered to be the root causes for resource depletion, waste generation and pollution, impeding sustainable human development. UNDP advocates for the integration of sound chemicals management priorities into national environmental and poverty reduction planning frameworks and helps countries access resources to improve their chemical and waste regimes.

## **Chemical Safety in the European Union (EU)**

Previously, decision-making concerning marketing of chemicals took place at the national level. Today, nearly all these decisions take place at the level of the EU. Therefore, legislation of chemicals is largely harmonized in the EU, for example, through the requirement that National legislation must be in accordance with EU law resulting in a uniform level of protection in all Member States. Concerning toxicological testing of substances, there are, in addition to the EU harmonized methods, supranational test strategies such as the test guidelines provided by OECD (Munn and Hansen 2002).

A number of EU regulatory institutions have been established.

## **European Chemicals Agency (ECHA)**

Established 1 June 2007 in Helsinki, Finland, ECHA regulates the technical, scientific, and administrative aspects for the registration, evaluation, authorization, and restriction of chemical substances in the EU following uniform procedures.

ECHA is central to the European REACH Regulation (Registration, Evaluation, and Authorization of Chemicals) by being the recipient and the agency that verifies the registration documents submitted by manufacturers and importers.

In collaboration with agencies in Member States, ECHA develops statements concerning the risks associated with the substances themselves as well as concerning the socioeconomic consequences associated with related risk mitigation measures (prohibition, restrictions, approvals). A network of agencies in EU Member States has been established for the implementation and monitoring of chemical safety activities within the EU. It maintains a central database and develops guidance material to assist businesses. With the acceptance of all EU Member States, ECHA defines the toxicological and ecotoxicological investigations to be carried out to describe possible dangerous properties. An appeal may be brought to Board of Appeal against decisions of the agency.

### **European Chemicals Bureau (ECB)**

The ECB in Ispra (Italy) is the central reference for toxicological information on new and old substances within the EU. It provides scientific and technical support for the development, implementation, and monitoring concerning EU regulation, especially related to toxic chemicals. It fulfills the legal requirement to classify and label chemicals based on their hazardous and toxicological properties. It assesses the risks of industrial chemicals. Furthermore, the ECB contributes to the development and harmonization of test methods within the EU. It notifies about new substances, authorizes and evaluates biocides, and facilitates information exchange for the import and export of hazardous substances. The ECB's main partners are the corresponding scientific institutions in Member States and Norway.

### **European Food Safety Agency (EFSA)**

EFSA's role is to provide independent scientific risk assessment advice directly or indirectly of concern to food safety and consumer protection. All stages of food production and supply are covered, and scientific assessments can be made for each stage, starting from animal feed safety, primary production, to distribution to consumers (from stable to table). Related animal and plant health issues are covered as well. EFSA's main customer is the EC Commission which in turn can also address scientific requests of the European Parliament and Member States directly and initiate risk assessments on its own. EFSA's scientific advice is provided through scientists in a number of scientific panels. A Scientific Committee coordinates the work ensuring coherence of the scientific advice produced by the various panels.

The scientific panels are composed of independent experts of different subject areas (Table 1).

The Advisory Forum is at the heart of EFSA's collaborative approach to working with EU Members States. Its members are representatives of national food safety authorities and use the forum to advise EFSA on scientific matters, its work program, and priorities and to address emerging risk issues as early as possible.

**Table 1** EFSA's scientific panels

Scientific Committee (SC)
Additives and products or substances used in animal feed (FEEDAP)
Animal health and welfare (AHAW)
Biological hazards (BIOHAZ)
Contaminants in the food chain (CONTAM)
Nutrition, novel food and food, and allergies (NDA)
Food additives and flavorings (FAF)
Food contact materials, enzymes, and processing aids (CEF)
Genetically modified organisms (GMO)
Plant health (PLH)
Plant protection products and their residues (PPR)

## National Chemical Safety

The space of this chapter does not allow to describe the situation in different nations. Therefore, the example of just one country, in this case Germany, will be described.

## German Federal Institute for Risk Assessment (BfR)

BfR is the German scientific authority responsible for the development of risk assessment reports and expert opinions concerning food safety and consumer protection. The development of risk assessment reports and expert opinions is based on international scientific criteria, for example, the process is transparent open and comprehensible for stakeholders, including the public, the scientific community, as well as other interested groups. In general, the results are published by maintaining the confidentiality of private data. In addition to and based on the evaluation of risks, BfR develops recommendations concerning actions to be taken to manage/mitigate the risks aimed at improving food safety and consumer protection.

In particular, the role of the BfR is to evaluate possible health risks of food and feed as well as of dietetic products and novel foods with regard, for example, to natural ingredients, food additives, and contaminants. Another role of the BfR is to assess the risks of industrial chemicals, plant protection and biocidal products with regard to human safety. It is then, for example, the responsibility of the BVL to authorize/register plant protection products, while it is the BAuA that is in charge of registration/authorization of biocidal products. Furthermore, BfR provides scientific advice to the federal ministries and the BVL, and it cooperates with a number of scientific institutions and organizations in other nations with EFSA being one main partner. Finally, BfR initiates and conducts scientific research in relation to the assessments it undertakes regarding food safety and consumer protection.

## **Federal Office for Consumer Protection and Food Safety (BVL)**

BVL has a number of responsibilities concerning risk management. It acts, for example, as the national focal point for the European rapid alert system in the food and feed sectors (RASFF) as well as in certain sectors of product safety. RASFF warns about dangerous food and feed. In addition, BVL is responsible for the management of crises in the food and feed sectors. One aim is to make a proper risk communication and management of risks before they turn into a crisis. Among other aspects BVL's role is to warn other relevant competent authorities in Germany as early as possible about products that might cause a risk to the consumers. Furthermore, BVL provides support to the federal states to oversee the market concerning food, tobacco products, cosmetics, and any commodities as well as feed, for example, by ensuring that food surveillance is being undertaken in a harmonized way in all federal states. For that purpose, BVL hosts the European and national reference laboratory for measuring residues in food and acts as the national contact point for monitoring and measurements. Data obtained from food monitoring campaigns are sent by the federal states to the BVL for analyses, documentation, and reporting.

In addition, BVL is the responsible agency for the registration/authorization of plant protection products. The decisions of the BVL with regard to plant protection products are based on the scientific input provided by other competent authorities, for example, BfR, UBA, and JKI. Finally, BVL is the responsible agency for the registration/authorization of veterinary drugs.

## **Federal Institute for Occupational Safety and Health (BAuA)**

BAuA is a governmental research institution within the Federal Ministry of Labor and Social Affairs. Its role is to monitor and analyze the situation with regard to occupational safety and health. BAuA advises the Federal Ministry on all matters related to occupational safety, occupational health, and workplace design. The agency provides recommendations on medical care, surveillance, and the control of occupational diseases related to working conditions. In addition, BAuA assesses possible health risks due to the exposure of chemicals at the workplace, establishes occupational exposure limits, and develops protection strategies for handling hazardous substances. BAuA is the federal authority for chemicals based on the chemical law, and it manages the national office for the implementation of the REACH regulations. It coordinates the national tasks concerning these regulations and cooperates with ECHA. According to REACH, producers and importers are required to notify new chemicals before they can enter the market. Data and information need to be submitted to BAuA on the physical-chemical, toxicological, and ecotoxicological properties, classification, and labeling as well as on the safe handling of these substances. BAuA reviews the data in collaboration with other national agencies such as BfR and UBA and shares it with ECHA at the EU level.

Furthermore, BAuA is the responsible agency for the authorization/registration of biocidal products.

### **German Federal Environment Agency (UBA)**

UBA advises the German Federal Ministry for Environment, Nature Conservation, and Nuclear Safety on environment and health issues, particularly in the field of air pollution, noise pollution, waste and water management, soil conservation, and environmental chemicals. UBA's main role is to provide the scientific and technical knowledge for the drafting of legislation aimed at protecting human health and the environment, especially concerning the control, restriction, and ban of environmentally hazardous substances and preparations as well as genetically modified organisms. In particular, UBA has a role in the ecotoxicological evaluation of different types of chemicals. In collaboration with other federal agencies (e.g., BAuA and BfR), UBA is involved in the evaluation of, for example, pesticides, biocides, and genetically modified organisms in relation to a number of various laws, including the Washing and Cleaning Agents Act, Act on water pollutants, Plant Protection Act, Biocides Act, Federal Communicable Diseases Act, and the Genetic Engineering Act. In particular, the UBA is responsible for the evaluation of chemicals hazardous to the aquatic environment and their storage and transportation (classification of these chemicals).

Regulations concerning the sound management of chemicals and genetic engineering are essentially determined by the laws of the European Union.

### **Julius Kühn Institute (JKI: German Federal Research Institute for Cultivated Plants)**

JKI activities are in the field of plant health and nature. Its role is given by the Plant Protection Act. As the Federal Research Institute for Cultivated Plants, the JKI is dealing with the efficiency, efficacy, and benefits of pesticides. In addition, JKI has a role in the diagnoses of plant diseases, including the identification of harmful organisms and pathways and routes of infection. Methods are being developed for the detection and characterization of viruses, bacteria, and other pathogens.

JKI studies the effects of pesticides on organisms, especially on organisms present/living near crops and in adjacent water bodies (ecotoxicology); it studies the impact of climate change on pests and pest management strategies; and it contributes to the further development of integrated pest management. The latter includes the development of eco-friendly methods of plant protection, the study of natural pest resistance of crops, and the promotion of production of crops with high natural pest resistance.

Additional mandatory tasks include evaluations for the registration and use of genetically modified organisms (GMO Act).

### **German Federal Institute for Drugs and Medical Devices (BfArM)**

The BfArM is an independent federal authority in the Federal Ministry of Health with the aim of preventing health risks by continuous improvement in the safety of

medicinal products and by risk monitoring of medical devices as well as by monitoring the legal traffic in controlled substances. Main activities focus on the authorization and registration of medicinal products on the basis of the German Medicines Act. This includes the assessment of the efficacy, safety, and pharmaceutical quality of these products on the basis of pharmaceutical, pharmacological-toxicological, and clinical studies. The license of medicinal products is limited to 5 years. Renewals are granted upon application and after new evaluation. In addition, the BfArM has a role in the registration of pharmaceuticals in the European Union with EMA (European Medicines Agency) being responsible for the evaluation of medicinal products.

After marketing, the use of medicinal products might present rare adverse drug reactions which had not been observed during clinical trials. BfArM collects and assesses reports of adverse drug reactions and decides whether the information for the corresponding drugs needs to be revised. In case where the risks of medicinal products outweigh their benefits, BfArM withdraws the license of these products. In such cases, BfArM shares the information with agencies of the European Union and the World Health Organization (WHO).

On the basis of the Narcotics Act (BtMG), the Federal Opium Agency of BfArM issues licenses for the trade in narcotics. In addition, it controls the production and/or importation of narcotic and psychotropic substances.

The term “medical devices” refers to a wide range of products, including products for diagnosis, prevention, monitoring, treatment, or alleviation of disease and injury and handicaps as well as products for the replacement or modification of the anatomy such as pacemakers, X-ray, radiotherapy, and surgical instruments as well as in vitro diagnostic medical devices, prostheses, artificial teeth, etc. Health risks related to these products need to be reported to the BfArM by manufacturers, operators, and users. In turn, the role of the BfArM is to provide recommendations for risk mitigation.

## Abstract

The regulation to avoid or reduce potential health and *environmental risks* due to chemicals or physical factors in Germany, the European Union, and worldwide carries extremely heterogeneous features. Fundamental differences are encountered not only with regard to institutional responsibilities but also – and in particular – to nomenclature(s); definition of aims of protection; types of organization; scientific basis and extent of justification, implementation, and controls; as well as the legal status. The situation is even more complicated by interfering mandates. The system suffers from a crisis of credibility. However, recent efforts toward harmonization gain pace.

**Possibilities of Regulation**

On principle, there are four organizational types of regulation: *banning of production, sale, and uses of toxic materials*; *restrictions on use*; *mandatory use of protective procedures to avoid/reduce hazardous exposure(s)*; and the introduction of *health-based environmental threshold limit values*. Banning of production is only realized for materials with very high hazard potential. As voluntary *withdrawals from the market* by producers, bans regarding production or import (e.g., 2-naphthylamine, PCBs, pentachlorophenol) may be reduced in their effectiveness by imports due to globalization and removal of trade barriers. Bans are also excluded in case of materials which cannot be waived due to technical reasons, are formed by transformation processes in the environment, or have natural sources (such as heavy metals). In these situations, more and more preference has been given to the development and introduction of *alternative compounds* which are designed to avoid undesirable properties such as high stability in the environment. While intelligently designed alternatives may have significant advantages such as reduced potential for specific toxicities, complete toxicological data and experience from practical use of such alternatives are often not available; thus, other potential risks may be present. Another domain is *restrictions in practical applications* – a field of activities more for administrators than for toxicologists. *Protective measures in loco* (exposure prevention by personal protective equipment or using closed processes) are mostly dealt with by specialists in occupational toxicology. The most important protective instrument is the establishment and application of *threshold limit values (TLVs)*. They constitute the most frequently used method of health-based protection. Therefore, the following description will focus on such limit values.

---

**Threshold Limit Values (TLV)**

Threshold limit values (and environmental standards) are maximum permissible concentrations of chemicals (and physical stressors such as electromagnetic radiation) in specified environmental compartments, in specific tissues of organisms, or in excretion products. They are presented in the form of definitive figures, expressed as mass/volume, mass/mass, volume/volume, or doses in the form of mass/time. In case of *physical stressors* (radiation, noise, heat, pressure), physical quantities are valid accordingly. Such *official limit values* are established in laws, enactments, or regulations. They are either to be adhered to or function as recommendations. *Nonofficial limit values* are established by private institutions in the form of recommendations,

which may or may not be taken over in legal technical rules (e.g., *MAK values*) (DFG = German Research Association, VDI = Professional Organization of Engineers, DIN = Administration for Technical Norms).

## Stock-Taking

According to a systematic analysis performed by the Expert Council for Environmental Questions in Germany, there are more than 150 types of limit values in Germany alone. Chronologically, these were first developed for pharmaceuticals. The first dose limit for a pharmaceutical was introduced by the official German Pharmacopoeia (second edition in 1882) in the form of a maximum single or daily dose. The first limit values for workplace exposures to chemicals were introduced in 1886 (K.B. Lehmann). The numbers of limit values for chemicals in occupational or environmental settings were steadily increasing since 1960 with an exponential tendency, often enforced by increasing public pressure. More recently, ca. 20% of the derived limits each account for victuals and soil, ca. 10% each for air and water, and less than 10% each for chemicals, noise, and radioactivity. Human health is the predominant aim for the protective measures and presents 93%, followed by general protection of environment (19%), plants (16%), and animals (14%) (in part repetitive counting). Regarding the legal status, 50% each are introduced as official and nonofficial standards. At least 30 different nomenclatures are in use (see Table 1).

The authorization for the organization of work to be performed to justify a derived value varies widely, from multidisciplinary recruited commissions or committees, down to the desk of a single clerk of an agency. This confusing complexity is, in its major proportion, due to the historical development: different academic disciplines picked up, mostly incidentally, a problem and made use of their

**Table 1** Designations of threshold values as used in 154 German systems of regulation of hazardous materials (according to SRU = Council of Experts of Environmental questions, 1996)

Environmental values	Unhesitating values
Tolerance values	Maximum values
Maximum tolerance values	Precairium values
Scrutiny values	Background values
Encumbrance values	Input values

Action values	Coordination values
Occasion values	Damaging values
Restoration values	Threshold values
Alarm values	Preliminary values
Release values	Hesitation values
Release threshold	Environmental standards
Orientation values	Toxicity values
Scruple values	

categories of reasoning and evaluation, thus paving the way for a great variety of experience and competence. Since approximately two decades, increasing criticism of status and further development is arising, mainly driven by the interest of industry and jurisdiction to achieve reliability for planning and legal status. The lack of clear-cut targeting and rules of procedure induced activities to improve harmonization, standardization, and simplification. As a result, useful and intentionally calibrated criteria have been elaborated (SRU = Council of Environmental Questions 1996); a new commission for risk evaluation has been charged with establishing and handling uniform rules.

---

## Profiles of Demand

Regulatory processes are understood as political decisions – ideally in the form of consensus – based on scientific assessment of potential risks, under adequate participation of societal groups. The substantial elements of demand are:

1. *Participation of the public* before and in the course of procedures
2. *Complete transparency of all steps of procedure*, e.g., publish intentions and timing
3. An essential element of transparency is to be seen in the obligation of a detailed *justification* of
4. *All scientific evaluations and proposals for regulations and decisions* in the form of detailed documents which should be available to everybody
5. Concerned *societal groups should be involved* in the discussions for the preparations of decisions
6. Accomplished decisions, particularly regarding the level of a standard, need to be enforced by validated analytical methodology to warrant *compliance*

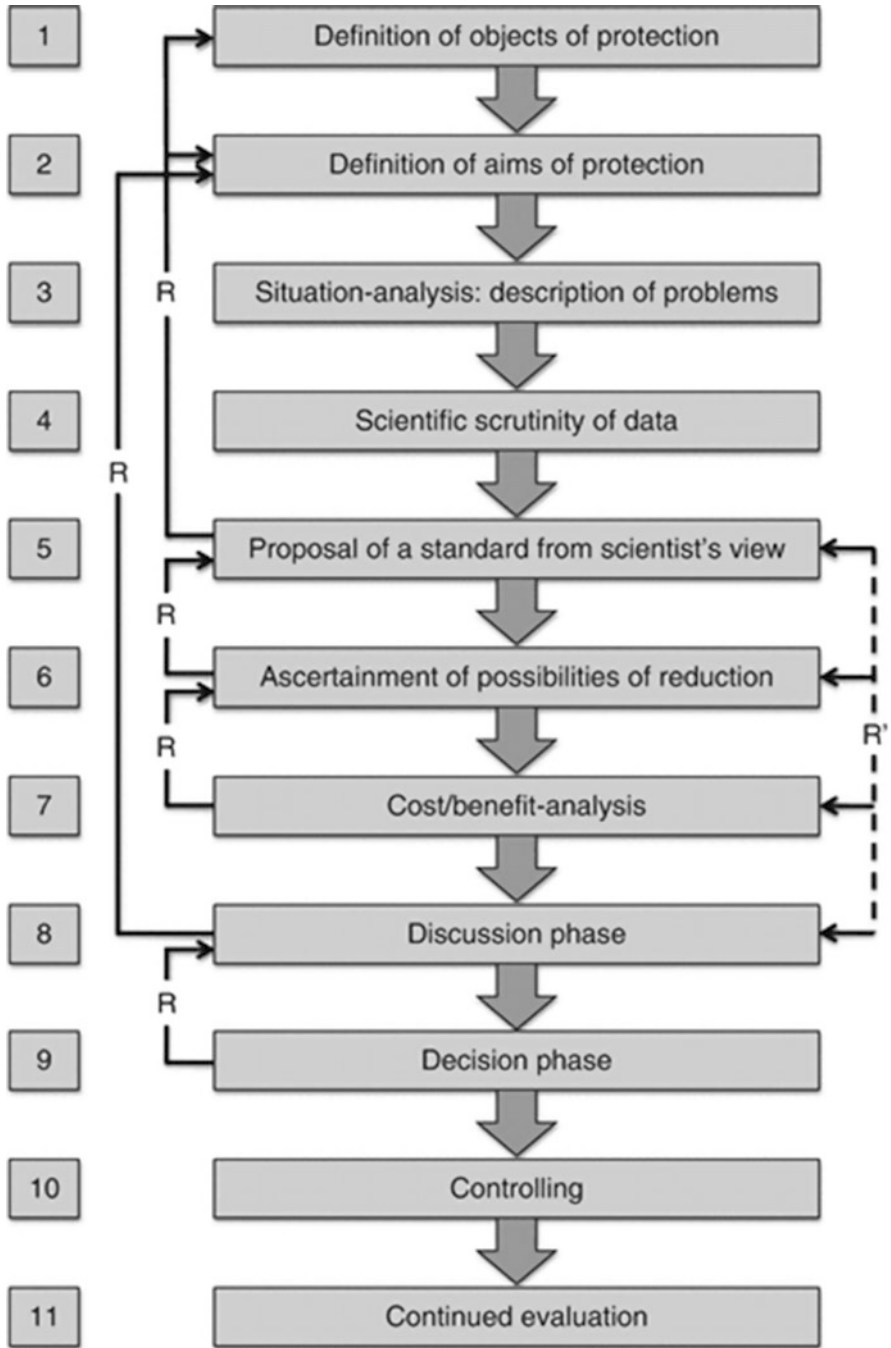

A new element has been introduced later: obligation of *continuous reevaluation in predetermined intervals*, taking into consideration new scientific data and eventually changes in sociopolitical principles.

---

## Procedural Steps

The profiles of demand require the integrated cooperation of expertise of different scientific domains, making the process of regulation a multidisciplinary task. The evaluations to be performed require working elements of different groups of experts. This necessitates a *sequential procedure* of defined steps, which allows for recourses from one step to each other. A model of sequential steps is presented in Fig. 1.

The process starts with the determination of *objects of protection* (targets) (human beings, plants, soil, etc.) and with *aims of protection* (e.g., complete elimination or gradual reduction of risk). Right and duty of making proposals is not restricted to governmental institutions but open to everybody. The decision about the aim(s) of

**Fig. 1** Scheme of sequential progress in the form of an ideal model of steps in the regulatory process (R, R' = checkback; SRU 1996)

protection is bound to the duty of detailed justification. This is followed by a *scientific analysis*, including a risk evaluation mostly based on published data on toxicological information or results of targeted toxicity test. Normally, a *proposal for a standard* is elaborated by the group of scientists who evaluated the data as a result of the critical evaluation of all data for which a detailed justification is mandatory, including the identification of gaps of knowledge. This step is followed by the ascertainment of *possible technical reduction of risk(s)* (often called “status of technology”), as well as the elaboration of a *benefit/risk analysis* and a *cost analysis*, both steps involving experts in engineering and economy. Again, these proposals have to be justified in detail.

After these basic steps have been accomplished, a *discussion phase* tries to set a starting point for a solution, may be in the form of several alternatives. Participants are societal groups (producers, users, employers); for checkback questions, scientists who participated in the foregoing steps should be available. The guidance of the discussions should be handled by those responsible for the (final) decision-making (governmental and/or nongovernmental). They should prepare, in the following *decision phase*, the finalized version of the standard proposal, including the detailed justification, and put through the final decision. The same group of participating experts shall also prepare the operational steps of *control of compliance* to the standard and for a *continued reevaluation* in predetermined intervals, taking into account new developments in data production and interpretation. For this purpose, a new standard necessitates the provision of suitable analytical methodology according to internationally accepted rules.

---

## Historic Developments

The classical form of organization of the process of regulation is the *commission of experts*. This has a long tradition in Germany, particularly by the DFG (German Research Association) who, according to their statutes, provides recommendations for health-related issues. Since 1952, DFG has established so-called Senate Commissions in different domains of regulations (occupational toxicants preparing MAK values = maximum tolerable concentrations, plant-protecting chemicals, foodstuffs, cancer research, etc.). The MAK Commission has held a pilot function for many other commissions. For ambient air pollution regulations, numerous commissions have been established and are still active in the VDI (Union of German Engineers). In addition, governmental agencies – from federal down to community level – have established their own committees for giving advice in environmental problems or setting standards of their own. Some are working permanently, some ad hoc only; the latter ones suffer, in some cases, from a lack of consistency and continuity.

*Membership* in these commissions of scientists in general, and of toxicologists in particular, should be based on independency in their professional activities and reasoning. There is a legal basis for proving the evidence of independency in the form of official rules of administration: new members of a commission have to declare by signature that they do not hold contracts with industry, share holding

included. In this context, there remains an open issue of membership of professionals in industry: on the one hand, they may contribute a high amount of special knowledge and competence, and they may contribute to the process by submitting valuable data (sometimes unpublished) and by specific experience. One way out of this conflicting situation may be seen in having them participate by seat but not by vote. But this certainly is not satisfactory to everybody. The agencies should create clear regulations referring to this sensitive point, now and forever.

Finally, there remains one important question to be solved: Who should participate in which sector of the regulatory process and who should take which part of responsibility? Two models are in operation: (1) Unitarian, every member of the commission participates in all steps of the procedure, participates in voting, and thus carries full responsibility. (2) Separatistic, the activities in the scientific analysis, discussion, and decision are strictly separated from each other, which means everybody participates just in that sector where he/she is professionally competent and thus takes responsibility just in that part. The separation shall avoid influences upon the scientific evaluation and decision by members of interested societal groups. Further development indicates preference of the separatistic model. However, the lawmakers in Germany have not yet taken decision toward a clear and comprehensive regulation of this issue.

---

## **Types of Organization**

Similar processes as those described above for Germany have been developed on the level of the European Union and internationally. However, within the different legislative contexts, the involvement of scientific expert committees varies between the sole responsibility of the advisory group regarding limit values developed to an advisory role after the value has been defined by a regulatory authority.

For example, panels of the *European Food Safety Authority (EFSA)* and Scientific Committees of the European Commission with specific legislative mandates develop tolerable limits for food additives, food contact materials, food contaminants, or cosmetic ingredients based on scientific principles for health risk assessment and carry the sole responsibility for the process. In contrast, in the Registration, Evaluation, Authorization of Chemicals (REACH) process, the manufacturer or importer of a chemical (registrant) is responsible for performing risk assessment and for developing tolerable exposure following specific and detailed guidance outlined in REACH regulations. The Agency (ECHA – European Chemicals Agency) interacts with the registrant and can require specific information to address issues identified in the derived exposures and potential uncertainties in the evaluation. However, due to resource constraints, it is expected that only a limited number of the submitted registration dossiers will be evaluated in great detail.

In addition, a significant role of scientists employed by regulatory agencies (governments) in risk assessment is also frequently observed. In many cases, scientific advisory boards have the role to provide comments to the developed documents regarding risk assessment. For example, in the United States, many

regulatory decision documents regarding chemical safety are drafted by regulatory agencies, and conclusions are presented to a scientific advisory board and the general public requesting comments on the conclusions.

## Abstract

Reliable data are essential for the assessment and evaluation of the toxicological characteristics of chemical substances and of safe exposure levels for man and the environment. Data reliability is closely linked with the exclusion or minimization of errors and mistakes in the generation of data. These objectives can be reached by the implementation of appropriate Quality Assurance (QA) systems as an

important part of the Quality Management (QM). The major characteristics and differences of the more important quality assurance systems are presented in this chapter.

---

**Keywords**

Quality Management · Quality Assurance · GxP · Accreditation · Certification · “Codes of Conduct”

---

## **Introduction**

Quality must be defined in advance: The quality of a finished product or of a service function at the end of a value creation chain is determined by a number of factors – the basic elements of quality first described by Kaoru Ishikawa (1968) and linked by him into a “fishbone” or “cause-and-effect” diagram. These factors include management, environment, methods, machines, materials, measurement, and – last but not least – people. “Quality” in this context is so defined that any activity, performance, or technical product should meet specific, predefined requirements and characteristics on completion. In order to reach and maintain such quality requirements, specific prerequisites and boundary conditions on the road to the finished product must be defined in advance. These will include quality criteria and quality control procedures applicable not only to the end product but also for all critical initial parameters and intermediate steps. In the case of reproducible or frequently repeated activities, such prerequisites and boundary conditions are often defined in Standards, Guidelines, or Directives according to the specific legal and administrative systems. This applies to the majority of physical, chemical, and biological-medicinal measurement systems and to methods for the generation of data relating to chemical substances and their properties.

---

## **Quality of Data**

Relevant and reliable data are required to assess and evaluate the toxicological characteristics of chemical substances or of exposure levels. The quality of the available data is of decisive importance and thus has to be carefully considered during the human health risk assessment process. Good quality means not only that the data provide an important or significant contribution in the sense of providing new insights or filling a previous gap of knowledge but also that the data is reliable, in the sense that both the probability of errors occurring and the extent of any which may occur are as small as possible.

Practically, every measurement (no matter how accurate) or other form of experimental or epidemiological data collection implies some risk of random or systematic errors, which then result in a deviation from the “true” value (which is – in general – not known). An important aim of any institution generating such data must thus be

to implement appropriate general conditions and control procedures so that there is a high probability that the data obtained approach the “true” value and can be confirmed – either by repeating the process or by some other method. Given a certain process or method, the probability of approaching the “true” value can thus only be improved by systematically eliminating all known sources of error and – gradually – identifying and eliminating unexpected or previously unimaginable sources of random and systematic error. Data quality in terms of reliability thus depends on the systematic elimination of sources of error. This necessitates a Quality Management approach with a suitable Quality Assurance system.

---

### **Quality Management (QM) and Quality Assurance (QA) (QM/QA Systems)**

The aim of *Quality Management* systems is firstly to ensure that errors in ongoing processes are excluded as far as possible. As part of a continuous learning and improvement process, any remaining errors should be identified, documented, and avoided in the future. This can be achieved by the choice and implementation of a QA system with appropriate boundary conditions, methods, and controls. The international standard ISO 9001:2015 is the most prominent approach to quality management systems, specifying requirements for QM systems.

The aim of every *Quality Assurance* system is to generate credibility and confidence in the reliability of the data internally and externally – that is within the organization, toward direct clients, and all others who may be interested in the data concerned. In practice, two different strategies can be identified, neither of which alone is sufficient but which supplement each other in various QA systems with varying degrees of emphasis on individual features.

---

### **First Strategy: Traceability and Transparency of Studies**

Data are usually generated in the course of experimental or in silico studies and any kind of projects. Many such studies cannot be easily repeated, should doubt about the reliability of the data arise. Reasons may be ethical grounds, cost grounds, or the huge workload involved. Examples of such studies are long-term experimental studies in animals (often with large numbers of animals), studies in human beings, and field studies with crop protection agents. Any attempt to reconstruct such studies shortly or long after they have been conducted requires extensive and detailed recording of all initial conditions, methods, working steps, and the results obtained. In such cases, an extensive documentation and archiving system is required, such as that particularly described in the *Good Laboratory Practice* (GLP) system. The workload for the testing facilities and test sites involved with such systems is significant, even for relatively small or short-term studies.

---

## Second Strategy: Reproducibility and Comparability of Data

Ideally, experimental toxicological research produces statistically significant effects that can be interpreted as causal effects. Naturally, every single experiment is a singular observation. In order to assume a generally valid causality, individual observations should be reproducible. The requirements to obtain reproducible data in toxicological studies have been intensively discussed in recent years (e.g., Miller 2014; Briner and Kirwan 2017). Many studies to determine, e.g., physicochemical properties of substances such as melting or boiling point or the presence of substances in biological matrices can be fairly easily and quickly repeated under the same methodological conditions or can be easily checked by other means. This applies to the majority of chemical-bioanalytical and many other physicochemical determinations. The stringent application of the International System of Units (SI) facilitates comparison of data. This implicates increased requirements regarding technical expertise, calibrations, and comparison measurements (e.g., participation in inter-laboratory tests) for data validation and quality management procedures in the laboratories concerned. However, the documentation effort is then reduced and more flexible. Quality assurance systems of this type include accreditation and – for products and services – certification.

---

## Good Laboratory Practice (GLP) and Other “GxP” Systems

Some quality assurance systems are required in relevant laws and regulations and thus fall under legal controls, for example, those for *Good Laboratory Practice* (GLP). The first GLP regulations were issued by the US Food and Drug Administration (US FDA) in the late 1970s after irregularities were discovered in the planning, conduct, and reporting of animal safety studies submitted in the registration dossiers for medicinal products (U.S. FDA 1978). Similar regulations were subsequently issued by the US Environmental Protection Agency (US EPA) covering studies conducted with pesticides under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and other chemical substances under the Toxic Substances Control Act (TSCA) (U.S. EPA 1983). The need to comply with these regulations acted as a nontariff barrier to international trade in such substances, which led the *Organisation for Economic Co-operation and Development* (OECD) to develop internationally harmonized “Testing Guidelines” and “Principles of GLP” which were then recommended for worldwide use to ensure the Mutual Acceptance of Data (MAD) generated according to the Testing Guidelines and GLP Principles (OECD 1981). The GLP Principles were recommended for use within the European Communities in 1987. The GLP Principles represent general quality requirements for the conduct of studies, and the OECD Testing Guidelines form the basis for the scientific or methodological approach. Both the GLP Principles and the OECD Testing Guidelines are the common basic concept to ensure the data quality of studies, for trust building and for the Mutual Acceptance of Data worldwide. At the end, it is up to the competent authorities to evaluate the study data with regard to

reliability, relevance, and adequacy. The latter term is used for the comparison of studies. Evaluation criteria for these three terms have been developed (Klimisch et al. 1997) and refined. For a recent overview, see, for instance, Beronius et al. (2018).

The GLP Principles (and the Testing Guidelines) are reviewed on an ad hoc basis by OECD Expert Groups and – where appropriate – revised to ensure best scientific practices. The last revision of the GLP Principles took place in 1995–1996, and the Revised Principles were formally adopted by the OECD in 1997. The Revised Principles were adopted in the European Communities in 1999 and are now binding within all Member States (in Germany, e.g., as Annex 1 to the Chemicals Law (Chemikaliengesetz)). The OECD Testing Guidelines have also been implemented into the European legislation and are being continuously updated according to the technological progress (Regulation (EC) No 440/2008). The European Regulations and Directives relating to biocides, chemical substances, cosmetics, detergents, feeding stuffs, foodstuffs, medicinal products, medical devices (where applicable), novel foods, and veterinary products all require that at least some of the test data required for the registration or regulatory approval of such products for use within the European Union be generated in compliance with the GLP Principles or with equivalent standards (EC website 2020).

The OECD has also developed procedures for governments on the inspection and verification of good laboratory practice in order to monitor the compliance of testing facilities with the GLP Principles (first adopted 1983, first revision 1989, second revision 1995). These documents have also been implemented by the individual Member States within the European Union (Directive 88/320, now replaced by Directive 2004/9 of March 2004). In addition, the OECD has sponsored the preparation and publication of a series of *Guidance Documents for Compliance Monitoring* (No. 2, 3, 9, 20), *Consensus Documents* (No. 4, 5, 6, 7, 8, 10, 13), and *Advisory Documents* (No. 11, 12, 14, 15, 16, 17, 19) providing further comments and explanations on certain specific items of the GLP Principles (for instance, quality assurance, laboratory supplies, field studies, short-term studies, computerized systems, full listing available on OECD website (OECD 2020)). These documents have no legal force but are – in practice – regarded as “state of the art” and are widely used by test facilities and test sites as well as by compliance monitoring authorities. The OECD Position Paper No. 18 *Regarding the Relationship between the OECD Principles of GLP and ISO/IEC 17025* states that laboratory accreditation (see below) is not applied to non-clinical health and environmental safety testing because ISO/IEC 17025 does not contain all of the requirements of the OECD GLP Principles. Nevertheless, laboratory accreditation can make a valuable contribution within the GLP compliance structure. Although common rules and more detailed regulations exist, there may be differences in their interpretation, application, and enforcement between countries and even between monitoring authorities in the same country. For instance, whereas Seiler (2005) describes the implementation and application of the GLP Principles from a more “European” point of view, the same GLP Principles may be in part differently interpreted and applied in the United States and even between the two monitoring authorities US FDA and US EPA (Weinberg

2003; U.S. FDA 2020). The European Commission provides support under [https://ec.europa.eu/growth/sectors/chemicals/good-laboratory-practice\\_en](https://ec.europa.eu/growth/sectors/chemicals/good-laboratory-practice_en).

*Good Manufacturing Practice (GMP)* is a QA system (also first developed in the United States) to control in particular the manufacture of medicines, veterinary medicines, and medical devices. GMP is also prescribed by law for the manufacture of food contact materials and cosmetic products. The application and monitoring of GMP requirements is also largely harmonized, within Europe initially (1989) as “Guidelines to Good Manufacturing Practice,” subsequently by Commission Directives 91/356 and 91/412 and Directive 2003/94. For details, for example, see also the websites of the European Medicines Agency (EMA 2020) and the European Food Safety Authority (EFSA 2020).

*Good Clinical Practice (GCP)* provides a quality assurance system for planning, conducting, and reporting clinical studies carried out – for example – to provide data in support of applications for marketing authorizations for medicinal products. The requirements were first developed by an expert working group of the “International Conference on Harmonisation of technical requirements for registration of pharmaceuticals for human use” (E6(R1) Step 4 version (ICH 1996), current update: E6(R2) Addendum Step 4 version (ICH 2016))) and adopted by the regulatory bodies in the European Union, Japan, and the United States. In 2015, ICH has renamed itself as the International Council for Harmonisation and has become a legal entity under Swiss law. Among other issues, the GCPs require that clinical studies be planned and carried out according to the ethical standards described in the World Medical Association “Declaration of Helsinki.” Further information on GCP can be found, for example, on the website of the European Medicines Agency (2020).

---

## Accreditation and Certification

Most accreditation and certification systems are based on voluntary participation and are not governed by legal requirements. However, the use of such systems is often a prerequisite before a facility or laboratory may conduct studies if the results should be used in legally controlled activities. This applies, for instance, to laboratories performing analyses for the control of foodstuffs, the monitoring of ambient air or drinking water quality, or measurements to be used as part of health and safety requirements in the working environment as laid down in ISO/IEC 17025. Both systems give high priority to the use of appropriate quality management procedures. *Accreditation* is a system to monitor and approve the competencies of testing laboratories and their Quality Management systems. The organizations issuing such approvals are – themselves – monitored and accredited by the so-called Accreditation Bodies, as laid down in the International Standards Organization (ISO) Standards ISO/IEC 17011 and – when appropriate – 17020–17025. For instance, in Germany, the *Deutsche Akkreditierungsstelle* (DAkkS) is the national Accreditation Body (since January 2010). Pursuant to Regulation (EC) No. 765/2008, DAkkS acts in the public interest and as the sole provider of accreditations in Germany. *Certification* according to the international standard ISO 9001:2015 relates to the

quality of products and/or service functions in the sense of a guarantee that certain defined characteristics are provided by the product or function. ISO 9001:2015 is compatible with other management systems standards and specifications, such as ISO 45001 *Occupational Health and Safety* and ISO 14001 *Environmental*. Appropriate certification and the establishment of a quality management system according to ISO Standard 13485 for medical devices is – for example – a prerequisite for the use of the CE Mark on certain types of products to be placed on the market within the European Economic Area (EEA). Another example is ISO 22716 for the manufacture of cosmetic products.

---

## “Codes of Conduct” and Quality Assurance

A number of scientific societies and professional associations (e.g., those for medical practitioners, pharmacists, or toxicologists) have developed codes of conduct which are binding on their members. These Codices contain certain elements which help toward a quality assurance but are – usually – directed to ensuring a responsible and ethical behavior in professional activities. Such elements, for example, a requirement for scientific honesty, are important but alone cannot be regarded as a quality assurance system. The concept of “Safeguarding Good Scientific Practice” has been developed by some major institutions for basic research in response to spectacular cases of scientific misbehavior or fraud. For example, the German Research Foundation (Deutsche Forschungsgemeinschaft) (2019) has recently updated its “Safeguarding Good Scientific Practice” with some 16 detailed recommendations and suggested their use in scientific institutions, particularly those in academia. Among the more important recommendations in the sense of quality assurance are those related to organizational structure of working groups and the need for complete documentation and long-term archiving of important primary data; however, it is unclear in how far these recommendations have been or are being followed by the institutions concerned.

## Abstract

Risk analysis encompasses the scientific review and evaluation of all relevant scientific data on the toxicity of, and the exposure to, a certain compound or mixture. To enable a systematic analysis of the different types of information needed, various risk analysis paradigms have been developed. Among these, the scheme developed in 1983 by the US National Academy of Sciences (NAS) has been the most widely utilized. Risk analysis provides the scientific basis for regulatory actions within the context of risk management.

**Introduction**

The term “risk analysis” is not used in a uniform manner. In some instances, the term is considered to have the same meaning as “risk assessment,” while some institutions, as is the case with the Codex Alimentarius Commission, employ the term to describe the broader concept of risk regulations, encompassing risk assessment, management, and communication. For others, risk analysis is seen as the mathematical analysis and quantification of risks. Given these differences in using the term risk analysis, a clear, uniform definition cannot be given. For the purposes of this chapter, risk analysis will be described as the broader process encompassing the scientific assessment, management, and communication of risks.

**Why Risk Analysis?**

The toxicity of a given substance can be defined as its ability to harm living organisms. This is an inherent characteristic of any compound and will only be expressed as a function of the dose as described already by Paracelsus. Thus, any compound can be toxic if a certain threshold of exposure is surpassed. This is the reason why a distinction between “toxic” and “nontoxic” or “harmful” and “safe” substances makes no sense. In fact, the toxicity of a given substance cannot be defined without reference to the administered/absorbed amount (dose); the route through which the exposure and distribution of the substance take place (e.g., by inhalation, ingestion, dermal absorption); the level, frequency, and duration of exposure; the type and grade of the damage caused; and the lag time required to illicit the toxic effect.

It is only once the potential to cause harm and the probability of a damage are known that options to reduce/eliminate potential harm can be assessed and regulatory action be taken (risk management). Such measures need to consider other factors besides the scientific evaluation of risks, for example, socioeconomic impacts and the risk-benefit relation. The aim of risk management is to avoid risk or, if this is not possible, to reduce it as far as achievable. The basis for meaningful risk management decisions remains, however, a thorough characterization and evaluation of scientific data on toxicity and exposure: risk assessment.

---

**Steps in Risk Regulation**

In the scheme of the German Risk Commission (Deutsche Risikokommission), risk regulation encompasses the whole societal process of dealing with risks. Ideally, the process should cover three areas of risk analysis: risk assessment, risk evaluation, and risk management.

---

## **Risk Assessment**

Risk assessment is the process of identifying and quantifying the potential harm due to a certain exposure to a substance (risk). Normally, it targets individuals, but there are several instances in which population risk is assessed. To accomplish this task, knowledge about toxicity and exposure, but also information on the dose-response (or exposure-effect) relation, and target populations including vulnerable groups is required (see below).

## **Risk Evaluation**

Risk evaluation bridges risk assessment and risk management. It encompasses a value judgment of the risk posed by the substance under consideration. Questions addressed here include whether or not the risk is higher than seen with other comparable compounds, what the risk-benefit ratio is, and if there are any protective measures that can be taken to reduce the risk. In addition, social, cultural, and political factors may also be considered. The outcome of this process is a recommendation for risk management.

## **Risk Management**

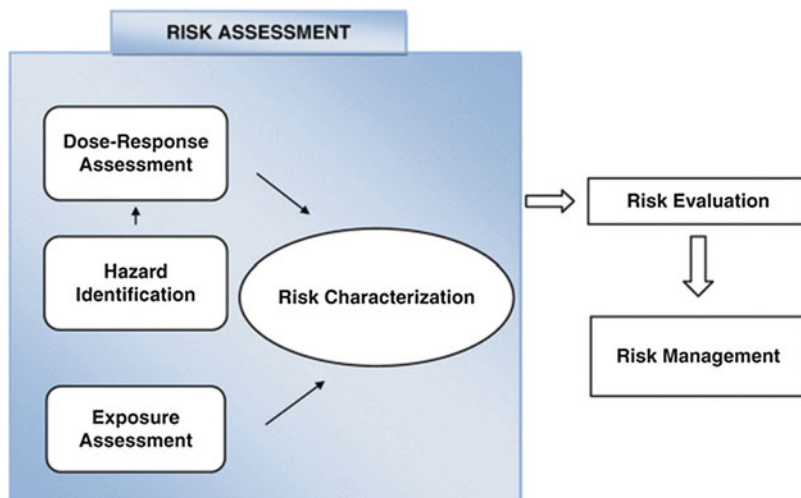

Risk management is the decision process during which the results of the risk assessment are used to develop and analyze options for avoiding or minimizing risks of exposure to a given substance, taking into consideration political, social, cultural, economic, and technical aspects. The aim of this process is to define the best possible and feasible action(s). Risk assessment and management are distinct, though closely related, interactive processes: while risk assessment is a scientific, technical discipline, risk management is a sociopolitical decision-making process. Newer models of risk analysis have endeavored to develop a closer interlink between the two processes (see below).

---

## **The Process of Risk Assessment**

Scientific information needed to conduct risk assessment includes qualitative and quantitative data on the toxicity of the agent in question, on the dose-response relation, as well as on the exposure (WHO 1999; Younes et al. 1999).

The process of collecting or extracting relevant data to be used for the risk assessment includes various steps which are tightly related to the problem formulation (the scientific question to be answered), the conceptual framework, and the definition of the evidence needs. The aforementioned considerations should always be clearly addressed in advance before the actual risk assessment begins. When the collection of the data has been completed, the risk assessment can be conducted.

**Fig. 1** Schematic presentation of the risk analysis process: Following risk assessment, with its four components, risk evaluation is conducted to allow for consideration of additional factors, such as socio-economic impacts, before risk management decisions are taken

Various paradigms have been developed to facilitate a systematic analysis of such complex data and, consequently, to allow for the development of a comprehensive estimation of potential risks. The most commonly used scheme worldwide is the one developed by the US National academy of Sciences (NAS) in 1983 (NRC 1983, 2009). It is currently in use by many regulatory agencies, though some variations of it are also applied, and more modern approaches have expanded on it to provide a better link between the processes of risk assessment, management, and communication. The NAS model divides the process of risk assessment into 4 distinct steps (Fig. 1).

## Hazard Assessment

In order to better understand the important step of hazard assessment, it will be subcategorized below in two steps which altogether consist the process of assessing the hazardous properties of an agent.

### Hazard Identification: Assessing the Potential to Cause Harm

It is worth noting that the terms “hazard” and “risk” are often used synonymously. This is incorrect. The term “hazard” describes the “potential to harm,” that is, the principal ability of a given substance to exert a toxic effect (which, logically, will

only occur at a certain exposure level). Hazard is therefore an inherent characteristic of the agent in question. “Risk,” by way of contrast, describes the probability that a harmful effect will, in fact, occur. Risk is the actual or potential danger posed by an existing or an expected exposure.

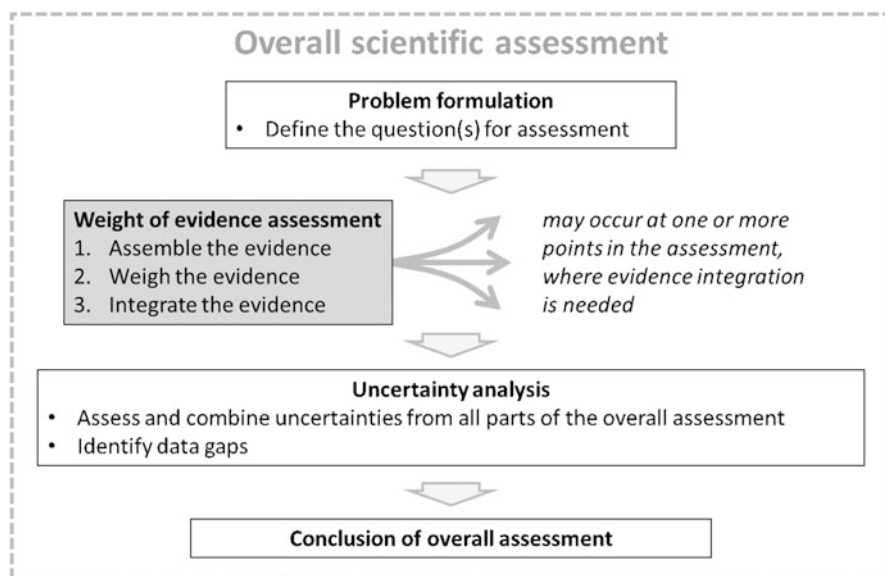

Hazard identification is the step during which all relevant data are analyzed that provide information to assess the inherent potential of an agent to exert harmful effects.

When the scientific question is relatively simple and can be addressed directly then a straightforward assessment can be conducted to reach an outcome following the steps described in this chapter.

In many assessments, however, questions may need to be subdivided to yield more directly answerable questions, and a weight of evidence assessment needs to be conducted.

The weight of evidence is comprised by three basic steps (see Fig. 2):

1. Assembling the evidence into lines of evidence of similar type which involves searching for and selecting evidence that is relevant for answering the question at hand, and deciding whether and how to group it into lines of evidence
2. Weighing the evidence which involves detailed evaluation and weighing of the evidence

**Fig. 2** Diagrammatic illustration of weight of evidence assessment as a 3-step process which may occur at one or more points in the course of a scientific assessment (EFSA 2017)

### 3. Integrating the evidence to arrive at conclusions, which involves weighing the relative support for possible answers to the question

It is important to note that reliability, relevance, and consistency of data are the three basic considerations for weighing evidence.

- Reliability is the extent to which the information is correct.
- Relevance is the contribution a piece or line of evidence would make to answer a specified question and how much could alter how decisions for a specific problem are taken, if the information comprising the evidence was fully reliable. This includes biological relevance.
- Consistency is the extent to which the contributions of different pieces or lines of evidence to answering the specified question are compatible.

Relevance and reliability may be considered in both the first and second steps since they are essential elements in order to identify the evidence to be used for the risk assessment but also when weighing the identified evidence.

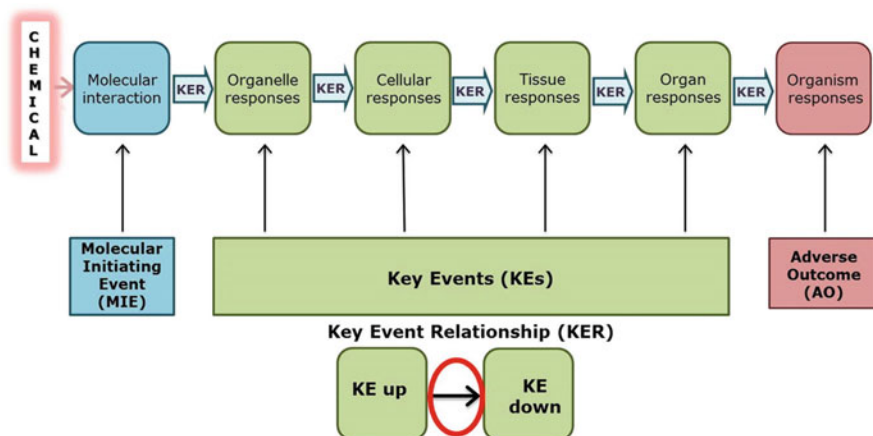

Sources of data to be used for the hazard identification can be *in vivo* studies, *in vitro* studies, *in silico* (QSAR, read across, etc.), epidemiological studies, and control clinical studies on humans. A variety of studies are used to identify potential hazards of a chemical. More specifically, toxicokinetics considers how the body absorbs, distributes, metabolizes, and eliminates chemicals while toxicodynamics focus on the effects that chemicals have on the human body.

Especially, when assessing a chemical for potential adverse effects, analysis of a mode of action (MoA) and the development of an “adverse outcome pathway” (AOP) are currently used.

MoA is a biologically plausible sequence of key events leading to an observed effect supported by robust experimental observations and mechanistic data. A given agent may work by more than one MoA. For instance, when assessing a chemical for carcinogenic effects, the chemical might be involved in MoA both at different tumor sites as well as at the same site (Boobis et al. 2008).

The AOP approach provides a framework for organizing information at the chemical and biological level, allowing evidence from both *in silico* and *in vitro* studies to be rationally combined to fill gaps in knowledge concerning toxicological events. Fundamental to this new paradigm is a greater understanding of the mechanisms of toxicity and, in particular, where these mechanisms may be conserved across taxa, such as between model animals and related wild species. (Madden et al. 2014).

An AOP is defined as the information on the causal links between a molecular initiating event (MIE) which is the initial point of chemical-biological interaction within the organism that starts the pathway, intermediate definable key events (KEs) which make sense from a physiological and biochemical perspective and an adverse outcome (AO) of regulatory concern that is adverse at the individual level if discussing human health or population level if discussing environmental effects (see Fig. 3) (Ankley et al., 2010; Meek et al. 2014; OECD 2013).

**Fig. 3** An AOP consists of key events (KEs) and key events relationships (KERs) at different levels of biological organization starting from an initial interaction of a chemical with the biological system (molecular initiating event; MIE) through a sequence of KEs (cellular, tissue, organ, and organism) leading to an adverse outcome (AO) of regulatory relevance that represents overt adversity at either organism or population level. At sufficient concentrations and durations of exposure, KE up will trigger KE down, overcoming cell defense mechanisms and adaptation processes. (Anna Bal-Price et al. 2017)

### Dose-Response Assessment: The Relation Between Exposure and Effect

The objective of hazard characterization is to document the dose-response relationship. Usually, as the dose increases, the measured response also increases. At low doses there may be no response. The adverse effect that occurs at the lowest dose is selected as the critical effect for risk assessment which serves for the derivation of a health-based guidance values. Different definitions can be found in bibliography (e.g., Acute Reference Dose (ARfD), Lowest or No-Observed-Adverse-Effect-Level (LOAEL/ NOAEL) or ideally BMD limit (BMDL)), but they all serve the same scope, which is to identify a reference point which will be consequently used for the derivation of a health based guidance value such as Margin Of Exposure (MOE) or Tolerable Daily or Weekly Intake (ADI/TDI). When this exercise is done, and the risk characterization is quantified, the risk assessor can conclude about the risk.

In the course of this step, a quantitative estimation of toxic effects, be it the severity of an observed outcome, such as the level of liver damage as evidenced by an increase in blood levels of liver-specific enzymes, or the frequency of occurrence of a yes-or-no outcome, such as cancer or even death, at different exposure levels is conducted. This allows for a characterization of potential toxic outcomes as a function of exposure or dose.

Table 1 shows the different reference points, health based guidance values, and ways to characterize the risk as they are used in risk assessment.

**Table 1** Reference points and health based guidance values

Reference points (RPs)	Health based guidance value (HBGV)	Risk characterization
Benchmark response (BMR)	Acceptable daily intake (ADI)	Margin of exposure (MOE)
Lowest benchmark dose (BMDL)	Tolerable daily intake (TDI)	Risk characterization ratio (RC)
Benchmark dose (BMD)	Acute reference dose (ARfD)	Hazard quotient (HQ)
No observed (adverse) effect level (NO(A)EL)	Reference dose (RfD)	Margin of safety (MOS)
Lowest observed (adverse) effect level (LO(A)EL)	Derived-no-effect-level (DNEL)	Population at risk
No observed (adverse) effect concentration (NO(A)EC)	Derived-minimal-effect-level (DMEL)	
Lowest observed (adverse) effect concentration (LO(A)EC)	Population adjusted dose (PAD)	

## Exposure Assessment

Exposure assessment encompasses the qualitative and/or quantitative determination of the level and frequency of exposure, potentially the lag time between subsequent exposures, the exposure media (air, drinking water, soil, recreational water, food), as well as the exposure route(s) (inhalation, ingestion, dermal absorption).

## Uncertainty Analysis

A separate step is still needed to take account any uncertainties arising at all stages of the risk assessment. They should be addressed and described together with any data gaps. A separate step of uncertainty analysis is needed to take account of any uncertainties affecting the overall assessment. These are further categorized according to the source of uncertainty.

- A. Uncertainties associated with assessment inputs which include:
- 1) Ambiguity
  - 2) Accuracy and precision of the measures
  - 3) Sampling uncertainty
  - 4) Missing data within studies
  - 5) Missing studies
  - 6) Assumptions about inputs
  - 7) Statistical estimates
  - 8) Extrapolation uncertainty (i.e., limitations in external validity)
  - 9) Other uncertainties

- B. Uncertainties associated with assessment methodology which include:
- 1) Ambiguity
  - 2) Excluded factors
  - 3) Distributional assumptions
  - 4) Use of fixed values
  - 5) Relationship between parts of the assessment
  - 6) Evidence for the structure of the assessment
  - 7) Uncertainties relating to the process for dealing with evidence from the literature
  - 8) Expert judgment
  - 9) Calibration or validation with independent data
  - 10) Dependency between sources of uncertainty
  - 11) Other uncertainties

---

## **Risk Characterization: The Synthesis of Risk Information**

The last step in risk assessment is risk characterization (see also ► [Chap. 56, “Risk Characterization in Regulatory Toxicology”](#)), which is a synthesis of all evaluated data and information. Strengths and weaknesses of the database must be clearly identified, methods, and criteria of all evaluations described, and the results of the evaluation of all data outlined. The outcome of risk characterization is the basis for developing strategies to avoid or, if this is not possible, to minimize the risk (risk management). Vulnerable groups, which are at particular risk due to higher exposure levels and/or an enhanced susceptibility, must be characterized in order for risk management decisions and actions to take their particular situation(s) into consideration.

The scheme described is a conceptual framework which should help in organizing all scientific data in a manner that allows a sequential, logical analysis. Other models/schemes have been developed, but the NAS paradigm is the most widely used till now. Individual steps of the process are more exhaustively described in other parts of this book.

Recent advances have been made to better link risk assessment with risk management. The US National Research Council recommended in 2009 that risk analysis should be divided in three phases. The first phase should cover problem formulation and scoping in order to better identify data needs and target risk assessment. The second phase should encompass the planning (stage 1) and conduct (stage 2) of risk assessment, pretty much following the NAS paradigm, but with an additional stage 3 to confirm the utility of the assessment. In this latter stage, questions to address include if the assessment had the attributes called for in the planning, if the assessment provides sufficient information to discriminate among risk management options, and if the assessment has been sufficiently peer-reviewed. Only then phase 3, risk management, actions can be evaluated and decided upon.

## The Need for Harmonization

Despite the fact that the scientific data used for risk assessment purposes by different institutions are mostly identical for the same compound, they are often analyzed and treated differently and may result in different outcomes. For example, carcinogenic risk is characterized in the USA through a calculation of an exposure corresponding to a theoretical tumor incidence. In this context, dose extrapolation is conducted via different methods to very low levels, often below analytical detection limits. In this manner, exposures leading to a tumor incidence of, for example, 1 in 100,000 or 1 in 1,000,000 are calculated. Such methodologies are seldom used in Europe. Still, it is possible to compare the results of risk assessments conducted in different ways and to use performed data analysis to a certain degree, as long as the methodology, including all assumptions and uncertainties, is clearly outlined. It should be noted that there are recommendations to unify risk assessments for carcinogens and non-carcinogens, for example, in the 2009 report of the NRC.

At the international level, efforts are underway to harmonize, though not to standardize, risk assessment methods. In this context, the aim is to promote the understanding of different approaches to risk assessment, so that the results of such assessments conducted by a different institution can be understood by other institutions and eventually adapted to their specific needs. Thus, risk assessments can be utilized universally.

Risk assessment and the subsequent risk evaluation are the basis for regulatory decisions to manage risks. Regulatory measures are obviously different in different areas of regulation: In the case of pharmaceuticals, for example, the risk related to treatment must be put in relation to its therapeutic value. In the case of chemicals, it is important to estimate the potential direct exposure of workers in all areas (production, use, storage, and transport) and consumers, as well as the indirect exposure through various environmental media in order to reach regulatory decisions that would, indeed, eliminate or reduce to a minimum the exposure of the respective groups of the population.

## Abstract

In the past three decades, protein therapeutics have become an indispensable class of drugs approved by regulatory authorities for the treatment of a variety of diseases. Technological advances were key to allowing the generation of fully human therapeutic antibodies.

Protein engineering is a powerful tool to modify biophysical and biochemical properties, allowing control of posttranslational modifications (PTMs) and enhanced efficacy by modulating affinity. The mode-of-action can be tailored, best epitope selected, potential immunogenic regions eliminated, and pharmacokinetic properties optimized. This process helps to deliver molecules with superior efficacy and safety profiles, allowing the best protein therapeutic candidate to enter preclinical and clinical development. Detailed information on the protein

therapeutic characteristics needed within a particular drug development program can be generated, monitored, and regularly updated using high-performance modeling tools.

### Keywords

Protein engineering · Antibody discovery · Antibody engineering · Protein therapeutics · Pharmacokinetics · Immunogenicity · Bispecific · Scaffolds · Antibody drug conjugates · Biologics · Half-life extension

### Definitions

Protein therapeutic	Any protein-based drug.
Large molecules	The name originates from the fact that proteins are, other than chemically well-defined small molecules, comprised of a long amino acid chain folded into a three-dimensional structure and is usually produced in different isoforms.
Biologic	A biologic drug is produced from living organisms.
Monoclonal antibody	A monoclonal antibody derives from a single cell clone. The clone can be expanded and stored as a defined Master Cell Bank to produce the antibody in large quantities as a well-defined product.
Antibody fragments	Antibody fragments consist of part(s) of an antibody resulting in smaller functional molecules compared to a full antibody.
Bispecific	Bispecifics are engineered antibodies with the ability to bind to two distinct targets (different antigens or epitopes).
Alternative protein scaffolds	Protein therapeutics of a non-antibody type. They provide a robust, conserved structural framework and a variable region which can be engineered for specific recognition of a target.

### Introduction

In the past three decades, protein therapeutics have become an indispensable class of drugs approved by regulatory authorities for the treatment of a variety of diseases like cardiovascular, respiratory, hematological, kidney, immunological, oncological, and orphan diseases. The first FDA-approved monoclonal antibody in 1986 was Orthoclone OKT3<sup>®</sup> for the prevention of organ transplant rejection. In the meantime, the number of protein therapeutics approved by the FDA has dramatically increased, especially within the last 10 years, reaching its peak in 2018, where 17 new biologic license applications (BLAs) were approved (Mullard 2020). Antibodies transitioned from being research tools towards effective therapeutics for the treatment of diseases, where millions of people are treated every year worldwide. Patients clearly benefit from protein therapeutics, particularly where no adequate treatment is available, as targets or mode of action is not druggable by small molecules.

Generally, protein therapeutics are very specific and selective for the target exhibiting only few off-target liabilities in contrast to small molecules, where off-target effects are often seen due to lower specificity. Hence, protein therapeutics such as monoclonal antibodies, antibody fragments, bi- or multispecifics, Fc-fusion proteins/fusion proteins, and antibody-drug conjugates (ADCs) (Fig. 1) became a substantial part of drug development pipelines.

Antibody therapeutics, compared to small molecules, are large in size with a molecular weight of an antibody being roughly 150 kDa. Due to the size, effective tissue or tumor penetration, and intracellular targeting, as well as crossing the blood–brain barrier can still be seen as limitations of the antibody-based therapeutics (Smith 2015). Antibody fragments, however, have the potential to penetrate tissues and tumors in a much more efficient way due to their smaller size, but exhibit a much shorter serum half-life compared to a full-size antibody.

The structural complexity of protein therapeutics is not only due to their size (primary amino acid sequence) but also their ability to form secondary, tertiary, and even quaternary structure.

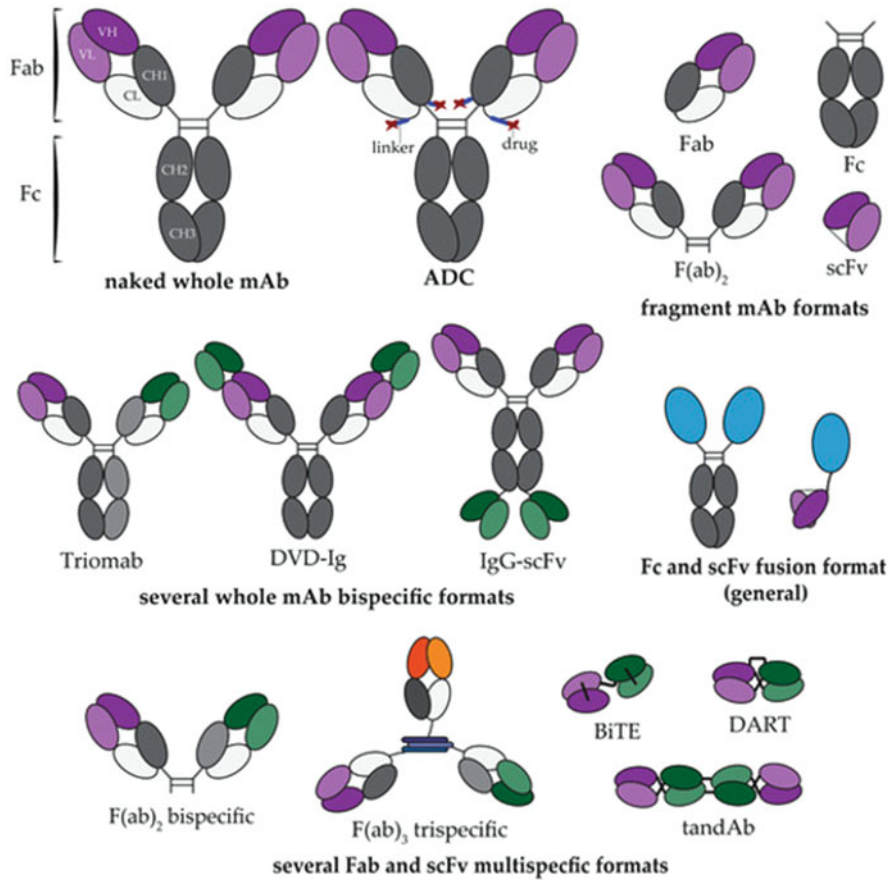

An antibody consists of two heavy (H, 50 kDa) and two light (L, 25 kDa) chains. A heavy and a light chain associates through disulfide bonds and non-covalent interaction to form a heterodimer. Two heterodimers associate to complete the antibody, via the formation of disulfide bonds within the hinge region of the heavy chains.

Both heavy and light chains have constant (C) and variable (V) regions. The variable region, especially the CDRs (complementarity-determining regions), are key in mediating the target-antibody interaction (Fig. 1). Due to the bivalent nature of the antibody structure, an avidity effect can have a remarkable impact on the target binding kinetics.

Using antibody fragments such as single-chain variable fragments (scFvs) or Fabs (Fig. 1) allows the drug developer to play around with avidity and valency effects of the target binding interaction. Furthermore, the smaller size of such antibody fragments might allow binding to otherwise less accessible epitopes.

Even more complexity is introduced by the fact that proteins undergo posttranslational modifications (PTMs), which are heavily dependent on the expression system used. PTMs, such as glycosylation within the Fc part of an antibody, influences its stability and mediates important immune effector functions, underlining the importance of PTMs and its characterization in the final product.

Technological advances and discoveries made as well as experiences gained over the last years in the field of protein engineering have made the transformation from murine to chimeric to humanized to fully human antibody therapeutics possible (Fig. 2). The progress that was made towards fully human therapeutics allowed the immunogenicity risk to be reduced tremendously, as a human anti-mouse antibody (HAMA) response in patients treated with murine antibodies can be avoided. In contrast to small molecules, immunogenicity, namely the ability of a drug to induce an anti-drug antibody (ADA) response and thereby inducing an unwanted immune response in patients, is a unique feature of protein therapeutics and one of the biggest safety concerns.

**Fig. 1** Schematic representation of a whole monoclonal antibody (mAb), fragment mAb, and prominent fusion mAb formats for therapeutic use. A monoclonal antibody consists of two heavy (H) and two light (L) chains which are further divided into a constant (CH and CV) and a variable (VH and VL) regions which are covalently linked via disulfide bonds located in the hinge region (here shown as lines) forming its characteristic Y-structure. Based on papain digest, antibodies can be separated into a crystallizable (Fc) and antigen binding (Fab) fragments. Proteins fused to mAb fragments are depicted as blue ovals for a general representation; however, fusion proteins may vary in size and structure. Fragment formats include the Fc, Fab and F(ab)<sub>2</sub>, and single-chain variable (scFv) fragments. Further whole mAb formats include the antibody–drug conjugate (ADC), triomab, dual variable domain immunoglobulin (DVD-Ig), and immunoglobulin–scFv fusion (IgG-scFv). Multispecific fragment formats include the F(ab)<sub>2</sub> bispecific, bispecific T-cell engager (BiTE), dual affinity retargeting molecule (DART), and tandem diabody (tandAb). (Sifniotis et al. 2019, (CC BY))

To optimize an antibody-based therapeutic, one must understand how an antibody is constructed and the function of each part. Manipulation of the protein sequence and structure is known as protein engineering. Understanding the connection between sequence, structure, and function allows us to design protein therapeutics

by building-in desired properties. A variety of technologies are available to engineer proteins based on the therapeutic need. Nowadays, even machine learning can be applied to protein function optimization which will help to reveal unknown protein functions in the future and to uncover the relationship between protein sequence and its corresponding function (Yang et al. 2019).

Protein engineering is a powerful tool in the development of safe and efficacious next generation protein-based therapeutics, bringing more convenience to the patient.

## Antibody Discovery

Technological advances were key to allowing the generation of fully human antibodies. As shown in Fig. 2, antibody therapeutics evolved from murine to fully human therapeutics over time. Replacing the constant regions of a murine antibody by the human counterpart can generate chimeric antibodies. One example for such a chimeric antibody is Rituxan<sup>®</sup>, an anti-CD20 antibody for the treatment of leukemia and lymphoma. Introducing a further protein engineering step to replace the murine framework regions in the variable domain of an antibody with human sequences results in a so-called humanized antibody. Examples of approved humanized antibodies are Avastin<sup>®</sup> and Zynbrite<sup>®</sup>. As the CDRs (complementarity-determining regions) in humanized antibodies are of nonhuman origin, they still bear a higher risk of unwanted immunogenicity compared to fully human antibodies (see section “[Derisking the Immunogenic Potential of Protein Therapeutics by Protein Engineering](#)”).

**Fig. 2** The evolution of murine, chimeric (~70% human sequence), humanized (~90% human sequence), and fully human monoclonal antibodies through protein engineering to reduce the immunogenicity risk. Red and blue represents mouse and human sequences, respectively. The antigen-binding complementarity-determining regions (CDRs) are shown as sticks. Chimeric antibodies consist of a human constant region and a mouse variable region, whereas in a humanized format, only the hypervariable region is of murine origin and the framework within the variable region as well as the constant part is of human origin. The generic suffix of the international nonproprietary names (INN) for antibodies indicates its origin as shown in the figure. (Adapted from Leung et al. 2020, (CC BY))

The first approved murine and chimeric antibodies were generated either using immunization or hybridoma technology. Both technologies were transferred successfully to human donors allowing the generation of fully human antibodies, but this is limited to a few indications, where human donors have developed a natural antibody response. For that reason, not all identified targets were druggable using this technology and protein therapeutics were limited to specific indications. In the 1990s, various companies have developed transgenic mice or rats, allowing the generation of human antibodies by *in vivo* immunization and hybridoma technology. These transgenic animals were endowed with the human antibody gene repertoire or parts of it.

To overcome the challenge that not all types of antigens are suitable for an immunization approach, *in vitro* selection technologies such as antibody phage display (Fig. 3), have been established (Frenzel et al. 2016). Phage display allows discovery of suitable candidates even when the target is highly conserved between species, toxic, unstable, a transmembrane protein or a protein with allosteric conformational changes. In addition, it broadens up the range of epitopes to include ones that are naturally suppressed by the immune response, thereby overcoming the limitations of immunological tolerance mechanisms. While the advances in technology allowed the use of antibodies for broader targets, oncology and hematology remain the most prevalent medical applications so far (Fig. 4b).

Using phage display technologies, large libraries containing more than  $10^{10}$  different antibodies give access to an expansive antibody repertoire. Generally, different types of libraries are established: (1) immune libraries, constructed from V genes isolated from plasma cells derived from immunized donors (unrearranged V genes) and (2) naïve libraries generated from natural naïve human germ lines (rearranged V gene pools of nonimmunized individuals) (Frenzel et al. 2016). Humira<sup>®</sup>, one of world's best-selling drug, was the first approved phage-display-derived, fully human monoclonal antibody.

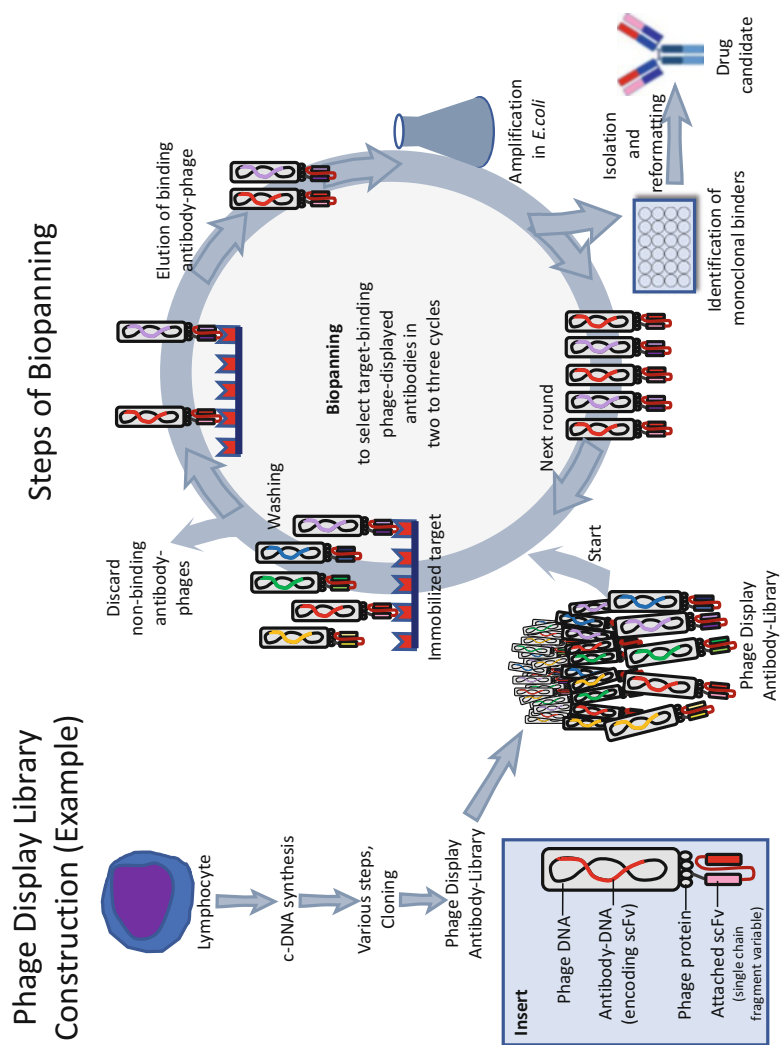

Antibody discovery is nowadays a fast process of 2–4 weeks with high success rate, typically yielding affinities in the low picomolar range. Even femtomolar binders are not uncommon.

---

## Fc Engineering to Modulate the Mode of Action

Antibodies (also named immunoglobulins, Ig) can be divided into different classes and subclasses based on their sequence. The determination of the immunoglobulin G (IgG) subclasses, namely IgG1, IgG2, IgG3, and IgG4, is based on differences in the constant region of the heavy chain (CH), leading to structural variations in both the Fc part and the hinge region (Fig. 1).

The hinge region is a short sequence that links the Fab (fragment antigen binding) to the Fc (fragment crystallizable) region, where the heavy and light chains are covalently bound by forming disulfide bonds (Fig. 1). The effector function of the IgG subclasses is impacted by these structural differences.

**Fig. 3** Schematic representation of phage display technology for drug discovery including library generation, selection, screening, and reformatting. Characteristics of the antibody-like biophysical and biochemical properties, epitope and confirmation specificity, interspecies cross-reactivity, reduction of off-target binding, can be influenced during the selection process. Parameters, the protein engineering can play with to influence the outgoing antibody

The Fc part of the antibody brings in additional options for a protein engineer, due to the natural effector functions which can be modulated in tandem with the target specific interaction. The choice of the antibody subclass together with protein engineering approaches can impact the mode-of-action. Fc-mediated effector functions can thereby be either eliminated or even enhanced.

To date, the majority of the antibodies developed are of an IgG1 type with a kappa light chain and are produced almost exclusively using mammalian cells (Fig. 4c). IgG3 antibodies exhibit a long hinge region that is prone to proteolytic cleavage and is therefore not favorable for therapeutic use, whereas IgG4 antibodies on the other hand lack effector functions, which can be favorable for specific applications.

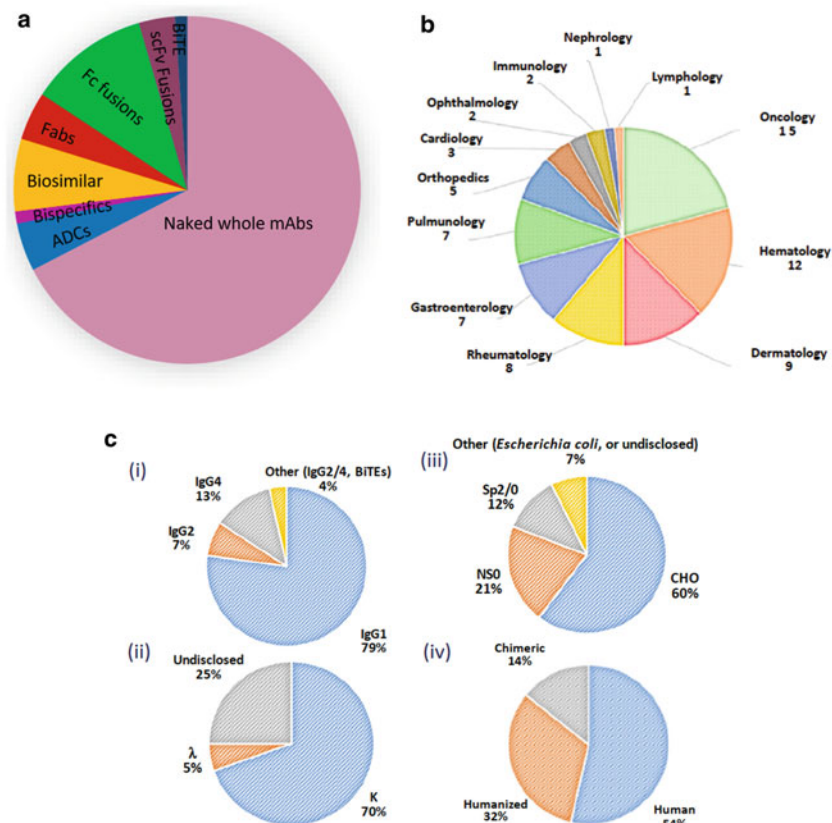

The ability of the Fc-part to bind to the neonatal Fc receptor (FcRn) is a key determinant in maintaining and prolonging long serum half-life of antibodies (Mackness et al. 2019). FcRn binding promotes antibody recycling, rescuing the protein from normal lysosomal degradation. The binding is strongly pH-dependent: high affinity binding is achieved at low pH, whereas under physiological pH conditions, no binding occurs, ensuring antibodies are returned to the cell surface rather than directed to a degradation pathway.

The average half-life of non-engineered IgG antibodies is around 21 days in humans. In contrast, the half-life of antibody fragments, proteins or peptides lacking a functional Fc is hours rather than days, as molecules below 50–60 kDa are subject to rapid renal clearance (Smith 2015). Thus, so-called Fc-fusions, in which an Fc is fused genetically to a protein of interest, have emerged to confer antibody-like properties on proteins and peptides of therapeutic interest (Levin et al. 2015).

Beside the influence on half-life by the Fc, important immune system effector functions can also be mediated by engagement of Fc gamma receptors (FcγR) and C1q binding (Saunders 2019; Corraliza-Gorjón 2017), namely antibody-dependent cell-mediated cytotoxicity (ADCC), complement-mediated cytotoxicity (CDC), and antibody-dependent cellular phagocytosis (ADCP) (for more details, see Fig. 5).

**Fig. 3** (continued) characteristics, are: the library used in first place, the nature and immobilization strategy of the target antigen, as well as binding and washing conditions. Phage display technology is based on the presentation of proteins encoded in a library on the phage surface by fusion to a coating protein of the phage. Phage display libraries can be generated by cloning the relevant information into a phage background. Such libraries can contain more than  $10^{10}$  different clones resulting in phages, expressing different proteins of interest on their cell surface. The information of the specific protein expressed on the surface is genetically encoded within the phage. The *in vitro* selection of binding proteins from libraries is called panning or biopanning. A panning cycle contains the following steps: the antibody phage display library is incubated with an immobilized or soluble target. In a next step, nonbinding and nonspecific binding phage is removed by extensive and stringent washing. Subsequently, the bound antibody phage will be eluted and amplified by infection of *E. coli*. Such sublibrary will be used as new starting material for the next round until a significant enrichment of antigen-specific phage is achieved. Each sublibrary can be analyzed for the selected clones by screened for individual binders by ELISA. Promising candidates can be characterized by converting into appropriate formats for further testing

**Fig. 4** (a) Approved therapeutic antibody formats as of 2018: pie chart of the proportions of therapeutic antibody formats approved for therapeutic use as of December 2018, IMGT<sup>®</sup>: 60 naked whole mAbs, 4 ADCs, 1 whole mAb bispecific, 4 Fabs, 10 Fc fusions, 3 scFv fusions, 1 scFv bispecific (BiTE), and 6 biosimilars. Adapted from Sifniotis et al. 2019 (CC BY). (b) While mAbs are increasingly used for broader targets, oncology and hematology remain the most prevalent medical applications. (Grilo and Mantalaris 2019 with kind permission from Elsevier). (c) Inspection of the molecular structure of mAbs and production organisms of choice reveals the human nature of mAbs, which are mostly engineered on the IgG1 subclass with a kappa light chain and are produced almost exclusively using mammalian cells. (Grilo and Mantalaris 2019 with kind permission from Elsevier)

Glycosylation, in particular the N-linked glycan structure of the heavy chain at Asn297, plays an important role in effector function as this specific posttranslational modification influences the binding to FcγR (Zheng et al. 2011). Consequently, glycoengineering became an attractive way to specifically modulate Fc-effector function of antibody therapeutics.

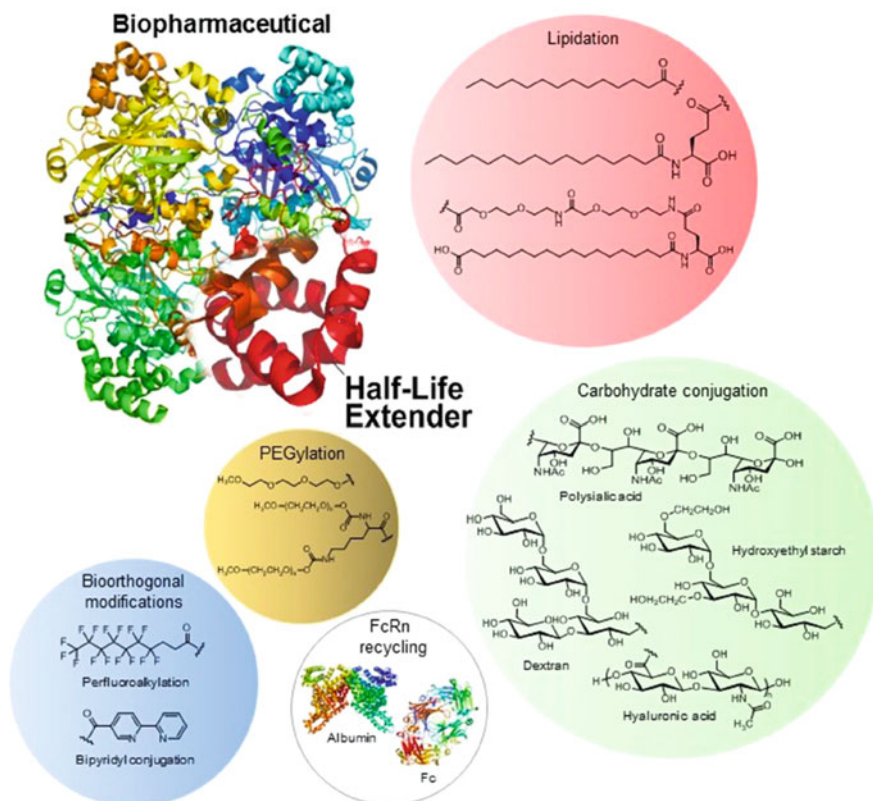

**Fig. 5** Schematic representation of the mechanisms of action used by naked antibodies to inhibit tumor growth. Naked antibodies can inhibit tumor growth through effector functions such as ADCC (antibody-dependent cell-cytotoxicity) where the antibody bound to the tumor antigen is recognized by the natural killer (NK) cell and triggers cytotoxic activity; can also trigger antibody-dependent cell-phagocytosis (ADCP) when the antibody bound to the tumor antigen opsonizes the cell and activates phagocytic cells; the antibody can also fix complement after binding to the tumor cell and trigger complement-dependent cytotoxicity (CDC). Conversely, naked antibodies can kill the tumor cells by interfering with important signal pathways, either by binding to the ligand (Ligand Blocking) or by binding to the receptor (receptor blocking). In addition, they can trigger direct apoptosis after binding to an antigen on the tumor cell surface. (Corraliza-Gorjón et al. 2017 (CC BY))

## Engineering Half-Life of Protein Therapeutics

The desire to increase circulating half-life of protein therapeutics is based on the advantages associated with it. Direct results of a prolonged serum half-life include increased efficacy, reduced dose, and less frequent dosing regimen, which positively impact patient convenience.

As the average half-life of antibody therapeutics compared to other drugs is rather long and in a range of 2–3 weeks, half-life extension technologies focus on antibody fragments or scaffolds exhibiting a high systemic clearance usually induced by glomerular filtration in the kidney. To improve the PK of such protein therapeutics, PEGylation, glycoengineering, and engineering of Fc effector functions are instruments in the toolbox of the drug developer to extend the serum half-life (Fig. 6). The most common and so far most commercially successful approach to prolong the half-life of protein therapeutics has been PEGylation. PEGylation describes the covalent attachment of polyethylene glycol (PEG) chains to a protein therapeutic. However, there is growing concern about the safety of PEGylation, as this modification may lead to hypersensitivity reactions, ADA formation, and PEG bioaccumulation (Witteloostuijn et al. 2016). Alternatively, albumin conjugation and Fc-fusions are well-established methods to reach an antibody-like half-life (Fig. 6). Such therapeutics

**Fig. 6** Half-life extension possibilities for protein therapeutics. Native peptides and proteins suffer from an inadequate pharmacokinetic profile, and their outstanding pharmacological potential can only be realized if this issue is addressed during drug development. To overcome this challenge, a variety of half-life extension techniques relying on covalent chemical modification have been developed. These methods include PEGylation, fusion to unstructured polypeptide-based PEG mimetics, conjugation of large polysaccharides, native-like glycosylation, lipidation, fusion to albumin or the Fc domain of IgG, and derivatization with bio-orthogonal moieties that direct self-assembly. (Witteloostuijn et al. 2016 with kind permission from John Wiley and Sons)

are easy to generate by genetically linking the protein therapeutic via a short amino acid linker to albumin or an Fc-part. In addition to the anticipated positive effect on the PK, Fc-fusions can simplify the purification process of the protein drug.

## De-risking the Immunogenic Potential of Protein Therapeutics by Protein Engineering

Immunogenicity, the development of antibodies against therapeutic proteins (ADA = anti-drug antibodies), is one of the challenging liabilities of protein therapeutics. The risk associated with a treatment-induced immune response needs

to be carefully considered during drug development. Immunogenicity risk assessment has become an integral part that goes beyond the molecular design phase to development and post-marketing evaluation that is required by regulatory authorities.

The immunogenicity rate observed in the early days of protein therapeutics has been dramatically reduced by evolving from murine to chimeric or humanized to fully human protein therapeutics (Fig. 2). However, even fully human therapeutics may be able to induce an immune response. Until now, a lot of effort has been made to generate and develop comprehensive and accurate *in silico*, *in vitro*, *ex vitro*, and *in vivo* immunogenicity prediction tools.

Immunogenicity de-risking strategies are routinely used and guide the de-immunization of drug candidates by knowledge-based protein engineering, and where possible B-cell or T-cell epitopes are eliminated. Not only the primary sequence, also patient-, product- (e.g., manufacturing procedure), and treatment-related (e.g., route of administration) factors are known to influence the immunogenic potential of a protein therapeutic (see Fig. 7) and are optimized to mitigate the overall risk within the drug development program.

An unwanted immunogenicity response by the induction of ADAs can alter the pharmacokinetic and pharmacodynamic properties of a drug raising a concern for both safety and efficacy. ADAs usually result in an accelerated drug clearance and may induce hypersensitivity responses leading to severe safety issues. In addition, the appearance of neutralizing antibodies can lead to a dramatic impairment of treatment efficacy, beside loss in exposure.

---

## A Two-in-One Approach: Bispecific Protein Therapeutics

Using protein engineering technologies, antibodies or antibody fragments can be designed in a way that a second specificity or even multiple specificities can be combined in one therapeutic molecule. Making use of these possibilities has expanded the therapeutic treatment opportunities for diseases where more than one target or pathway is critical (Smith 2015). One example for antibody-based bispecific molecules is the Duobody platform, which is inspired by the naturally occurring Fab arm exchange observed for IgG4s. In short, the generation of bispecific molecules includes three steps. In a first step, two IgG1s, each containing single matched mutations in the third constant ( $C_{H3}$ ) domain, are produced separately using standard mammalian recombinant cell lines. After production and purification of the two IgG1 antibodies, they are recombined using favorable conditions resulting in a bispecific antibody product with a very high yield (Labrijn et al. 2013).

Another example is the knob-into-hole technology, where heterodimerization of the heavy chains is promoted by introducing mutations: a “knob” and a “hole” are engineered into the two heavy chains of different antibodies to favor the heterodimerization process (Xu et al. 2015).

Bispecific formats allow for introducing new mode of actions. The Bispecific T-cell Engagers (BiTEs<sup>®</sup>) platform is a good example, where the single-chain variable

**Fig. 7** The possible causes of anti-drug antibodies are either patient related (**a**) or drug related (**b**). Drug-related risk factors such as origin, posttranslational modifications, as well as dose and frequency can be positively influenced by protein engineering technologies. (Vaisman-Mentesh et al. 2020; © 2020 Vaisman-Mentesh, Gutierrez-Gonzalez, DeKosky and Wine, (CC BY))

(scFv) fragments of two antibodies are fused to each other using short linkers (Fig. 1). In the case of the 2014 approved BiTE<sup>®</sup> Blincyto<sup>®</sup>, an anti-CD3 scFv is combined with an CD19-binding scFv. This results in therapeutic molecule that links the patients T cells via CD3 binding to the tumor-associated antigen (TAA) CD19, resulting in effective tumor cell killing.

Bispecifics bear the potential to overcome the blood–brain barrier hurdle or membranes by targeting with one specificity a cargo or transporter molecule. This will open the space for protein therapeutics towards intracellular targets or targets in the brain.

---

## Scaffolds: The Alternative Protein Therapeutics

Alternative scaffolds complement the antibody derivatives as possible protein therapeutics. Notably, typical properties for which the scaffolds were earlier advertised, such as small size, high-level recombinant expression, and advantageous biophysical properties, have become less relevant, as antibody engineering has advanced into the field of single-domain antibodies (Gebauer and Skerra 2019).

Computation protein design (CPD) has the unique ability to design functional scaffolds de novo and to create artificial proteins bearing the desired function. The majority of scaffolds worked on are inspired by naturally occurring domains that are involved in protein–protein interactions (Ernst and Plückthun 2017).

---

## Antibody-Drug Conjugates (ADC): Combining the Best of Two Worlds

ADCs are generated to combine the best properties of both worlds, the small and large molecules, for the treatment of cancer. The beauty of this technology is the use of specific delivery by the antibody combined with a cytotoxic drug, reducing toxicity and improving efficacy compared to a systemic delivery of conventional chemotherapies. The first generation of ADCs in the 1990s failed due to various reasons including: immunogenicity (antibodies used were of murine or chimeric nature) and linker instability. In addition, no efficacious quantity of drug could be delivered into the tumor cells, for reasons including low potency of the payload, low antibody–drug–ratio and antigen density on the tumor cell. Within the second generation of ADCs, fully human antibody conjugates with stabilized linkers have successfully delivered potent chemotherapeutic and radioactive agents to specifically kill tumor cells and thereby overcome the liability of chemotherapy and radiation to distinguish between healthy and tumor cells (Leung 2020). To date, four ADCs are approved for the treatment of cancer including Kadcylo<sup>®</sup> and Adcetris<sup>®</sup>.

While engineering a suitable ADC, carefully consideration should be given to find a selective target, an antibody exhibiting suitable binding properties towards the

target, type, and stability of the linker, potency of the payload, the conjugation method, and the drug-to-antibody ratio (Smith 2015).

To avoid systemic toxic release due to linker instability, the ideal situation would look as follows (Leung 2020): the payload is inactive while stably linked to the antibody in circulation, but upon target-dependent internalization, the cytotoxic drug is rapidly released after lysosomal degradation of either the linker or the antibody.

Antibodies can be labelled using unspecific technologies like labelling of lysine and cysteine residues or site-specific, which allows for a better-controlled process in terms of homogeneity of the resulting drug product. Engineering approaches to site-specific conjugation include substitution or addition of accessible cysteines or incorporation of non-native amino acids (Smith 2015). In addition, enzymatic methods have been established, where site-specific sequences have been engineered into the antibody to facilitate site-specific conjugation (Leung 2020).

To aim for less systemic toxicity, other approaches than ADCs are currently tested including antibody-directed enzyme therapy (ADEPT), antibody-cytokine fusion proteins or immunocytokines, immunotoxins, and radioimmunoconjugates (Smith 2015).

## Abstract

Toxicological tests are only meaningful and interpretable, when the chemical composition and the physicochemical properties of the applied substances are known. These properties determine to a large extent the behavior of a substance in the environment and in the living organism. Thus, knowledge of physicochemical properties is important for the development of therapeutic drugs as well as for the risk assessment of all chemicals.

## Introduction

In most fields of toxicology, including industrial chemicals, environmental pollutants, or pharmaceutical products, the chemical's physicochemical features are of great relevance, since they determine solubility, volatility, absorption, and toxicokinetics. In environmental toxicology, knowledge of physicochemical features allows to anticipate, whether a substance will be transported in the environmental media air, water, and soil. The Organisation for Economic Co-operation and Development (OECD) publishes international guidelines for testing of chemicals (OECD 1 2020) and environmental pollutants (OECD 2 2020). Guidelines for pharmaceuticals are published by the International Committee of Harmonization (ICH 2020) for small chemical drugs as well as biopharmaceuticals. We focus here on some aspects that are relevant for pharmaceutical drug development.

A drug-like chemical molecule is not only characterized by its binding to a target like a receptor or enzyme. A chemical molecule has to be signed for more, for the optimal biological activity, for a broad therapeutic window, to be optimally formulated, and last but not least for optimal absorption, distribution, metabolism, and excretion (ADME) behavior. All these parameters are finally driven by the physicochemical features of a chemical molecule. Therefore, assessing the physicochemical parameters of a pharmaceutical (test article) early on in hit and lead molecule screening is essential for the success.

---

## Physicochemical Properties and Bioavailability

Physicochemical properties, like solubility and coefficient of distribution (octanol/water at pH 7.4), combined with particle size or crystal structure, usually influence and correlate with absorption, distribution, metabolism, and excretion (ADME) of drugs (Krämer and Wunderli-Allenspach 2001). In-depth knowledge of these basic physicochemical characteristics of a drug substance are important for the characterization of chemicals as well as for the development of innovative and ideal drug formulations and to optimize bioavailability of drugs. Figure 1 shows some simple methods to study physicochemical properties.

With regard to physicochemical properties, solubility and coefficient of distribution of a drug substance are mainly of interest for the toxicologist. The paramount of a toxicological investigation is to show adverse effects in order to be able to estimate the risk associated with human (or environmental) exposure to the substance. Therefore, the maximal dose, given in a toxicity test, and the resulting systemic exposure (measured in plasma or serum) should be as high as possible.

The systemic exposure is a delicate mixture of a series of events: the extent of absorption, extent of distribution, extent of metabolism, and extent of excretion. While of course drug molecules can be substrates of cellular transport systems (not discussed here), absorption, distribution, and accessibility for metabolism are influenced by the physicochemical properties like solubility and coefficient of distribution of the drug molecules. For the absorption of an orally administered

## Simple methods for assessing physicochemical properties of chemicals

**Fig. 1** Simple methods for assessing the physicochemical properties of chemicals

encapsulated powder or an administered suspension, the drug substance has to be solubilized in advance in the gastrointestinal tract. This sometimes rate-limiting step could be circumvented by the intravenous route, but for the practicability of a daily administration and for the convenience of the patients, an oral formulation for a therapeutic agent is highly preferable. Therefore – if possible – the oral administration of a solution to the animal species (e.g., rat) is not only the most simple approach; an oral solution usually guarantees high plasma concentrations ( $C_{max}$ ) and high systemic exposure ( $AUC$ ).

Usually solubility is tested in a series of organic solvents. For the toxicologist, solubility in dimethylsulfoxide (DMSO) is important because this solvent is used to solubilize molecules to be tested in the Ames test. Of course, in addition, substantial knowledge should be available on the solubility of the test compound in buffer systems used for i.v. or oral administration to animals (e.g., rodents, dogs, monkeys). In pharmaceutical industry, the close interaction of the toxicologist with the chemist and pharmacist sets the basis of a straightforward risk assessment process.

To ensure the reliability of a toxicological study, the quantitative determination of the test article in the test solution is a must. Usually specific HPLC-based techniques like HPLC-UV or HPLC-MS are used for small molecule drugs.

For biotherapeutics like monoclonal antibodies (mAbs) or protein replacement therapies, partly other measurements and methods are of importance compared to small molecules (Swami and Shahiwala 2013). Proteins usually are not given via the oral route. The main administration routes for proteins in toxicology are either the intravenous or the subcutaneous route. Solubility and stability of the protein is of

great importance especially to prepare highly concentrated subcutaneous formulations (>100 mg/ml) for mAb toxicity testing. Aggregation of the protein has to be prevented; therefore, a series of buffer systems should have been tested before starting the toxicity testing of proteins. Quantitative determinations of the specific protein concentration in the solution, and of levels in plasma/serum, are still done by immunoassay techniques.

At present, many pharmaceutical companies face challenges in their drug development programs because of increased costs and reduced efficiency. Artificial intelligence (AI), machine learning (ML), and deep learning (DL) combined with new experimental technologies are expected to make the hunt for new pharmaceuticals cheaper and more efficient. One example is the use of AI/ML in drug screening. With the help of AI, a virtual compound library of several billion of molecules can be screened within a few days compared to several months when doing the traditional screening process (Voosen 2017; Baig et al. 2016).

AI tools are used in multiple aspects within the drug discovery process for predicting physical properties (Andrysek 2003; Lynch and Bothwell 2007), bioactivity, and toxicity (LeCun et al. 2015; Dixon et al. 2016; Wu et al. 2018) of a potential drug, to structure predictions. AI-based structure predictions only take a few hours to a few days compared to months or even years for the traditional experimental structural biology methods.

---

## Identification, Content, and Stability of the Test Article

The test article tested *in vitro* or *in vivo* toxicology studies should be comparable to the test article used for clinical studies in humans. Therefore, information on the identity, the content, and the storage as well the benchtop stability of the test article are important information for the toxicologist and should be available before testing.

Testing the identity primarily tells the toxicologist if the test article has still the quality required for testing. As mentioned above, it is important to measure the concentration in the test solution to calculate the exact dose administered and to exclude that there is precipitation or adsorption of the test article to glass or plastic vessels used for the preparation of the test solution which could invalidate the toxicological study.

---

## Methods

Methods to assess the identity of the test article should be able to discriminate the test article from structural similar molecules, i.e., the analytical methods should be specific (e.g., IR spectroscopy and mass spectroscopy). To identify a test article only by a single HPLC method is not acceptable. A second chromatographic method using a different separation or detection technique is necessary to ensure the identity of a molecule.

If the test article is an enantiomer, the method used to describe the identity of the test article should be able to discriminate between the enantiomers.

Compared to small molecules, the biotherapeutics (mAbs and other proteins) are complex molecules and only in rare cases exist as a single unique molecule. Proteins produced by expression in mammalian cells or bacteria usually exist in different isoforms, and their glycosylation pattern usually varies. These isoforms may have different pharmacokinetics, binding affinity, and bioactivity (European Medicines Agency 2007). Independent of the complexity of applied protein therapeutics, the test article tested in toxicology studies has to meet the specifications (melting temperature, SDS-page, molecular weight, glycosylation pattern, binding, bioactivity) of the material produced for human use.

Immunogenicity is a very special event following the administration of proteins to animals or humans. The resulting antidrug antibodies (ADAs) may influence not only bioactivity but also clearance of the protein. Therefore, it is necessary to assess immunogenicity using respective assays that not only measure ADAs as such but can also discriminate between neutralizing and non-neutralizing ADAs, which is important for the further toxicological testing strategy (Jefferis 2011).

---

## Inhalative Toxicology

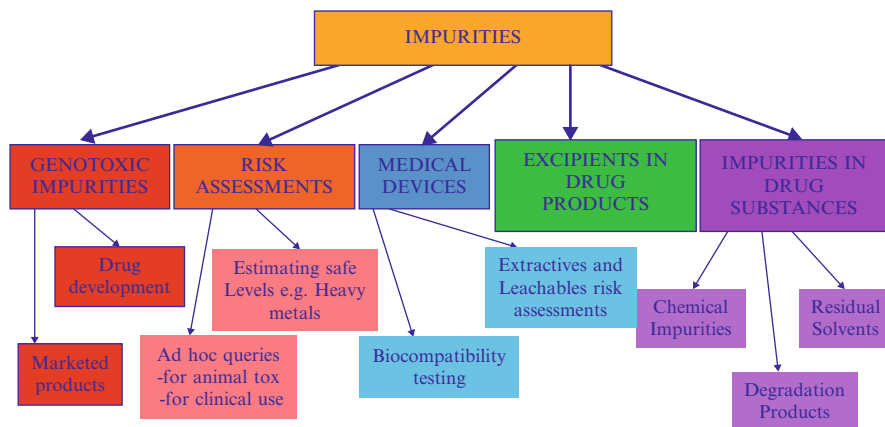

Inhalative toxicological studies ask for high analytical demands. The test article will be delivered as gas, aerosol, or powder that is aspirated by the test animals. Therefore, in addition to the usual analytical control of the test article, the particle size of the aerosol or powder as well as their homogeneous distribution within the experimental system has to be assessed.

---

## Impurities and Content

The test article already used in early safety studies (safety pharmacology and short-term toxicology) should be comparable to the test article later tested in clinical studies and finally reaching market approval. Therefore, it is important that the content of the test article and the impurity profile – the specifications – of the early available drug substance meet the specifications of the drug product marketed later. At the beginning of drug development process, test article specifications should not be too tight; on the other hand, a high level of impurities may negatively influence results of toxicology studies, e.g., the Ames test. Specifications of the test article batches tested in safety relevant studies have to be listed in the regulatory documents and have to be compared with the specification of the batches used in clinical trials (Fig. 2).

The impurity profile is an important characteristic data set for the drug substance as well as the drug product and is related to the synthesis/production process of the test article. A major change in the impurity profile of a marketed product, e.g.,

**Fig. 2** Impurities and their importance in drug development

**Fig. 3** Safety assessment – it's all about risk assessment

because of a process change, requires a new safety assessment that may include preclinical and clinical studies (Fig. 3).

For biotherapeutics aggregates, viral contaminations and host cell proteins are a major source for impurities. Therefore, a harvest and downstream process (purification process) has to be established using methods to separate the impurities from the products and with special procedures for virus inactivation.

Today, for small molecules, HPLC-MS/MS is the method of choice to quantify the test article and the impurities. For protein drugs, immunoassays (ELISA) are usually used to quantify the test article, and chromatographic, electrophoretic, or PCR methods are used to quantify impurities. But protein drugs have to be characterized further. In addition to the content, the bioactivity of the test article measured in a validated cell-based assay is usually required to characterize the test article and

to ensure the comparability of test article used in preclinical and clinical drug development with the marketed product.

---

## Guidelines

For drug development, the International Conference on Harmonization (ICH) has published a series of guidelines for all aspects and phases (e.g., quality, efficacy, safety) of drug development (<http://www.ich.org/products/guidelines.html>).

Information on requirements to assess the quality (e.g., stability, impurities, specifications, analytical validation) can be found in the quality guidelines Q1–Q11. All regulatory requirements with regard to drug safety are summarized in the safety guidelines S1–S10. A special notice has to be given to the guideline S6. This guideline is only valid for the safety assessment of biotherapeutics.

It is well known that toxicological as well as safety pharmacological studies have to be performed according to the regulations of GLP. Therefore, the analytical methods used to characterize the test article have to be validated, and the analysis has to be performed accordingly. If analytical investigations are not performed accordingly, this has to be described and explained. In the USA, GLP regulations are described in the “21 CFR 58 – Good Laboratory Practice Regulations.”

## Abstract

Determination of the toxicological profile is necessary for hazard identification and hazard characterization for human health. Acute studies mainly serve the purpose of hazard identification for the classification and labelling of substances

or mixtures. Repeated-dose toxicity studies using subacute, subchronic, or chronic exposure durations are used for hazard characterization. Such studies deliver the point of departure for setting health-based reference values, e.g., acute reference dose (ARfD), acceptable operator exposure level (AOEL), or acceptable daily intake (ADI).

## Introduction

### Aim and Study Protocol

Toxicity studies have to be performed with chemicals and mixtures subject to chemical legislation or regulation (e.g., pharmaceuticals, pesticides, industrial chemicals, biocides). Before starting a study, a study protocol has to be issued according to accepted testing guidelines e.g., OECD (see references), European Union, US EPA, which exactly lays out the aim and methods of the investigation in detail. The methods have to be fixed by standard operating procedures (SOPs) to reduce as much as possible the systematic error rate and to ensure the transparency of the procedures and the resulting data (Good Laboratory Practice, GLP). The basic study types are shown schematically in Fig. 1. Acute studies involve administration of a single oral dose, 4 h inhalation exposure, or 24 h of dermal exposure.

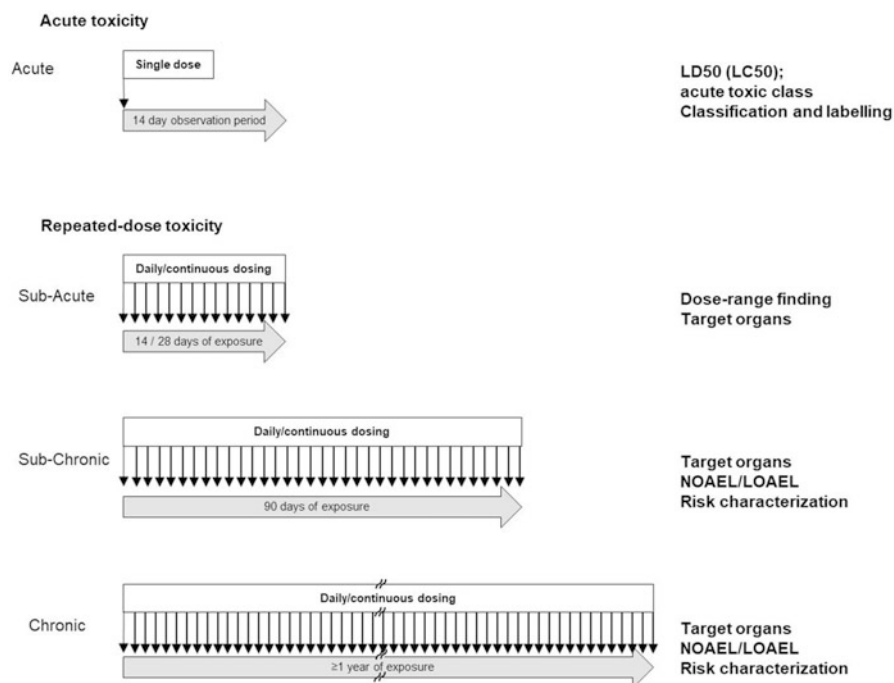

Repeated-dose studies are conducted either by continuous exposure via feed or drinking water (oral), daily gavage administration (oral), or daily exposure via inhalation or dermal contact for 6 h/day.

### Investigated Parameters

Acute toxicity studies aim at the identification of lethal doses or concentrations for the purpose of classification and labelling. Therefore, only a limited set of parameters is typically investigated: survival, clinical signs of toxicity, weekly body weight, and gross necropsy.

In repeated-dose toxicity studies, body weight development, feed consumption, detailed clinical observations (including functional observational battery), hematology, clinical chemistry, urinalysis, gross pathology (including organ weights), and microscopic pathology.

Where applicable, relevant statistical methods have to be employed to inform on the statistical significance of any treatment-related changes that are observed.

**Fig. 1** Type and aim of the studies (schematic)

## Reporting Requirements

The following experimental conditions have to be recorded: selection of an accepted species including the strain, starting weight/age, food/water quality and source, quality of substance (purity grade, homogeneity, stability in the application medium), temperature, air humidity/exchange/pressure and duration of lighting in the stall, size of cages/inhalation chambers, litter, hygiene management, use of validated methods and appropriate material, as well as follow-up of historical control data. The results have to be listed in the report as individual values and deposited as raw data – signed and dated – in an archive certified by GLP. Study protocol, test procedure, as well as the transfer of the results to the final report have to be proofed and certified by a designated and independent quality assurance unit. According to animal welfare regulations, animal studies which are not requested by authorities are subject to approval; *in-vitro* studies are notifiable only.

## Acute Toxicity

The aim of acute toxicity evaluation is to estimate a dose or concentration that would lead to an expected 50% mortality of the exposed animals.

The main application routes are oral, dermal, as well as inhalation which are relevant routes of human exposure. There are further application routes like intra-peritoneal or intravenous application that can be relevant for medical research. The further process is comparable. The single oral application is carried out as a bolus application (gavage/capsule) using 3–5 animals/dose/sex. Rats are the preferred species for the oral route of exposure.

Dermal application is performed moistened or as a paste related to the physical condition (liquid/solid). The skin is treated under semi-occlusive coverage over 24 h. Rats or rabbits are the preferred species for the dermal route of exposure.

Testing via inhalation may employ exposure to dusts, liquid aerosols, or gases/vapors, depending on the physical properties of the test substance. Rats are typically used for acute inhalation studies. To determine the hazard/risk potential, the “nose-only” system is preferred where the animals are exposed exclusively via the respiratory tract (nose/mouth) over 4 h. This ensures that potential effects can be reliably ascribed to the intended application route and not, e.g., to oral ingestion of test material deposited on the coat from grooming behavior. After the single application, a 14-day post-application observation period follows which has to be enlarged if symptoms still continue. During this period progressing symptoms are protocolled related to intensity and start/end time in minutes/hours/days. Time of death of dead/moribund killed animals is protocolled in addition. Thus, conclusions can be made about symptoms and death related to the latency. Short latency periods hint to a substance, longer-lasting periods to an accumulated impact. At the end of the observation period, surviving animals are anesthetized, dissected, and assessed macroscopically (anatomic-pathological; dead animals directly). As further parameter, body weight has to be determined before treatment, weekly post-application, and before section. Based on the results (type, intensity, duration of symptoms, body weight gain), the acute toxic profile of a substance can be gained. Based on the number of dead animals/groups, the LD<sub>50</sub> (median lethal dose, i.e., dose where 50% of the animals die) can be calculated according to Litchfield and Wilcoxon (Table 1), for example.

## Acute Toxic Class Method

The Acute Toxic Class (ATC) Method (OECD guideline 423, see Reference) has largely replaced the conventional LD<sub>50</sub> testing shown in Table 1. This method employs the use of fewer animals than the conventional method. Depending on the number of humanely killed or dead animals, the test procedure follows the indicated arrows. The scheme in Fig. 2 shows the procedure when the highest dose is chosen as starting point. This is appropriate if low toxicity of the substance is expected, e.g., from structurally related substances with known toxicity. Selection of the correct starting dose is essential for using the minimum possible number of animals.

Instead of distinct LD<sub>50</sub>/LC<sub>50</sub> values, ATCs are obtained which are directly related to existing national/international classification systems (WHO, EU). The ATC method allows the derivation of LD<sub>50</sub>/LC<sub>50</sub> cut-off values that can be used as surrogates for defined LD<sub>50</sub>/LC<sub>50</sub> values.

<sup>a</sup>No. of dead animals/No. of animals with symptoms/No. of animals in dose group

## Long-Term Studies

The aim of the chronic toxicity studies is the compilation of the profile of a substance after repeated intake of low doses over a longer time period. Three categories can be differentiated: subacute (28 day), subchronic (90 day), as well as chronic (52 weeks and more) in two different mammalian species (e.g., rat/dog). The examination of two clearly different mammalian species reduces false-negative findings caused by potential species specificity, but increases the percentage of false-positive findings. Anyhow, not all relevant effects/ findings can be detected adequately in one species considering sensitivity for man (e.g., teratogenicity of thalidomide). All repeated application studies comprise in general four dose groups (control-, low-, medium-, as well as highest-dose group) whose number can be increased if necessary. The dose range should be spread widely and derived in an algorithmic manner. Ideally, the low dose should show no effects; the medium dose exerts no or slight effects and the highest dose should produce toxicity, but no death or severe suffering. Impaired body weight gain, reduced by at least 10% compared to controls, is typically considered an indication of sufficient toxicity at the top dose.

**Fig. 2** Acute Toxic Class Method: Rectangles show dose and number of animals used (one sex, preferentially females), figures in ellipses show the number of dead or moribund animals for every step GHS: Globally Harmonized System (mg/kg bw)

## **Subacute Studies (28 Day)**

The subacute study is intended to identify potential target organs and to support dose-range finding for longer-term studies.

### **Performance Ratio**

Besides the investigation of minimum parameters required by the relevant testing guideline, a high-performance ratio should be pursued to reduce the overall number of animal testing for a given substance. Standard investigations need only small amounts of biological material, so that further investigations can be conducted, e.g., into immunotoxicity (thymus, spleen, lymph nodes, Peyer-plaques) or phase-I and -II enzymes in the liver, or a liver foci test as a short-term carcinogenicity test. Such additional investigations can provide valuable information on the toxicological profile and indicate where special attention is needed in the longer-lasting studies (subchronic/chronic) to avoid additional dose groups or even repetition of entire studies.

### **Dose-Range Finding**

A further important function of the subacute study is the dose-range finding for subsequent studies (subchronic/chronic). Based on the large spread of the dose range, one can identify tentative NOELs (no observed effect levels) as well as clear, non-toxic/low toxic doses to determine the profile. In case of doubt, the dose range has to be enlarged.

### **Reversibility**

The reversibility of findings can be studied by adding satellite (recovery) groups. The animals of the satellite group are not treated with the test substance after the application period, whereas all other activities continue over a variable time period in general over 4 weeks. (Non-)recovery of organ functions can be detected as hint to (non-)intact repair mechanisms or adaptation capacities of the organs. Related to the target, the proof of reversibility can be useful also in subacute dermal as well as inhalation studies.

---

## **Subchronic and Chronic Studies**

Based on the results of the subacute studies, the performance of subchronic/chronic studies is more or less comparable to that of the subacute studies. The basic difference is the treatment period and the number of animals per dose group (subchronic

**Table 2** Combined chronic toxicity/carcinogenicity study in rats: schedule of investigations

Check for morbidity or mortality	Twice daily, once daily, on weekend/holiday
Detailed investigations of clinical findings	Once weekly
Functional observation battery	Week 53
Determination of:	
Body weight	Weekly until week 13, then every 2 weeks
Food intake	Weekly until week 13, then every 4 weeks
Water intake	Every 4 weeks
Feeding period	7 days/week
Absolute feeding period <sup>a</sup>	>730 days
Ophthalmological investigations	Start, week 1, 2, 53, 104 (end)
Clinical-chemical investigations:	
Hematology	Week 27, 54, 79, 105
Clinical chemistry	Week 27, 54, 79, 105
Investigations in urine	Week 27, 54, 79, 105
Investigation of calcium/phosphorus	In bones (optional): 1 and 2 years after start of treatment
Organ weights	1 and 2 year(s) after start of treatment
Interim/end section	1 and 2 year(s) after start of treatment
Anatomic/histopathological investigations	1 and 2 year(s) after start of treatment (including number of tumors and incidences)

<sup>a</sup>Number of days which are used to calculate the food intake

13 weeks, 10–20 animals/dose/sex); chronic from 26 weeks to 52 weeks or 105 weeks as carcinogenicity studies on rats and mice (50–70 animals/dose/sex). For non-rodents (e.g., dog) at least four animals per dose group per sex are used.

The longer treatment period allows detecting effects which need a certain latency period to develop, for example, tumors or secondary effects based on primary impact (idiosyncrasy, late reaction, proliferation of tissue due to permanent irritation). Those effects complete the toxicological profile after repeated application. A typical course (data collection) of a combined chronic toxicity/carcinogenicity study in rats is shown in Table 2.

## Definition of NOAELs

Besides the determination of the toxicological profile, chronic studies are used to define a NOAEL (no observed adverse effect level). Considering the definition of NOAELs, there is a prominent influence of the dose range finding on the effect range (profile) as well as the nontoxic range. The term “adverse” is interpreted differently under various regulatory regimes and this interpretation may also change over time. Are transient increases of hepatic phase-I and -II enzyme activities “adverse,” or do they reflect an adaptive physiological reaction of the organ? Which percentage of cholinesterase activity inhibition due to an organophosphate is considered a

toxicological relevant effect and in consequence to be seen as “adverse”? Effects can show a statistical significance without having any biological/toxicological relevance and should therefore not be considered “adverse.” In general the NOAELs of subacute, subchronic, and chronic studies serve as point of departure for limit values like ADI (acceptable daily intake), AOEL (acceptable operator exposure level), and others, which are crucial for human health risk assessment. Severe toxic effects pertaining to teratogenicity, genotoxicity, or carcinogenicity can lead to an increase of the safety factor (SF), which accordingly lowers the respective limit value. The treatment period has to be seen in analogy to the expected duration of human exposure, e.g., whether it is incidental (acute) seasonal (subacute/subchronic) or lifelong (chronic).

## Abstract

As a result of their anatomy and physiology, the organs and tissues of animals and man may show different morphological responses and sensitivity to xenobiotics. Toxic responses can manifest systemically (e.g., the immune system) or may produce specific toxic effects in a single organ system (skin) or single organ (liver). Organ toxicity may therefore result from a direct and primary effect on a target organ or as a result of secondary effects in organs and tissues that have a physiological dependence on the primary target (Haschek 2009). The

---

**Introduction**

While there have been advances made in the field of in vitro toxicology testing, the safety assessment of novel drugs and agrochemicals relies on in vivo studies utilizing appropriate laboratory animal species. These laboratory animal species are administered the drug or chemical by an appropriate route of administration, and the potential for target organ toxicity is assessed using a variety of endpoints. These endpoints include clinical observations in life, clinical chemistry of blood and urine, necropsy with organ weight measurement, and the collection and histopathology examination of tissues to assess the potential for structural changes associated with toxicity. The robust assessment of target organ toxicity relies on an integration of all these endpoints to provide a weight of evidence approach to assess the potential for toxicity within tissues and organ systems.

---

**Basic Principles for the Examination of Organ Toxicity**

Toxicological alterations of the morphology and structure of organs and tissues are detected by anatomical pathology examination following single or multiple doses of a drug or chemical administered to a laboratory species. During the in-life phase and at the end of an animal study, clinical pathology parameters (e.g., hematology and urinalysis) are assessed and provide important biomarkers for functional metabolic disturbances and maybe the first indicators for potential organ toxicity (e.g., liver or kidney). Both anatomical and clinical pathology disciplines offer a broad diagnostic repertoire to analyze organ toxicity in a well-considered, stepwise, so-called tiered approach concept.

---

**Gross Pathology**

After the in-life phase of an animal experiment, all study animals are necropsied according to a standardized, systematic procedure. As a rule, the study design is based on the most recent effective guidelines (e.g., OECD guideline for the testing of chemicals or US EPA Health Effects Test Guidelines OPPTS); however, the study design should always be adapted if the mode of action of a chemical is already known. All observations and macroscopic lesions identified at necropsy are recorded in a validated electronic data system for each single study animal. A standard study

**Fig. 1** Necropsy of laboratory animals with organ and tissue collection. The figure shows the removal of the liver from the abdominal cavity of a Wistar rat

protocol lists a wide range of tissues and organs that have to be removed for further histopathology examination. Some selected organs (e.g., liver, kidneys, adrenal glands) are weighed. Organ weights are often sensitive indicators of a treatment-related effect and may provide initial information on potential target organs during or shortly after necropsy (e.g., *increased liver or thyroid gland weights* are often recorded for compounds that act as enzyme inducers). Macroscopic observations during necropsy also have the potential to alert the toxicologist to possible target organs (e.g., *yellow-brown or clay-like discoloration of the liver* is indicative of a degenerative change, and the finding of a *mass* could turn out to be a chronic inflammatory process, an abscess, or a malignant tumor). The careful consideration of organ weights and macroscopic findings are an essential part of the detection of organ toxicity in experimental animal studies (Fig. 1).

---

## Histopathology

The histopathological examination (by light microscopy) of a diverse range of organs and tissues by a well-trained toxicological pathologist is one of the most important and time-consuming elements in the assessment of organ toxicity

(Greaves 2012). With the advances in digital technology, slide scanners can now produce digital whole slide images from histopathology slides that can be reviewed by a pathologist in a similar way to a microscope. The minimum scope for histopathology examination is dictated by the various guidelines already mentioned above. In principle, organs and tissues are selected that are considered highly relevant determinants of basic metabolic and detoxification processes (e.g., the liver), organs that act as portals of entry for drugs/chemicals and may have been in direct contact with the test compound (gastrointestinal tract, lungs, skin), and organs that are crucial for excretion (e.g., kidneys, urinary bladder, and biliary system in the liver). Furthermore, representative samples are also examined from the immune and hematopoietic systems (two lymph nodes, one close to the site of exposure, thymus, spleen, bone marrow), the skeletal system (bone, joints, skeletal muscle), and the nervous system (various coronal sections from the brain including the cerebrum and cerebellum, two to three cross and longitudinal sections from the spinal cord, and one peripheral nerve). The cardiovascular system (arteries, veins) is examined as a constituent of many of the routine organ samples but specifically in one or more targeted sections from the heart and one section of the aorta. The reproductive system (including the testes, epididymides, prostate, accessory sexual glands and ovaries, oviducts, uterus, vagina, and mammary gland) is also included in the organs and tissues examined (Fig. 2).

A thorough histopathological examination is essential as toxicological changes can manifest microscopically in the absence of alterations to organ weights and clinical pathology parameters.

**Fig. 2** Histopathology. Scope of examination for one single test animal in a carcinogenicity study (*left* paraffin blocks, *right* histological slides)

---

## Diagnostic Approach, Procedures, and Considerations

As a minimum, all organ and tissue alterations from the high-dose and concurrent control group are recorded systematically in a validated data entry system to produce a pathology finding incidence table. The pathologist chooses an appropriate morphological diagnosis for the lesion observed and may describe the findings in more detail in the narrative pathology report. The pathologist must also grade the severity of findings where appropriate in order to help establish the presence of a dose–response. The grading system used by the pathologist will take into account the type of study (duration of exposure) and the nature of findings observed. The pathologist relies on his knowledge of the spontaneous pathology of the test species used to help differentiate spontaneous from treatment-related findings. A thorough understanding of the potential impact of any histopathology findings on the test species used also helps the pathologist to ascribe adversity to any treatment-related lesions present (Kerlin et al. 2015; Palazzi et al. 2016). The provision of accurate and up-to-date historical control data for spontaneous lesions in test species concerned may also be required to help support the pathologist’s conclusions.

There has been an ongoing debate as to whether the study pathologist should have knowledge of which animals are treated and which animals are controls to guarantee a more *objective examination*. However, the approach of *blind reading* is not recommended by toxicological pathologists or their societies for the initial histopathology examination. The risk of introducing “bias” or the potential to overlook or to misinterpret minor treatment-related variations in the morphology of organs is high, and blind reading should therefore not be performed. However, blind reading of histological slides is often used at a later stage during slide evaluation, e.g., to find a no-observed-effect level (NOEL) for a specific organ toxicity and to allow the study pathologist to consistently identify a subtle or borderline lesion. “Blinding” slides with codes can also be performed if there are different opinions on the interpretation of a lesion between pathologists and the lesion is being considered by a pathology working group (PWG). A PWG is a formal and well-documented process to resolve different opinions on the diagnosis and relationship to treatment of pathology findings from a toxicology study by an independent panel of expert pathologists, which also includes the study and peer-reviewing pathologist. These experts undertake a “blind reading” so as not to be biased (Fig. 3).

---

## Clinical Pathology Parameters

In addition to the analysis of anatomical pathology data after completion of an animal study, the analysis of the clinical pathology data will add significant value for the detection of organ toxicity. For clinical pathology, blood and urine samples are taken during the in-life phase of a study at scheduled time points and, as a minimum, at least once before the final sacrifice of the test animals. Diverse hematology parameters are measured and calculated (e.g., number of red and

**Fig. 3** Evaluation of histological slides by light microscopy. Pathologists during an internal review of histopathological findings at a multiheaded microscope

white blood cells, hemoglobin concentration, mean corpuscular volume, coagulation tests, and differential blood count). As these tests are highly automated, the results can provide an initial assessment of such things as anemia and inflammation prior to the histopathology results. Blood sample analysis also includes clinical chemistry parameters (e.g., enzymes, biochemical analytes in plasma, like transaminases, urea, creatinine, electrolytes, serum protein levels) that may indicate organ toxicity in the liver or the kidneys. As a rule, the selection of the standard minimum panel of clinical pathology parameters in animal experiments follows guideline recommendation and aims to detect major metabolic impacts of a potential toxic compound. If the mode of action of a test item is known, clinical pathology tests may be specifically designed and additional parameters analyzed (e.g., hormones). The clinical pathology data are another important component and, together with the gross pathology, organ weights, and histopathology data analysis, allow the detection of specific organ toxicity with a high degree of certainty.

---

### **Results of a Well-Concerted Combination of Anatomical and Clinical Pathology Data Analyses**

For the majority of cases, standard approaches like the analysis of hematoxylin and eosin-stained histological slides by light microscopy are sufficient to detect organ toxicity. However, there are also exceptions where more sophisticated methods are required. A liver cell swelling (*centrilobular hypertrophy of hepatocytes*) noted by

light microscope may indicate a degenerative or an adaptive response of the liver parenchyma (Fig. 4a). A degenerative process that leads to liver cell death is much more critical than an adaptive process, where the morphological change is based on a physiological and fully reversible response of the liver tissue. There are a number of different chemicals, so-called enzyme inducers, that produce an adaptive liver cell swelling by a proliferation of the smooth endoplasmic reticulum (SER). A

***p<0.002		

**Fig. 4** Example of a successful contemporary approach using three different methods to analyze organ-specific lesions and to correlate structure and function: (a) Centrilobular liver cell hypertrophy (arrowhead) is detected in a histological slide by light microscopy examination. (b) The liver cell hypertrophy is characterized by electron microscopy examination as proliferation of specific cell organelles in the cytoplasm, the peroxisomes (here stained as black rounded bodies). (c) The clinical pathology examination of the cyanide-insensitive palmitoyl-CoA oxidation in liver homogenates resulted in a statistically significant functional increase and shows a clear dose–response relationship

proliferation of the SER is the morphological correlate for an induction of the cytochrome P450 enzyme superfamily (CYP) and major enzymes in the metabolism of xenobiotics (toxic chemicals and drugs). Morphologically, a definitive diagnosis can be made by using electron microscopy of the liver, and clinical biochemistry allows a diagnosis by the analysis of specific enzymes (e.g., ethoxyresorufin-*O*-deethylase and pentoxyresorufin *O*-deethylase).

Both methods are also appropriate approaches to identify another group of substances that also induce a centrilobular hypertrophy of hepatocytes, e.g., peroxisome proliferators. The latter result in an accumulation of specific intracytoplasmic cell organelles, the peroxisomes, which play a significant physiological role in lipid metabolism. Peroxisomes can be selectively stained by cytochemical or immunohistochemical methods and can be morphologically quantified. Results from the latter techniques correlate well with a significant increase of the cyanide-insensitive palmitoyl-CoA oxidation that can be analyzed from liver homogenates taken during necropsy (Fig. 4b, c (table)).

These examples show the complementary use of clinical pathology and anatomical pathology approaches to assure the accurate diagnosis and interpretation of certain types of organ toxicity and to contribute to the understanding of the mode of action of xenobiotics.

---

## International Activities on Harmonization in the Use of Diagnostic Terms

For many years, the major scientific societies of toxicological pathology in Europe (European Society of Toxicologic Pathology [ESTP] and British Society of Toxicological Pathology [BSTP]) and the United States (Society of Toxicologic Pathology [STP]) have worked on harmonizing the nomenclature and diagnostic criteria used in toxicology studies. These activities were guided by the need for pathologists globally to use the same pathomorphological diagnostic criteria in the description of findings from toxicity studies using drugs and chemicals. For example, a *hyperplasia of the mammary gland* should be always differentiated from an *adenoma of the mammary gland* using the same diagnostic criteria regardless of geographical location. As pharmaceutical and chemical companies become more globalized, preclinical safety and toxicology studies for a single compound may be performed in research facilities in different geographical regions. As a result of these trends, it was considered extremely important to come to a common understanding in the use of diagnostic criteria. Initially, the primary focus was given to proliferative lesions in rodents as these findings were easier to harmonize among the international community of toxicological pathologists. As a result working groups of toxicological pathologists from Europe and America published a series of *International Classification of Rodent Tumours* for rats and mice between 1992 and 2001. The subsequent use of these published criteria significantly helped to harmonize the diagnosis of tumors in rodent oncogenicity studies. However, there will always be borderline lesions and growth patterns of tumors where harmonized criteria do not fit

the lesion and the pathologist has to make their own informed judgment based on experience.

On the basis of an initiative of the European Society of Toxicologic Pathology (ESTP) and the US Society of Toxicologic Pathology (STP), a further important step forward was started in 2005. In conjunction with the German-based Registry of Industrial Toxicology Animal-data (RITA), a collaborative process of review, update, and harmonization of existing diagnostic nomenclature, documents, and databases of rodents was initiated. The British Society of Toxicological Pathology (BSTP) and the Japanese Society of Toxicologic Pathology (JSTP) joined this process in 2006. This project, known as INHAND (International Harmonization of Nomenclature and Diagnostic Criteria for Lesions in Rats and Mice) project, includes efforts to harmonize nomenclature not only for proliferative lesions but also for non-proliferative lesions at a level that gains international acceptance (Mann et al. 2012). Up to 2020, INHAND nomenclature has been published for the cardiovascular (Berridge et al. 2016), integument (Mecklenburg et al. 2013), soft tissues/skeletal (Fossey et al. 2016), respiratory (Renne et al. 2009), hepatobiliary (Thoolen et al. 2010), urinary (Frazier et al. 2012), nervous (Kaufmann et al. 2012), endocrine (Brändli-Baiocco et al. 2018), hematology (Willard-Mack 2019), special senses (Ramos et al. 2018), reproductive systems (Creasy et al. 2012), gastrointestinal tract (Nolte et al. 2016), and the mammary gland (Rudmann et al. 2012). Guides for non-rodent species are in preparation. The INHAND nomenclature is also available electronically at the goRENI webpage and is presented at the international annual meetings of the societies of toxicological pathology to discuss the practical use of these harmonized diagnostic criteria.

---

## Summary and Future View

Organ toxicity is the result of physiological dysfunction and structural alteration. Clinical pathology and histopathological examination are complementary approaches that underpin the detection and characterization of organ toxicity. Despite the many advances in molecular biology (genomics, metabolomics), the use of routine clinical pathology measurements and histopathological examination of hematoxylin and eosin-stained tissue sections are unlikely to be replaced in the near term as a first-tier approach for detecting organ toxicity in animal toxicology studies. The latter techniques can be complemented by more sophisticated examination using electron microscopy, immunohistochemistry, and molecular pathology approaches, once the target organs have been identified, and may help to identify the mode of action of the toxicity in question.

Steady advances have been made in the validation and use of *in vitro* systems for predicting organ toxicity. These have mainly involved the evolution of primary cell cultures into more sophisticated microphysiological systems (MPS) that contain more than one cell type (Truskey 2018). With advances in stem cell biology, these MPS can be humanized, to allow for a direct comparison of results between laboratory animals and man.

## Abstract

The specific test methods used in toxicology classically include tests for reproductive toxicity, genotoxicity, and carcinogenicity. There are now also other test methods such as testing for possible immunotoxic or neurotoxic properties of a substance. Special, usually internationally applicable, test guidelines form the regulatory basis for the test methods, which apply to chemicals, crop protection products, and medicinal products.

## Keywords

Reproductive-toxicity · Teratogenicity · Embryo-fetal toxicity · Fertility · Genotoxicity · Point mutation · Chromosomal aberration · DNA damage · Carcinogenicity · 2-year rat study · Neurotoxicity · Immunotoxicity

Pharmaceuticals, Translational Sciences, Bayer AG, Wuppertal, Germany

## Introduction

In principle, toxicity testing can be separated into two major groups. One is more general in nature and includes (general) toxicity tests ranging from acute (single-exposure) studies to repeat-dose (multiple-exposure) studies, whereas the other group involves (specific) toxicity tests which examine specific types of adverse effects, also known as endpoints. Such endpoints cover well-known risks such as reproductive toxicity, genotoxicity, and carcinogenicity but also very specific risks such as immunotoxicity or neurotoxicity. The aim of this chapter is to describe the current regulation and the specific test methods used in toxicology to elucidate and characterize these particular risks. Most of the test guidelines (TGs) mentioned in this chapter are based on the internationally harmonized TGs for chemicals (see OECD 2020) and the harmonized TGs for pharmaceuticals (see ICH 2020).

In the past, most toxicity tests were performed in animals, and as a consequence, today's regulation is still mainly based on results obtained in animals. It should, however, be mentioned that in line with the protection of animals used for scientific purposes in the meantime, basically all legislations that rely on toxicological information either require or strongly encourage the use of alternatives to animal testing. With new technologies and alternatives becoming available (for more details, see ► Chap. 12, "Toxicity Testing In Vitro: Regulatory Aspects"), it can be expected that new testing strategies and testing methods will be evaluated also in the context of specific toxicity tests and will find their way into new regulations (EMA 2020; EPA 2020; FDA 2020).

---

## Reproductive Toxicity Testing

The importance of reproduction toxicology as part of the assessment of safety gained sad notoriety in the wake of the thalidomide (Contergan) tragedy. At that time, routine testing for possible teratogenic properties of a substance was not yet established. This was because such a possibility was not expected on the basis of the scientific knowledge back then. We now know that chemical substances are fundamentally capable of causing damage in all stages of reproduction. The maturation of gametes can be disturbed in women or men, for example. But the release of mature gametes can also be disturbed, as can fertilization; cell division; egg implantation in the uterus; intrauterine development, i.e., the development of organs during the embryonic phase and fetal maturation; and development after birth (postnatal phase). In order to clarify whether and at what point in time reproductive effects can occur, the treatments must be carried out during specific periods of time. A distinction is therefore made between testing for effects on male or female fertility (from spermatogenesis/follicle maturation to implantation), on intrauterine development (during organogenesis), and on peri- and postnatal development (from fetal development to the end of lactation).

Testing for possible *teratogenic/embryotoxic properties* is now mandatory for all substance classes. The procedures for carrying out this testing are described in

publications including the *OECD Guideline for Testing of Chemicals* No. 414 (“Teratogenicity”) and in ICH Guideline S5(R3) (“Guideline on reproductive toxicology: Detection of toxicity to reproduction for human pharmaceuticals”). Testing is based on the principle that two different animal species (usually the rat and the rabbit) are exposed to the substance to be tested during the most sensitive stage of pregnancy. Immediately before the natural end of pregnancy, the fetuses are delivered by cesarean section and then examined for external and internal malformations. Rats are treated from day 6–15 and rabbits from day 6–18 of pregnancy. The most important organs are formed during these periods. Any teratogenic/embryotoxic potential a substance may have should therefore have its greatest impact under this treatment regimen and should therefore also be detectable with the greatest degree of reliability. While in the past the majority of data was generated in animals, current testing strategies are expected to consider minimizing the use of animals. Alternative assays and/or in vivo studies with fewer animals can be used to identify hazards in a tiered manner. The use of qualified alternative assays is appropriate for risk assessment under certain circumstances where they are interpreted in conjunction with in vivo reproductive testing. Although they are not a replacement for all in vivo reproductive testing, they can reduce in vivo animal studies and/or animal usage (see also EMA 2020).

*One- or two-generation studies* in rats, conducted for chemicals and crop protection products, represent additional test methods that investigate the effects of a substance on male or female fertility and on progeny. The methods are described in the *OECD Guidelines for Testing of Chemicals* No. 415 (“One-Generation Reproduction Toxicity Study”) and 416 (“Two-Generation Reproduction Toxicity Study”). For medicinal products, the legislation stipulates testing for *effects on male or female fertility* in the rat (ICH Guideline S5 (R3)) and *testing for pre- and postnatal toxicity*, also in the rat (ICH Guideline S5 (R3)), in addition to testing for teratogenic or embryotoxic properties.

Study objectives and common study types:

- Testing for embryotoxic or teratogenic properties in the rat and rabbit (embryo-fetal developmental (EFD) toxicity study)\*
- Testing for effects on male or female fertility in the rat\*
- Testing for pre- and postnatal toxicity in the rat\*
- One- or two-generation studies in the rat

\*Some of the endpoints may be combined in one study, e.g., the combined fertility and embryonic development study (FEFD) or the combined fertility and pre- and postnatal development study (FPPND).

There are also guidelines available which classify reproductive risks. For chemicals, there is guidance on classification of reproductive toxicity under the Globally Harmonized System of Classification and Labelling of Chemicals (GHS). This document offers guidance on the determination of level of concern as a measure of adversity and the level of evidence to ascribe classification based on data from tests in laboratory animals. For pharmaceuticals, there is a guideline on risk

assessment of medicinal products on human reproduction and lactation. This document describes how to assess the risk of adverse reproductive/development effect in humans based on reproductive toxicity studies in animals and human clinical data. It addresses information to be included in the summary of product characteristics on how to use the medicinal product taking into account the nature of the risk.

---

## Genotoxicity Testing

The strategy for testing for genotoxicity covers three main areas, namely, gene mutation, chromosome aberration or breakage (clastogenicity), and chromosomal loss or gain (aneuploidy). Testing for genotoxic properties (effects on the cell's genetic material) is mandatory for most substances. A multitude of test methods (in vitro and in vivo) are available for this, and these can be used to detect a variety of harmful effects. More specifically, these include gene or point mutations, structural chromosome changes (chromosomal aberrations), and changes in chromosome number (changes in the DNA). Mutations are significant for humans in a number of respects. On the one hand, mutations in somatic cells can pave the way for cancer, and they therefore have a direct effect on the individual concerned. Germline mutations, on the other hand, can lead to prenatal death or to malformations ("hereditary diseases") in offspring. They therefore have effects on subsequent generations.

Because *point mutations* are not visible under the microscope, the induction of these mutations is detected indirectly via their effects. These consist mainly of protein changes, with enzyme functions often being used as a means of detection. Bacteria are eminently suited to this task, as they enable individual mutants to be detected among millions of cells with the aid of selection media. Probably the best-known mutagenicity test of all is the Ames test, which will be described briefly here as an example of a method for detecting point mutations. The object of the test is a defective (mutant) strain of *Salmonella typhimurium* that is no longer capable of synthesizing histidine. The mutated bacteria have the ability to revert to the normal wild type under the influence of mutagens. A concentration-dependent increase to the point of histidine independence is considered as evidence of point mutagenicity. Because of the simplicity of the method, the Ames test is a suitable screening test for many substances. It is a quick and sensitive assay. A high degree of mathematical correlation has been shown in some cases by comparison of the mutagenic effects of substances in the Ames test and their carcinogenic effects in animal studies.

In vitro tests to detect *chromosome or ploidy mutations*, known as "cytogenetic studies," can generally be performed with all primary or permanent cell lines possessing a relatively constant set of chromosomes. Chinese hamster, mouse, and rat cells are used most often, although human lymphocytes are also used. In vivo studies are usually conducted in small mammals, and the assay in Chinese hamster bone marrow can be mentioned as an example of the basic procedure. The test substance is administered to the animal which is then sacrificed after exposure of the organism to the substance for a period of time. Shortly before sacrifice, cell division

is arrested at metaphase by administration of a spindle inhibitor. The bone marrow is removed from the sacrificed animal and examined under the microscope for chromosomal changes.

Another option for testing consists of investigating whether a substance has caused *DNA damage*. Historically, the preferred assay for measuring DNA damage has been the rodent liver unscheduled DNA synthesis (UDS) assay, but this has been superseded in the meantime by the single cell gel electrophoresis (SGCE) assay or comet assay. The comet assay is a versatile, reliable, cost-efficient, and fast technique for detecting DNA damage and repair in almost any cell type and applicable to both eukaryotic and prokaryotic organisms.

Detailed descriptions of the test methods can be found in the OECD Guidelines (*OECD Guidelines for Testing of Chemicals* Nos. 471–486). For medicinal products, the corresponding information can be found in ICH Guideline S2 (R1).

Study objectives and common study types:

- Testing for point mutations (e.g., Ames test in *Salmonella typhimurium* strains)
- Testing for chromosomal aberrations
- In vitro, e.g., cytogenetic studies in Chinese hamster cells
- In vivo, e.g., tests using hamster bone marrow or micronucleus test in the mouse
- Testing for DNA damage (e.g., comet assay in vitro and in vivo)

It is not possible to assess the possible mutagenic risk of a substance on the basis of just one test. Instead, the different ways in which damage can be caused must be addressed and studied on the basis of specific endpoints. This can only be done within the context of a testing strategy in which the test systems must be considered hierarchically. A combination of a bacterial test (e.g., Ames test using various strains of *Salmonella typhimurium*), an in vitro test in mammalian cells (e.g., cytogenetic studies in Chinese hamster ovary cells), and an in vivo study (e.g., micronucleus test in the mouse) represents a standard battery of tests. If a substance has been tested sufficiently for mutagenic properties without any evidence of mutagenic potential being found, it can be assumed that the risk to humans is negligibly small. The risk assessment in the presence of positive findings in lower organisms which cannot be confirmed using relevant methods in mammalian organisms is more complex. As a general rule, for the assessment of any potential risk a substance might pose to humans, the significance of the method increases the more the test system corresponds to the conditions in mammals. If in vivo studies in mammals yield positive findings, this must be seen as a clear indication of the possibility of mutagenic effects in humans. Because positive findings must also always be viewed in the context of a risk of cancer, they are of predictive significance in the assessment of the possible carcinogenic potential of a substance. Herein may lie the true value of these tests that are so quick and easy to perform. Positive findings in genotoxicity studies must always be taken seriously and require careful further investigation. The question of what risk must be deduced from the results of genotoxicity studies can be answered only after an assessment of all the studies. The ultimate classification and evaluation of the findings must take place within the overall context of the risk/benefit assessment.

## Carcinogenicity Testing

One of the most complex toxicological tests is the testing of a substance for possible tumorigenic (carcinogenic) properties. The tests are usually performed in two rodent species, specifically rats and mice, and more rarely in hamsters. Ideally, the substance to be tested should be metabolized similarly in the animal species used to the way it is metabolized in humans. The study duration is generally 24 months in rats and 21–24 months in mice and hamsters, depending on the animal strain used, and thus covers the majority of the life expectancy of the study animals. This mimics almost in fast motion the lifelong exposure to a substance in humans. The way the substance to be tested is administered is guided by the conditions in humans (administration in the feed, in the drinking water, by gavage, by inhalation, etc.). The testing includes three-dose groups and an untreated control group. Fifty animals of each sex are generally used per dose level. The doses are selected in such a way that there are clear intervals between them. The highest dose should be close to the maximum tolerated dose (MTD). If this dose were exceeded, the animals would die from the effects of the substance before it was possible for cancer to develop in the first place. Administering the maximum tolerated dose makes the carcinogenicity study particularly sensitive. This is also necessary because it is only ever possible to study the substance in a limited number of animals, although the risk needs to be assessed for a large number of exposed people. The exact procedure for conducting carcinogenicity studies is described in the OECD Guidelines (*OECD Guidelines for Testing of Chemicals* Nos. 451/453).

A few particularities need to be taken into account in the testing of medicinal products for possible tumorigenic properties. The option exists, for example, to replace the long-term study in mice with a meaningful short-term test. Various transgenic animal models can be used for this. Which model is the most suitable must be decided depending on the substance and the particular parameter(s) being studied. Ideally, this should be done in close consultation with the competent authorities. In the case of medicinal products, the dose is selected taking into account pharmaceutical considerations, with a key role being played by the comparison of human/animal exposure on the basis of the achieved/achievable plasma concentrations. Information on conducting carcinogenicity studies for medicinal products can be found in ICH Guidelines S1A, S1B, and S1C (R2). It should be mentioned that for medicinal products, analyses are ongoing in order to explore new and eventually better ways to predict a carcinogenic potential. The results of these analyses hold promise in driving to support modifications to current carcinogenicity testing guidelines while maintaining patient safety, accelerating patient access, and significantly reducing animal testing.

Basic structure of carcinogenicity studies:

- Two rodent species (rat and mouse or hamster)
- Three-dose groups and an untreated control group
- High numbers of animals (50 animals of each sex per dose level)
- Lifelong treatment (24 months)

- Highest possible dosages (maximum tolerated dose = MTD or exposure calculations, if relevant)

The crucial evidence in respect of the outcome of carcinogenicity studies is provided by the necropsy of the study animals and the subsequent histopathological examination. There are no hard and fast rules on how the results of carcinogenicity studies, whether positive or negative, should be evaluated. An assessment of the risk can be performed only on the basis of well-planned and conducted studies and by a committee of experienced top specialists.

As mentioned above, for medicinal products, efforts are ongoing to introduce a more comprehensive and integrated approach to address the risk of human carcinogenicity and to define conditions under which the 2-year rat carcinogenicity studies add value to that assessment. There is growing evidence that knowledge of pharmacological targets and pathways together with toxicological data can, in certain cases, provide sufficient information to anticipate the outcome of the 2-year rat carcinogenicity studies and their predictive value for a given pharmaceutical. Based on this knowledge, it may be possible to conclude that a given pharmaceutical in certain cases presents a negligible risk or, conversely, a likely risk of human carcinogenicity without conducting a 2-year carcinogenicity study. This hypothesis is currently tested by a prospective evaluation.

---

## Neurotoxicity Testing

Specific tests for neurotoxic effects are required for crop protection products in particular. The range of tests covers three main elements: the “functional observational battery” (FOB), motor activity (MA), and neuropathology.

In the *functional observational battery (FOB)*, a series of noninvasive tests is performed which can be used to detect and quantify behavioral abnormalities and neurological effects in the study animals (usually rats). The initial focus is on close observation. Even the tiniest changes in posture, appearance, and movement are noted, with a distinction being made, for example, between observation of the animal in its own cage, during handling, and outside the cage (on a free surface). In addition, a range of responses (including the approach, touch, noise, and tail-pinch responses) and reflexes (including pupil response, righting reflex, and grip strength) are assessed. The basic requirement for the reproducibility of these tests is the standardization of the test conditions. This includes, for example, all the animals in a study always being assessed by the same investigator. For *motor activity (MA)* testing, the animals are placed in chambers equipped with infrared light barriers and their movements observed closely. The automated recording of findings enables even the tiniest changes in the motor activity of the study animals to be recorded. Possible substance effects can result in an increase or decrease in motor activity. Testing for neurotoxic effects includes a thorough *neuropathological examination*. For this purpose, different localizations of the central and peripheral nervous system are prepared at the end of the study using specific techniques

and examined and assessed in respect of morphological effects. A detailed description of the test methods can be found in publications including the *OECD Guideline for Testing of Chemicals* No. 424 and the EPA Health Effects Test Guidelines (OPPTS870.6200).

Key elements of neurotoxicity testing:

- Functional observational battery (FOB)
- Motor activity (MA)
- Neuropathology

Possible neurotoxic properties of a substance can have particularly serious consequences for the developing organism. It is therefore not surprising that particular importance is attached to this aspect in connection with specific tests, the main focus of interest being the recording of behavioral changes and neurological deficits in progeny/young animals.

---

## Immunotoxicity Testing

Testing substances for possible immunotoxic properties has taken on much greater prominence in recent years and is now established in numerous test guidelines.

According to the FDA (1999), immunotoxicity refers to any adverse effect on the structure or function of the immune system, or on other systems as a result of immune system dysfunction. An effect is considered adverse or immunotoxic if it impairs humoral or cellular immunity needed by the host to defend itself against infectious or neoplastic disease (immunosuppression) or it causes unnecessary tissue damage (autoimmunity, hypersensitivity, or chronic inflammation). This definition incorporates the concept that the immune system is in a complex balance with other systems (e.g., nervous and endocrine) that may utilize or be affected by the same biological mediators (e.g., neuropeptide and steroid hormones).

Some immunotoxicological tests have been an established component of toxicological testing for many years. This applies to investigations of the possible skin-sensitizing/allergic potential of a substance, for example. The *Buehler test* and the *Magnusson and Kligman maximization test* represent typical methods for detecting these kinds of reactions. Both tests are conducted in guinea pigs, with a distinction being made between adjuvant (maximization) and non-adjuvant (Buehler) tests. Freund's adjuvant is administered additionally to boost any immune response induced by the test substance in the test concerned. The principle of the test consists of the animals, after initial exposure to the substance ("induction") and after a waiting period (generally 14 days) has elapsed, being confronted with the substance a second time ("challenge"). The responses which then occur are used to assess whether the substance has skin-sensitizing potential or not. A detailed description of these tests can be found in the *OECD Guideline for Testing of Chemicals* No. 406 and in the EPA Health Effects Test Guidelines (OPPTS870.2600). A more recent test is represented by what is known as the *local lymph node assay*, which is described in

the *OECD Guideline for Testing of Chemicals* No. 429. For medicinal products, the aspect of skin sensitization plays a role with dermal dosage forms in particular. Testing is required specifically in the European “Note for Guidance on Non-Clinical Local Tolerance Testing of Medicinal Products” (CPMP/SWP/2145/00).

Some of the parameters studied in standard toxicological testing can themselves provide information on immune system involvement. These include hematological parameters (white blood cell count, differential blood count), clinical chemistry parameters (protein electrophoresis and albumin/globulin ratio), organ weights (spleen, thymus, lymph nodes), and especially histopathological examination of the spleen, lymph nodes, Peyer’s patches, thymus, and bone marrow. Specific tests are now also available in addition to these standard parameters. These are functional tests such as the *plaque assay*, which involves immunizing the test animals against sheep red blood cells a few days before necropsy and measuring the resulting immune response on the day of necropsy, or more in-depth cytofluorometric analyses of *lymphocyte subpopulations* in the spleen and blood using FACS. If any of these tests yield evidence of immunotoxicity, the range of tests must be expanded (“tier approach”). In such cases, consideration should be given to performing a *host resistance (HR) assay*, for example, in which the treated animals are infected with bacteria or viruses, and any impairment of immunity by the substance is measured.

The exact procedure for testing for immunotoxic properties of a substance is described in various test guidelines. Specific reference should be made here to the EPA Health Effects Guideline, “Immunotoxicity” (OPPTS 870.7800) and the ICH Guideline S8 (“Immunotoxicity Studies for Human Pharmaceuticals”).

## Abstract

In vitro testing in toxicology was limited for a long time to testing for possible genotoxic properties of a substance. Cell or tissue culture methods are now used for the early toxicological assessment of new substances within the context of screening tests and for mechanistic investigations. In this respect, in vitro methods represent a valuable adjunct to animal studies, without being able to replace animal studies completely at the present time. New developments in the area of microphysiological systems (MPS) suggest that in specific cases like the development of biologics as pharmaceuticals, where relevant animal models are not available due to the human-specific nature of the biologic, but also for improved mechanistic evaluations, human in vitro models will be required or at least deliver helpful information.

**Introduction**

“In vitro” tests are known colloquially as “test tube experiments,” i.e., they are performed outside the living organism. According to this definition, in vitro testing encompasses tests with isolated organs or tissues, cells, cell organelles, receptors, or ion channels. The culture of cells from different organs is the in vitro method most commonly used in toxicology, with a distinction being made between *primary cell cultures* and permanent *cell lines*. Primary cell cultures are prepared from freshly isolated cells obtained during a necropsy or from surgical specimens, for example. Permanent cell lines, such as tumor cell lines, are obtained from cells which have been transformed spontaneously or in a targeted manner such that they can be passaged without limit and kept in stock. They can now be acquired easily from cell banks. Another source for human cells is stem cells. *Adult stem cells* are isolated from donor fetal or adult tissue(s), whereas *pluripotent stem cells* can be isolated from the inner cell mass of the blastocyst, as with *embryonic stem (ES)* cells, or through nuclear reprogramming, as with induced pluripotent stem cells (iPSC). Which culture systems should be used must be decided individually, depending on the specific parameter(s) being studied.

With regard to their aims, in vitro tests can be viewed in two ways: firstly, as a method of screening and, secondly, in the context of *mechanistic evaluation*. Whereas pharmacological research has been making use of cell and tissue cultures for a long time in efficacy testing of new medicinal products, the use of such systems in toxicology was previously limited to just a few areas of investigation. In vitro methods now represent a vital tool in the early toxicological characterization of new substances, however. This can be attributed, using pharmaceutical research as an example, to the significant increase in efficiency (higher output) and the resulting need to subject potential candidates for development to toxicological assessment at an early stage and to support optimization. It is clear that, because of their low throughput and the large amounts of substance required, conventional toxicological methods, and animal studies in particular, are not able to meet the requirements placed on screening. In vitro methods, on the other hand, have low substance requirements; they can be performed quickly and they are in many cases cheaper. The relatively simple in vitro systems do, however, often show limitations when it comes to generating data on a substance about which little or no previous information exists. This kind of information can usually be provided only by methods with a high level of complexity, which naturally cannot be achieved with simple in vitro methods used for screening. The particular value of in vitro methods therefore lies in the investigation of questions arising on the basis of specific evidence from an

animal study. In this connection, early screening must always be seen as *screening via knowledge*, i.e., based on previous information. Once a data pool generated under in vivo conditions is available, this can be examined in detail with the aid of cell or tissue culture methods. Another particular benefit of in vitro methods lies in the fact that human material (such as surgical specimens) can be used, and the basis for human risk assessment can thus be improved. In vitro methods can therefore represent a useful adjunct to animal studies with the possibility of evaluation of the human relevance of findings obtained in animals.

Possible uses of established in vitro screening models are the following:

- Detection of cellular toxicity in defined organ models
- Testing for specific toxicity (e.g., phototoxicity)
- Tests using receptors or ion channels in the context of safety pharmacology studies
- Genotoxicity testing

Some of the currently common in vitro methods and their possible uses are described below. New developments in the area of MPS which strive for in vivo-like complexity will be described in a separate chapter.

---

## Tests with Liver Cell Cultures (Biotransformation and Cytotoxicity)

The liver plays a central role in the metabolism of foreign substances. Its extraordinary capacity to convert and break down substances is largely attributable to the parenchymal cells of the liver or hepatocytes. From a toxicological point of view, the liver is one of the most important target organs for toxicity. It is therefore not surprising that, in the context of in vitro testing, particularly great importance is attached to tests using isolated liver cells. Hepatocytes from the common study animal species (mouse, rat, dog, or monkey) are relatively easy to obtain because most toxicological studies end with necropsy of the animals. Obtaining human tissue is more difficult, and use must be made here of surgical specimens obtained, for example, from resected liver tissue, following tumor surgery. The hepatocytes obtained at necropsy or from surgical specimens via perfusion are used as primary cultures. They can be maintained in culture for days to a few weeks depending on the culture method, but lose their full functionality over time, with a particularly sharp decline in their cytochrome P450 enzyme (CYP) activity. The use of newer culture methods such as sandwich culture, in which primary hepatocytes are sandwiched between layers of a collagen matrix or cultured as 3D spheroids, potentially as a coculture with non-parenchymatous liver cells, significantly prolongs the period for which metabolic activity can be maintained. Under these conditions, it is possible to maintain hepatocytes in culture for up to 14 days with rather stable basal and inducible CYP metabolic activity, although at a likely lower level than in vivo (Gómez-Lechón et al. 2014).

Tests on the metabolism and cytotoxicity of substances can be performed with liver cells obtained and maintained in culture in this way. Preliminary statements can thus be made about their biotransformation without animal studies or trials in humans having been conducted. Within the context of drug development, these tests are therefore also of particular importance because the results obtained in human hepatocytes can be compared with the results from the hepatocytes of the study animal species in which the toxicological studies have been or should be carried out. On the basis of the comparability of the metabolic pattern (human compared with animal *in vitro*), conclusions can then be drawn as to whether the study animal species used in the toxicological studies can be classified as relevant in terms of their applicability to humans.

Cytotoxicity tests with liver cells involve measuring the levels of certain enzymes in the culture supernatant. Alanine aminotransferase (ALT), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) can be mentioned here as examples. Increased levels of these (cellular) enzymes in the supernatant are an indicator of cell damage, following the same principle as is applied in the diagnosis of liver damage in patients (increased levels of liver-specific enzymes in the blood as an indicator of liver damage). Determination of mitochondrial dehydrogenase activity (e.g., with the MTT assay) allows to assess the effect of a compound on the metabolic activity of hepatocytes, which essentially correlates with the level of viable cells in an incubation. The use of liver cell cultures in the context of early screening has proven particularly effective when previous information is available from *in vivo* studies. Under these conditions (“screening via knowledge”), tests with hepatocytes can be used for further chemical optimization with a view to avoiding or eliminating hepatotoxic properties in a new substance. Inconclusive findings from animal studies or significant species differences resulting in uncertainty in assessing the possible risk to humans provide the basis for another possible use. In these cases, testing with human specimens can improve the basis for the risk assessment. Although tests with liver cell cultures are not a regulatory requirement, they represent an important internal decision-making criterion in the context of substance preselection or supplementing/supporting *in vivo* data with regard to their applicability to humans.

---

## Tests with Mouse Fibroblasts (Phototoxicity)

The term “phototoxicity” is used to refer to reactions triggered when an organism exposed to light or the sun shows particular sensitivity to certain (phototoxic) substances, resulting in harmful health effects. These kinds of reactions can range from local symptoms resembling sunburn (redness) to severe burns (extensive skin necrosis) and general health effects. A large number of substances (especially cosmetics, medicinal products) are now known to have phototoxic potential. It is therefore appropriate that the legislation requires manufacturers to provide information on phototoxicity in the presence of relevant grounds for suspicion (photo instability, presence/accumulation of the substance in the skin) or for certain indications (dermally applied substances). Traditionally, these kinds of tests were

performed in animals and involved mice, rats, guinea pigs, or rabbits being irradiated with UV light after being treated with the substances to be tested.

The most widely used in vitro assay for phototoxicity is the “in vitro 3T3 Neutral Red Uptake Phototoxicity Test” (3T3 NRU-PT) for which a guideline (OECD 2004) is available, which has recently been updated (OECD 2019). The assay was developed under the leadership of the Center for Documentation and Evaluation of Alternatives to Animal Experiments (ZEBET) of the Federal Institute for Consumer Health Protection and Veterinary Medicine (BgVV). It is performed using a permanent mouse fibroblast cell line (Balb/c 3T3) and is based on the testing and comparison of the cytotoxic effects of a substance in the presence or absence of exposure to UV light. This in vitro assay is also part of a sequential phototoxicity testing strategy proposed in a CPMP guidance document (CPMP/SWP/398/01 2002), and it is also mentioned in an ICH guideline for the testing of pharmaceutical drugs (CHMP/ICH/752211/2012 2015). While it is acknowledged that the 3T3 NRU-PT assay is a very sensitive test and many positive findings are not confirmed in in vivo follow-up studies, the importance of the 3T3 NRU-PT assay within the context of a sequential testing strategy lies in the fact that if a negative result is obtained, i.e., if evidence is obtained of the absence of phototoxicity, no other tests, and specifically no animal studies, need to be performed, something which is to be greatly welcomed from the point of view of limiting the number of animal studies. However, a positive result in the 3T3 NRU-PT should not be regarded as indicative of a likely clinical phototoxic risk, since it is primarily a hazard identification test. Even in the case of a positive in vitro phototoxicity test, the concentration at which cytotoxicity is observed in vitro after UV irradiation can be used for calculation of safety margin in the context of expected human blood concentrations at therapeutic dose levels.

---

## Tests with Isolated Ion Channels (Cardiotoxicity, ECG Changes)

In the context of the risk assessment of medicinal products, possible cardiotoxic properties, particularly in medicinal products used primarily in non-cardiovascular indications, have been the focus of attention for some time now. The properties concerned are characteristic ECG changes (prolongation of the QT interval as evidence of delayed cardiac repolarization) which are considered predictive in respect of the induction of arrhythmias. This kind of potential must be identified at an early, i.e., preclinical, stage, and the legislation therefore consistently requires appropriate nonclinical (safety pharmacology) studies. Reference should be made in this connection to an ICH test guideline entitled “The non-clinical evaluation of the potential for delayed ventricular repolarization (QT interval prolongation) by human pharmaceuticals” (CPMP/ICH/423/02 2005). Among the tests stipulated in this test guideline are tests using human potassium channels which are expressed in a cell line in a stable manner (hERG). The background for the tests is the fact that cardiac repolarization is essentially mediated by potassium flow and that drug-induced inhibition of the ion channels leads to prolongation of the action potential, which

makes itself apparent in the ECG in the form of prolongation of the QT interval. Tests using hERG channels represent an additional and new example of *in vitro* studies that are established in regulatory terms. Enhanced evaluation of proarrhythmic risk is now being conducted by international initiatives including the Comprehensive *in vitro* Proarrhythmia Assay (CiPA) and the Japanese iPS cardiac safety assessment initiatives (Kanda et al. 2018; Blinova et al. 2018). The CiPA approach is based on several key modalities including (1) testing of further major ion channels in addition to hERG in correspondingly transfected cell lines, (2) *in silico* modeling of the ion channel effects, (3) proarrhythmic assessment in human-induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs), and (4) clinical assessment of electrocardiograms from phase I human studies.

Most recent developments in *in vitro* cardiotoxicity testing expand the use of hiPSC-CM, by testing not only for proarrhythmic risk but also for other relevant parameters like compound-induced effects on changes in contractility, voltage, and/or Ca handling of cardiomyocytes (Saleem et al. 2020).

---

## Tests with Mammalian Cell Cultures (Genotoxicity)

*In vitro* methods are already long established and stipulated by test guidelines as standard in the field of genotoxicity testing. These kinds of test were in fact already in use even before the development and use of *in vivo* methods. For the testing of a substance for genotoxic properties, it is assumed that no single test system is capable of predicting a possible risk to humans in a reliable manner. This is why batteries of tests are used to test substances for possible genotoxic effects. A typical battery of tests, stipulated for the testing of medicinal products, for example, consists of two *in vitro* tests (gene mutation test in bacteria, chromosomal aberration test in mammalian cell cultures) and one *in vivo* test (micronucleus test in the bone marrow) (Galloway 2017). To perform chromosomal aberration tests under *in vitro* conditions, cells in culture are treated with the substance to be tested in both the presence and absence of external metabolic activation, arrested at metaphase by administration of a spindle inhibitor, fixed, and then evaluated under the microscope. Permanent fibroblast cells originating from various Chinese hamster tissues are most often used for these tests, including V79, CHO, or CHL cells. These are particularly suitable for chromosome analyses because of their small number of chromosomes and especially their uncomplicated karyotype. Human peripheral lymphocytes are also used.

---

## Tests with Incubated Chicken Eggs (Various Parameters)

Incubated chicken eggs have long been a well-established test system in biomedical research. Development stages without any sensitivity to pain are also used as a model. Both the embryo and the extraembryonic vascular systems are considered as target structures. The substances to be tested are administered directly or via the

intravascular route. Functional and/or morphological parameters are end points. The results of numerous studies show that incubated chicken eggs are used to determine the irritation potential; to screen for cardiovascular effects, phototoxicity, and angiogenesis; and in cancer research. More recently and since in vitro cell culture tests have been developed for these toxicities, testing with incubated chicken eggs is being used less frequently, especially for skin and eye irritation.

---

### **Human Embryonic Stem (hES) Cells for Use in Toxicity Testing, E.g., Early Development Toxicity Testing**

Early developmental toxicity assays for screening of various compounds for the potential risks for abnormal development in the growing embryo have been traditionally based on animal cells. As species differences might affect the accuracy of the assessments, there is an increasing need for alternative cell sources. In vitro differentiation of hES cells bears a resemblance to the early stages of human embryonic development and offers in principle the possibilities for alternative toxicity testing.

Developmental toxicity evaluations, as used in safety assessment assays, are sometimes suffering from a lack of normal, reproducible, and easily available human cell systems. In this context, pluripotent hES cells and their derivatives have the potential to improve the quality of targets, hits, and leads, thus reducing late-stage attrition. The promise of hES cells for in vitro toxicology is the indefinite access to starting material of identical origin in combination with highly human-relevant assays for, e.g., developmental toxicity testing (Luz and Tokar 2018). Very recently such developmental toxicity testing in stem cells has been evaluated in hiPSC, which yielded promising results with a list of relevant reference compounds (Aikawa 2020).

---

### **Possibilities and Limitations of Established In Vitro Toxicity Testing**

It is no longer possible to imagine modern toxicity testing without in vitro test systems. They enable initial information on toxicological properties to be obtained within the context of early screening and can provide chemical research with important indications with regard to the possibilities for optimization. The reliability of such screening is enhanced considerably if previous information is already available on the substance (“screening via knowledge”). Mechanistic investigations represent a second focus of in vitro methods. The same principle applies here as with “screening via knowledge,” i.e., that the real role of in vitro methods lies in the targeted investigation of specific questions based on previous information obtained from in vivo studies. In vitro methods can add major value, however, e.g., by making it possible for tests to be carried out using human specimens, and thus improve the basis for the risk assessment. Quantitative assessments aimed at extrapolating concentrations from in vitro tests to the in vivo situation (doses) are problematic. It is therefore not surprising that the in vitro test systems established so far for

regulatory purposes (e.g., *in vitro* genotoxicity, phototoxicity, or cardiotoxicity testing) are almost always part of an integrated battery of *in vitro/in vivo* tests, and the results of *in vitro* testing are assessed in the sense of a yes/no answer and not in terms of a quantitative assessment of the risk.

---

## **New Developments: Microphysiological Systems (MPS)**

To overcome some of the limitations of simple 2D culture systems, several approaches are being pursued to make *in vitro* models more *in vivo*-like. From simple to more and more advanced, this includes the following:

1. 2D cell lines in static culture condition representing mostly dedifferentiated cells, i.e., most current screening systems
2. Primary cells in static culture which are associated with some *in vivo* functionality like CYP enzyme activity in the case of primary hepatocytes and which can be improved with (a) extracellular matrices (ECM), e.g., the hepatocyte sandwich model for shorter-term studies, or (b) co-culture of two cell types, e.g., so-called micro-patterned liver models containing hepatocyte and fibroblasts (Khetani et al. 2015)
3. 3D spheroids either in static culture or in a microfluidics system for at least 2 weeks use (Messner et al. 2013)
4. 3D organoids generated by seeding stem or progenitor cells into an ECM, which then differentiate into different cell types and arrange themselves into organ-like structures (Kretzschmar and Clevers 2016)
5. Microfluidic models for longer-term studies in which microfluidic flow mimics *in vivo* blood flow and shear stress (Marx et al. 2020; Fabre et al. 2020)
6. 3D-bioprinted models whose major goal is to reach an *in vivo*-like organ structure with the possibility to print blood vessels and which can be kept in either static or microfluidic modes (Mota et al. 2020)

Currently there is no consensus yet about the exact definition of MPS. Sometimes 3D spheroids or static co-cultures of at least two cell types are counted as MPS, that is, any culture design beyond simple 2D. In a narrower sense, an MPS should be composed of several cell types organized into an *in vivo*-like structure within a relevant ECM and equipped with flow or other mechanical cues. More advanced systems may contain immune system components.

For MPS models to be useful in preclinical testing and to allow better assessment of potential human safety issues than simple cell line models, they need to contain relevant cell types and should be evaluated for characteristic function of the organ they are supposed to model, including expected responses to a list of reference agents. Specific guidance is given for major organs like the liver (Baudy et al. 2020), lung (Ainslie et al. 2019), kidney (Phillips et al. 2020), and gastrointestinal tract (Peters et al. 2020). In the case of the liver, a recent example showed that it is possible to reproduce species-specific toxicities in an MPS format (Jang et al. 2019). Microfluidics systems also allow to combine different organ models in an *in vivo*-like circuit, which are called body-on-a-chip systems. With a liver-heart-on-a-chip

system with both hepatocytes and cardiomyocytes derived from the same hiPSC line, a clinically relevant drug-drug interaction could be modeled, in which inhibition of biotransformation of an arrhythmogenic to a non-arrhythmogenic drug in the liver MPS leads to arrhythmia induction in the downstream cardiac MPS (<https://www.biorxiv.org/content/10.1101/2020.05.24.112771v2>).

A challenge for many advanced models, especially of more elaborate 3D structures, is the introduction of blood vessels to allow supply of oxygen and nutrients in an in vivo-like manner. With 3D bioprinting such vessel structures can be integrated into organ models, as reported for a heart model which allowed the printing of contracting cardiac patches and of thicker vascularized tissues (Noor et al. 2019). To be able to print whole organs, this technology must still overcome many challenges, from recreation of the in vivo blood vessel network to producing sufficient amounts of mature cells. But even such small patches which can be printed already may be used for safety testing or developed toward disease models.

## Abstract

During the past decade regulatory toxicology has been changing its general approach, since it is implementing the “Toxicity Testing the 21st Century” (Tox21) vision proposed by the US National Research Council NRC to reduce and replace traditional safety testing in animals by more predictive toxicity data generated with human cell tissues and organs. New the Adverse Outcome Pathway (AOP) concept allows to integrate non-animal data with existing knowledge into computation models, which allow to predict adverse effects in humans and

the environment after exposure to hazardous chemicals with sufficient confidence for safety assessment. The OECD is closely collaborating with national regulatory agencies in Europe and the USA on implementing the AOP concept into “Integrated Approaches for Testing and Assessment” (IATA), which allow regulators to assess the results generated with the new AOP approach for specific endpoints. The Tox21 concept, which is relying on advanced technologies, using human stem cells, multiorgan-chips and in silico models will most probably prove that the future of toxicology will be in vitro.

## Challenges for Regulatory Testing in the Twenty-First Century

Regulators and the general public are facing increasingly complex challenges that require harnessing the best available science and technology on behalf of patients and consumers. Therefore, we need to develop new tools, standards, and approaches that efficiently and consistently assess the efficacy, quality, performance, and safety of products. However, up to now, the importance of regulatory science has not been sufficiently appreciated and it is underfunded. New scientific discoveries and technologies are not being sufficiently applied to ensure the safety of new chemicals, drugs, and other products to which consumers are likely to be exposed. In addition, members of the public are demanding that greater attention is paid to many more chemicals and products already in commercial use, but the existing testing systems do not have the capacity to deliver the in vivo data required. Thus, we must bring twenty-first-century approaches to twenty-first-century products and problems (Andersen and Krewski 2009).

Most of the toxicological methods used for regulatory assessment still rely on high-dose animal studies and default extrapolation procedures that have remained relatively unchanged for decades, despite the technological revolutions in the biosciences over the past 50 years. The new technologies allow to test tens of thousands of chemicals a year in high-throughput systems, and thousands of chemicals a year in organotypic cultures and low through-put systems. However, we now need to develop better predictive models, in order to identify concerns earlier in the product development process, to reduce time and costs involved in testing, and to reduce the loss of promising biological molecules due to false positive results. We need to modernize the tools used to identify potential risks to consumers who are exposed to drugs, new food additives, and other chemical products.

The challenge today is that the toxicological evaluation of chemicals must take advantage of the on-going revolution in biology and biotechnology. This revolution now permits the study of the effects of chemicals by using cellular components, cells, and tissues – preferably of human origin – rather than whole animals.

The novel regulatory science would take advantage of new tools, including functional genomics, proteomics, metabolomics, high-throughput screening, human-organs-on-a-chip, and systems biology, and could then replace current toxicology assays with tests that incorporate the mechanistic underpinnings of disease and of underlying toxic side-effects. This should allow the development, validation and qualification of preclinical and clinical models that accelerate the evaluation of toxicity during the development of drugs and other chemicals to which humans are exposed. The goals include the development of biomarkers to predict toxicity and screening at-risk human subjects during clinical trials, as well as after new products are made available on the market. The new methods also should enable the rapid screening of the large number of industrial chemicals that have not yet been evaluated under the current testing system, for example, according to the EU chemicals regulation (REACH).

The above-described new technologies enable to generate large datasets (also termed “big data”), which can be utilized in computational toxicology utilizing artificial intelligence tools and machine learning approaches. Currently, the global capacity to test chemicals thoroughly in traditional animal studies would probably not be more than 50–100 chemicals a year. By contrast, the new high-throughput methods developed in the US Environmental Protection Agency (EPA) *Comptox* program (Williams et al. 2017), involving the robotic systems at the National Center for Advancing Translational Sciences (NCATS) at the National Institutes of Health (NIH), could test 30,000 or more chemicals in several hundred functional tests within a year, while by using human cells and systems. This flood of new biological data would drive the development of more-satisfactory, more-predictive computer algorithms that could assist regulatory decision-making. With the addition of data from new human “multi-organ- chip” technologies (*see below*), the regulatory relevance of the data from the high-throughput systems (HTS) could be further refined (Rowan and Spielmann 2019).

---

## Adapting Toxicity Testing to the Challenges of the Twenty-First Century in Europe

To adapt toxicity testing to progress in the life sciences and to end toxicity testing in animals, in the 1980s, various government institutions of the European Commission (EC) and EU Member States promoted and funded the development and validation of *in vitro* toxicity tests, which were accepted at the international level by the OECD in the early 2000s. Initially, the research activities in Europe were stimulated by the requirements of the EU Cosmetics Directive (EC 2009) and were aimed at ending the suffering of experimental animals in safety tests for cosmetics, and especially in local toxicity tests on the skin and eye. The funding of research in the *Alternative Testing Strategies Programme* of the 6th (FP6) and 7th (FP7) EU Framework Programmes of the Research and Innovation Directorate General of the EC was quite successful, since, for this specific field of toxicology, *in vitro* tests were developed, validated, and accepted by regulators, and the full ban on animal testing

for cosmetic products manufactured or marketed within the EU finally came into force on 11 March 2013 (EC 2013). Although this was a unique success story, and represented a breakthrough from the scientific, regulatory, and ethical points of view, which was acknowledged around the world, those *in vitro* toxicity tests were based on the progress with *in vitro* culture techniques achieved in the twentieth century.

To speed up the change to challenges of the twenty-first century in collaboration with the cosmetics industry the EU FP7 multi-center SEURAT-1 project was established to replace repeat-dose systemic toxicity testing *in vivo* in animals. In addition, the EU launched another FP7 project, Accelerate (XLR8), to implement the transition to a toxicity pathway-based paradigm for chemical safety assessment, a concept proposed in 2007 by the US National Research Council (NRC) report, *Toxicity Testing in the twenty-first Century: A Vision and a Strategy* (NRC 2007).

---

## **The US Vision Toxicity Testing in the Twenty-First Century (Tox21) (US NRC 2007)**

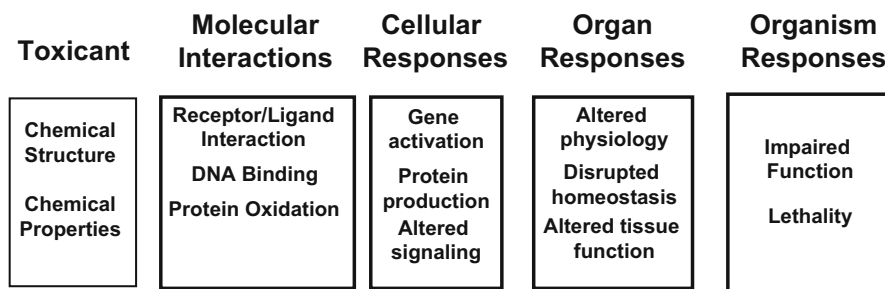

The new concept for a toxicity testing paradigm relies mainly on understanding “toxicity pathways” – the cellular response pathways that can result in adverse health effects when sufficiently perturbed (NRC 2007; Andersen and Krewski 2009; Krewski et al. 2010). In the new approach biological significant alterations are evaluated without relying on animal studies. In addition, “targeted testing” had to be conducted, to clarify and refine information from toxicity pathway tests for chemical risk assessments. Therefore, targeted testing in animals will become less necessary, as better systems are developed to understand how chemicals are metabolized in the human body, when applying only tests in cells and tissues. Testing in animals may then be phased out in the next 10–15 years, provided that more resources are devoted to improving regulatory toxicology.

A toxicity pathway refers to a chemically induced chain of events at the cellular level that may ultimately lead to an adverse effect such as tumor formation. Such pathways ordinarily coordinate normal processes, such as hormone signaling or gene expression. For example, a protein that, upon chemical binding, blocks or amplifies the signaling of a specific receptor could alter the pathway’s normal function and induce a “pathway perturbation.” Dose-response and extrapolation modeling will permit the translation of cellular tests to exposed humans. Specifically, the modeling will estimate exposures that would lead to significant perturbations of toxicity pathways, observed in cellular tests.

---

## **The Adverse Outcome Pathway (AOP) Concept**

The **adverse outcome pathway** (AOP) concept was proposed as essential element of the Tox21 vision by the US Environment Protection Agency (EPA), which defined that an AOP is a sequence of key events linking a **molecular initiating event** (MIE) to an **adverse outcome** (AO) through different levels of biological organization

**Fig. 1** The adverse outcome pathway (AOP) concept

(Ankley et al. 2010). AOPs span multiple levels of biological organization, and the AO can be at the level of the individual organism, population or ecosystem. Each AOP is a set of chemicals, biochemical, cellular, or physiological responses, which characterize the biological effects cascade resulting from a specific exposure (Ives et al. 2017). The key events in an AOP should both be definable and make sense from a physiological and biochemical perspective. By using the AOP approach, it is possible to identify endpoints of regulatory concern and to ask which toxicity mechanisms are most likely to lead to these outcomes. AOPs are the central element of a toxicological knowledge framework being built to support chemical risk assessment based on mechanistic reasoning.

Meanwhile, the AOP concept has been accepted by the international scientific community, and the OECD launched a new program on the development of **AOPs** in 2013 (OECD 2013). Consequently, the OECD requires that the AOP concept should be considered when new toxicity tests are introduced, or existing ones are updated (OECD 2017a, b). The **AOP knowledge base (AOP KB)**, set up by the OECD, is a formal Internet-based repository (<http://aopkb.org>) for information on AOPs. The content of the AOP KB, which contained 284 AOPs in March 2020, continues to evolve, as more information is gained on AOPs, their **key events (KEs)** and **key event relationships (KERs)**.

Approaches such as the development of AOPs and the identification of **modes of action (MoA)**, together with the use of **integrated approaches to testing and assessment (IATA)** (OECD 2017b) as the means of combining multiple lines of evidence, are seen as the fundamental pathway to the hazard identification and characterization of a chemical. MoAs and AOPs are conceptually similar: MoAs include the chemical specific kinetic processes of **Absorption, Distribution, Metabolism and Elimination (ADME)**, and describe the mechanism of action of the chemical in the human body, whereas AOPs focus on nonchemical specific biological pathways starting with a **molecular initiating event MIE** (e.g., binding to an enzyme), resulting in perturbations (KEs) leading to an AO at the organism level as outlined in Fig. 1.

An AOP is a conceptual framework that links a molecular-level initiating event with adverse effects relevant for risk assessment. Each AOP consists of a set of chemicals, biochemical, cellular, and physiological responses, which characterize

the biological effects cascade resulting from a specific toxic insult (Ankley et al. 2010). AOPs span multiple levels of biological organization. AOPs often start out being depicted as linear processes; however, the amount of detail and linearity characterizing the pathway between a molecular initiating event and an adverse outcome within an AOP can vary substantially, both as a function of existing knowledge and assessment needs (OECD 2017a).

---

## **Integrated Approaches to Testing and Assessment (IATA)**

Complex endpoints cannot be predicted by a single stand-alone non-animal test as it will never be possible to reproduce a whole organism, mainly due to the lack of kinetic relationships and cross-talk among cells, tissues, and organs (Rowan and Spielmann 2019). It is instead necessary to use integrated approaches to testing and assessment (IATA) based on a weight-of-evidence (WoE) approach, where information and evidence from a battery of tests can be incorporated (OECD 2017b). Data can then be integrated by means of modeling. This will lead to a shift toward the use of more human data in terms of biologically significant perturbations in key toxicity pathways.

IATA are scientific approaches to hazard to risk characterization, based on an integrated analysis of existing information coupled with new information by using testing strategies. IATA can include a combination of methods and integrating results from one or many methodological approaches ranging from flexible to rule based ones, so-called defined approaches. IATA should ideally be based on knowledge of the MoA by which chemicals induce their toxicity. Such information is, of course, quite often missing for complex endpoints, for example, carcinogenicity or developmental toxicity. This approach has been used successfully to partially replace skin sensitization testing in animals: the first three in vitro AOP-based OECD TGs have been adopted covering the skin sensitization AOPs for protein binding (TG 442C; OECD 2015a), as well as for keratinocyte activation (TG 442D; OECD 2015b) and dendritic cell activation (TG 442E; OECD 2016).

---

## **New Technologies**

During the last 30 years significant increase in knowledge and technology allows us today to conduct safety testing on human cells and on 3D tissue models and organoids rather than on animal models.

The first important step was the discovery and application of stem cells, in particular of embryonic stem cells (ESC) and of adult induced pluripotent stem cells (iPSC) from both animals and humans. At the same time perfused human 3D cell culture organ culture models, multiorgan-chips (MOC), were developed to model human diseases and also to study beneficial and adverse effects of drugs and other chemicals on human tissues and organs. Moreover, quite independently computer based virtual models of organ system have been developed, which

incorporate biological structure and extend the data from *in vitro* toxicity testing to a higher level of biological organization.

Advancing toxicology in the twenty-first century by applying the new technologies with human tissues – stem cells, perfused organ chips, 3D-bioprinting, virtual models, and use of artificial intelligence (AI) – will be highlighted in this section.

## Stem Cells as Advanced Tools in Predictive Toxicology

Stem cells have the ability to differentiate along different lineages and the ability to renew themselves. Stem cells are broadly classified into embryonic stem cells (ESCs) found in the embryo, stem cells isolated from adult tissues, and induced pluripotent stem cells (iPSCs). Along with self-renewal capacity, ESCs are pluripotent cells with the ability to differentiate into three embryonic germ cell layers. Almost 30 years ago, we developed the first stem cell-based toxicity test, the mouse embryonic stem cell test (mEST) (Laschinski et al. 1991), which has become most popular after it was successfully validated by ECVAM (Genschow et al. 2002) and we provided a robust protocol (Seiler and Spielmann 2011). Meanwhile, many variants of the EST have been developed and high-throughput-screening (HTP) variants are used during preclinical drug development.

The most apparent advantage of using hESCs instead of mESCs is to limit the possibility of false negatives that may arise due to species-specific differences. The advanced versions of the humanized hEST are using reporter genes and other biomarkers as endpoints for embryotoxicity. In the US ToxCast program the commercial hiPSC high-throughput assay (Stemina STM) that predicts the developmental toxicity potential based on changes in cellular metabolism following chemical exposure (Palmer et al. 2013, 2017), 1065 ToxCast phase I and II chemicals were screened in single-concentration or concentration-response for the targeted biomarker (ratio of ornithine to cystine secreted or consumed from the media). The encouraging results of this extensive study support the application of the Stemina STM platform for predictive toxicology and further demonstrate its value in ToxCast as a novel resource that can generate testable hypotheses aimed at characterizing potential pathways for teratogenicity and HTS prioritization of environmental chemicals for an exposure-based assessment of developmental hazard (Zurlinden et al. 2020).

Ethical issues of obtaining hESCs from human pregnancies have led to the development of hiPSCs generated from mature somatic cells and reprogrammed to a pluripotent state. hiPSCs possess properties of self-renewal and differentiation into many types of cell lineage that are similar to hESCs. In fact, owing to their ability to differentiate into all the lineages of the human body, including germ cells, stem cells, and, in particular, hiPSC can be utilized for the assessment, *in vitro*, of embryonic, developmental, reproductive, organ, and functional toxicities, relevant to human physiology, without employing live animal tests and with the possibility of high throughput applications. Noteworthy, patient-derived disease-specific hiPSCs with genetic background sensitive to disease pathology could provide evidence to understand disease mechanisms for developing and testing compounds. Although

variations in differentiation efficiency of various hESC lines may induce significant variability of experimental toxicity data, hESCs can help develop more reliable toxicity testing. Additional significant advantages in using human hESCs are unlimited self-renewal capabilities and differentiation into a variety of specialized cell types. Thus, stem cell toxicology will tremendously assist in the toxicological evaluation of the increasing number of synthetic chemicals that we are exposed to, of which toxicity information is limited.

## **Human-on-a-Chip (Multiorgan-Chip) Technology Applied to Toxicity Testing**

Pressures to change from the use of traditional animal models to novel technologies arise from their limited value for predicting human health effects and from animal welfare considerations (Andersen and Krewski 2009). This change depends on the availability of human organ models combined with the use of new technologies in the field of omics and systems biology, as well as respective evaluation strategies. Ideally, this requires an appropriate *in vitro* model for each organ system.

In this context, it is important to consider combining individual organ models into systems. The miniaturization of such systems on the smallest possible chip-based scale is envisaged, to minimize the demand for human tissue and to match with the high-throughput needs of industry (Huh et al. 2011; Esch et al. 2015). A multiorgan-chip technology has been developed, based on a self-contained smartphone size chip format, in a project funded by the German Ministry for Research and Technology (BMBF) (Marx et al. 2016, 2020). An integrated micro-pump supports microcirculation for 28 days under dynamic perfusion conditions. The inclusion of human organ equivalents for liver, intestine, kidney, and skin allowed ADME and toxicity (ADMET) testing in a four-organ-chip. The system holds promise for developing disease models for preclinical efficacy and toxicity testing of new drugs. An encouraging example is a human microfluidic two-organ-chip model of pancreatic islet micro-tissues and liver spheroids, which maintained a functional feedback loop between the liver and the insulin-secreting islet micro-tissues for up to 15 days in an insulin-free medium (Bauer et al. 2018), which is a promising simulation of human type 2 diabetes mellitus.

It has been hypothesized that exposure of *in vitro* assembled premature iPSC-derived organoids to the physiological environment of a **micro-physiological system** (MPS), such as perfusion, shear stress, electrical stimulation, and organoid cross talk in interconnected arrangements, might constitute the missing step for their final and complete *in vitro* differentiation. The final aim is to combine different “organoids” to generate a human-on-a-chip, an approach that would allow studies of complex physiological organ interactions. The recent advances in the area of induced pluripotent stem cells (hiPSCs, Ramme et al. 2019) provide a range of possibilities that include cellular studies of individuals with different genetic backgrounds, for example, human disease models. However, throughput remains a significant limitation and there will continue to be a need for emphasis on “fit-for-purpose” assays.

Since 2012, the NIH and the US Food and Drug Administration (FDA) have been funding a major multi-center program for development of a technology platform that

will mimic human physiological systems in the laboratory, by using an array of integrated, interchangeable engineered human tissue constructs — “a human-body-on-a-chip” (NIH 2012). The program, which is coordinated by the National Center for Advancing Translational Sciences (NCATS), intends to combine the technologies to create a microfluidic platform that can incorporate up to 10 individual engineered human micro-physiological organ system modules in an interacting circuit. The goal of the program is to create a versatile platform capable of accurately predicting drug and vaccine efficacy, toxicity, and pharmacokinetics in preclinical testing.

Results obtained with chips and microfluids systems indicate that static and dynamic conditions of *in vitro* cultures may provide significantly different predictions for some endpoints, but they also bring different view on the possibility of future *in vitro* assessment of the absorption, distribution, metabolization and excretion of drugs and xenobiotics. The developers of chips and microfluids systems anticipate that once these systems get validated for specific applications in toxicology, they will also be swiftly adopted into the pre-clinical stages of drug development. The new culture systems will be adaptable to the integration of future technologies, for example, advances in stem cell culture, 3D-bioprinting, and into personalized medicine using individual patient-derived tissue (Marx et al. 2020; Marrella et al. 2020).

### 3D-Bioprinting

3D bio-printing is a new type of tissue engineering technology that is expanding hand in hand with advances in material engineering and bio-polymer chemistry. In this technology, cell-laden biomaterials are used as “bio-inks” and raw materials. Compared to the classic tissue engineering that provided highly standardized *in vitro* skin and epithelial models, 3D bioprinting allows to produce highly organized 3D tissue models, which are physiologically and morphologically similar to their *in vivo* biological counterparts (Weinhart et al. 2019). In addition to vascularize the 3D-printed *in vitro* models, in combination with microfluidic and micro-physiological systems it offers a very promising platform for precisely monitored, long-term toxicity studies. It is expected that the 3D bioprinting technology will be used to construct tissues and organs with complex responses and will especially be applied in safety and efficacy studies of novel drugs.

The use of 3D bio-printed tissues and organs will also provide new approaches for high-throughput toxicity testing that will improve the prediction of human responses to chemical and drugs. In order to implement these technologies into the regulatory framework, it will be necessary to adapt the concept of “open-source” models and to integrate them it into existing TGs. The standardization and validation of these systems will be challenging but they are inevitable.

### Virtual Organ Models

Cell-agent based models are useful for modeling developmental toxicity by virtue of their ability to accept data on many linked components and implement a morphogenetic series of events. These data may be simulated (e.g., what is the

effect of localized cell death on the system?) or data derived from in vitro studies. In the latter case, perturbed parameters are introduced as simple lesions or combinations of lesions identified from the data, where the assay features have been annotated and mapped to a pathway or cellular process implemented in the virtual model. Whereas in the EPA ToxCast program predictive models are built with computer-assisted mapping of chemical-assay data to chemical endpoint effects (Judson et al. 2010), the virtual tissue models incorporate biological structure, and thus extend the in vitro data to a higher level of biological organization. A developing system can be modeled and perturbed “virtually” with toxicological data, then the predictions on growth and development can be mapped against real experimental findings.

The goal of the US “Virtual Liver” project is to develop models for predicting liver injury due to chronic chemical exposure, by simulating the dynamics of perturbed molecular pathways, their linkage with adaptive or adverse processes leading to alterations of cell state, and integration of the responses into a physiological tissue model. When completed, the Virtual Liver Web portal and accompanying query tools will provide a framework for the incorporation of mechanistic information on hepatic toxicity pathways, and for characterizing interactions spatially and across the various cells types that comprise liver tissue. The German BMBF funded Virtual Liver Project focuses on the establishment of a 3D model of the liver that correctly recapitulates alterations of the complex micro-architecture, both in response to, and during regeneration from, chemically induced liver damage <https://fair-dom.org/partners/virtual-liver-network-vln/>. The long-term goal will be to integrate intracellular mechanisms into each cell of the model, as many of the critical intracellular key mechanisms still need to be elucidated.

The US EPA program, the Virtual Embryo Project (v-Embryo™ <https://www.ehd.org/virtual-human-embryo/>), is a computational framework for developmental toxicity, focused on the predictive toxicology of children’s health and developmental defects following prenatal exposure to environmental chemicals. The research is motivated by scientific principles in systems biology, as a framework for the generation, assessment, and evaluation of data, tools, and approaches in computational toxicology. The long-term objectives are: to determine the specificity and sensitivity of biological pathways relevant to human developmental health and disease; to predict and understand key events during embryogenesis leading to adverse fetal outcomes; and to assess the impacts of prenatal exposure to chemicals at various stages of development and scales of biological organization.

## **Artificial Intelligence (AI) and Machine Learning**

High amounts of newly generated in vitro data present an opportunity for using artificial intelligence (AI) and machine learning to improve the knowledge on toxicity pathways and offer a broader insight into the safety assessment of chemicals

and mixtures. The upcoming decade will be certainly an era of “big data” requiring novel approaches to traditional methods of data analysis. This will present both a challenge and an opportunity for toxicologists and regulators. While in the twentieth century, the community only slowly accepted *in silico* as a discipline of toxicology, in the twenty-first century, we will be more and more exposed to the new QSARs, artificial intelligence and machine learning methods leveraging neural networks (Tang et al. 2019).

These technologies are very promising and already in use by the pharmaceutical industry and some regulatory agencies in the USA. They will reduce the use *in vivo* and *in vitro* experiments due to the predictions based on computational (“*in silico*”) modeling, which is risk-free, low-costly, and high-throughput. On the other hand, it will be a challenge to introduce these and more complex systems into the non-expert community.

---

## The Future of Toxicology Is *In Vitro*

The process of validation of new approaches needs to be reconsidered in terms of efficiency and time to completion (Rowan and Spielmann 2019). In particular, the scientific community needs to understand that if it is possible for advanced non-animal methods to meet some or all regulatory needs. Furthermore, the fate of the animal testing in this transitional phase toward IATA is unclear.

Therefore, it is not surprising, but encouraging, that by the end of 2017, in the USA the FDA and the NIH had published new roadmaps for toxicity testing, which were based on the new principles of safety testing without animals by employing the novel molecular and computational techniques, for example, the *FDA Predictive Toxicology Roadmap* (FDA 2017) and the *ICCVAM Strategic Roadmap for Establishing New Approaches to Evaluate the Safety of Chemicals and Medical Products in the United States* (ICCVAM 2018). In this context, the FDA makes the most pragmatic proposal, and suggests that “Rather than validation, an approach we frequently take for biological (and toxicological) models and assays is qualification. Within the stated context of use, qualification is a conclusion that the results of an assessment using the model or assay can be relied on to have a specific interpretation and application in product development and regulatory decision-making” (FDA 2017).

It is also very encouraging that, early in the twenty-first century, the US regulatory agencies are giving the “long sought goal of refining, reducing, and replacing testing on animals” the high priority that it deserves, both for scientific and for animal welfare reasons, in accordance with the hopes expressed 60 years ago by the pioneers of the Three Rs concept, William Russell and Rex Burch (1959).

**In conclusion, twenty-first-century technologies are providing multi-dimensional human data at the molecular and cellular level that will significantly advance regulatory toxicology.**

## Abstract

The increasing regulatory safety demands for the submission and registration of chemicals, pesticides, or pharmaceuticals as well as tightening animal protection legislation have exacerbated the dilemma of regulatory toxicology, where on the one hand the required scientific contributions for the protection of workers, consumers, or patients are constantly augmented while on the other hand the number of experimental animal studies should be reduced.

One way to resolve this dilemma could be the use of computer-assisted systems to predict toxic effects. These so-called “in silico” tools have experienced improvements in their performance and predictive power over the past three

decades. They are therefore able to contribute to hazard identification and risk assessment at least for some toxicological endpoints. However, knowledge of how these systems work, the importance of the underlying data quality, and their respective limitations are prerequisites for a sensible application.

---

## Introduction into the Principles of Predictive Systems

Providing a current overview of available predictive systems is not a meaningful exercise for a textbook since the pace of development would make such a list outdated at the time of print. Therefore, this chapter will rather focus on the illustration of the basic principles of predictive tools in toxicology, give an overview of the current fields of application, and provide an outlook on expected future developments.

Comparing a new substance of unknown toxicity to compounds with reasonable structural or biological similarities for which useful toxicological information exists in the scientific literature represents a significant effort. Searching publications to compare an unknown compound with a structure which has been toxicologically characterized would require knowing all the chemical and trivial names and synonyms of the old and new compound as well as subsequently carefully curating the collected literature information. For these reasons, the classical literature search is often replaced by database searches, especially if these databases allow for structure or substructure (i.e., a smaller moiety contained in the larger chemical structure) queries. The structural comparison is performed in the context of the toxicological endpoint of interest. Once the user is convinced that the chemical structures retrieved in the database search is sufficiently similar to the new compound, they can *read-across* any findings from the existing compounds and data in the database and thereby come to conclusions regarding potential toxicological issues of the new compound. The number of publically or commercially available toxicology databases is constantly growing. Particularly in the field of pharmaceuticals, endpoint-specific databases have evolved (Luo et al. 2017); however, the possibility for structural searches is still a rare feature. A list of the most relevant databases is included at the end of this chapter.

With the accumulation of toxicological data around a specific endpoint, it has become possible to generate relationships between chemical structure and toxicological effect. Structure activity relationships (SARs) can be performed by correlating both the chemical structures with the toxicological data. The resulting SAR can then be coded into a computer program which is able to read in a new chemical structure, recognize the presence of structures or substructures for which toxicological data is available. The results are then presented to the user with an estimate of the toxicity of the new structure. In principle, there are two different approaches for constructing SAR: expert system and quantitative structural activity relationships, though hybrid systems combining the two underlying methods have been developed over the recent decade.

*Expert systems*, the most commonly used of which is DEREK (*Deductive Estimation of Risk from Existing Knowledge*) from Lhasa Ltd., analyze the compound under investigation for substructures with toxicological relevance. Usually an expert system provides the information (rule) why a specific (sub-)structure causes a warning (“alert”) such as “acid halides may cause skin sensitization.” This offers the opportunity to the user to assess the plausibility of the alert. Many of the well-established alerts have been made available in the public domain, i.e., a user may screen a compound of interest via internet-based tools (Sushko et al. 2012). In the original versions of expert system, such alerts related almost exclusively to the graphical comparison of the two-dimensional (2-D) chemical structure, i.e., conformational changes of a molecule are ignored. Other properties such as the physicochemical nature of the compound, which can significantly influence the toxicological properties of the chemical under investigation, are not necessarily accounted for, though they may influence the occurrence of toxicity. This shall be illustrated for the prediction of the endpoint skin sensitization. For a chemical to cause skin sensitization, a particular reactivity with proteins is required to elicit the immune response. To identify the chemical reactivity knowing the 2-D structure of the compound often suffices. However, the reaction with skin proteins can only occur if the compound shows penetration into the skin. Skin absorption is a parameter which cannot always be derived from the 2-D structure of the chemical, but rather requires knowledge of additional properties (“descriptors”) to determine the lipophilicity or the octanol-water partition coefficient of the compound which correlate with skin penetration. Advanced Expert systems thus calculate the parameters for reactivity and absorption individually and then combine these values with a prediction of the chemical reactivity using “if...then” rules.

An alternative approach to Expert systems is the *quantitative structure activity relationship* (QSAR). QSAR systems (represented in commercial systems like Leadscope, Sarah Nexus [Lhasa Ltd.], MultiCASE, TOPKAT [BIOVIA], or freely available systems implemented in the OECD Toolbox) use chemical, physicochemical properties, or other descriptors such as molecular fragments, indices of electron density, or polarity and correlate them with either the binary outcome of an experiment (positive or negative such as “mutagenic” or “non-mutagenic”) or a quantitative (or continuous) outcome, e.g., number of revertants in an Ames mutagenicity assay, inhibition constants of an enzyme, receptor, or ion channel (Tropsha 2010). In its simplest form, the relationship can be calculated based on a linear or nonlinear regression. The quality of the correlation can then be assessed by calculating the partial least squares regression. In case more descriptors are used to characterize compounds, multivariate statistics are applied. The statistical methods to establish these correlations are numerous and beyond the scope of this chapter. The choice of both the descriptors and the statistical method to correlate toxicological outcome with the chemical structure is dependent on the nature of the data set and size as well as the toxicological endpoint (how many details of the toxic effects shall be modeled). One way to characterize the chemical structure is the use of so-called fingerprints which are able to cover several fragments contained in a structure.

Depending on the available computer power also the 3-D conformation, which can be of relevance if the toxic effect is caused by binding to receptors or enzymes, can be included. To calculate the correlation between the fingerprints and the biological effects, powerful statistical machine learning algorithms (neural network, support vector machine, random forest) are applied. The drawback of these methods is that they sometimes suffer from a lack of interpretability, either because the underlying mechanisms of toxicity cannot easily be identified for endpoints such as hepatotoxicity, or the interpretability is hindered by the lack of an ability within the machine learning algorithm to clearly identify what structural features or properties of the molecules are contributing to the toxicity endpoint (Hasselgren et al. 2013). To allow for interpretation of QSAR models, the dataset that has been used to “train” the model should always be made available in order to be able to assess in how far a new compound is covered by the original training set (the “applicability domain,” discussed below). This is critical for the interpretation of the outcome of the model as discussed in the following sections.

---

## Assessment of Predictive Systems

The prediction quality of *in silico* tools can be described with similar statistical parameters also established for medical diagnostic procedures. The predominant criteria are *sensitivity*, *specificity*, and *accuracy*. A definition for these parameters and further assessment criteria are provided in Table 1.

---

### Definitions

*Sensitivity (true positive rate)*: The ability to predict positives when they actually exist

*Specificity (true negative rate)*: The ability to predict negatives when they actually exist

*Positive predictive value*: The ability of the predictive system to distinguish between true positives and false positives

*Negative predictive value*: The ability of the predictive system to distinguish between true negatives and false negatives

*Overall (observed) accuracy (concordance)*: The total number of correct predictions divided by all examples

In order to determine sensitivity and specificity, a certain amount of compounds with known toxicological properties, usually those which have not been used in the development of the model (“validation set,” which is not included in the “training set”) are predicted in a given model or system. The predicted effects are then compared to the effects observed in the actual experiment. The simple example of a two-class categorical model is shown in Table 1 and can be applied to binary models of the type “toxic” or “nontoxic,” i.e., are particularly relevant for hazard

**Table 1** Confusion matrix for a categorical two-class model

		Experimental outcome		
		Test positive	Test negative	
Prediction outcome	Predicted positive	<b>True positive (TP)</b>	<b>False positive (FP)</b>	Positive predictive value TP/(TP + FP)
	Predicted negative	<b>False negative (FN)</b>	<b>True negative (TN)</b>	Negative predictive value TN/(FN + TN)
		Sensitivity TP/(TP + FN)	Specificity TN/(FP + TN)	

identification (e.g., prediction of mutagenicity) or where cut-off values are used to distinguish between toxic and nontoxic. It has to be noted though that the calculation of these parameters is always dependent both on the data set used to develop the model as well as on the compounds selected for prediction, i.e., the parameters do not represent absolute or constant quality indicators for a specific model (Simon-Hettich et al. 2006). Even for well-established endpoints such as mutagenicity, these parameters may vary widely, but as a rule of thumb values above 80% indicate good model performance (Sutter et al. 2013).

As noted above, many toxicological-relevant endpoints are recorded as continuous variables, e.g., inhibition of a receptor or a cellular transporter. In these cases, the confusion matrix cannot be used, but rather a QSAR's predictive performance has to be evaluated by an analysis of correlation between the predicted values and observed values for compounds which are not included in the training set. A common parameter for assessing the quality of the QSAR is the root mean squared error (RMSE), i.e., the standard deviation of the residuals between predicted and measured toxicity. RMSE evaluation has become a quality-preferred parameter for QSARs since it relates the prediction error, as an expression of RMSE, with the experimental error which is frequently expressed as RMSE as well (Alexander et al. 2015).

Regardless of the data type or evaluation method, the results of such comparisons are not absolute, but again rather dependent on the training set.

The selection of the structures for building the expert or QSAR system determines the quality of the predictions. Many QSAR systems are built on data from industrial chemicals or pesticides as abundant data sets are available in the public domain for these compound classes. As a consequence, these systems are predictive primarily for a similar so-called chemical space, i.e., for structures which have similar chemical properties. Predictions for other areas of chemical use, especially for pharmaceuticals tend to perform worse in these systems for above-mentioned parameters. Comparisons of industrial chemicals, pesticides, pharmaceuticals, and food-related chemicals show that these various classes are both chemically and toxicologically distinct and should probably be modeled separately. As a consequence, it is now common practice to provide information on the prediction limits of the model or

system, otherwise known as the “domain of applicability.” The domain of applicability usually represents the chemical domain for which robust prediction can be made based on the selected training set. A common approach to assess the domain of applicability lies in the analysis of chemical similarity of the compound under investigation with the list of compounds used to build the system. Alternatively, a system could be split up on several “local” models, each of which represent a distinct chemical class for which it can be applied (e.g., prediction of ecotoxicity of different classes of environmental pollutants in silico tool ECOSAR provided by the US Environmental Protection Agency [EPA]).

Even if the chemical space for a specific model is wide and the underlying training set is of good quality, a perfect concordance between prediction and the experimental result should not be expected. Several factors prevent obtaining a perfectly predictive SAR or QSAR system. Paramount among these factors is the toxicological endpoint itself. Most endpoints are observations of a complex series of biochemical and biological events that culminate in an observed toxicity. Many toxicological observations can be caused by more than one mechanism and thus expecting a single chemical structure-toxicity relationship to reflect these various mechanisms is expecting too much from both the method and the data. The second layer of complexity in toxicological data is data reproducibility. Inter-laboratory variability means that even well-known and mechanistically simple (relatively speaking) endpoints like the Ames mutagenicity assay have an imperfect concordance and thus a “positive” in one laboratory may be “negative” in another (McCann et al. 1984). While perfectly understandable, variability in the underlying data means that SAR or QSAR models built with these data will possess inherent limitations in prediction. Regarding the prediction of human safety, the translatability of preclinical toxicological outcomes to human effects is also an issue. A comparison of effects reported in animal studies with those observed in humans results in a concordance which ranges around 60%, where some endpoints show a better predictivity than others (Olson et al. 2000). It should be noted that a perfect concordance between preclinical toxicological outcomes and human outcomes may not be possible due to the fact that many substances which are found to have significant toxicity in preclinical models (animals, in particular) are never administered to humans and thus the completeness of the preclinical-clinical comparison datasets may always pose a validation challenge. Thus, predictive systems built on data from animal studies will not be able to achieve a better prediction of human effects than the animal studies themselves. However, higher concordance rates should be achievable for specific human endpoints if mechanistic information is integrated into the models and the specific mechanisms are linked to human outcomes.

*Data quality assessment* is one of the cornerstones of good SAR and QSAR modeling practice. Whereas expert systems often reference the scientific literature and thus allow the user to assess the quality of the data used, such a quality assessment (was the study performed according to international guidelines, according to GLP regulations, was the study published in a peer reviewed journal, etc.?) is often difficult to evaluate in QSAR systems because the supporting quality

information of the training set is only rarely made available. Data quality assessment schemes have been developed for regulatory context to assess both relevance and reliability of experimental data (Klimisch et al. 1997; Kaltenhäuser et al. 2017). These schemes also provide a systematic way to combine data of similar quality for the development of predictive tools. In addition to questions regarding data quality, often there are issues with data completeness as well. The construction of toxicological QSARs relies mainly on data from experiments for which a toxic effect was recorded. The unfortunate consequence of this is that negative effects, i.e., the absence of any effect, are only rarely published in the scientific literature. As a consequence QSAR training data sets collected from the scientific literature often show an overabundance of compounds which cause toxicity even though in the experimental system actually very few positive compounds were observed, i.e., the training set is often unbalanced. For example, in the Registry of Toxic Effects of Chemical Substances (RTECS), which was initially curated by the US National Institute for Occupational Safety and Health (NIOSH), the endpoint mutagenicity contains only compounds which show a positive effect in the different assays for genotoxicity. Negative results, i.e., nonmutagenic outcomes are not reported. Systems built on such databases risk overpredicting the effects under investigation. Such systems usually have a high sensitivity at the cost of a low specificity, i.e., many compounds are forecast to be mutagenic, even though they might contain certain properties (e.g., groups causing steric hindrance) which prohibit the activation to a mutagenic intermediate. Such compounds might have been tested but are not published and therefore their negative effects are not reflected in the QSAR. This situation is gradually improving, as the scientific community begins to see the utility of publishing and sharing data showing that a certain compound has been characterized for a toxicological effect and been found to be negative.

In order to resolve some of these issues, initiatives or consortia which gather unpublished data for the construction of new predictive tools have been formed. The advantage of such initiatives is the possibility of sharing unpublished, proprietary data and structures in a controlled way. This approach is particularly important for the pharmaceutical industry. In this field, only very few toxicological studies are published in comparison to the number of compounds that is actually experimentally evaluated, but fail to become drugs for various reasons. As an example, the eTOX project (“electronic toxicity”) performed under the European Innovative Medicines Initiative over the last years developed a preclinical drug safety database of unpublished systemic toxicity results of more than 8000 animal studies, which can now be used for read-across or predictive tool development (Steger-Hartmann and Pognan 2017).

---

## Use of Predictive Tools in Regulatory Toxicology

In 2004, the OECD guidance document on principles for the validation of (Q)SAR was adopted (OECD 2004). In 2008, the first version of the OECD QSAR Toolbox was released. The OECD Toolbox is intended to be used in the context of European

*industrial chemical assessment* and registration REACH (Regulation, Evaluation, Authorization, and Restriction of Chemical Substances) (OECD 2013). The toolbox represents a collection of databases, tools for read-across, and predictive systems. The systems allow for retrieval of structurally similar compounds which have already been assessed or are registered and for which toxicological data are available. Based on these comparisons, the systems provide data for read-across and expert hypotheses on potential effects for the compound without toxicity data.

In an alternative approach, the REACH data available via IUCLID (International Uniform Chemical Information Database) was subjected to a complex analysis of chemical fingerprints, similarity measures, and machine learning algorithms to derive prediction systems for six human health hazards (skin sensitization, eye irritation, acute oral toxicity, mutagenicity, skin irritation/corrosion, acute dermal toxicity) (Luechtefeld et al. 2016). The software was subsequently commercialized under the name of REACHAcross™.

In the US-EPA initiative ToxCast, which is part of the Toxicology in the twenty-first century (Tox21) US federal agency collaboration, more than 8000 chemicals (industrial, consumer and environmental chemicals as well as drugs) have been investigated in a multitude of high-throughput assays for different endpoints (gene expression, enzyme inhibition, receptor binding, cell cycle arrest, etc.). The data sets have been made publicly available through the ToxCast Dashboard (<https://www.epa.gov/chemical-research/toxcast-dashboard>) and can be used for read-across particularly regarding mechanistic hypotheses on chemical actions or for establishing new predictive models, e.g., for endocrine disruption through activity on estrogen receptors. Several predictive models have been developed based on this data set which fulfills many of the criteria discussed above regarding data quality and consistency.

For *cosmetics and toiletries*, the Cosmetics Regulation (replacing the Cosmetics Directive 76/768/EEC) resulted in a complete ban of animal studies for the human risk assessment of cosmetics since 2013, irrespective of the availability of alternative nonanimal methods. While in vitro replacement methods for a number of the endpoints have been developed such as skin and eye irritation or skin sensitization and found international regulatory acceptance, this is not the case for the more complex endpoints such as repeated-dose toxicity or reproductive toxicity. In 2013, the OECD (revised guidance: OECD 2017) proposed a concept to approach these complex endpoints with the help of “adverse outcome pathways” (AOPs), which “delineates the documented, plausible, and testable processes by which a chemical induces molecular perturbations and the associated biological responses which describe how the molecular perturbations cause effects at the subcellular, cellular, tissue, organ, whole animal and population level.” The objective of AOPs is to identify the crucial mechanistic steps which lead to the effect observed in vivo. Based on these analyses, replacement methods or predictive tools can be built which represent these mechanisms. Currently, skin sensitization is the only endpoint which has been successfully deconvoluted with the AOP approach into three in vitro assays replacing the in vivo study (local lymph node assay in mice). It has also triggered numerous approaches to combine the in vitro results into prediction models for this

endpoint, though a model with broad regulatory acceptance is yet not available. Despite these efforts in AOPs, a complete replacement of animal studies for cosmetics assessment is not possible within the near future.

Currently, the only case where the exclusive use of *in silico* tools has achieved regulatory acceptance is the assessment of potentially mutagenic impurities in *pharmaceuticals* (ICH M7(R1) 2017). Impurities may occur in the drug product from degradation of the active pharmaceutical ingredient or as remaining traces of synthetic intermediates. In many cases, these impurities occur in extremely low concentration and/or are unstable or reactive making it impossible to be isolated and tested separately in *in vitro* or *in vivo* assays. As long as the chemical structure has been elucidated, the DNA reactive (mutagenic) potential of such an impurity may be assessed with predictive tools (Glowienke and Hasselgren 2010; Sutter et al. 2013). If such an assessment based on *in silico* tools (usually an expert system and a QSAR methods are applied) does not identify a structural alert for mutagenicity, and the prediction of a lack of mutagenic potential can be supported by expert knowledge (i.e., read-across of pre-existing data), the mutagenicity assessment exclusively based on *in silico* prediction is usually accepted by the regulatory authority.

---

## Future Perspectives

The last decade has seen the gradual obliteration of the boundaries of classical read-across, trend analysis, and *in silico* prediction particularly for the purpose of closing data gaps in the field of industrial and consumer chemical safety assessment. It has become evident that the application of predictive tools not only speeds up the process, but may also lead to standardization and a higher reproducibility. On the other hand, it is also obvious that the prediction of *in vivo* toxicities is still a remote goal, particularly when it comes to predict the exposures at which toxic effect might occur, which is, however, paramount for risk assessment particularly in the pharmaceutical domain.

Four areas of development are identified, which will contribute to the advancement of the tools in the future:

1. Enhanced availability of high-quality standardized and curated data: Besides providing access to large data sets as done by EPA (ToxCast) or ECHA (REACH database), regulatory agencies undertake efforts to standardize toxicity data used for submission. The FDA has required since 2016 that the pivotal preclinical studies are submitted according to the Standard of Exchange of Nonclinical Data (SEND). Industry consortia have been established to also collect and share such data for the purpose of read-across and data mining (e.g., IMI eTransafe; <http://www.etransafe.eu/>).
2. New approaches to data analyses and visualization: As soon as the more complex data from systemic toxicity studies are used for data mining and development of predictive tools, the classical two-class or regression models will not suffice to fully represent evident or hidden relationships between chemical structure and

toxicity. Neural networks or so-called deep learning approaches might contribute to uncover some additional underlying knowledge. In addition, automated ways to intuitively visualize both the data mined in these large data sets as well as predictive outcome for large data sets are being developed. It is also foreseeable that these new approaches will provide inroads to definitions of “biological similarity” complementary to the chemical similarity which currently still represents the backbone of predictive models.

3. Quantitative adverse outcome pathways (qAOPs) and systems toxicology: The concept of AOPs has contributed to a better mechanistic understanding of certain toxicological processes and has imposed more discipline in parsing the various molecular mechanisms that could contribute to a toxicological outcome. In order to make AOP applicable for risk assessment, the quantitative aspect of pathways is required to predict tipping points, where a key initiating event changes from an adaptive process into toxicity. Systems toxicology, i.e., the integration of classical toxicology with quantitative analysis of molecular and functional changes occurring across multiple levels of biological organization together with technologies for predicting organ or tissue exposure will help facilitate the step from *in silico* hazard identification to *in silico* risk assessment.
4. Improved methods to determine applicability domain and uncertainty of prediction: The level of trust in predictive models is largely dependent on the definition of boundaries of what they can predict and what they cannot. Methods for evidence combination which take into account the sources of uncertainty throughout the modelling process (including applicability domain) and express the resulting prediction as a probability while still maintaining transparency regarding the sources of uncertainty in the conclusion will contribute to the improvement and ultimate acceptance of predictive models in risk assessment.

---

## Resources

List of noncommercial toxicological internet data sources including a short description:

CTD (Comparative Toxicogenomics database; a publicly available database focusing on gene expression data that aims to advance understanding about how environmental exposures affect human health. Structure-based searches are not possible): <http://ctdbase.org/>

COSMOS (toxicological data and information from regulatory submissions and the literature, focusing on chronic toxicity assessment. The database was developed in the framework of the European SEURAT project. Structure-based searches are possible): <http://www.cosmostox.eu/what/COSMOSdb/>

DrugBank (a chem- and bioinformatics resource supported by the Canadian Institutes of Health Research that combines drug (i.e., chemical, pharmacological and pharmaceutical. Structure-based searches are not possible) data with drug target information): <https://www.drugbank.ca/>

DSSTox (Distributed Structure-Searchable Toxicity Database; a resource for public chemistry data, including bioassay and physicochemical data maintained by US EPA. Structure-based searches are not possible): <https://www.epa.gov/chemical-research/distributed-structure-searchable-toxicity-dsstox-database> Chemicals from the DSSTox can be either downloaded as sd files or accessed via the two dashboards:

- ToxCast (EPA's ToxCast data can be queried for assays and chemical names or CAS numbers): <https://actor.epa.gov/dashboard/>
- Chemistry Dashboard: <https://comptox.epa.gov/dashboard>

eTOXsys (user interface of the IMI eTOX project containing a sample set of systemic toxicity studies and predictive tools developed in the project): <https://etoxsys.eu/etoxsys.v3-demo-bk/dashboard/>

IUCLID (REACH study results; a collection of nonconfidential substance data that was submitted to ECHA under the REACH regulation): <https://iuclid6.echa.europa.eu/reach-study-results>

LiverTox (a database hosted by the US National Library of Medicine providing information about drug-induced liver injury caused by prescription and nonprescription drugs, herbals, and dietary supplements): <https://livertox.nih.gov/>

Liver Toxicity Knowledge Base (LTKB) (a database hosted by the FDA containing drugs whose potential to cause DILI (Drug-Induced Liver Injury) in humans has been established using the FDA-approved prescription drug labels): <https://www.fda.gov/ScienceResearch/BioinformaticsTools/LiverToxicityKnowledgeBase/default.htm>

### National Toxicology Program

- Tox21 Toolbox (tools for visualizing dose-response curves or profiling activities of the compounds tested within the Tox21 program): <https://ntp.niehs.nih.gov/results/tox21/tbox/>
- Tox21 Data Browser: <https://tripod.nih.gov/tox21/index>
- Drug Matrix Database (toxicogenomic reference resource for drugs and environmental chemicals): [https://www.niehs.nih.gov/drug\\_matrix](https://www.niehs.nih.gov/drug_matrix)
- TG-GATES database (public toxicogenomics database supported by the National Institutes of Biomedical Innovation, Health and Nutrition containing data on gene expression and detailed toxicity data from rats and the primary cultured hepatocytes of rats and humans): <http://toxico.nibiohn.go.jp/english/index.html>
- ToxNet (resources for searching databases on toxicology, hazardous chemicals, environmental health, and toxic releases maintained by the US National Library of Medicine. Structure-based searches are not possible): <https://toxnet.nlm.nih.gov/newtoxnet/toxline.htm>
- Subsets of mutagenicity and reproductive toxicity data (DART) can be found:
  - <https://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?GENETOX>
  - <https://toxnet.nlm.nih.gov/newtoxnet/dart.htm>
- Toxic Exposome Database (formerly called T3DB, a database supported by the Canadian Institutes of Health Research with a focus on providing mechanisms of toxicity and target proteins for chemical compounds. Structure-based searches are possible): <http://www.t3db.ca/>

## Abstract

Most small drug molecules are metabolized in the liver and other drug-metabolizing organs. This has considerable consequences: The available concentration of the original active compound decreases, and metabolites may possess a

pharmaceutical or toxic activity. Advanced separation and detection methods are used in drug development to reveal the complete metabolic pattern. Likewise, protein-based biopharmaceuticals tend to get degraded in the living organism by proteinases, or are otherwise modified, yielding potentially toxic products.

The importance of drug metabolism in drug development and for drug safety is discussed, and common investigation techniques described.

---

**Introduction**

Investigations on the metabolism of drugs are meaningful for two reasons. Firstly, drug metabolites can be pharmacologically active or cause adverse reactions via on-target or off-target interactions. Secondly, potential interactions with other co-medications are linked to metabolic enzymes which can be investigated in suitable *in vitro* test systems. Both provide predictive information to assess the potential risk for patients before approval of a drug and even before the first clinical trials and thus, contribute to the minimization of risk for healthy subjects and patients in clinical trials. The strategies and approaches assessing the metabolism of small molecule drugs – also known as new chemical entities (NCE) – are well established with defined study packages throughout the discovery and development phase, and with regulatory guidance provided by the authorities. In contrast for the emerging biotherapeutic drugs – also known as new biological entities (NBE) – the current situation is more unclear and therefore is not the focus this book chapter.

---

**Profiles and Structure Elucidation**

To properly assess the impact of metabolites on efficacy and safety, it is necessary to have some knowledge of their structure and concentrations in the body.

As a rule of thumb, 70% of drug-related material of an NCE, present either as parent compound or metabolites, excreted via urine and feces or circulating in blood, should be structurally identified in animals and human. These investigations typically employ radiolabeled drugs in order to quantify drug and metabolite concentrations in various biological matrices regardless of the knowledge of the chemical structure. Radionuclides applied are typically carbon-14 [ $^{14}\text{C}$ ] and tritium [ $^3\text{H}$ ] due to ease of use, the synthetic accessibility, and the analytical traceability without change of the biological properties of the investigational compound.

**Fig. 1** In vitro-test systems used for metabolism studies in comparison to in vivo models

## In Vitro Test Systems

In vitro investigations on metabolism give rise to basic information on the biotransformation of a compound before animal studies or clinical investigations. Drug metabolism is due to biotransformation during transfer into the systemic elimination, e.g., for orally administered compounds, a potential degradation in the gastrointestinal tract and in the gut mucosa, or for inhaled compounds, biotransformation happens in lung tissue. After oral absorption, the liver is the main site for drug metabolism and can be involved in the first-pass elimination of a drug before it attains the systemic circulation. Special compound classes, e.g., peptides, predominantly undergo metabolism in the kidneys, other compounds such as many prodrugs are prone to metabolism by plasma esterases.

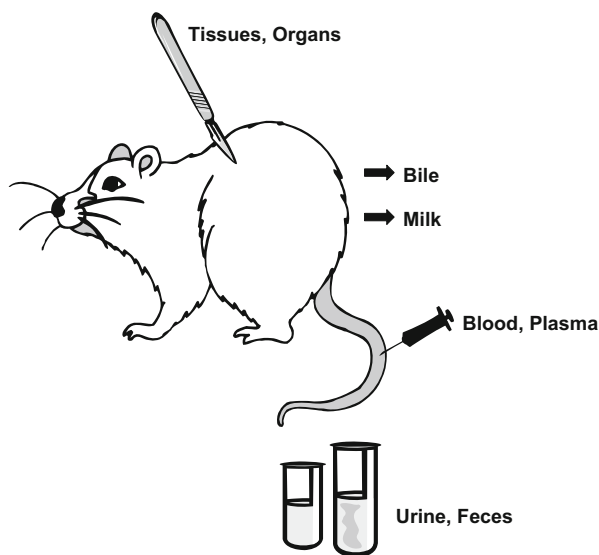

For the selection of the suitable in vitro test system, e.g., to investigate the metabolism in the liver, predictivity of in vitro–in vivo extrapolation ranges from whole liver perfusion studies to recombinant enzymes as shown in Fig. 1. In other words, decreasing complexity of a test system decreases their accuracy of prediction in the clinical state but allows rapid implementation and higher throughput. Selection of a particular test system depends on the required information at key decision points along the value chain of research and development (Dudda and Kuerzel 2006).

## In Vivo Test Systems

Metabolism investigations in the whole body are key to obtain a complete picture of qualitative and quantitative biotransformation of a drug. Radiolabel studies are the method of choice in order to exhaustively detect and quantify all metabolites, including structurally unknown ones or those for which no reference compounds

are available (e.g., to allow quantification using standard bioanalytical assay methods). Moreover, use of radiolabeled compounds facilitates validation of sample processing for matrices like feces, organs, and tissue homogenates by determination of extraction yields or recoveries. The selection of animal species for these investigations is determined by the species used in chronic toxicology studies, both a rodent and a non-rodent species, in general rat and dog, as well as those additional species used in carcinogenicity (mouse) and embryofetal studies (rabbit). The human ADME study, investigating absorption, distribution, metabolism, and excretion in humans, is of particular importance to detect and quantify all human metabolites. The radiolabeled study in animals can help to define the human NOAEL (no-observed-adverse-effect level) dose and to help set a dose for human ADME study (Krone et al. 2011). Important matrices for analysis in the animal radiolabeled study are blood, plasma, urine, fecal homogenates, and in addition to animals' bile, milk, organs, and tissues (Fig. 2). Of importance is the difference in the metabolism due to sex, dose, race age, as well as possible persistent accumulation of the drug and/or its metabolites in organs and tissues as indicated in tissue distribution studies. Alternatively, to the classical human ADME study, a radiolabeled "microtracer" study could be applied with negligible amount of radioactivity, respectively of carbon-14. This study type allows the detection of drug related material with long internal exposure time, due to low systemic elimination of the drug and/or metabolites, or due to covalent binding to endogenous material. Though the sensitive detection of carbon-14 requires costly accelerated mass spectrometry (AMS) analytics, human metabolites can be monitored with this method already in the early clinical phase I studies (Frédéric et al. 2018).

**Fig. 2** Important matrices for in vivo metabolism studies

## Structure Elucidation of Metabolites

Samples from in vitro studies, as well as radioactive ADME studies in animals and humans, and high dose nonradioactive in vivo studies are collected in order to elucidate metabolite structures by suitable techniques such as mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy, often coupled with liquid chromatographic methods (“LC-MS,” “LC-NMR”), often after complex and time-consuming concentration and purification steps. The application of radio-labeled material enables the quantification and definitive detection of drug-related material. Pending on the radionuclide, on the amount and specificity of the radioactivity, and the demand of sensitivity, various detection methods (online with LC/ offline in fraction collected/accelerated mass spectrometry) can be applied.

A definitive identification of the structure of relevant metabolites (abundant and/or pharmacologically active) is the prerequisite for their chemical synthesis. Availability of metabolites for further tests allows the bioanalytical quantification in all toxicological and clinical pharmacokinetic studies.

---

## Regulatory Considerations on Metabolites in Safety Testing

For the safety assessment of a NCE and its metabolites recommendations are provided by Food and Drug Administration (FDA) (*Safety Testing of Drug Metabolites – Guidance for Industry, Revision 2, Final, March 2020*) and the European Medicines Agency (EMA) (*ICH guideline M3(R2) on nonclinical safety studies for the conduct of human clinical trials and marketing authorization for pharmaceuticals, Revision 2 adopted guideline, December 2009*).

Generally, the safety testing of the metabolites is regarded as sufficient if the metabolic profile in humans is similar to that in at least one of the animal species used in nonclinical toxicological studies. But metabolic profiles “*can vary across species both quantitatively and qualitatively, and there are cases when clinically relevant metabolites have not been identified or adequately evaluated during non-clinical safety studies*” (FDA). The guidelines advice the early identification of metabolites “*found only in humans (unique human) and is absent in the animal test species, or if the metabolite is present at disproportionately higher levels in humans (human disproportionate) than in the animal species used in the standard toxicity testing with the parent drug*”(FDA). “*In vitro metabolic profile data for animals and human should be evaluated before initiating human clinical trials*” (EMA).

The focus is on metabolites formed from Phase I reactions (e.g., by oxidation, hydroxylation). These are more likely to be chemically reactive or pharmacologically active than Phase II conjugation products, with the exception of acyl-glucuronides. Both guidelines refer to a threshold of greater than 10% of total drug-related exposure at steady state of human metabolites that can raise a safety concern, and thus recommend the identification of the differences in metabolism as “*early as*

*possible in the drug development*” (FDA) or at least *“before exposing large numbers of human subjects or treating long duration”* (EMA).

For assessing metabolite safety, the FDA guideline provides detailed information on the different approaches for metabolite identification including recommendations of studies (general toxicity, genotoxicity, embryo-fetal development toxicity, carcinogenicity) needed to characterize the adverse potential of the disproportionate human metabolite.

---

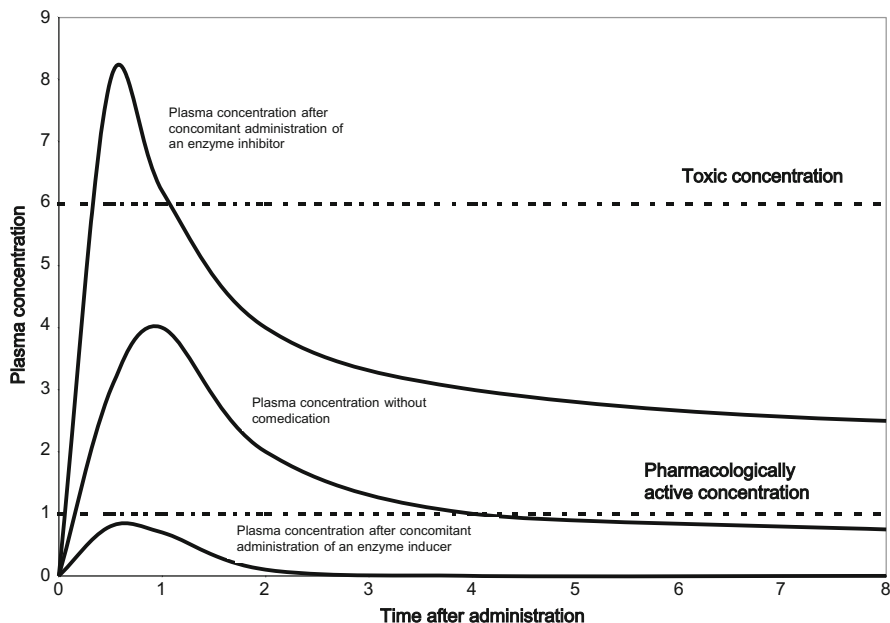

## **Investigation of Drug–Drug Interactions**

A drug is intended not only to be pharmacologically active with as little toxicity as possible but also as safe as possible in relation to both individual genetic differences of patients and concomitant administration of other drug(s). In the latter cases, only human *in vitro* metabolism systems are able to predict safety in human due to the lack of relevance of animals, due to significant enzymatic differences between animals and human. These *in vitro* experiments are the prerequisite to time-consuming, costly, and perhaps risky clinical studies. Various modelling approaches (e.g., physiologically based pharmacokinetic (PBPK) model) assist the translation of *in vitro* results into *in vivo* prediction, of potential *in vivo* drug–drug interactions (DDI), and provide the first assessment of the requirement to conduct a clinical interaction study (Fig. 3).

## **Elucidation of Enzymes Involved in the Metabolism of a Drug**

Majority of drugs are eliminated from the body after biotransformation into more hydrophilic metabolites which facilitates their excretion. The safety or the efficacy of a drug in patients can be affected by the interindividual differences in enzyme activities or by co-medication, possibly leading to inhibition or induction of these enzymes. Thus, enzymes involved in the biotransformation of a drug have to be elucidated as early as possible in a phenotyping study. Of importance are enzymes revealing a genetic polymorphism. The major enzymes implicated in the biotransformation of most marketed drugs are the cytochrome P450s, a superfamily of enzymes and its many isoenzymes. Inhibition experiments in human liver microsomes can be performed using selective inhibitors or antibodies. In addition, human recombinant P450 enzymes are available to identify enzymes capable for metabolizing a drug. Correlation analysis of turnover observed in individual donors with different enzyme activities can be done. All these investigations contribute to verify or rule out the involvement of a particular enzyme. Similar studies can be applied to investigate non-P450 enzymes, although availability of recombinant enzymes or selective inhibitors might be limited.

The quantitative effect on the pharmacokinetics of the drug and a possible interaction with other co-medications has to be determined in clinical studies based on these *in vitro* findings.

**Fig. 3** Potential effect of co-medications on plasma levels of a drug by inhibition or induction of drug metabolizing enzymes

## Enzyme Inhibition

A drug can act as an inhibitor of drug metabolizing enzymes through a reversible mechanism, e.g., competitive inhibition, or irreversible, e.g., covalent interaction. This can lead to a prolonged elimination of the victim drug and thus, to higher plasma concentrations, which are potentially toxic. The determination of the inhibition potential of a new drug is therefore important. This can be performed in human hepatocytes or liver microsomes applying enzyme-specific marker substrates or in recombinant human enzymes. Reversible inhibitors are characterized by determination of the  $IC_{50}$  or inhibition constant ( $K_i$ ). Risk assessment based on these data is acknowledged by health authorities to or not to conduct a clinical interaction study.

## Enzyme Induction

After repeated administration, drug metabolizing enzymes can be induced. The resulting increased enzyme activity can lead to a more extensive metabolism of a co-medication metabolized by this particular enzyme. Decreased plasma levels can lead to the loss of efficacy. Enzymatic induction can be evaluated at mRNA, protein, or enzyme activity levels and thus, can be studied by real-time PCR, western blot, or enzyme activity determination. Suitable in vitro test systems for the determination of

enzyme induction are human hepatocyte cultures using a 3-day incubation of the test drug. High-throughput screening in discovery is possible using reporter gene assays in cell lines, such as PXR.

---

## Regulatory Considerations on DDI (Drug–Drug Interaction)

In January 2020, the US Food and Drug Administration (FDA) published two final guidelines, one entitled “*In Vitro Drug Interaction Studies — Cytochrome P450 Enzyme- and Transporter-Mediated Drug Interactions Guidance for Industry*” and the other entitled “*Clinical Drug Interaction Studies — Cytochrome P450 Enzyme- and Transporter-Mediated Drug Interactions Guidance for Industry*.” They represent the current framework from the US health authority on how to conduct in vitro assays to evaluate the P450 and transporter mediated DDI potential, and how to conduct clinical DDI trials to assess the DDI risk in patients.

The in vitro FDA guidance recommends the evaluation of metabolism-mediated DDI of the drug and of its metabolite(s) (pending on pharmacological activity, exposure – expressed by area under the curve (AUC) – and polarity, compared to parent drug) before the first in human studies by the conduct of the following investigations:

1. Drug/metabolite is a substrate of metabolizing enzymes (phenotyping study) – for drug, if the enzyme is responsible for  $\geq 25\%$  of drug’s elimination – for metabolite(s), if pharmacologically active and contributes to  $\geq 50\%$  of the overall activity
2. Drug/metabolite is an inhibitor of metabolizing enzymes (inhibition study) – for metabolite(s), if
  - (a) The metabolite is less polar than parent drug, and  $AUC_{\text{Metabolite}} \geq 25\% \text{ of } AUC_{\text{Parent}}$
  - (b) The metabolite is more polar than parent drug, and  $AUC_{\text{Metabolite}} \geq AUC_{\text{Parent}}$
3. Drug is an inducer of metabolizing enzymes (induction study).
4. Drug is a substrate or inhibitor of transporters (transporter study)

Detailed information on in vitro DDI test assays including a recommendation of the enzymes and transporters to be investigated, as well the models for the prediction of in vivo DDI are provided by the FDA guidelines, and are regularly updated.

The drug interactions guideline of European Medicines Agency (EMA) (*Guideline on the investigation of drug interactions, CPMP/EWP/560/95/Rev. 1 Corr. 2, June 2012*) gives a more general view of pharmacokinetic (PK) interaction of the NCE, considering the effect of food intake or of other medicinal products on the PK of the investigational drug, and the effect of the NCE on the PK of other medicinal products. A comparison of the recommendations of metabolism-mediated DDI the EMA guidelines shows a high similarity to those provided by the FDA.

## Metabolism of Biotherapeutics

Interest of the field of biologics for new treatments is increasing. The number of approved therapeutic proteins is continuously increasing. These new biological entities (NBE) cover a wide range of proteins, including antibodies (IgG), antibody drug conjugates (ADC), nanobodies (VHH), and fusion proteins. These NBEs can undergo biotransformation, that usually does not include the typical phase I or phase II enzymes. The biotransformed protein may be pharmaceutically active, inactive, or, like in the case of antibody drug conjugates, potentially toxic (Schadt et al. 2019). A typical biotransformation reaction for therapeutic proteins is the proteolytic cleavage, leading to a truncated protein and peptides in the circulation. In addition to proteolytic cleavages, de-glycosylation, deamidation, oxidation, or other amino acid modifications can occur. The clearance of therapeutic proteins ultimately is associated with degradation to small peptides and individual amino acids (catabolism).

While for small-molecule drugs, strategies and approaches to assess biotransformation are well established (Schadt et al. 2018), and regulatory guidance for the assessment of metabolites is provided by the authorities (see section above), therapeutic proteins biotransformation studies are not conducted by default procedures, as the commonly expected consequence is the degradation to small peptides and individual amino acids. Therapeutic proteins are slowly cleared through proteolytic digestion mechanisms, partly after cellular uptake in, e.g., target cells, endothelial cells, and macrophages, with a typical half-life of approximately 3 weeks for conventional IgG antibodies. However, for complex multi-specific antibodies or fusion proteins, high unexpected clearance, with or without species differences as well as a mismatch in PK/PD relationship may trigger biotransformation studies, with the aim to understand observed differences in exposure and or in pharmacological activity. This reflects the agencies view that biotherapeutics may have a limited potential to form catabolites/degradation products with unwanted off-target activity. A guidance on preclinical studies is provided by the International Council for Harmonization (ICH) S6 (R1) “Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals” (ICH 2011).

Nevertheless, it can be important to optimize the candidate’s stability to get favorable *in vivo* properties. Vulnerable positions in the molecule can be identified and be further reengineered, obtaining more stable constructs. The triggers for such biotransformation studies are commonly unexpected high clearance, species differences, mismatch in the PK/PD relationships, or observed differences between the results of bioanalytical methods (e.g., LC-MS assays vs. ligand bind assays).

The use of appropriate *in vitro* systems can facilitate the identification of vulnerable molecular positions with higher throughput by reduction of preclinical *in vivo* studies according to the principle of 3Rs (replacement, reduction, and refinement). However, simple systems such as plasma, serum, or subcellular fractions of tissues are poorly predictive, as a low biotransformation rate significantly limits such models, which do not contain the relevant proteases or/and cells concentration (Sender et al. 2016). Therefore, biotransformation studies are preferably conducted in animals. Serum and tissue samples are purified by using immunoaffinity methods followed by separation

of the biotherapeutics and their degradation products with high performance liquid chromatography (HPLC). Alternatively, two-dimensional HPLC can be used for sample preparation and separation, if the adequate immunoaffinity system is not available, or the metabolites are not retained by the system.

Then the analysis of biotransformation products can be achieved by mass spectrometry (MS). The most straightforward approach is intact mass analysis of proteins using high-resolution mass spectrometry (HRMS). It allows the measurement at high mass to charge ratio ( $m/z$ ), the resolution of individual charge states, and the deconvolution to exact mass of proteins and their proteoform or biotransformation products. A complimentary approach to intact mass analysis is the “bottom up” analysis performed by the digestion of biotherapeutics, using site-specific proteases (trypsin). The lysine- and arginine-specific cleavage provides small charged peptides, which are easier to analyze and still retain information about molecular composition, and show subtle changes in the molecule in a more sensitive manner.

---

## Quality Assurance

Health authorities do not require metabolism studies to be conducted under GLP (Good Laboratory Practice) or GCP (Good Clinical Practice). However, due to the importance of these investigations for drug safety, it is recommended to conduct these studies in the spirit of GRP (Good Research Practice) to ensure quality and validity of the data. This requires study plans, standard operating procedures (SOP), proper documentation of analytical methods and results, but no need for Quality Audits.

## Abstract

Toxicokinetics is an integral component of toxicological studies in order to interrelate the administered dose with the associated effect. Pharmacokinetic tests are essential for judging absorption, bioavailability, and

---

e-mail: [juergen.pauluhn@icloud.com](mailto:juergen.pauluhn@icloud.com)

bioefficacy across routes, regimens, and species. In case substances are administered by inhalation, it provides a means to identify substance accumulation and clearance in the lung. Also in other subdisciplines such as oral and skin toxicology, toxicokinetics is important for the assessment of persistence and bioaccumulation. Toxicokinetics includes analyses of temporal change of concentration profiles of the parent substance, its metabolites, or degradation products. Accordingly, toxicokinetic data provide indispensable estimates for systemic and organ-specific substance burdens and contribute significantly to the interpretation of toxicological data and their significance for humans. Many examples, mainly for inhalation testing, are provided.

**Objectives of Toxicokinetic Investigations**

Toxicokinetics deals with the study and with the mathematical description of the time dependence from the disposition (absorption, distribution, biotransformation, and excretion) of xenobiotics in the whole organism. Absorption is the translocation of the administered substance to the blood stream. Once in the blood, the substance is distributed through the body and delivered to tissues, where it may leave the blood and enter the cells of the tissue or it may remain in the blood, particularly when bound to plasma proteins, and simply pass through the tissue. In certain tissues, such as the liver, the substance may be effectively removed from the body by metabolism. Other tissues, such as the kidney and lung, serve to eliminate xenobiotics from the body by excretion. The factors influencing the disposition are conceptualized in Fig. 1. Substances may show complex pattern distribution within an organism depending on the partition to and affinity of the particular tissue for the parent compound or its metabolite. When its absorption and distribution is complete, the concentration in blood depends on the amount absorbed and the extent of tissue distribution.

Knowledge of the specific time profiles of concentrations within tissues or specific compartments is important for assessing the total organ dose (AUC, area under the curve) as well the associated peak concentration ( $C_{\max}$ ). The AUC is represented best by the dose or concentration administered per unit of time  $\times$  dosing duration ( $C \times t$ ). Depending on whether any specific toxic outcome is AUC- or  $C_{\max}$ -dependent, the same AUC can produce markedly stronger effects when  $C_{\max}$ -dependent mechanisms play a role (Fig. 2). In case the rate of dosing exceeds that of elimination or clearance, a substance may accumulate at the portal of entry or the organ showing the highest partitioning/affinity to the substance administered. Typically, such accumulation occurs in the lung following long-term exposure to insoluble dust particles deposited and retained in the lower respiratory tract.

**Fig. 1** The four steps of toxicokinetics: absorption, distribution, metabolism, and excretion (ADME)

**Fig. 2** Theoretical curves representing the plasma concentration of a chemical at different times of dosing. *Curve A* represents the systemic dose from a substance administered by gavage, which is rapidly absorbed. *Curve B* represents the systemic dose from the dermally applied substance that is slowly absorbed. Assuming the area under the two curves is the same and the elimination capacity becomes saturated at a plasma concentration shown by the broken line, the toxic effect in A will be greater than in B and extrapolation between the two routes will either underestimate (B to A) or overestimate (A to B) the hazard.  $C_{max}$ -dependent toxicity, such as neuroexcitation, can reliably be estimated by route A only

Cumulative doses lead to a compartmental (alveolar macrophages) lung overload that may overproportionally increase their residence time in the lung as detailed in the later sections.

For the inhalation route, as long as the dosing variables are kept constant, the well-known reciprocal relationship of concentration and time, that is,  $C^n \times t = \text{constant effect}$ , is a valid approach (Haber's rule is fulfilled with  $n = 1$ ). This rule is commonly understood in inhalation toxicology as a constant product of the two factors "exposure concentration in the inspired air" (C) and the "duration" (t) during which this concentration is inhaled to yield an identical intensity of biological response. A third factor has been considered, namely, the actual volume inhaled by the animal during the exposure period (t). The negligence of this last variable implies that the inhaled volume of a specified concentration of a hazardous substance in air is constant across exposure groups and need not be considered any further. This simplification is subject to challenge, especially when analyzing  $C^n \times t$  relationships of irritant gases in small laboratory rodents which are known to instantly change their ventilation and respiratory pattern concentration-dependently. Historically, Haber's rule has been used for time  $\times$  concentration extrapolations assuming that each unit of damage is irreversible, that no repair takes place during the exposure period, and, therefore, that each unit of exposure is 100% cumulative.

Physiologically based pharmacokinetic (PBPK) models are being used increasingly by regulatory agencies to estimate the internal dose of toxic/drug agents or their metabolites to target tissues. Using this technique, risk assessment for toxic substances can be based on estimates of the amount of the agent that reaches the target tissue, rather than the applied dose. In PBPK modeling, the pharmacokinetic behavior of a compound in the various compartments of the body is represented by equations that attempt to quantitatively describe actual physiological processes. The parameters of these equations are key anatomical and physiological descriptors of the organism. Thus, compartmental pharmacokinetic modeling is a powerful *in silico* tool for interrelating the accumulated target organ dose with the associated toxicological effect. Such models are useful for designing organ-specific drugs, "equivalent dose" testing protocols across species at differing exposure regimens, and to verify route-to-route extrapolations. Toxicokinetic studies pursue multiple objectives; these are summarized in Table 1.

---

## Extrapolation Across Species and Systems

Testing guidelines recommend standardized approaches on selected animal species for the evaluation of specific toxicological endpoints. The use of common laboratory animals for inhalation toxicity studies continually supplements the database and furthers the understanding of toxicity data in experimental animals and their relevance for man. Kinetic cornerstones become ultimately important when examining novel substances with a species-specific mode of action. When using alternative species or testing approaches, kinetic data from target organs are indispensable to

**Table 1** Requirements for kinetic analyses

Data requirement	Test system	Finding
Disposition “kinetic base set”	Single-dose studies to evaluate route-specific kinetic cornerstones	$C_{max}$ , $t_{max}$ , AUC, $t_{1/2}$ bioavailability, absorption rate (flux), parameterization for PBPK modeling, and invasion and evasion kinetics
Disposition, “accumulation,” and organ-specific toxicity	Repeated dose study (e.g., oral, dermal, inhalation, intranasal, and intravenous)	Parameterization for PBPK modeling, distribution within the organism at steady state, organ burden vs. associated organ-specific toxicity, saturation and/or adaptation, and accumulation
Dosimetry and biomonitoring	Single to repeated administration/exposure (e.g., oral, dermal, and inhalation)	Proportionality of external or administered dose with “internal” biomarkers of exposure, including fate. Each exposure pathway displays its own relationship
Across-species comparisons/extrapolations	Single to repeated administration/exposure (e.g., oral, dermal, inhalation, intranasal, and intravenous)	Species-specific differences in disposition, protein binding, organ burden, and associated toxic effects
Route-to-route extrapolation, exposure regimens	Single to repeated administration/exposure (e.g., oral, dermal, and inhalation)	$C_{max}$ and AUC of the parent chemical or metabolite in the blood or selected tissues
Modulation of absorption overload	Single to repeated administration/exposure (e.g., oral, dermal, and inhalation)	Vehicle, particle size, including solubility, surface area, and surface functionalization; amorphous or crystalline; excipients to modify absorption/clearance for drug delivery applications; competitive effects
PBPK-based study design	Single to repeated administration/exposure (e.g., inhalation)	Optimization of particle size for pulmonary deposition, dose selection based on TK properties (accumulation, dissolution, and translocation) of particles to attain lung burdens at nonoverload to overload

disentangle effects in regard to their dynamic (susceptibility) or kinetic (disposition) cause. The choice of animal species for regulatory testing is usually based on guideline requirements and practical considerations rather than validity for use in human beings. An animal species must be small enough to allow handling and exposure in sufficient numbers in relatively small inhalation chambers. An animal species, however, must be large enough to allow measurement of all endpoints relevant to identifying the inherent toxicity of the substance under investigation. Exposure paradigms may vary from small to larger animals, from animal bioassays to humans, as well as within the human population.

In summary, no animal species mimics man in all respects. Therefore, animal models are, at best, a necessary compromise and must be used because they offer the advantages of experimental control and reproducibility. Accordingly, animal model selection may often be contingent upon toxicodynamic or pathological identification of early changes consistent with the pathomechanism of the test substance. In general, the uncertainties of extrapolation of toxicological results across different species are minimized if a maximum of mechanistic understanding is gained from a study. This is achieved by measurement of a sufficient number of procedures, endpoints, and incorporation of kinetic endpoints accounting for any species-specific differences in dosimetry and fate.

Recent progress in *in vitro* toxicology makes it necessary to consider pharmacokinetics also on cellular level to make comparisons possible of *in vivo* and *in vitro* models. New methods in the cultivation and exposure allow the direct exposure of lung cells thus providing means to analyze biological responses of cells during and following direct exposure to airborne materials at the air/liquid interface. Such systems are amenable of using cultured cells as an integrating biological dosimeter. Nonetheless, one has to recall that *in vitro* systems are typically designed for homogenous systems with water-soluble substances rather than insoluble and lipophilic particles which may have limited access to cells in aqueous culture media. To make cellular *in vitro* systems more practicable to human risk assessment, improved concepts for cellular dosimetry and kinetics are urgently needed.

---

## Extrapolation Across Routes

Risk assessors frequently have to use data obtained using a single route of administration. Most studies are carried out using the oral route (by gavage or in diet or drinking water). This is because such studies tend to be the most straightforward to perform and interpret, and dosimetry is easiest to quantify, particularly when a chemical is given by gavage. However, the differences that may occur due to exposure via high “bolus” systemic dosing resulting from administration by gavage, intratracheal or intranasal instillation, compared with prolonged systemic dosing resulting from administration via food or drinking water, the skin, or inhalation, need to be recognized. If the metabolism or action at the target site of a chemical is critically influenced by concentration at any one time, rather than the total integrated systemic dose, the toxicity of that chemical may differ with route of administration or dosage regime if these affect the systemic concentration  $\times$  time relationship (AUC) as shown schematically in Fig. 2.

The toxicity of a chemical may also be altered by previous exposure, for example, as a result of induction of metabolizing enzymes. Although these effects of the dosing regimen are important factors in the assessment of hazard, they are not specific to route-to-route extrapolation. Inhalation toxicity studies are technically much more complex: It is necessary to monitor the levels to which the animals are exposed, and in the case of aerosols, their size matters as it will influence the amounts that penetrate the upper respiratory tract (inhalable) and the alveoli

**Fig. 3** Time course of methemoglobin (MetHb) formation in beagle dogs. The dogs were either head-only exposed to aniline vapor for 4 h to  $174 \text{ mg/m}^3$  or received  $15 \text{ mg aniline/kg body weight}$  by gavage. Blood was collected before exposure and thereafter in 45 min intervals. (Data reproduced from Pauluhn (2002))

(respirable). Other factors that govern deposition include water solubility and reactivity. Calculation of dose is much more complex compared with using the oral route, being dependent on the lung morphology, ventilation, etc., as well as the applied  $C \times t$ . There is therefore commonly a need to extrapolate toxicity data obtained using the oral route of administration in order to assess human health risks resulting from inhalation exposure.

Toxicity via oral and inhalation routes can differ remarkably when a dose rate-specific-activating first-pass metabolism occurs. Aniline is given as an example. This substance is known to be bioactivated in the gastrointestinal mucosa and especially in the liver to become a MetHb-forming agent. It exerts toxicity to the red blood cells (RBC) through an active/reactive metabolite mechanism, mainly N-hydroxylated metabolites, which take part in cyclic redox processes. This *vicious cycle* depletes the RBC of factors to regenerate oxidized hemoglobin. Dogs were exposed by head-only inhalation to exclude dermal uptake for 4 h to  $0.174 \text{ mg aniline/L air}$ . When applying the typical respiratory minute volume of dogs, the total exposure dose is equal to  $15 \text{ mg/kg body weight}$  ( $0.36 \text{ L/kg-min} \times 240 \text{ min} \times 0.174 \text{ mg/L} = 15 \text{ mg/kg}$ ). The same dose was administered by gavage (Fig. 3). A fivefold lower potency of MetHb formation was observed following inhalation as compared to the bolus gavage. This appears to be related to the more efficacious hepatic first-pass bioactivation when administered via the gastrointestinal tract. Thus, for agents known to be bioactivated by a hepatic first-pass metabolism, the conversion of findings obtained from oral dosing to inhalation exposure concentrations is subject to errors. Likewise, in contrast to studies where the uptake is by the gastrointestinal route, the passage time-dependent modification of the test agent may be decisive for the toxic outcome.

Likewise, complex molecules can spontaneously decompose pH-dependently in the gastrointestinal (GI) tract as shown for the zinc-propylenbisdithiocarbamate fungicide propineb (Fig. 4). The degree of decomposition can be estimated by the nonenzymatically formed reaction product TTCA (2-thiazolidinethione-

**Fig. 4** Conceptual scheme of decomposition of the zinc-propylenebis(dithiocarbamate) fungicide propineb under physiological conditions showing the generation of carbon disulfide ( $\text{CS}_2$ ) and the subsequent reaction with free cysteine (or the cysteinyl moiety of glutathione) to form a metabolite that cyclizes to TTCA. In concept, this decomposition may also lead to the formation of propylene thiourea (PTU), a thyreotropic substance. (Adapted from Pauluhn and Rosenbruch (2003))

4-carboxylic acid) in urine, a metabolite and biomarker of exposure to  $\text{CS}_2$ , through direct reaction with cysteine or glutathione. The dithiocarbamate formation is reversible under physiological conditions and provides a reservoir of  $\text{CS}_2$  within biological systems. As can be deduced from Fig. 4, the intermediate concentrations of  $\text{CS}_2$  and TTCA, including the new toxic entity PTU (propylenthiourea), and ionized zinc are substantially different following gastrointestinal and pulmonary exposure. Portal-of-entry-specific pulmonary changes may occur at lower doses due to the higher local concentrations of zinc and a diminished capacity of metabolizing  $\text{CS}_2$ . This makes different patterns of distribution likely to occur. In contrast to dietary routes, thyroidal (goitrogenic) effects have not been found following inhalation exposure, presumably because PTU is unlikely to be formed within the pulmonary environment. Thus, the formation of new toxicophoretic entities and portal-of-entry specific types of toxicities, including site-specific, often

rate-dependent compensatory mechanisms, needs to be accounted for before attempting such extrapolations.

The above considerations suggest that extrapolations from the oral to inhalation routes are by far not straightforward in the absence of adequate toxicity and biokinetic data. For route-to-route extrapolation to be appropriate, the toxicological concern often relates to systemic toxicity, that is, toxicity expressed in tissues/organs distant from the site of administration. However, even at this level of simplification, expert judgment and PBPK data are needed to arrive at scientifically sound conclusions.

The key factors that need to be considered are briefly summarized below:

- Is the toxicity of concern a local or systemic effect?
- Is there any dependence on the extent of absorption and on the balance between any activation (where appropriate) and detoxification mechanisms? In case this can be materialized, the systemic toxicity may be the result of complex interactions, some of which could be route specific as well as dose-rate specific.
- Absorption is a determinant as to how efficiently a substance can be transported across biological barriers of the target organ dose, and implications of first-pass-like metabolism.
- Decomposition of a substance within the gastrointestinal tract with the formation of new toxicological entities (toxicophoresis) needs to be appreciated. This means the toxicodynamics and spectrum of organ toxicity change from one route to another.

---

## Toxicokinetic Data and Risk Assessment

In the application of pharmacokinetic models in risk assessment, the differences in compound disposition between humans and experimental animals are of particular interest. Therefore, there is a need to establish appropriate physiological values for humans and for the more commonly used laboratory species. To address this need, representative values and biologically plausible ranges of these values are provided for a number of anatomical and physiological parameters in multiple species. Representative values are available from the literature for most of the species commonly used in toxicology and risk assessment. As a result, these values can serve as reasonable, empirically based defaults that can be used in PBPK modeling when case-specific data are unavailable. Clearly, it is preferable to determine physiological and anatomical values directly on the individuals under study or, at least, on individuals known to be drawn from the same population and subjected to similar conditions.

Toxicokinetic studies provide historically an integral part of toxicological studies with drugs in order to allow direct comparisons of internal doses from preclinical animal studies to humans dosed with optimized drug delivery systems under clinical conditions. They also allow a specific search for the most relevant human-like animal species in regard to metabolism and pharmacodynamics.

## Toxicokinetic Readouts

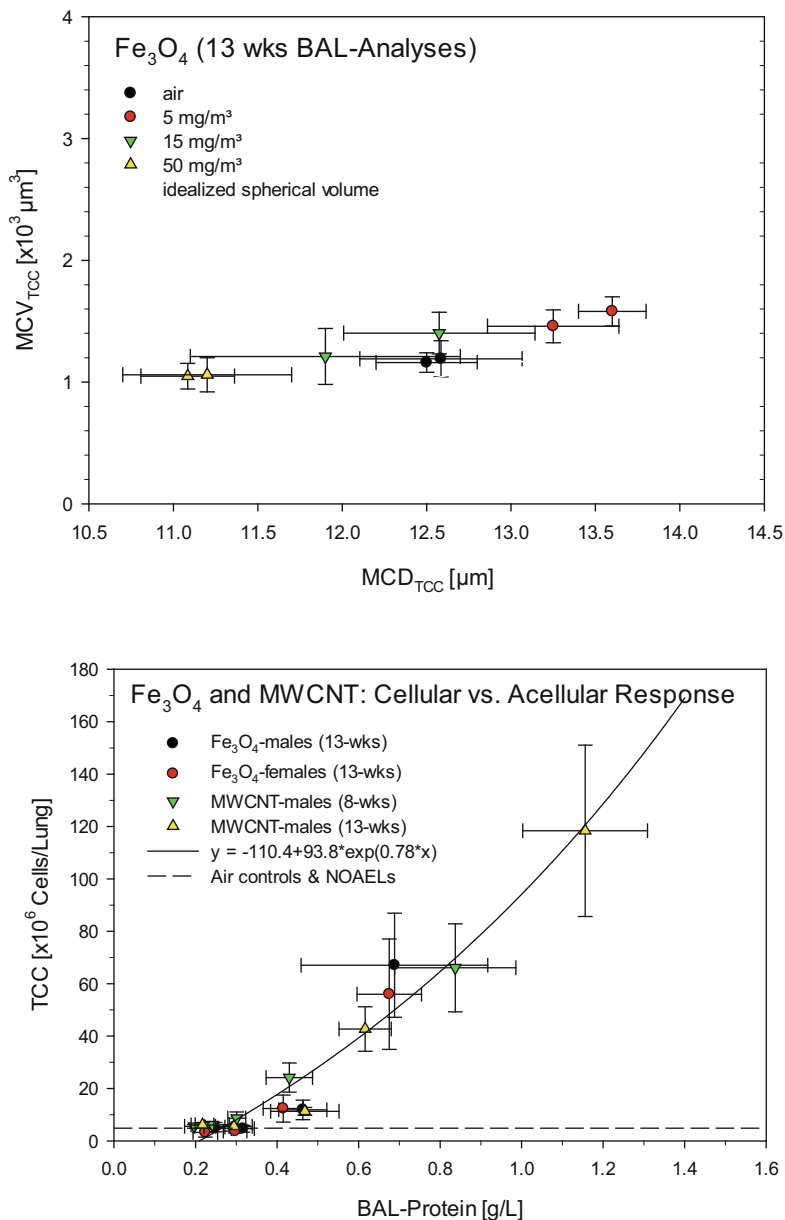

### Time-Course Changes

Toxicokinetics commonly captures concentration measurements in plasma or blood of the parent substance or its metabolites. In inhalation toxicology, the information on extrapulmonary organ burdens, including blood, and lung burdens is of paramount importance for inhalation dosimetry and risk assessment. Apart from non-inhalation routes, physical factors may determine whether inhaled substances are cleared from the lung into the GI-tract with or without absorption. They also play a role in the lung where their kinetic of dissolution in pulmonary surfactant differs appreciably from that after their phagocytosis by alveolar macrophages. The elimination kinetics of insoluble particles from the lung depends on the degree of lung overload (see below). Thus, kinetic hallmarks characterizing the threshold dose of lung overload are a basic requirement for any meaningful extrapolation from animals to humans. Commonly, toxicokinetics focuses on the following parameters, AUC, which is a measure of the total systemic exposure to the chemical. AUC is an integral of the rate of change of concentration in plasma as a function of time.  $C_{\max}$  is the maximum plasma concentration (see Fig. 2), and  $t_{\max}$  is the time required to reach this maximum concentration after administration. They are determined at various time points after a dosing. Bioavailability, which is the fraction of chemical that is absorbed, is determined for extravascular administration with reference to an intravenous dose. An example for the compartmental kinetics of poorly soluble inhaled particles from the lung is given below (see Fig. 5).

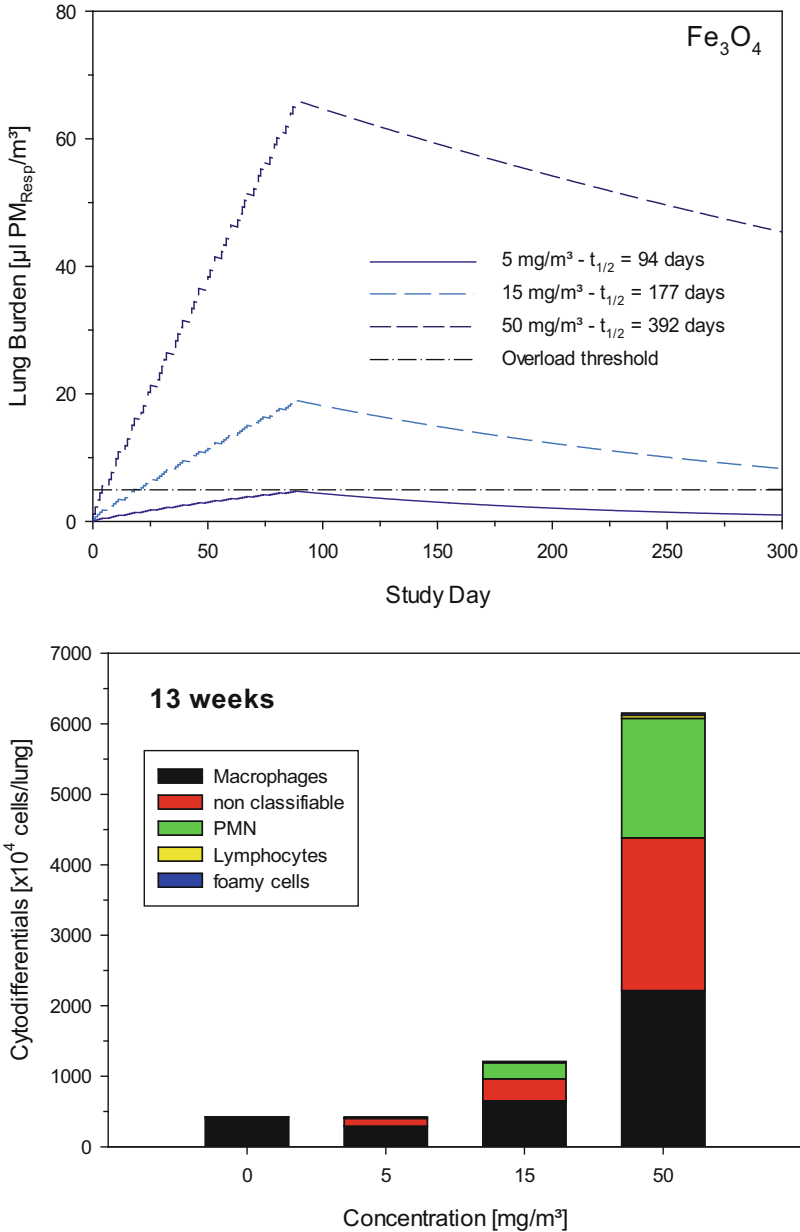

### Selection of Compartment

The pharmacological efficacy of a drug substance depends on its time-dependent concentration at the site of targeted action (target organ). Especially in humans, this target site is often not directly accessible for specimen collection. As a surrogate, concentration of drug is commonly determined in the blood assuming a state of equilibrium among organs. Drugs targeted to the lung are preferentially administered by inhalation to increase the  $C_{\max}$  and AUC within this organ at equally lower systemic  $C_{\max}$  and AUC which then substantially reduce the systemic dose with less side effects. As a result of this strategy, the concentrations in the blood and in the target tissue may differ considerably. PBPK models can be used to calculate the most appropriate dosing interval to prevent accumulation and local toxicity from occurring.

Aminoglycosides have several potential antibiotic mechanisms and are frequently administered by inhalation to attenuate/cure pulmonary infections. This class of drugs is known to have strong, irreversible binding to the ribosome and remains intracellular long after plasma levels drop. This allows a prolonged dosage interval. Depending on their local concentration, they act as bacteriostatic or bactericidal agents. These properties make these drugs amenable to interact inhaled dose proportionally with the phospholipids lining the lung resulting in dysfunctional

**Fig. 5 Top** Comparison of the mean corpuscular volumes (MCV) and diameters (MCD) of total cell counts (TCC) in the BAL of rats exposed to Fe<sub>3</sub>O<sub>4</sub> as modeled in Fig. 6-top. **Bottom:** Interdependence of BAL-TCC and BAL-protein (Fe<sub>3</sub>O<sub>4</sub>: male and female rats, 13-wks sacrifice; MWCNT: male rats, 8 and 13 wks sacrifices). Animals were exposed to MWCNT and Fe<sub>3</sub>O<sub>4</sub> as illustrated in Fig. 6-top. Whiskers represent the mean  $\pm$  SD of six male rats/group examined at the end of study. This comparison demonstrates that the size and volume of the phagocyte (alveolar macrophage) is not appreciably affected by lung overload. However, the pool size of phagocytes (TCC) parallels favorably the degree of lung overload. Notably, the low density nano-MWCNT and high density iron oxide follow the same principle of volumetric lung overload

**Fig. 6** Modeling of time- and particle volume-dependence of cumulative lung burdens of Fe<sub>3</sub>O<sub>4</sub> solid aerosol in rats exposed for 13 weeks for 6 h/day on 5 days/week. The exposure concentrations selected were modeled to be tolerated without effects at 5 mg/m<sup>3</sup> and mild-to-moderate reversible overload-dependent pulmonary inflammation at 15 mg/m<sup>3</sup>. Kinetic overload occurred at 50 mg/m<sup>3</sup>, respectively (top). The cytodifferentiation of BAL-cells (end of exposure period) mirrors the modeled time-cumulative inhaled dose-response relationship (bottom). Nonclassifiable cells are macrophages stained black as a result of the engulfment of black magnetite

surfactant due to aminoglycoside-phospholipid complexes which are engulfed by alveolar macrophages. Dose-proportional elevations suggestive of drug accumulation in the lung provide evidence of reversible drug sequestration in the lung with clearance proportional to the degradation of drug-phospholipoprotein complexes. By virtue of PBPK modeling, the complex relationship of drug sequestration and elimination can be estimated by PBPK modeling in spite of its potential to accumulate.

---

## Absorption, Distribution, and Elimination

### Absorption

For drugs, the absorption is usually as large as technically feasible to maximize systemic bioavailability or alternatively small when limited to the site of application (e.g., the lung). Absorption can potentially take place from all exposure routes (oral, dermal, inhalation, and intranasal). The absorption rates and yields are highly route- and excipient-dependent or formulation-dependent. Therefore, PBPK modeling requires exposure information to account for these differences. Biomonitoring using biomarkers of short-term or long-term exposure integrates the dose from all exposure routes. Caution is therefore advised to attribute data to one single route without considering the potential impact of other routes.

For rapidly absorbed chemicals, equilibrium may be established between blood and the site of absorption. The rate of entry into the blood is limited by the blood flow rather than any diffusion across the membrane barrier. In this case, any increase in blood flow will also increase the rate of absorption, and absorption is said to be perfusion- or blood-flow-limited. For poorly absorbed substances, absorption is not dependent on the blood flow which means it is diffusion-rate-limited. Absorption is taking place by passive (mainly via pores or simple diffusion processes), active transport (against a concentration or electrochemical gradient) utilizing transcellular (through the cell) or paracellular (between cells) pathways. Solubility is an important factor driving the rate of absorption. For instance, particles deposited in the lower respiratory tract, in the absence of any specific protein binding or chelation, even less soluble substances (solubility in the range  $\leq 1$  mg/L water at physiological pH) are still rapidly cleared from the lung by dissolution.

### Absorption from the Skin

For the penetration and absorption of substances through the skin, the flux needs to be calculated using Fick's first law of diffusion to relate the flux rate ( $J$  in  $\text{mg}/\text{cm}^2/\text{h}$ ) to the permeability, concentration, area of exposed surface, and length of exposure. An additional important parameter that needs to be utilized is the chemical's permeability coefficient ( $K_p$ ). The permeability coefficient (in  $\text{cm}^2/\text{h}$ ) should be

consistent regardless of exposure concentration (provided that the concentration is infinite) and surface area for any given exposure site and chemical, but it can vary between exposure sites. Unless a mathematical model is used, the calculation of flux or permeability coefficient must be assessed at steady state. Mathematical models have been developed to attempt to describe percutaneous absorption kinetics. In almost every case, absorption through rodent skin is more than threefold higher than through human skin, and the increased absorption through rodent skin does not show a consistent pattern between compounds. The higher absorption in rodent skin may be due to differences in skin appendages (e.g., hair follicles) and different morphology of the individual skin layers. An additional difference between human and rodent dermal absorption is the difference in the lag phase before the appearance of chemical in the blood; human absorption is delayed, whereas chemical absorption through the skin of rodents occurs with no apparent delay.

### **Gastrointestinal Absorption**

The rate of gastrointestinal absorption from the gastrointestinal tract depends on the  $pK_a$ , solubility, lipophilicity, and degree of ionization, as well as its residence time which is influenced by the tract's filling state, pH of microenvironment, and the active surface area of the respective segment. The milieu of the GI tract and the respective bacterial microflora can promote spontaneous intraluminal decomposition or chemical modification of substances (e.g., formation of nitrosamines in the stomach). Metabolic activation or deactivation of the absorbed substance from the intestine can take place in the subsequent passage through the liver (first-pass metabolism). The rate and extent of absorption of weak organic acids and bases varies with the location in the GI tract; weak acids are nonionized and are absorbed in the stomach, whereas weak bases are nonionized and are absorbed in the intestine. Removal from the site of absorption by blood flow maintains a concentration gradient, thus enhancing absorption of chemicals. The protonation of lipophilic chemicals within any specific subcompartment may lead to intracellular substance accumulation by a "pH trap."

### **Pulmonary Deposition, Retention, Clearance, and Absorption**

The various species used in inhalation toxicology studies do not receive identical doses in comparable respiratory tract regions when exposed to the same external particle or gas concentration. The total body burden per unit body weight may also differ from one species to another because of differences in respiratory patterns and the respiratory minute volume. The dose metrics is also dependent of the local and/or systemic pathomechanism and may range from "total body burden" to "critical dose per alveolar macrophage" or "critical dose per cell

volume or surface area of the most susceptible lung region.” The biologic endpoint or health effect of concern may be more directly related to the quantitative pattern of mass deposited within the respiratory tract than to the external exposure concentration.

Retention is the actual amount of inhaled agent found in the lungs at any time and is determined by the relative rates of deposition and clearance. Retention and the toxicologic properties of the inhaled agent are related to the magnitude of the pharmacologic, physiologic, or pathologic response. For particles, deposition mechanisms include inertial impaction, sedimentation (gravitational), diffusion, interception, and electrostatic precipitation. Generalizations regarding the site of deposition of particles of a given size are problematic due to the many factors involved. However, in the average adult human, most particles larger than 10 $\mu$ m in aerodynamic diameter are deposited in the nose or oral pharynx and are unlikely to penetrate to tissues distal to the larynx. Very fine particles (0.01 $\mu$ m and smaller) are also trapped relatively efficiently in the upper airways by diffusion. Particles that penetrate beyond the upper airways are available to be deposited in the bronchial region and the deeper-lying airways. Sedimentation brings about deposition in the smaller bronchi, the bronchioles, and the alveolar spaces, where the airways are small and the velocity of airflow is low. As a particle moves downward through air, buoyancy and the resistance of air act on the particle in an upward direction, while gravitational force acts on the particle in a downward direction. Eventually, the gravitational force equilibrates with the sum of the buoyancy and the air resistance, and the particle continues to settle with a constant velocity known as the terminal settling velocity. Diffusion is an important factor in the deposition of submicrometer particles or gases. The clearance of deposited particles is an important aspect of lung defense. Rapid removal lessens the time available to cause direct tissue damage. Particles are cleared by the mucociliary escalator from the airways or may be phagocytized by alveolar macrophages and are ultimately transported to the mucociliary escalator. Even moderately soluble particles dissolve relatively rapidly in the lining fluids of the lung.

The mechanisms important for gases include convection, diffusion, chemical reaction (including metabolism), dissolution, and perfusion. Especially in obligate nose-breathing animals, absorption or “scrubbing” of a relatively water-soluble and/or reactive gas may occur from the inspired airstream as it travels from the extrathoracic to the pulmonary region. That is, the dose to the peripheral regions is affected by the dose to the region immediately proximal. For lung irritants, commonly an anterior-posterior gradient of intensity of damage of airways is observed, whereas the severity of toxicity also progresses distally with increased exposure concentrations. Although the deposition, clearance mechanisms, and physicochemical properties of the agent are often described as distinct properties, assessment of the overall toxicity requires integration of the various factors. Regional deposition pattern determines not only the initial lung tissue doses but also the specific pathways and rates by which the inhaled agents are cleared and redistributed or translocated.

## Compartmental Pulmonary Biokinetics of Poorly Soluble Particles

### Kinetic Lung Overload

The elimination of deposited and retained poorly soluble particles (PSP) from the lung usually is a logarithmic process – that is, a constant proportion of the substance is eliminated per unit time which is described by a first-order relationship:  $C_t = C_0 e^{-k t}$  where  $C_t$  is the concentration after the time  $t$ ,  $C_0$  is the initial concentration at  $t = 0$ , and  $k$  is the elimination constant ( $k_e$ ). The relationship between the elimination rate constant ( $k_e$ ) and half-time ( $t_{1/2}$ ) is given by the following Eq. 1:

$$C = C_0 e^{-k_e t} \text{ with } k_e = \frac{\ln 2}{t_{1/2}} \quad (1)$$

Half-time is dependent on the clearance (CL) and the volume of distribution ( $V_d$ ) which are combined using the following relationships:

$$t_{1/2} = \frac{\ln 2 \times V_d}{CL} \quad (2)$$

with

$$CL = V_d \times k_e \quad (3)$$

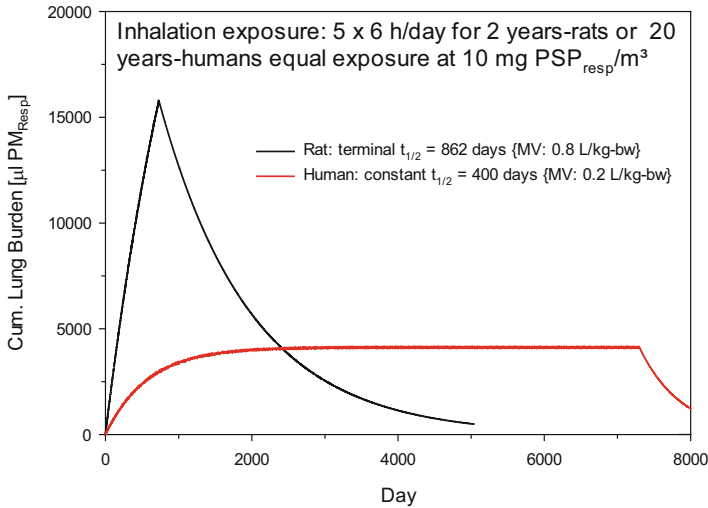

There is a common strong relationship between the volume of distribution ( $V_d$ ) and body weight across species. This aspect has been observed when adjusting this endpoint across species. Regarding the lung, the  $V_d$  increase with the increased particle retention and load by alveolar macrophages (AM). The increased  $V_d$  decreases the clearance of PSP from the lung. In other words, the *greater the  $V_d$ , the longer* is the elimination half-time. This has significant bearings on the elimination kinetics of PSP being sequestered within a dynamically increasing pool of the migratory AM. The size of this  $V_d$ -equivalent pool is determined by the cumulative retained displacement volume within the AM followed by an adaptive influx of alveolar macrophages. The displacement volume is the space consumed by agglomerated PSP within the AM. This explains why low-density PSP commonly appear to be more toxic as compared to high-density materials because a smaller mass displaces a larger volume within the AM. However, this apparently higher toxicity is caused by an earlier attainment to kinetic lung overload and not necessarily any substance-specific toxicity. Once endocytosed by the AM, PSP may undergo multiple processes such as dissolution and/or elimination by translocation of particle-laden AMs out of the pulmonary system. Notably, dissolution is by far not trivial because dissolution may be facilitated or impeded depending on the localized pH and binding capacity of the adjacent microenvironment and its degree of saturation. When escaping this microenvironment, metal cations may be scavenged by chelating proteins or undergo precipitation often of much lower solubility than the parent PSP.

Thus, unlike the substance-specific kinetic cornerstones of soluble materials, the kinetic cornerstones of PSP are determined by the degree of the cumulated particle

load, called “kinetic lung overload.” Accordingly, with increasing lung particle burdens, the increased elimination half-time is causally linked to the pool size of phagocytes and not any significantly increased size of the AM (Fig. 5, top). This illustration delineates that the average diameter of cells retrieved by bronchoalveolar lavage (BAL) yields a cellular diameter of 12.5 $\mu\text{m}$  in air-exposed control rats with a  $\pm 10\%$  shift into both directions. BAL cytodifferentiation from control rats is predominated by AM whereas that of highly dose rats contains also neutrophils. Overall, the relationship shown in Fig. 5 (top and bottom) demonstrates clearly that the pool size of AMs is determined by the increased number of BAL-cells constituting Vd rather than any significant change in cellular volume. The relationship depicted in Fig. 5 (bottom) compares iron oxide (Magnetite,  $\text{Fe}_3\text{O}_4$ ; concentration: 5, 15, and 50  $\text{mg}/\text{m}^3$ ) and Multiwalled Carbon Nanotubes (MWCNT; concentrations: 0.1, 0.4, 1.5, and 6  $\text{mg}/\text{m}^3$ ) with specific densities of 4.5 and 0.2  $\text{g}/\text{mL}$  powder, respectively, and exemplifies the dependence on particle volume, increased pool size of total cell counts (TCC), and ensuing pulmonary inflammation evidenced by increased extravasated BAL-protein.

The clearance of deposited particles via endocytosis is an important aspect of the constitutive lung defense. Rapid removal lessens the time available to cause direct tissue interaction and damage. Retention is defined as the actual mass of inhaled particles found in the lungs at any postexposure time and is determined by the relative rates of deposition and clearance. Those PSP deposited in the alveoli are primarily phagocytized by AM which are ultimately transported toward the mucociliary escalator with mechanical clearance via the airways. A small fraction of particles is also cleared via the lymphatic (interstitial) draining system draining the lung. The translocation of particles to the draining hilar lymph nodes (LALNs) commonly increases significantly at lung burdens high enough to cause pulmonary inflammation with increased barrier disruption and access to the interstitial system. PSP may also be cleared via the pleura, depending on their morphology (granular vs. fibrous). The pleural region of the parietal pleura was identified as a critical region rich in which all particles and fibers that are small enough to negotiate the parietal pores (stomata) are cleared, if not, they may accumulate at this mesothelial location followed by site-of-accumulation specific adversities. In rats, particles are preferentially retained in the airspaces, whereas in humans chronically inhaled PSP gain increasingly access to the interstitium.

As a corollary of their function, AM engulf and retain inhaled particles. As illustrated in Fig. 5, with increasing volumetric lung burdens, this may lead to an increased recruitment of phagocytic cells constituting the Vd. The relationship of accumulated lung burden and resultant terminal outcomes suggestive of lung overload-related inflammation at 13-wks are modeled in Fig. 6 (top). The PBPK modeling of lung burdens demonstrates that no-adverse-effect levels can reliably be predicted. Notably, under conditions of lung overload, lung burdens (and associated toxic effects) increase overproportionally due to the fractionally increasing elimination half-time as a result of kinetic lung overload. Toxicologists must observe this mismatch of clearly defined and spaced exposure concentrations relative to the overproportionally increased lung burdens at the end of repeated exposure studies.

**Fig. 7** Simulation of retained respirable volumes of PSP in rats and humans using a 5-days-per-week exposure (6 h per exposure day), over a prolonged period. Overproportionally, lung burdens may occur in rats under the conditions of lung kinetic lung overload whereas the larger Vd of humans prevents such state of overload to occur. Caution is advised to compare nominally inhaled cumulative lung burdens across species by “Area Under the Curves” in the absence of kinetic profiles

Regarding the available pool size for inhaled PSP, differences between laboratory rats and humans must be observed. Humans have large and higher numbers of AMs compared to rats. Hence, the fractional exhaustion of pool size changing an entirely adaptive process toward a potentially adverse process needs to be conceptualized. Accordingly, when exposed to the same concentration of PSP, rats may produce overload-specific adversities whereas humans still maintain in the state of non-overload (Fig. 7).

Thus, unlike humans, rats appear to be more susceptible to overload-related effects due to apparently “impaired macrophage-mediated alveolar clearance” which, however, appears to be better described as an overadapted rat-specific kinetic phenomenon. It was proposed that the threshold of causing particle-induced chronic effects is the pulmonary dose that results in a first reduction in macrophage-mediated clearance due to an increase in TCC (Fig. 6).

In summary, the comparison of a modeled kinetic hypothesis with any overload-specific pulmonary inflammation delivers important pieces of information concerning the increased elimination time with increasing lung burdens. In the past, testing approaches used postexposure too short to demonstrate kinetic reversibility. Their common conclusions were to highlight the “irreversible retention of particles” (due to the ostensibly immobilized overloaded and “enlarged” AM). Either conclusion is not supported by more recent evidence showing that reversibility can only be demonstrated if the length of postexposure

periods is adjusted to the increased elimination half-time causing the over-proportionally increased particle load and TCC. Kinetic predictions should be accompanied by proof of principle evidence as illustrated in Fig. 6 (bottom). The predicted NOAEL should empirically be demonstrated by minimal increased BAL-cell counts of controls within a range of  $t_{1/2}$ s of 60–90 days. At higher  $t_{1/2}$ s, PMNs (neutrophilic granulocytes) increase proportionally to the increased pool of migratory cells. In this context, it is important to recognize that the increase of PMNs often is caused by kinetic overload rather than any substance-specific attribute (except the agglomerate-specific density). Notably, potency comparisons of PSP require a normalization to kinetic overload (at similar elimination half-times), otherwise any apparent substance-specific pulmonary response would be scaled to the rat-specific physiological adaption to cumulative dose rather than substance properties.

### **Dissolution and Bioavailability**

No doubt, dissolution is tightly linked to the reciprocal relationship of particle size and surface area which determines the thermodynamic phase boundary, where the physical and chemical properties of the adjacent phases change abruptly (Pauluhn 2014a, b). As in any chemical reaction, surface processes involve breaking and making of bonds. This is what catalysis is all about. Mere reversible physical adsorption may occur; however, the adsorbent may immediately be lost by desorption, in the presence of substances with competing or stronger binding isotherms. Hence, the term “surface area–/reactivity-dependence,” often preferred by toxicologists, is a highly dynamic process depending both on the kinetic and thermodynamic factors present in the intimate microenvironment of the retained particle as well as of the physical and chemical properties of the particle itself. Hence, from any modeling perspective, many surface-related factors are highly probe-of-determination-dependent. The characteristics of the probes used for the physicochemical qualification of PSP may not have any resemblance to those present in the biological system. Likewise, many simplified calculations of surface area based on idealized spherical structures cannot reliably mirror the more complex tree-dimensional assembly of nanostructures and associated void spaces.

Particle dissolution is dependent on the rate of solubilization (in mass/time), the surface area of particle and its crystallinity, or lack thereof in the case of amorphous solids. Critically, the dissolution rate may depend on the presence of other factors that determine the degree of undersaturation in the liquid solvent layer immediately adjacent to the solid solute particle. The term “interfacial solubility” was proposed to describe the average concentration of the boundary layer involved in the dissolution process of particles. Interfacial barrier models consider interfacial transport rather than diffusion through the layer. “Solubilization” is the kinetic process involving both dissolution and precipitation, which occur at the same time but in different ratios, and usually proceed by diffusion. The disjoining pressure of small particles is greater than that of large particles, so small particles have a higher interfacial solubility. Due to their higher differential

concentration, thinner diffusion layer, and increased surface area, small particles dissolve faster than larger particles. Accordingly, a thermodynamically more stable state is attained when larger particles grow at the expense of smaller particles. Thus, even if “particle disintegration” would occur it would result in thermodynamically instable conditions. Moreover, slightly soluble micron-sized particles become smaller with elapsed time, that is, before “disappearing” they transiently pass through a nanosized range. From that, a clear-cut distinction of micron- and submicron-sized PSP is difficult to make.

The solubilization kinetics, as well as apparent solubility, can be accelerated by complexation, e.g., metal ion binding by peptides or proteins present in the lung. Solubility is commonly expressed as a concentration (e.g., mass of solute per kg of solvent). The maximum equilibrium amount of solute that can dissolve per amount of solvent is the solubility of that solvent under a given condition. The advantage of expressing solubility in this manner is its simplicity, while the disadvantage is that it can strongly depend on the presence of other species in the specific microenvironment of the particle. Despite the advances of *in vitro* dissolution in particle qualification, the *in vivo* bioavailability of retained particles in the lung remains to be difficult to judge by *in vitro* tests. The toxicological significance of translocation and disintegration of agglomerated particles commonly ignores the complex equilibria of dissolution and precipitation processes that may occur in highly compartmentalized biological systems. For example, the solubility of any inhaled metal oxides mechanically translocated from the airways into the gastrointestinal tract may show their highest solubility in gastric fluids – due to low pH – with resultant high concentration and mucosa-to-blood gradients as the prerequisite for transport across barriers and absorption. With increasing pH following absorption, supersaturated concentrations with precipitation may ensue. Such precipitates may eventually be retrieved in the liver and spleen. Thus, caution is advised to inextricably link particles found in the extrapulmonary circulation or organs to pulmonary barrier disruption.

These elaborations demonstrate that any meaningful *in vivo* dissolution kinetics should use inhalation instead of instillation, insufflation, or aspiration procedures to define the fate of PSP. Likewise, to make the kinetic cornerstones comparable across different substances, any dissolution kinetics should refer to the cumulative lung burdens within a meaningful range of the threshold of kinetic overload. Typically, the dominating pathway of elimination of PSP from the lung occurs via alveolar macrophages. At yet nonoverload conditions, elimination half-times of PSP retained in the lung are in the range of  $t_{1/2} = 60\text{--}90$  days as alluded to above. In case evidence of facilitated or enhanced dissolution of PM exists, a shortened half-time is observed (Pauluhn 2014).

### **Interdependence of Metrics on Dose**

As conceptualized above, two metrics of dose must be distinguished when interrelating the pulmonary kinetics and toxicity of PSP (Pauluhn 2014). The *deposition-related metric* is frequently conceived as the conceptually better alternative to particle mass as a measure of dose would be the PSP-surface

thermodynamics. Surface area rather than mass accounts for the fact that biopersistent particles can interact only by contact of their surface, determining an effective dose-rate by a catalytic surface reaction rate that accumulates to an effective dose with increasing residence time in the target tissue. However, a finite proportion of soluble fractions of particles that may dissolve on contact with the fluids lining the airways of the lung do not contribute to “surface area dose” (apart from the fact of surface-area-dependent-facilitated dissolution). Especially for less soluble particles in a  $C_s$ -range 1–10 mg/L water, the dissolution flux is not only highly dependent on the physical characteristics of the particle itself, but also the degree of saturation of the matrix surrounding the particle has great impact. Along with these concerns, issues regarding the most appropriate unifying metric of dose are still unresolved for potentially soluble particles, of which dissolution rates increase reciprocally with PM-size. In contrast, the *retention-related metric* must observe several major variables controlling the response to any increased endocytosis of endogenous (e.g., precipitated or denatured surfactant, pulmonary phospholipidosis, and cellular debris) and exogenous poorly soluble materials. These variables include hypertrophy (enlargement commonly caused by excessive amounts of phospholipids) of the AM with minimal, if any, increase of the pool of macrophages. To the contrary, an increase of the AM pool in the absence of any hypertrophy of cells is the most common response observed in inhalation studies with PSP. At unequivocal overload, coexistence of both may occur. Typically (in rats), at yet reasonable dose rates used in repeated inhalation toxicity studies, the pool volume of AM adapts to higher PM-load by the increased influx of cells rather than their enlargement.

## Distribution

Once in the bloodstream, the substance is available for distribution and elimination throughout the body as detailed in Fig. 1. Metabolism and excretion, which are components of elimination, are discussed in other chapters.

Factors that influence the rate and extent of distribution of a chemical to a particular tissue include blood flow to the tissue (rate of delivery), the mass of the tissue, the ability of the chemical to cross membranes, and the affinity of the chemical for the tissue relative to blood. The rate of distribution of a chemical from blood to tissues can be perfusion- or diffusion-rate-limited. For lipophilic chemicals that rapidly cross membranes, the rate of delivery to tissues is limited by blood flow (perfusion-rate-limited). For polar and ionized chemicals that do not readily cross the plasma membrane, the rate of delivery to tissues is limited by diffusion (diffusion-rate-limited). Plasma protein binding increases the rate of distribution to tissues for toxicants that are not diffusion-rate-limited. The free toxicant may readily cross the capillary wall, effectively decreasing its free concentration in blood. Bound toxicant then dissociates from plasma proteins to maintain the equilibrium between the bound and free forms, yet the new free molecules rapidly leave the blood, which further increases dissociation of bound toxicant, and so on. In contrast, distribution of more polar compounds that are diffusion-rate-limited is dependent on the extent of protein binding.

Initial distribution is influenced primarily by blood flow to tissues, whereas final distribution is influenced primarily by the relative affinity of the chemical for various tissues relative to blood (i.e., the tissue partition coefficient). In the early phase of distribution, tissues that receive a high blood flow (e.g., liver, kidney, and brain) may achieve high concentrations of the chemical even though the tissue partition coefficient for that chemical is low. Likewise, tissues that are slowly perfused (e.g., adipose) may achieve a low concentration of the chemical in the early phase of distribution even though the tissue partition coefficient for that chemical is very high. Later in the distribution phase, however, the chemical redistributes to tissues based on tissue partition coefficients, and the chemical is more concentrated in tissues with relatively high partition coefficients.

## Excretion

In mammalian organism, several routes of elimination are available. The main excretory organ is the kidney. The kidneys receive 25% of the cardiac output; about 20% of this volume is glomerular filtration. Substances with a molecular weight less than 60 kDa are filtered by the glomeruli. As a result of this, protein-bound chemicals cannot readily be eliminated via this pathway. For effective renal elimination, lipophilic substances require biotransformation to more water-soluble metabolites, as lipophilic substances are subject to renal reabsorption, while hydrophilic metabolites may preferentially utilize active transport systems for organic anions and cations. Other excretory pathways are the gastrointestinal tract (excretion via the bile), secretory glands (e.g., milk, sweat, and tears), and, for volatile substances, the lung (Fig. 1).

---

## Toxicokinetic Parameter

### Time-Course Analyses

Toxicokinetic processes are commonly described by either zero-order or first-order kinetic profiles. When applying zero-order kinetics, the same amount of the substance, regardless of its initial concentration, is eliminated. Alcohol is a good example that is eliminated by zero-order kinetics; that means it is eliminated at a rate of about 25 mg/dL/h, a steady amount rather than a steady percentage in case of a first-order kinetics. Most substances are eliminated in something close to first-order kinetics. The biological half-life or elimination half-life of a substance is the time it takes for a substance or its metabolite to lose half of its biological activity. In a toxicological context, half-life describes the time it takes for the organ or blood plasma concentration of a substance to halve (“organ or plasma half-life”) its steady state. The relationship between the biological and plasma

half-lives of a substance can be complex depending on the substance in question, due to factors including accumulation in tissues, active metabolites, and receptor interactions. A typical example of a first-order retention and elimination kinetics has already been shown above (Fig. 5).

## Volume of Distribution

The apparent volume of distribution ( $V_d$ ) is a proportionality constant that relates the amount of substance in the body to its concentration in plasma. It is the theoretical volume of fluid the substance would occupy to achieve the observed concentration in plasma. For instance, a substance that is sequestered in a particular tissue will have a low concentration in plasma and a corresponding high volume of distribution, which may in fact be greater than the total body water. Thus, the volume of distribution has nothing to do with the actual volume of the body or its fluid compartments but rather involves the distribution of the drug within the body. Volume of distribution provides a reference for the plasma concentration expected for a given dose but provides little information about the specific pattern of distribution. Each drug is uniquely distributed in the body. Some drugs distribute mostly into fat, others remain in extracellular fluid, and others are bound extensively to specific tissues. Only unbound drug is available for passive diffusion to extravascular or tissue sites where the pharmacologic effects of the drug occur. Therefore, the unbound drug concentration in systemic circulation typically determines drug concentration at the active site and thus efficacy. The initial volume of distribution describes blood concentrations prior to attaining the apparent volume of distribution and uses the same formula.

## Area Under the Curve

The degree of systemic exposure is defined as the integral area under the concentration-time curve, area under the curve (AUC). It represents the change in concentration over time (Eq. 4):

$$AUC = \int_0^{\infty} C dt \quad (4)$$

Bioavailability (F) is the absorbed fraction of a substance according to extravascular (e.g., by inhalation, oral, or dermal), relative to the intravenous dose. The appropriate surface integrals under the plasma concentration-time curve represent the bioavailability and are dependent on many factors such as route of administration, vehicle, or species (Eq. 5).

$$F = \frac{D_{iv}AUC_{ex}}{D_{ex}AUC_{iv}} \quad (5)$$

## Significance of Toxicokinetics in Regulatory Toxicology

Toxicokinetic data are indispensable cornerstones to describe the fate, ecotoxicity, and mammalian toxicity of xenobiotics in the environment, to understand differences of their behavior in *in vivo* and *in vitro* bioassay systems, and are an essential prerequisite for risk assessment. The uncertainty involved in the extrapolation of animal-based dosimetry to humans is significantly reduced in case in-depth pharmacokinetic is available. Kinetic information is used for hazard classification and PBT (persistent, bioaccumulative, toxic) assessment as well as wildlife and human food chain exposure modeling for the chemical safety assessment. It is also a factor in deciding whether long-term toxicology testing might be necessary. This is because chemical accumulation may result in internal concentrations of a substance in an organism that causes toxic effects over long-term exposures even when external concentrations are very small. Highly bioaccumulative chemicals may also transfer through the food web, which in some cases may lead to biomagnification.

The expression of toxicity arising from exposure to a substance is a consequence of a chain of events that results in the affected tissues of an organism receiving the ultimate toxicant in amounts that cause an adverse effect. The factors that confer susceptibility to certain species and lead to major differences between animals and humans, in their response to such chemical insults, are based either on the nature and quantity of the ultimate toxicant that is presented to the sensitive tissue (toxicokinetics, TK) or in the sensitivity of those tissues to the ultimate toxicant, that is, the toxicodynamic response. While their toxicokinetic data are mandatory for pharmaceuticals, there is no specific requirement to generate toxicokinetic information in the notification or authorization process of chemicals. Nonetheless, in the European REACH regulation, Annex I states that “the human health hazard assessment shall consider the toxicokinetic profile (i.e., absorption, metabolism, distribution, and elimination) of the substance.” Likewise, REACH announces in Annex VIII that one should perform “assessment of the toxicokinetic behavior of the substance to the extent that can be derived from the relevant available information.”

Although TK is not a toxicological endpoint and is not specifically required by chemical regulations, the generation of TK information is definitely encouraged as a means to better interpret and amalgamate data from different sources and to assist testing strategy and study design, as well as category development, thus helping to optimize test designs: Prior to any animal study, it is crucial to identify the benefits that will be gained from conducting such a study. The TK behavior derived from available data might make further testing unnecessary in terms of predictability of other properties. The most critical factor influencing toxicity is the concentration of the ultimate toxicant at the actual target site (tissue dose). In this context, bioavailability is a relevant parameter for the assessment of the toxicity profile of a test substance. It links dose and concentration of a substance with the mode of action, which covers the key events within a complete sequence of events leading to toxicity.

The definition of actual TK studies on a case-by-case basis might further improve the knowledge about substance properties in terms of expanding knowledge on properties sufficiently to enable risk assessment. Overall, the formation of data that are unlikely to be used and that constitute an unnecessary effort of animals, time, and resources shall be

avoided using any supporting data to do so. Moreover, it can provide important information for the design of (subsequent) toxicity studies, for the application of read-across and building of categories. Taken together, along with other approaches, TK can contribute to reduction of animal use in toxicology and reduces uncertainty in risk assessment.

---

## Future Directions

With the advent of nanotechnology, nanostructures are increasingly investigated in *in vitro* cell culture systems. Particokinetics need to be improved and refined for insoluble structures for comparative *in vivo/in vitro* cellular dosimetry. Toxicokinetics may be playing a more significant role in predictive *in silico* toxicology with PBPK-modeled study design to illustrate the complex relationship between toxicity and physicochemical characteristics which make generalizations possible with less numbers of experimental animals. Theragnostic (a portmanteau of *therapeutics* and *diagnostics*) is a proposed process of a targeted diagnostic therapy for individual patients for new principles of medication and to tailor treatment by a combination of pharmacokinetics and pharmacodynamics.

**Abstract**

Toxicodynamic testing is aimed at the elucidation of adverse effects of chemicals including understanding of their mode of action. In many cases, the “standard program” of toxicological testing on acute, subchronic, or chronic toxicity, genotoxicity, carcinogenicity, teratogenicity, and developmental and reproductive toxicity, which is needed for many regulatory purposes, already provides important information on the mode(s) of action of a compound. Targeted mechanistic investigations often follow, which use specifically designed models such as genetically modified cells or animals, studies using specific cell types, subcellular fractions, enzymes, etc. The understanding of the mechanisms underlying a certain mode of action and gained information on the dose- or concentration-response from *in vivo* or *in vitro* studies is crucial to derive point of departures for further human risk assessment and for regulatory toxicology of chemicals since it allows decisions on the options for extrapolation of experimental data to the human situation. This text follows the different levels of experimental models in toxicodynamic testing from isolated target molecules up to whole organisms like laboratory animals and humans.

---

**Introduction**

Depending on the special toxicological question addressed (Gregus and Klaassen 2001; Hayes 2001; Krewski et al. 2020), experimental models in toxicodynamic testing can make use of different hierarchical biological stages beginning with isolated target molecules like enzymes or receptors up to whole organisms like laboratory animals and humans as depicted in Fig. 1. Of course, biological complexity increases in this direction, possibly along with other factors like availability, price, or ethical issues or hindrances. In the following sections, we summarize and discuss options, advantages, and disadvantages of different experimental models in toxicodynamic testing.

---

**Isolated Target Molecules****Nucleic Acids**

Isolated nucleic acids of various degrees of purification can be obtained from different sources (DNA from calf thymus, herring sperm, tissue cultures, etc.) and be incubated with a chemical and/or its metabolites to detect if covalent binding occurs which may implicate a genotoxic/mutagenic mode of action. Reactive metabolites can be generated *in situ* by adding activating enzymes (“S9 mix”) to the

**Fig. 1** Levels of experimental models in toxicodynamic testing

incubation. Subsequently, the nucleic acids are extracted, digested, and analyzed, e.g., for covalent binding of nucleosides to the chemical and/or its metabolites. Stable isotope-labeled DNA adduct standards can be added to the nucleoside preparation to quantify known DNA adducts most frequently via sensitive and specific LC-MS/MS methods. Alternatively, nucleotides (after hydrolysis) including modified nucleotides can be post-labeled with radioactive  $^{32}\text{P}$  containing phosphate for further separation and identification via autoradiographic TLC ( $^{32}\text{P}$ -Postlabeling) which may help to screen for structurally unknown DNA adducts. Also, epigenetic alterations can be investigated in cell lines or in vivo, e.g., DNA methylation pattern or several histone (protein) modifications in intact DNA.

## Proteins/Enzymes

The chemical or material of interest can be incubated with tissue or cell homogenates or with purified enzymes or other proteins. Assays are aimed at testing covalent or noncovalent binding but also functional effects on proteins (Pumford and Halmes 1997). Well-known examples are the inhibition of acetylcholine esterase by

organophosphates, binding of inhibitors of mitosis to tubulin in the spindle apparatus, or enzyme inhibition by certain heavy metals such as mercury ions. In the course of such tests, information on the type of inhibition can be derived from concentration-effect analysis using a variety of inhibitor concentrations.

## Lipids

Incubating purified lipids with test compounds or their metabolites can also be used to identify possible covalent or noncovalent binding or, for example, to study lipid peroxidation (via end products like malondialdehyde or 4-hydroxynonenal) as a marker for oxidative stress in a cell or organism (e.g., TBARS (thiobarbituric acid reactive substances) assay). Again, addition of an enzyme preparation can be used to modify, e.g., activate, the test compound in purified preparations.

---

## Subcellular Fractions/Organelles

### Membranes: Cytoplasmic Fraction

The common method to isolate membrane fractions is sequential centrifugation. Likewise, a total membrane fraction can be isolated from a liver homogenate ultracentrifugation at  $100,000 \times g$ , after nuclei, mitochondria, etc. have been sorted out at lower  $g$  numbers. The supernatant of the membrane fraction represents the soluble cytosolic fractions, sometimes called “cytosol.” The sediment (“membrane fraction”) can be resuspended and subjected to additional (gradient) centrifugation in order to enrich certain types of membranes. Following this approach, fractions enriched in endoplasmic reticulum (“microsomes”) – or outer cellular membrane-derived membranes – can be prepared. The degree of enrichment can be verified by measuring the presence or activity of marker proteins after addition of needed cofactors.

Such fractions can be used for the investigation of membrane-bound (CYPs, UGTs, etc.) or cytoplasmic (GSTs, STs, etc.) enzyme activities, induction, inhibition, etc. Furthermore, the metabolism of chemicals including genotoxic carcinogens, leading eventually to mutagenicity, DNA binding, etc., can be analyzed. Together with kinetic parameters obtained from such time- and/or concentration-dependent experiments, also biokinetic properties and eventually DNA-binding activities *in vivo* can be estimated (physiologically based biokinetic, PBBK modeling). The supernatant of a  $9000 \times g$  centrifugation of homogenized liver is called S9 mix or S9 fraction, which contains microsomes and cytosol.

## Receptors

In a strict sense, receptors act as triggers of signaling chains responding to agonistic molecules by binding and change in receptor conformation. A typical consequence of receptor activation is the formation of intracellular signal molecules called

“second messengers.” Likewise, the binding of noradrenalin to  $\beta_1$ -adrenoceptors can result in enhanced intracellular formation of the second messenger cAMP. Xenobiotic chemicals can act on both membrane-bound receptors on the outer cellular membrane and on intracellular receptors, being located, e.g., in the cytoplasm or the nucleus. Also, trafficking of activated receptors, i.e., translocation from the site of ligand binding to the site of effect, is common. Xenobiotic ligands can mimic endogenous ligands, thus activating receptors thought to be responsive to hormones, transmitters, etc. In some cases, endogenous ligands are unknown (“orphan receptors”), or there is no scientific agreement on the identity of “the endogenous ligand” although a variety of endogenous compounds can bind to the receptor.

Effects of xenobiotic chemicals on receptors have been widely described and are considered as a central field in toxicodynamic research. In many instances, such effects are wanted, representing a fundamental mode of action of many therapeutic drugs. In toxicology, receptor activation can be crucial for many adverse effects. One example is the activation of hormonal receptors like ER (estrogen receptors), allowing to determine the “endocrine-disrupting” effect of chemicals in a direct receptor-binding assays or via reporter gene assays for chemicals that otherwise may not have toxicological adverse effects (like being genotoxic or carcinogenic, etc.). Also, the binding of dioxins to the aryl hydrocarbon receptor (AhR) is a prominent example. A major field of research on xenobiotic-responsive receptors is the adaptive response of drug-metabolizing enzymes called “induction of drug metabolism.” This phenomenon, which can have adverse consequences for the organism, is used as a marker for certain types of receptor activation being monitored as a regulated battery of genes/enzymes. Some important examples for such concerted responses are given in Table 1 listing, e.g., the AhR, CAR (constitutive androstane receptor), PXR (pregnane X receptor; Fig. 2), or the PPARs (peroxisome proliferator-activated receptors).

Ligand binding to the receptor can be agonistic, partially agonistic, or antagonistic. This classification can depend on receptor subtype, cell type, species, etc. Furthermore, a compound can bind to an alternative (“allosteric”) binding site on the receptor, thus modulating the affinity and/or effect transmission capacity of the “real” ligand which binds to the ligand binding site. These phenomena can be studied including binding assays in receptor-enriched tissue fractions or transfected cell lines which (over-)express the receptor of interest, e.g., combined with a specific reporter gene construct.

## **Transfer Through Biological Membranes (Ion Channels, Transporters, and Pumps)**

In most cases, the function of ion channels, transmembrane transporters, and pumps is investigated using membrane fractions since most of these proteins are embedded in membranes. From the latter, vesicles can be prepared which can be used for transport studies, e.g., with radioactively labeled transport substrates. Such models are suitable for the analysis of the binding affinity of standard substrates, modulation of transport function, properties of a test compound as transport substrate,

**Table 1** “Xenobiotic” receptors regulating expression of drug-metabolizing enzymes

Receptor	Chemical/compound	Inducible enzyme(s)
Aryl hydrocarbon receptor (AhR)	DL-PCBs, PAHs, TCDD	CYP1A1, 1A2, 1B1
Constitutive active (androstane) receptor (CAR)	DDT, NDL-PCBs, phenobarbital,	CYP2B1, 2B2, 2B6, UGT2
Peroxisome proliferator-activated receptors (PPARs)	Fibrates, phthalates (diethylhexyl phthalate)	CYP4A
Pregnane X receptor (PXR)	Clotrimazole, dexamethasone (rodents), HBCD, pregnenolone 16 $\alpha$ -carbonitrile, rifampicin	CYP3A, 7A1, OATP2, MRP2, MDR1/Pgp
Nrf2 (via antioxidant-responsive element; ARE)	BHA, BHT, t-butylated hydroquinone	GSTYa, M, P1, NQO1

Abbreviations: *BHA* butylated hydroxyanisole, *BHT* butylated hydroxytoluene, *CYP* cytochrome P450, *DL-PCB* dioxin-like polychlorinated biphenyls, *GST* glutathione *S*-transferase, *HBCD* hexabromocyclododecane, *MRP* multidrug resistance-associated protein, *MDR/Pgp* multidrug resistance protein/P-glycoprotein, *NQO* NAD(P)H-quinone oxidoreductase, *NDL-PCB* non-dioxin-like polychlorinated biphenyls, *OATP* organic anion transporter, *PAH* polycyclic aromatic hydrocarbons, *TCDD* 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, *UGT*, *UDP*-glucuronosyl transferase

**Fig. 2** Induction of gene expression via the pregnane X receptor (PXR). Upon ligand binding, the receptor dimerizes with the retinoid X receptor (RXR). The dimer binds to consensus sequences (direct repeats, inverted or everted repeats) in the 5'-flanking region of responsive genes, thus modulating their transcription

conformational changes in protein structure upon substrate binding, etc. Furthermore, cell cultures can be applied in order to investigate the consequences of a targeted overexpression of a certain transmembrane protein, its genetic elimination (“knockout”), or selective inhibition by antagonists.

Finally, transmembrane transfer proteins can be regulated at the level of gene expression and localization within the cell (“trafficking”) or tissue, in tissue culture or whole organisms.

## **Mitochondria**

Mechanistic studies in isolated mitochondria comprise the investigation of mitochondrial damage (loss of physiological function) and mitochondrial signaling. Mitochondrial enzymes involved in oxidative phosphorylation/ATP production and oxygen consumption (“respiratory chain”) are typical targets of chemicals (blocking of respiration, uncoupling of oxygen consumption and ATP formation, etc.). Signaling compounds released by damaged mitochondria comprise cytochrome c, calcium ions, and many others. Gross change in mitochondrial function can be measured as changes in membrane potential, proton concentrations, oxygen consumption, calcium flow, ATP/ADP ratio, etc.

## **Nuclei**

Isolated nuclei are used for mechanistic studies investigating effects of chemicals on gene transcription (nuclear run-on assays), covalent and/or noncovalent (“intercalation”) binding to DNA, other types of DNA damage (e.g. by oxidation, strandbreaks), and modifications of chromatin and effects on nucleosomes or on DNA/chromatin processing enzymes (topoisomerases, nucleic acid polymerases, etc.).

---

## **Cells**

### **Permanent Cell Lines**

In contrast to many primary cells in culture, permanent cell lines always proliferate in culture being harvested from the culture plate and seeded onto empty cell culture dishes. This “passaging” can virtually be used as an infinite source of cells. However, permanent cells frequently change their properties after several rounds of passaging. Thus, the passage number should be provided as an additional source of information in experiments with permanent cells and tests with high passage numbers should be avoided.

Permanent cell lines are of limited use in the study of the mode of action of a chemical because they usually differ more or less from the corresponding primary

cell type. In many instances, permanent cell lines are derived from tumors exhibiting profound changes in genotype and phenotype when compared to normal cells. For the successful use of permanent cells lines, their properties should be investigated as far as possible. A focused analysis of effects on defined signaling pathways, which are known to be regulated in a similar way in primary cells, is a typical example for such use.

For instance, it has to be considered that ATP production in many classical proliferating cancer-derived cell lines is based on glycolysis under hypoxic conditions rather than oxidative phosphorylation which decreases cells susceptibility to mitochondrial toxicants. Thus, to study mitochondrial toxicity, glucose in the cell culture medium may be replaced by galactose to increase mitochondrial activity. Another important issue is to ensure that enzymes/transporters for the uptake of a chemical that has to be examined or enzymes to metabolize a chemical, e.g., to a mutagenic electrophile, are expressed and active in a used cell line. However, genetically modified permanent cells lines can be a well-suited tool to investigate several toxicological endpoints if it is warranted that all necessary enzymes are produced. Furthermore, genetically engineered permanent cell lines over- or under-expressing certain genes of interest provide a powerful tool to study the influence of the encoded proteins on various outcomes, pathways, etc.

## Primary Cells and Organoids

Cells isolated from certain organs or tissues of humans or experimental animals such as liver, lung, kidney, or immune cells usually comprise a mixture of several cell types. The cell preparations are obtained, e.g., by perfusion of the organs with media which disintegrate the tissue or by lavage of the organ surface (e.g., pulmonary epithelia). Individual cell types, e.g., hepatocytes (liver), alveolar cells type I (lung), or macrophages (blood, tissues), can be prepared from mixtures of different cell types by sequential centrifugation/density gradient centrifugation. Many primary cell types can be seeded and adhere on uncovered or specifically covered cell culture dishes or tissue culture flasks. The culture conditions usually aim at keeping the cells as long as possible in their differentiated state, i.e., to maintain their tissue-specific (“in situ”) properties and functions. In most instances, this aim cannot be achieved completely, and/or differentiation is partially lost during culture. Usually, permanent cells undergo senescence or lose their specific phenotype after a certain time in culture. This can partially be circumvented using 3D embedding or suspension techniques using extracellular matrix. Beside this, generating organoid structures from adult or pluripotent stem cells is a promising tool to study organ toxicity in a model near to the *in vivo* situation; however such models are not always commercially available (Messina et al. 2020). Parameters which allow conclusions on the mode of action of a chemical in cell cultures include cytotoxicity and cell death, effects on cell culture density, proliferation, apoptosis, as well as changes in protein synthesis or growth behavior (e.g., loss of contact inhibition, growth in soft agar). Likewise, the mechanisms leading to necrosis or apoptosis in cell culture are

investigated in detail (Wyllie 1997). Hallmarks of molecular pathways are activation of receptors (Fas receptor; TGF- $\beta$ 1 receptor, etc.), mitochondrial signaling, changes in apoptosis-regulating factors (TNF alpha, bcl-2, bax, p53, etc.), or activation of caspases. In such investigations, various cell types equipped with different receptors as well as various derivatives of the test compound can be used. Furthermore, “omics” analyses detecting changes in gene expression (gene arrays, etc.), protein patterns (proteomics), and endogenous metabolites (metabonomics) play a more and more important role in identifying the cellular mode of action of a chemical but also need bioinformatic methods for their analysis due to the large amount of gained data. In more specific studies, secretion of certain growth factors or tissue hormones, matrix-cell interactions, release of transmitters, etc. are analyzed. The effects of such changes can be measured directly in co-cultures with respective responder cells (e.g., immune cells). In addition, certain biochemical effects such as enzyme inhibition, binding to nucleophilic targets, generation of reactive oxygen species, etc. can also be analyzed in primary cell cultures.

Of particular interest in toxicology is the investigation of genotoxic events in primary cells. These analyses comprise the determination of modified DNA bases, DNA fragmentation, mutations, micronuclei formation, chromosomal changes, DNA repair, etc.

---

## Tissues

### Isolated Organs

Isolated perfused organs such as the liver, lung, heart, intestine, or kidney from rat, rabbit, or guinea pig represent widely used models for the study of the mode of action of a chemical in toxicological research. They allow, e.g., the study of necrotic cell damage and its modulation by inhibitors of metabolic activation or by the addition of protective substances (e.g., of acetylcysteine in paracetamol-mediated liver damage). Furthermore, the issue of localization of the damage or of the underlying biochemical pathway can be addressed. Likewise, perfusion with an acute nephrotoxicant allows the determination of the exact site of tubular damage or the role of glutathione depletion in such a scenario. The perfusion rate (flow) and pressure characteristics can be of interest in analyzing the pathogenesis of a damage, e.g., in particular in lung or kidney. In addition, “functional” effects in an isolated organ such as changes in heart rate, uterus contraction, etc. can be detected. The duration of experiments with isolated organs is limited by the lifespan of the organ being between minutes and a few hours. In many cases, this time is sufficient, however, to obtain relevant amounts of metabolites from a chemical or sufficient organ damage, depending on the start concentration of substrate. A novel development in tissue research is the use of organs isolated from domestic animals such as pigs or cows from slaughterhouses. This method allows the reduction in numbers of experimental animals and benefits from the relatively close relationship between porcine and human physiology when compared to rodents.

---

## Tissue Slices

Studies in tissue slices allow one to address many questions which can also be dealt with in isolated perfused organs or in cell culture. Thus, this model is positioned between cells and intact organs. Tissue slices are easy to prepare and use (no difficult preparation, no perfusion equipment, etc.) but lack the physiological perfusion via the blood vessels. Nevertheless, tissue slices in certain instances may allow relevant conclusions about the type of tissue damage, xenobiotic metabolism, and its modulation or complex changes in gene expression.

---

## In Silico Methods

In silico methods are aimed to complement existing toxicity tests to predict toxicity, prioritize chemicals, guide toxicity tests, and/or minimize late-stage failures in drugs design. Those methods are interesting, because they are faster and cheaper than in vitro or in vivo experiments and of course for ethical reasons because no animal experiments are needed. As mentioned before, e.g., toxicokinetic parameters can be obtained by PBBK modeling using in vitro data. Also, for some toxicodynamic endpoints in silico methods are somewhat useful or are even already accepted in some regulatory fields. Methods include knowledge-based (i.e., decision trees have to be completed guided by rules defined by experts), QSAR models (quantitative structure-activity relationship; using a set of chemicals with known effect to span a domain in which the unknown chemical is inter- or extrapolated using different determinants) and read-across methods (based on structural similarities). The most developed endpoint in this regard is probably genotoxicity/mutagenicity, whereas other endpoints may be rather poorly predictable yet. For example, the risk assessment of genotoxic impurities in pharmaceuticals can be performed using different in silico methods (at least one knowledge-based and one QSAR model) and the TTC approach (threshold of toxicological concern) under EMAs ICH M7 guideline. Other endpoints/mode of actions that can currently be evaluated with different quality include DNA and protein reactivity, metabolism by cytochrome P450 and phase II enzymes, skin sensitization, or even carcinogenicity (genotoxic/non-genotoxic). Free and proprietary software tools are ToxTree, QSAR toolbox, Lhasa Nexus, Vega, and many others.

---

## Adverse Outcome Pathways

An adverse outcome pathway (AOP) describes a series of so-called key events (KE) linked by key event relationships (KERs) on many hierarchical stages (from the molecular level to a whole organism) that are necessary to develop a toxicological adverse outcome, i.e., a disease or an effect like skin sensitization, followed by a molecular initial event (MIE). An important assumption of AOPs is that toxicological processes tend to share KEs and KERs, within an individual organism and also

across species. Furthermore, one MIE can be associated with different adverse outcomes and vice versa (Krewski et al. 2020). In case of skin sensitization, the MIE (after absorption) is the covalent reaction of a chemical with skin proteins, and KEs are keratinocyte response (activation of inflammatory cytokines), mobilization of dendritic cells and T-cell proliferation. All of these MIE or KEs are separately assessable with *in vitro* methods (see OECD Test guidelines: 428, 442C, 442D, 442E, 429). Together with the development of further specialized *in vitro* assays which address single KEs and MIEs as alternatives to animal testing and with *in silico* methods, assessment of AOPs may play a major role in the future in reducing and replacing animal experiments in line with the 3R concept.

---

## Experimental Animals

### Acute Toxicity/Organ Toxicity

Experimental animals represent the most relevant model for the comprehensive prediction of adverse effects of chemicals in humans. Also studies on the mode(s) of action of a chemical can be performed in animals covering many various aspects. For example, the effects of a chemical on certain enzyme activities, levels of hormones, growth factors, etc. in blood or target tissues can be investigated. Furthermore, a broad spectrum of parameters of organ function and morphology (histopathological analysis) can be carried out. From the complex picture thus obtained, conclusions can be drawn on the possible mode of action. These can be substantiated by the target application of modulators such as enzyme inhibitors. Furthermore, studies on effects on gene expression and transcription (“genomics/transcriptomics”), protein levels (“proteomics”), endogenous metabolites (“metabonomics”), or the metabolism of the xenobiotic chemical of interest (“metabolomics”) are essential parts of the current broad approach in toxicological research.

Using modern methods of genetic engineering and breeding, genetically modified strains can be obtained which allows further conclusions on molecular targets. Examples are rodent strains with deleted or silenced genes (“knockout” animals) or strains which overexpress a certain homologous or heterologous (“humanized”) gene. Likewise, the study of Ah receptor-knockout mice has provided crucial insight into the biology of this receptor and its role in dioxin toxicity. Another example is the use of DNA repair-deficient mice to investigate the role of DNA repair mechanisms on the genotoxicity of chemicals.

### Chronic Toxicity/Organ Toxicity

The investigations (and prediction) of chronic adverse effects, i.e., lifetime exposure, e.g., over a period of 1–2 years for a chronic rat study with daily (or 5 days/week) treatment of a chemical via the appropriate route (oral, dermal, inhalation), represent

the most challenging task in toxicological research (see ► [Chap. 9, “Examination of Acute and Repeated-Dose Toxicity”](#)). The relevant changes are mostly unknown when the experiment starts. Furthermore, exposure in a certain time window may be the most relevant. In any case, animal experiments still are the most reliable tool in predicting chronic toxicity in humans. Crucial endpoints can be clinical, (histo) pathological, biochemical observations including weight gain, food/water consumption, organ weights, hematological changes, mortality rates, any morbidity and histopathological changes in organs, etc. For a more comprehensive overview, see [OECD Test guideline 452 \(Chronic Toxicity Studies\)](#). Accompanying *in vitro* studies can be applied to obtain more information on the molecular mechanisms or mode of action underlying adverse effects observed in chronic animal studies.

## Other Modes of Action

Targeted analyses in animal testing are aimed at understanding mode(s) of action. They make use of the broad pattern of biochemical and pharmacological testing approaches such as changes in intestinal passage, blood flow, arterial blood pressure, bile flow, renal blood flow, and inulin clearance, to mention a few. However, a minor temporal change in bile flow or blood pressure does not necessarily represent an adverse effect since it also occurs under physiological conditions representing reversible, adaptive responses (see ► [Chap. 43, “Adverse Effects Versus Non-adverse Effects in Toxicology”](#)). Such observations can be very helpful, however, in the understanding of a mode of action and may even be useful in the development of new therapeutic drugs. Additional experiments frequently follow in order to clarify the molecular mechanisms leading to the observed mode of action, e.g., an induction of a biliary export pump in increased bile flow. The induction of drug-metabolizing enzymes is another example of a frequently observed, adaptive, and thus not necessarily adverse consequence of xenobiotic exposure in laboratory animals.

## Genotoxic and Carcinogenic Effects

Mechanisms of genotoxic effects can be found in many of the aforementioned experimental models. Following the paradigm that mutagenic effects and primary carcinogenic (“initiating”) lesions are permanent changes in nuclear DNA, the investigation of genotoxic events is focused on DNA. They include bacterial (Ames test, rec test) or yeast cells, mammalian cell lines (sister chromatid exchange, micronucleus test, HPRT assay, comet assay, etc.), or intact animals (mouse micronucleus assay) identifying DNA strand breaks, mutations, and aneugenic or clastogenic effects.

The enormous complexity of the carcinogenic process does not allow a comprehensive testing for carcinogenicity using short-term assays. Phenomenologically, carcinogenicity can be studied using laboratory animals ([OECD Test guideline 451](#)), most often rats and/or mice or non-rodent species. Although the main reason to conduct such a study is to obtain information on tumor formation and incidences in

different organs, data as mentioned for chronic studies (e.g., weight gain, hematological, clinical, biochemical data etc.) are collected as well. The multistage concept of carcinogenesis suggests the existence of a primary lesion, which predisposes the “initiated” cell for a development into a malignant cell passing various stages. These stages, also termed as promotion and progression, require the presence of additional factors which allows the cell to proceed on this way. It is unclear if these additional steps involve or even require specific genetic changes. Furthermore, predisposing genetic changes in “normal” cells may make those cells vulnerable to additional factors and may even be inherited by the organism. Examples for such predispositions are the familial polyposis coli with respect to colon cancer or the hereditary disposition for breast cancer. A widely used tool to investigate the multistage development of cancer is hepatocarcinogenesis in rodents. In this model, certain mutations in critical genes (hot spots), e.g., in the H-Ras proto-oncogene, are linked to the initiation step (Anderson et al. 1992). The subsequent phase of promotion can be facilitated by chemical factors (tumor promoters) which may inhibit apoptosis of initiated cells, e.g., by suppression of pro-apoptotic pathways or by inhibition of intercellular signaling, etc. Likewise, certain receptors, such as CAR (constitutive androstane receptor), PPAR alpha (peroxisome proliferator-activated receptor alpha), ER (estrogen receptors), and GHR (growth hormone receptor), can mediate the promotion effect. Detailed studies, e.g., with humanized mice have led to the suggestion that receptor-mediated liver tumor promotion, e.g., with phenobarbital, can markedly differ between rodents and human, depending on receptor-mediated signaling. These studies illustrate the difficulties in the use of rodent-derived tumor-promotion data in regulatory toxicology.

## **Teratogenicity and Developmental and Reproductive Toxicity**

These investigations make use of almost all aforementioned experimental models using subcellular, cellular, organ, tissue, or whole animal systems. In addition to animal experiments in rodents, birds, and amphibians, mechanistic studies are aimed at the role of receptors (retinoid receptors, PPARs). Exposure of dams during pregnancy/lactation does ideally not lead to maternal toxicity. While malformations are frequently seen after birth, developmental effects can occur at later life stages or even only become visible at more advanced stages (learning behavior, etc.) or when the fertility of the offspring is investigated (“multi-generation study”). Detailed studies on reproductive toxicity of a chemical in experimental animals comprise macroscopic and microscopic investigation of changes in the reproductive organs, reproductive behavior, perturbations of steroid hormone homeostasis and metabolism, receptor-linked effects, etc. including an analysis of fertility and reproductive success. OECD guideline tests to study developmental and reproductive toxicity include the test guidelines 414 (Prenatal Developmental Toxicity Study), 416 (Two-Generation Reproduction Toxicity), 421 (Reproduction/Developmental Toxicity Screening Test), and 443 (EOGRTS: Extended One-Generation Reproductive Toxicity Study).

---

## Alternatives to Animal Tests

In line with the 3R concept (replacement, reduction, refinement of animal testing) introduced by Russell and Burch already in 1959, many toxicity tests for certain endpoints/modes of action prior partly or solely performed using laboratory animals are nowadays replaced by *in vitro* and/or *in silico* methods as described above. Examples are, for example, the BCOP (Bovine Corneal Opacity and Permeability) assay for eye irritation or the 3 T3 NRU Phototoxicity Test. A complete, frequently updated status report on validated and accepted alternative methods can be obtained from EURL-EVCAM (2018).

---

## Investigations in Humans

Toxicodynamic studies in humans include those during development of new drugs. Here, pharmacological studies can provide information on possible unwanted/adverse effects. Furthermore, interferences of chemicals with the signaling or metabolism of other compounds or substrates including endogenous compounds are of interest. In the field of receptors and drug-metabolizing enzymes, genetic polymorphisms have been identified in humans such as polymorphisms in the CYP2D6, CYP2C19, NAT2, GST  $\mu$ , genes, etc. These can result in toxicokinetic effects on the fate of chemicals which may have strong implications for the toxicodynamics. The methods used to identify those polymorphisms comprise DNA investigations looking for individual point mutations or more frequent single nucleotide polymorphisms, as well as gene expression analysis such as RT-PCR, western blotting, enzyme assays, or next-generation sequencing methods. Metabolism tests in healthy human volunteers are widely used to investigate the consequences of genetic polymorphisms of this type on the kinetics of standard substrates such as caffeine (CYP1A2, NAT2), debrisoquine (CYP2D6), or chlorzoxazone (CYP2E1) (Keller et al. 2017).

Experimental studies on chemicals other than drugs have been carried out in human volunteers under strict ethical and technical rules aiming at the prevention of severe or sustained adverse health effects in the cohort. Epidemiological studies, both observational and interventional, can provide valuable additional information on possible correlations between exposure and adverse outcome in humans. These usually require, however, strong support from biochemical, cell culture and animal data to reach the level of causality.

## Abstract

The tremendous progress in the development of new technologies in the areas of molecular biology and bioinformatics enables interrogation of cellular responses to toxicant treatment at a global molecular level, allowing evaluation of toxic effects in the context of molecular pathways.

The major techniques currently employed, especially transcriptomics, but also proteomics and metabolomics, are being used and further evaluated in investigational toxicology. Since they already have been shown to provide increased insight into molecular mechanisms of toxicological effects, such data have been submitted to regulatory authorities to support regulatory assessment of new

compounds in few cases. Still, such data could be used more broadly for hazard identification and even risk assessment, which is now being supported by recent initiatives though precompetitive collaborations.

## Introduction

Advancements in molecular biology research, especially the development of the microarrays in the 1990s, allowed the development of new technologies to perform detailed analyses of fundamental processes in living organisms. These so-called omics technologies enable the simultaneous measurement of all definable entities of an “-ome,” corresponding to a certain class of molecules in biology. Due to rapid development of DNA sequencing techniques, many genomes have now been completely sequenced, including human, mouse, and rat (genomics). Parallel analysis of all expressed genes in an organ or cell at the mRNA (transcriptomics) and protein (proteomics) level provides much increased insight into biological processes at the molecular level. Recently, similar analyses of noncoding RNAs, including long-noncoding RNAs (lncRNA) and microRNAs (miRNA), have been added as omics tool. Finally, measurement of all metabolites in cells and tissues or in body fluids indicates functional changes of cellular metabolism (metabolomics).

In general, the different omics technologies deliver complementary data. One technology is likely not sufficient to reveal all molecular processes interacting at the cellular or organ level (Fig. 1). Yet even if just one technology is used, it does

**Fig. 1** Omics technologies, applied in toxicology for global analyses of the major molecules present in biological samples, represent the major levels of gene expression and cellular pathways. The term “toxicogenomics” may also be used as a general term for omics applied to toxicological studies

increase our knowledge of toxicological processes. Currently, the technical requirements and maturity of the individual technologies are different.

---

## Toxicogenomics

Measurement and analysis of gene expression profiles (transcriptomics) under the influence of chemical stressors or toxic compounds (toxicogenomics) or in disease states is technically the most advanced among omics technologies. This is due to the underlying low complexity of the molecules to be measured, which are represented by a combination of only four bases obeying to clear principles of complementary base pairing, and to the relatively simple chemistry behind these molecules being experimentally easily accessible. Efficient techniques for quantitative measurement of the expression levels of many genes in a single sample could therefore be developed.

The first methods for global expression profiling were relatively elaborate open-profiling methods like *differential display*, which are based on conversion of all mRNAs in a sample into cDNA and extensive further processing to display differential expression levels. These are hardly used anymore. The emergence of whole genome *microarrays* represented a breakthrough then enabling routine whole genome profiling analysis. Microarrays allow interrogation of the expression level of essentially all known genes and/or sequenced transcripts of a species of interest.

In the beginning's microarrays were available in different designs, yet a few major ones are used nowadays, including arrays based on oligonucleotides, either printed on a solid support, attached to beads, or synthesized in situ onto a wafer chip. These types of arrays can be produced with much higher reproducibility than printed cDNA arrays used in early times. The general method encompasses adding a label to the isolated mRNAs via enzymatic steps, hybridizing the labeled molecules to the array with immobilized DNA molecules, and then quantifying the label, which may be fluorescent on its own, or via binding of fluorescently labeled molecules allowing signal amplification. The strength of the signal at a certain localization representing a specific gene then is proportional to the amount of the corresponding mRNA in the original sample. A comparison between major microarray types, performed by the MicroArray Quality Control (MAQC) consortium, with participation by microarray platform providers, the US FDA National Center of Toxicological Research, and others, revealed high repeatability between and within platforms and high correlation between microarray results and other quantitative gene expression measurements (Guo et al. 2006).

Another now well-established method for transcriptomics is RNA sequencing based on next-generation sequencing (NGS). This technology allows much faster and cheaper sequencing of, for example, whole genomes than the sequencing technologies available before (Woollard et al. 2011). NGS is now widely applied for various omics investigations, e.g., in pharmacogenomics research to search, for mutations in cancer genomes, for evaluation of the epigenome concerning regulation

of gene expression, and for expression profiling. The latter is based on the fact that NGS can also count how many times the same sequence is available in a DNA pool.

A further major technique to measure RNA levels is quantitative polymerase chain reaction (Q-PCR), which allows sensitive quantification of one to several hundreds of known genes; Q-PCR may be used to validate expression profiling results or measure certain genes in many samples in a higher-throughput version.

Issues such as reproducibility of gene expression profiling techniques, standard practice for assays and analysis, relevance of the results to conventional endpoints, and robustness of statistical models on diverse data sets have been and are addressed by public consortia in addition to MAQC. Due to recommendations for technical aspects developed in such efforts, several expression profiling methods are now available for toxicogenomics investigations. These include highly standardized microarrays with reproducible performance and reasonable sensitivity, potentially more sensitive RNA sequencing protocols (Wang et al. 2014), and higher throughput versions of the latter like TempO-Seq (Bushel et al. 2018).

---

## Proteomics

Proteomics, which encompasses identification and quantification of all proteins within a given proteome, is rather challenging and therefore higher throughput versions are being developed only now, which have not yet been widely applied in toxicology.

Reasons are (1) the much bigger complexity of the proteome compared to the genome due to the many possible protein modifications, (2) the wide dynamic range, (3) detection limits of the available technologies, (4) challenges with respect to characterization of membrane proteins, and (5) requirement for pre-fractionation (Ly and Wasinger 2011). Pre-fractionation can be performed with diverse methodologies, including various electrophoretic and chromatographic techniques. Then the separated proteins need to be extracted and identified with mass-spectrometric methods. Due to this rather elaborate workflow, proteomics analysis on a global scale were mostly used for specific mechanistic investigations. Recent developments include specific methods for certain questions, like investigation of the plasma protein patterns associated with different health conditions (Williams et al. 2019), or higher-throughput versions of immune-based methods with improved sensitivity (Greenwood et al. 2015). They may in the future also be used for toxicological questions.

---

## Metabolomics

Metabolomics has the goal to comprehensively and quantitatively analyze all metabolites in a given sample, which could be cell or organ extract, or any biofluid. In toxicological studies, metabolomics may reveal affected metabolic pathways via

altered metabolite patterns which could either be causally involved in the toxic phenotype or represent the downstream effect of a toxic insult.

The large diversity in chemical and physical properties and the wide range of metabolite concentrations (nine orders of magnitude) pose great challenges to metabolomics methods. The two major technological platforms used are nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS)-based approaches, the latter usually with prior chromatographic separation like liquid (LC) or gas (GC) chromatography. Although NMR is the more quantitative method, it is less sensitive than MS. Furthermore, since annotation of NMR peaks is rather time-consuming, NMR may be used to define peak patterns for different classes of toxicants yet is of less use for clarification of toxicity mechanism. Since MS-based methods allow construction of databases containing spectra for known metabolites, they can be employed in mechanistic toxicology.

---

## Applications of Toxicogenomics in Toxicology

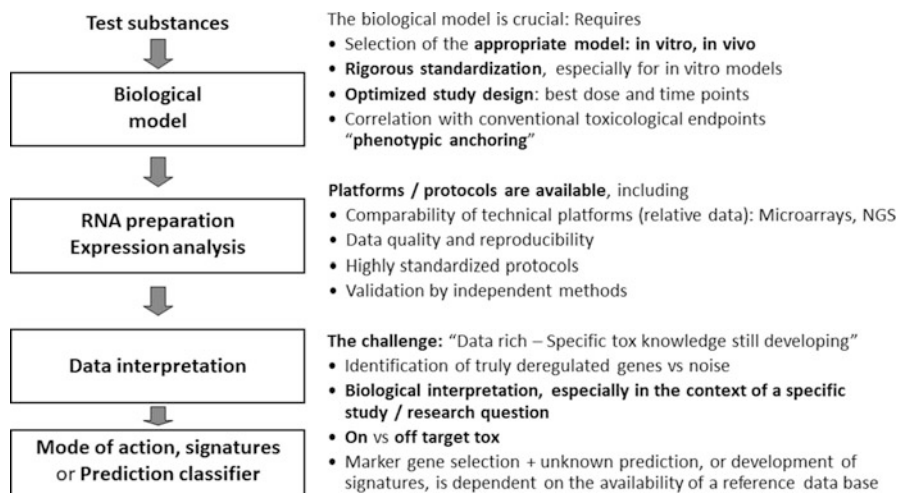

Fundamental assumptions of toxicogenomics are that all toxicological relevant effects are accompanied by gene expression changes and that similar toxicological mechanisms cause comparable expression changes, with potential exceptions being acute necrotic effects.

The idea to obtain insight into toxicological mechanisms from measurement of compound-induced gene expression has been around already before the appearance of expression profiling techniques, yet establishment of the latter permitted an analysis of these changes in their entirety, enabling to derive hypotheses about causative mechanisms.

A toxicogenomics study in general has three major components (Fig. 2): the biological model, the technological platform, and data analysis and interpretation, leading from application of a substance to a mechanistic hypothesis, to biomarker candidates or signatures, or to prediction of a potential toxicity. Both *in vivo* and *in vitro* models may serve as model, yet the studies need to be appropriately designed with respect to, e.g., time course and doses, and preferably should allow correlation of the expression profiles with conventional toxicological endpoints.

As outlined above, powerful technological platforms are nowadays available which enable examination of the influence of compound effects on essentially all genes in the corresponding target organs of the principle tox species. The major challenge then lies in analysis of the huge amounts of data being generated. Adequate methods must be applied for identification of a useful number of truly deregulated genes to derive a biological interpretation for the observed toxicological effects of a compound or compound class. Recommendations and best practices in this area have now been developed (Yauk et al. 2020).

Analysis of toxicogenomics data (Afshari et al. 2011; Chen et al. 2012) can broadly follow two major paths: (1) mechanistic analysis and (2) classification or prediction analysis. Biomarker genes, signatures or gene expression modules

**Fig. 2** Proper preparation and performance of the three major components of a toxicogenomic study is important to obtain good quality results

representing certain toxic effects may be derived from both approaches. A further extension of the mechanistic approach is benchmark dose (BMD) modeling of transcriptomic responses for derivation of provisional point of departure (POD) dose values for screening chemicals without published reference doses (RfDs) (Farmahin et al. 2017).

## Mechanistic Toxicogenomics

Mechanistic toxicogenomics encompasses the assignment of functional categories to significantly deregulate genes in a biological model in the context of dose and time dependence and their relation to possible mechanisms of toxic action. From this analysis, mechanistic hypotheses may be derived or mechanistic similarities between different toxic agents may be uncovered. This approach can nowadays be seen as “State of the Art” in toxicogenomics analysis, as revealed, for example, by the many publications to characterize toxic compound effects with gene expression profiling. Examples can be found in the chemical and pharmaceutical area and include evaluation of liver and kidney toxicity (Suter et al. 2011), of nanoparticle-induced lung toxicity (Bourdon et al. 2013), or of short-term molecular responses to rodent carcinogens (Ellinger-Ziegelbauer et al. 2009).

The increased insight gained by such investigations can contribute to development of so-called adverse outcome pathways (AOP). AOPs describe the development of an adverse outcome after toxicant treatment with a series of events starting with the molecular initiating event (MIE) followed by several key events (KE) at the organelle, cellular, tissue, or even organisms’ level, connected in a linear or branched

manner. This framework allows to organize information and knowledge on adverse events in a retrievable way and enables the development of simpler test batteries based on MIEs or KEs (Vinken et al. 2017).

---

## Predictive Toxicogenomics and Signatures

Predictive toxicogenomics relies on a database of expression profiles from samples representing organs or cells following treatment with compounds of predefined toxic classes. Then marker genes are selected, and classifiers are calculated by statistical or other algorithms to allow classification of unknown samples with respect to potential induction of these toxicity classes. For quite some time, due to challenges including compilation of a sufficient number of expression profiles derived from studies with well-defined compounds, and appropriate bioinformatics methods, toxicogenomics was not widely used for prediction. Yet recently, two of the largest toxicogenomic databases were made public: TG-GATEs from the toxicogenomics project in Japan (Uehara et al. 2011) and DrugMatrix, originally generated by Iconix Pharmaceuticals (Ganter et al. 2005). Both databases contain gene expression profiles of the liver after up to 4 weeks treatment of male Sprague Dawley rats and of hepatocytes treated *in vitro*, with compounds representing liver toxicants and non-liver-toxic controls, including several genotoxic and nongenotoxic rat hepatocarcinogens. Due to their uniform experimental design, availability of extensive metadata for classical toxicological endpoints, and the inclusion of marketed drugs which should allow an assessment of whether gene-expression profiles measured in preclinical models can help predict human toxicity, they are of great value for various investigations, e.g., evaluation of prediction classifiers. Based on an overlap of 72 compounds in the 2 databases, Gusenleitner et al. (2014) built a classifier with DrugMatrix data for prediction of a chemical's carcinogenic potential and validated this classifier with the TG-GATEs dataset. This yielded an overall 80% accuracy, suggesting that prediction of certain endpoints based on gene expression data is possible with a well-annotated and sufficiently large data set of robust quality. Such results and the availability of more and more well-annotated omics data from studies with similar designs led to reconsiderations of the use of omics data in risk assessment. In the chemical area, short-term toxicogenomic studies for chemicals associated with no or only few safety data can be used for prioritization of chemicals for further testing, e.g., for 2-year cancer bioassays.

To develop transcriptomics signatures associated with nuclear receptor or other stress responses in the liver, Podtelezhnikov et al. (2020) profiled the transcriptional changes in rat liver following administration of 120 different compounds including drugs and chemicals known to be associated with drug-induced liver injury. Their iterative bioinformatic approach, starting with a small set of well characterized compounds, enabled them to derive optimized gene expression signatures for five canonical xenobiotic nuclear receptors (AHR, CAR, PXR, PPAR $\alpha$ , and ER), three mediators of reactive metabolite-mediated stress responses (NRF2, NRF1, and P53), and one representing activation of the innate immune response in the liver. Although

not yet cast into a prediction classifier, further use of these signatures in collaborative settings is expected to aid in characterization of potential liver safety liabilities of drug candidates, especially when quantitative considerations are included in further testing. Overall these developments indicate that use of toxicogenomics for predictive approaches, or at least for characterization of potential chemical liabilities of chemicals is an option which will gain value through further use in chemical and pharmaceutical safety evaluation.

---

## BMD Modeling

Benchmark dose (BMD) modeling (Farmahin et al. 2017) was developed as a pragmatic approach for a preliminary quantitative risk assessment for chemicals, for which only few data, and especially for which no longer term study data, are available. It builds on mechanistic interpretation of compound-induced gene expression changes and does not need databases of expression profiles. Here genes showing a dose-dependent expression response are identified with statistical methods in biological samples after exposure of the corresponding model to at least three doses of a compound for a certain duration. After fitting the profiles of these genes to standard statistical models, e.g., linear or polynomial, the best model is used to estimate the BMD for each gene at which its expression significantly deviates from that in control animals. Matching each gene with its corresponding functional category, e.g., gene ontology (GO) categories, and calculation of summary values per category, allows to derive a benchmark dose (BMD) level for the treatment-dependent change of a function. As for “no adverse effect levels” (NOAEL), uncertainty factors can then be applied to these BMDs, to finally determine a reference dose (RfD) for the most sensitive category/function. Transcriptional BMDs for gene expression data may be calculated with a free software called BMDExpress 2 (Phillips et al. 2019).

Thomas et al. who originally introduced this application have developed a framework for application of transcriptomic BMD modeling for both cancer- and non-cancer-related chemical risk assessment (Thomas et al. 2013). BMD modeling has now been employed and refined for chemical assessment by researchers at, e.g., EPA, NIEHS, Health Canada, for in vivo and in vitro evaluations (Ramaiahgari et al. 2019).

---

## Weighted Gene Co-expression Network Analysis (WGCNA)

Weighted gene co-expression network analysis (WGCNA) is an approach to increase insight into the mode of action of toxicants inducing certain phenotypes, when only a limited number of treatments and thus expression profile data for the phenotypes of interest is available (Sutherland et al. 2018). When applied to the TG-GATEs rat liver data set, this analysis defined 415 modules of genes being co-expressed across all treatments, which can be organized in a visual representation of the transcriptome

(the “TXG-MAP”). Since the genes within a module represent certain functions, mechanisms or phenotypes of toxicity for certain compound treatments can be derived from the modules affected by these treatments. As an example, gene expression modules representing bile duct hyperplasia could be defined in rat liver, which were also perturbed in several human diseases with similar etiology.

The WGCNA modules originally described by Sutherland et al. (2018) were independently derived by a team at the University of Leiden within the TransQST consortium (<http://transqst.org/news/the-txg-rmap-an-innovative-wgcna-tool>). These modules are available in an open source application tool called TXG-MAPr (<https://txg-mapr.eu/>).

---

## ICH(S1) Revision: Potential Use of Transcriptomic Signatures

Based on extensive analyses of chronic rat studies (Sistare et al. 2011) by pharmaceutical companies and health authorities (FDA, EMA, JPMA), the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) proposed to reconsider the ICH (S1) Guidance on Rodent Carcinogenicity Testing of Pharmaceuticals, and published a regulatory notice document in August 2013, which was updated in 2016 (Peden 2016). The goal of this proposed change is a more comprehensive and integrated approach to address the risk of human carcinogenicity of small molecule pharmaceuticals, and to define conditions under which 2-year rat carcinogenicity studies add value to that assessment. Specifically, this could mean that the 2-year rat carcinogenicity may be waived. During an evaluation period starting 2013, pharmaceutical companies were asked to submit Carcinogenicity Assessment Documents (CADs) in which they justify a waiver (or no waiver) to omit (or need to conduct) a 2-year rat carcinogenicity study for an investigational new drug, yet still perform and report the 2-year rat carcinogenicity study outcome. Based on weight of evidence (WoE) for a categorical assignment in the CAD (S. Table 1 in Peden (2016)), the following elements/studies and results thereof could be used: (1) pharmacology of intended drug target, (2) genotoxicity study results, (3) chronic (up to 6 months) study histological observations with emphasis on risk factors for carcinogenicity, (4) evidence of hormonal disturbance, (5) immune suppression, (6) metabolic profile, (7) transgenic mouse carcinogenicity study (not required, but may contribute), and (8) special studies and endpoints. To decide on a potential revision of ICH(S1), Drug Regulatory Authorities (DRAs) are currently evaluating the results of the 2-year rat carcinogenicity study with the categorical assignment proposed by the sponsor’s in their CADs.

For the WoE element “Special Studies and Endpoints,” transcriptomics data are one option. Along these lines, Rooney et al. (2018) derived transcriptomics signatures together with a scoring system from short-term rat studies for several molecular initiating events (MIEs) suggested to be associated with rodent hepatocarcinogenesis, linked with doses previously shown to induce (or not) liver cancer in the rat. They thereby could rank chemicals based on their ability to activate these

MIEs. It appears even possible to make a connection to cancerogenic versus non-cancerogenic doses. This approach can be expanded and refined with further datasets, which will be evaluated within the Emerging Systems Toxicology for the Assessment of Risk (eSTAR) Committee of the Health and Environmental Science Institute (HESI) organization.

---

## Summary and Conclusion

After a hype in the beginning, as not unusual for new technologies, the application of “omics” in toxicology has had and still has its challenges, but after difficult times is now being reconsidered for use in regulatory risk assessment. It started with transcriptomics in 1999, when Spencer Farr suggested that all toxicological relevant effects are accompanied by gene expression changes, and that similar toxicological mechanisms cause comparable expression changes. This raised great hopes that toxicological outcomes might even be predictable from shorter term studies, which in the early years could not be confirmed. In the following years, researchers gained relevant experience with mostly mechanistic applications in the context of phenotypic anchoring. After several gene expression databases for compound classes causing certain toxicities in rodents were developed and became public, re-evaluation of predictive applications with renewed efforts enabled derivation of signatures which may enable classification of carcinogenic potential at least for rodent hepatocarcinogens including assessment of human relevance. These renewed efforts also led to development of alternative analyses strategies like WGCNA to improve mechanistic insight of toxicological phenotypes. Furthermore, benchmark dose modeling for transcriptomics data can deliver mechanistically anchored short-term *in vivo* study data for a first assessment of toxic levels for environmental chemicals associated with very few data.

Challenges still exist including further standardization of all elements of a toxicogenomics study, and development or refinements of gene expression signatures for potential qualification for a certain context of use. In addition, epigenomics data will need to be evaluated for use in toxicological assessments. Such investigations are most effectively pursued in precompetitive collaborative efforts which invite regulatory authorities as advisors. Examples for such collaborative efforts are working groups of the Predictive Safety Testing Consortium (PSTC) initiated by the FDA Critical Path Initiative, project committees belonging to the Health and Environmental Science Institute (HESI), and certain EU projects, e.g., the (now finished) IMI MARCAR project (biomarkers and molecular tumor classification for non-genotoxic carcinogenesis, <http://www.imi-marcар.eu/>). Furthermore, regulatory authorities, especially FDA and EMA, are evaluating (Goodsaid et al. 2010) and asking for submission of omics data and developed guidance documents for biomarker qualification to enable use of omics data in decision-making during drug development. Also, with respect to carcinogenicity assessment, researchers in the agrochemical and chemical area are considering approaches based on scientific understanding better suited to characterize the

carcinogenic potential of chemicals and to protect human health (Wolf et al. 2019). Therefore, it can be expected that these technologies will have significant impact on regulatory decisions in the future.

## Abstract

A major challenge in the field of toxicology is extrapolating the findings from *in vitro* and *in vivo* animal experiments to infer a causal effect of exposure on disease in people. Specifically, differences in species, exposure dose, route of administration, duration of follow-up, and co-exposures may lead to substantially different effects of exposures in animals or cells than in humans. Randomized trials or intervention studies in people provide an opportunity for assessing the health effects of exposures, but high costs and safety concerns often limit the types of exposures that can be evaluated with this approach. In the context of regulatory toxicology of potentially hazardous toxicants with little potential for benefit, safety and ethical concerns are paramount, leaving very few toxicants which can be ethically studied with randomized trials or intervention studies. Observational epidemiology provides a means to study the links between potentially harmful exposures and disease in people.

## Basics

### Definition

Epidemiology is often defined as the study of the distribution and determinants of diseases in people. By studying how specific exposures influence the distribution of diseases or physiologic variables, one can find evidence in support of or against the presence of an association between a given exposure and disease. Therefore, epidemiology offers an important alternative to human or animal experimentation in studying the etiology of disease and identifying the health effects of potentially harmful toxicants.

The distinguishing feature of epidemiologic studies compared to experimental studies is that in epidemiologic studies, exposure is determined by each individual (or their circumstances, environment, etc.) rather than by the investigator. Because each *individual's exposure is not assigned at random*, the major challenge of epidemiology is being able to interpret the results of epidemiologic studies as evidence in support of the presence or absence of causal effects.

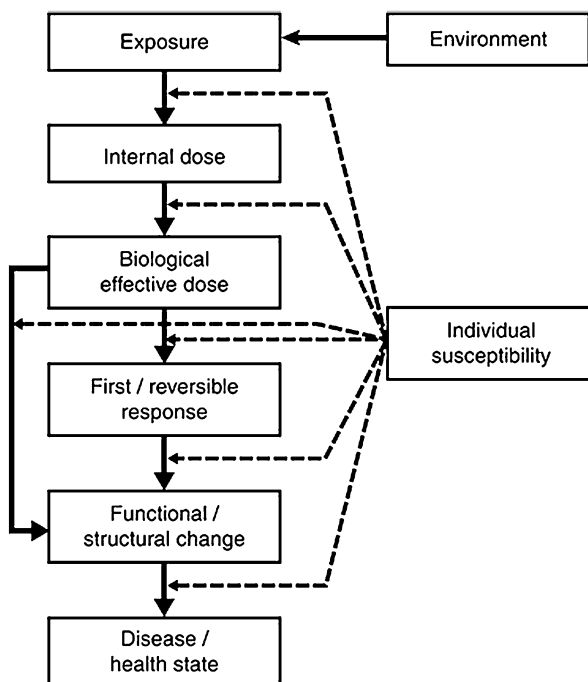

## Population

Toxicologic experiments typically compare the average or expected level of a given outcome in exposed versus unexposed cells or animals. Implicit in this approach is that the results are based on average effects across the population under study and may not apply to any single cell or animal. Similarly, the target of inference in epidemiologic studies is the population under study rather than the individual. For example, while we might find that exposure increases the average risk of a specific type of cancer, we generally cannot determine whether an individual that developed this cancer developed it as a result of the exposure under study. However, under certain assumptions, population effects can be used as *statements of probability* about the health risks of individuals. For instance, extending the prior example, we might be able to say that the risk of developing this cancer is higher in an exposed individual as compared to an unexposed individual.

## Exposure and Effect

Epidemiologic studies are designed to quantify the association between a given exposure and a given outcome or health effect. However, an important aspect of epidemiologic study design is clearly defining what is meant by “exposure” and “effect.” Figure 1 illustrates the *causal chain from exposure to outcome* as frequently

**Fig. 1** Causal chain from exposure to disease

conceived. For example, in a study of the health effects of water disinfection by-products, we must clearly specify whether the exposure of interest is the concentrations of these by-products in the water supply (potentially combined with some estimates of individual water consumption rates), the concentration of some biomarker of internal dose, or some estimate of the biologically effective dose of the by-products. Similarly, we need to be very specific about the definition of the outcome, which can range from subtle shifts in physiological variables to incidence of overt disease. Due to its importance, estimating exposure has its own chapter. To reliably differentiate the health effects of several simultaneous exposures presents a particular challenge for statistical analysis and interpretation.

## Association Versus Causation

As alluded to above, epidemiologic studies quantify the statistical association between a given exposure and disease. Two variables might be statistically associated because of the following: (1) uncontrolled confounding (as occurs when the two variables have a common cause), (2) selection bias (as occurs when participants are chosen in a way that is related to both exposure and outcome), (3) chance, and/or (4) one variable actually causes the other. A fundamental challenge of epidemiologic studies is to minimize the potential for confounding, selection bias, and chance so that the results of the study provide evidence in support of (or against) the presence of a causal effect of exposure on disease.

While much can be done during the study design and data analysis to minimize the potential for observing noncausal associations, in the end the interpretation of a statistical association as reflecting causality is based on judgment. An early formulation of guidelines for *inferring causation from observation* studies was provided by Sir Austin Bradford Hill (Table 1). Of the criteria shown, only temporality (exposure occurs before the outcome) is necessary for a causal relationship to exist. While the remaining Hill criteria are neither necessary nor sufficient to infer causation, they provide a useful framework for judging the strength of the evidence.

**Table 1** Hill criteria for the evidence of a causal relationship

Strength of association
Consistency
Temporality
Biological plausibility
Dose-effect relationship
Coherence among epidemiologic studies
Specificity
Coherence between epidemiologic and laboratory findings
Analogy

## Measures of Disease Occurrence and Association

Traditional epidemiologic studies aim to quantify the association between exposure and a dichotomous outcome, generally the presence or absence of a given disease. Disease occurrence is generally quantified using estimates of *prevalence*, *risk* (also called incidence proportion or cumulative incidence), and *incidence rate* (see Table 2, Fig. 2).

Common measures of association between exposure and a dichotomous outcome include the *risk ratio* (also called the cumulative incidence ratio), the *incidence rate ratio*, and the *odds ratio* (Table 2). When there is no association between exposure and outcome, the risk, rate, and odds of the disease will be the same in the exposed and unexposed groups, and the risk ratio, rate ratio, and odds ratio will all be equal to 1.

The nonspecific term *relative risk*, *relative* is often used to refer to any of these ratio measures. However, it is important to note that estimates of the risk ratio, rate ratio, and odds ratios have different mathematical properties and interpretations, and generally these terms cannot be used interchangeably. In particular, when exposure truly increases the risk of disease, estimates of the odds ratio will always be further from the null hypothesis of no association than the risk ratio, making the results appear more extreme.

**Table 2** Common measures of disease occurrence and association

Measures of disease occurrence
<i>Prevalence</i> : the ratio of the number of existing cases of disease observed at a given point ( <i>point prevalence</i> ) or during a certain time period ( <i>period prevalence</i> ) to the size of the population under observation. A proportion ranging from 0 to 1
<i>Risk, incidence proportion, cumulative incidence</i> : The ratio of the number of new (incident) cases of disease within a given time period of observation to the number of people at risk of the disease at the start of observation. A proportion ranging from 0 to 1
<i>Incidence rate</i> : The number of new (incident) cases of disease within a given time period of observation divided by person-time at risk of the disease. Person-time is defined as the sum of the time spent under observation and at risk of disease by each member of the population. Incidence rates are not proportions and range from 0 to positive infinity
Measures of associations
<i>Risk ratio</i> : Risk of disease among the exposed divided by the risk of disease among the unexposed
<i>Incidence rate ratio (rate ratio)</i> : Incidence rate of disease among the exposed divided by the incidence rate of disease among the unexposed
<i>Odds ratio</i> : Odds of disease among the exposed divided by the odds of disease among the unexposed where the odds of disease are defined as the probability of disease divided by (1 – the probability of disease)
<i>Relative risk</i> : a nonspecific term that can refer any ratio measure of association (i.e., risk ratio, rate ratio, or odds ratio)
<i>Risk difference</i> : Risk of disease among the exposed minus the risk of disease among the unexposed
<i>Incidence rate difference</i> : Incidence rate of disease among the exposed minus the incidence rate of disease among the unexposed

**Fig. 2** Definition of epidemiologic measures

Contingency table				
		Exposure		
		yes	no	
Disease	yes	a	b	a+b
	no	c	d	c+d
Total		a+c	b+d	n = a+b+c+d

Measure	Formula
Risk of exposed	$a / (a+c)$
Risk of non-exposed	$b / (b+d)$
Relative risk	$a(b+d) / b(a+c)$
Odds ratio	$ad / bc$
Risk difference	$(ad - bc) / (a+c)(b+d)$

Note:

When a, b, c and d are observed frequencies, then the formulae are estimates of the measures.

When a, b, c and d are probabilities (n=1), then the formulae are the true measures.

The association between exposure and a dichotomous outcome can also be quantified using difference measures, including the *risk difference* and *incidence rate difference* (Table 2). When there is no association between exposure and outcome, the risk (or incidence rate) in the exposed and unexposed groups will be the same and the risk (or incidence rate) difference will equal zero. Note that measures of relative risk assume that exposure acts to multiply the baseline risk (or rate or odds), while difference measures of association assume that exposures add to the baseline risk (or rate).

The above measures of disease occurrence and association are applicable to situations where the outcome is dichotomous. For simplicity, in the above discussion, we have implicitly also considered exposure as a dichotomous variable (i. e., comparing outcomes in those exposed vs. unexposed), but this is not necessary. The above measures of association can be generalized to situations where exposure is measured as a continuous variable.

A somewhat different set of metrics are used when studying the association between exposure and a continuous outcome such as blood pressure, heart rate, or

levels of a disease biomarker. In these settings, the expected values of the outcome (generally the arithmetic mean) among the exposed and unexposed subjects are compared.

---

## Common Epidemiologic Study Designs

### Descriptive and Analytical Epidemiology

*Descriptive epidemiology* is limited to the description of disease distribution using suitable measures, such as incidence rate, to enable comparisons between populations across space, time, or other contrasts. Descriptive studies are often carried out using routinely collected administrative or survey data. The results of descriptive epidemiologic studies are frequently used for public health planning or to generate new hypotheses about disease etiology. In contrast, analytical epidemiologic studies are used to test hypotheses about exposure-effect relationships. Study design and statistical evaluation focus on the initial assumptions and aim to make quantitative statements about associations which can be used to interpret the cause. The most important types of study in *analytical epidemiology* are briefly described below.

### Cohort Study

A cohort study is an epidemiologic study design where participants that are initially free of a disease are followed for a specified period of time and monitored for new cases of (i.e., incident) disease. Exposures of interest and potential confounders are measured at study entry and, optimally, at multiple times throughout the follow-up period. In a *closed cohort study*, participants enter the study at baseline and remain under observation until they develop the disease of interest, die, or are otherwise lost to follow-up. Prominent examples of closed cohort studies include the Women's Health Initiative, the Cardiovascular Health Study, and the Nurses' Health Study. In an *open cohort study*, participants may enter and leave the study multiple times during the follow-up. Examples of open cohort studies include studies of all current members of a health insurance plan or all current residents of a state.

Cohort studies can be either *prospective* or *retrospective*. In a prospective study, data on exposure and confounders are obtained before the development of disease. In a retrospective study, historical data on exposure and confounders are assembled from existing data sources, often after disease has already occurred. Prospective cohort studies can require long follow-up of a large number of participants and are therefore frequently very expensive. Retrospective studies that make use of existing data can be very cost-effective but may be subject to additional potential biases.

## Case–Control Study

A cohort study can be very inefficient if the disease of interest is rare. For example, suppose that we are interested in studying a disease that in a given population has an incident rate of 20 cases per 100,000 person-years. In this example, we could follow 100,000 people for 5 years and still only expect about 100 new cases of melanoma. Put another way, we would need to assess and follow for 5 years about 90,000 people that will not develop melanoma in that time frame.

Because the statistical power of a study is driven largely by the number of incident cases, in the above example, we could gain almost as much information if we were to assess only the 100 new cases of melanoma and a random sample of those participants that have not yet developed melanoma. Thus, the fundamental principle of a *case–control study* is that one can assess exposures and confounders in a *group of cases* (those with disease) and a (potentially small fraction) random sample of participants that have not yet developed the disease (*group of controls*). The strategy for selecting controls from the source population is very important for the interpretation and validity of the resulting estimate. For example, depending on the control sampling strategy, the odds ratio estimated from a case–control study may approximate either the incidence rate ratio or the risk ratio. The details of control selection strategies are beyond the scope of this chapter.

Sometimes a case–control study is nested within a larger cohort study such that the cases are those identified by the cohort and controls are sampled from among those participants in the cohort that have not yet developed the disease of interest. This is referred to as a *nested case–control study* and has the advantage that the source population giving rise to the cases is easily identified (i.e., the cohort participants). In other case–control studies, identification of the source population may be more challenging. For example, in a hospital-based case–control study, complicated referral patterns and changing catchment areas often make it difficult to clearly identify – and hence choose a random sample of – the source population that gave rise to the cases. Like cohort studies, case–control studies can be either prospective or retrospective in nature.

## Cross-Sectional Study

In a *cross-sectional study*, participants are selected at random from a population of interest and then examined for risk factors and disease at the same time. Thus, the key feature of a cross-sectional study is that exposures and prevalent (existing) cases are assessed simultaneously. Because cross-sectional studies study *prevalent disease*, they generally provide estimates of prevalence ratios or prevalence odds ratios rather than risk ratios or incidence rate ratios. Moreover, because cross-sectional studies assess exposure and outcomes simultaneously, it is often not possible to clearly determine the temporal direction of the association. However, the duration of these studies is generally comparably short, making cross-sectional studies a cost-effective type of study appropriate for exploring certain hypotheses.

## Panel Study

A *panel study* is a special type of cohort study where participants are followed longitudinally and both exposures and outcomes are assessed repeatedly over time within each participant. Panel studies are most appropriate for outcomes that vary over a relatively short time period such as blood pressure, weight, or levels of most serum biomarkers, but are not appropriate for most disease end points.

## Ecological Study

All of the study designs presented above make use of data collected from individuals. In contrast, *ecological studies* quantify associations between a given exposure and outcome, but both the exposure and outcome are measured in *aggregate* rather than in individuals. Prominent examples of ecological studies include studies showing that average per capita meat consumption is associated with incidence rates of certain types of cancer compared across several countries. The key feature of an ecological study is that the unit of observation is the country (or county, neighborhood, school, etc.) rather than the individual. Because data are aggregated, there is considerable potential for uncontrolled confounding in ecological studies and incorrect conclusion (i.e., *ecological fallacy*). For instance, continuing the above example, smoking is also an important determinant of many cancers and may also be associated with higher meat intake in individuals. However, in an ecological study, controlling for average population smoking prevalence would not necessarily control for confounding by smoking at the individual level. Thus, ecological studies are most useful for offering initial evidence in favor of novel hypotheses.

---

## Study Quality

### Validity

The overall objective of an epidemiologic study is to obtain a valid and precise *estimate* of disease occurrence or of the association between exposure and disease. It is useful here to differentiate between internal and external validity. *Internal validity* {validity, internal} refers to whether the results of the epidemiologic study can be used to make inferences about the source population for that particular study. On the other hand, *external validity* {validity, external} refers to whether the results of the current study can be generalized to other populations.

Errors in epidemiologic estimates can be classified as either *systematic errors* {error, systematic} (*bias*) or *random errors* {error, random} (*chance*). Of note, while the potential for random error decreases with increasing sample size, the potential for systematic errors is independent of sample size. Moreover, the precision or amount of random error present in an estimate can be easily quantified with routine statistical

methods. In contrast, predicting the direction or magnitude of the bias induced by systematic errors is quite challenging and seldom done in practice.

Systematic errors can be further classified as due to confounding, selection bias, or information bias. Each of these sources of systematic bias is discussed in more detail below.

## Confounding

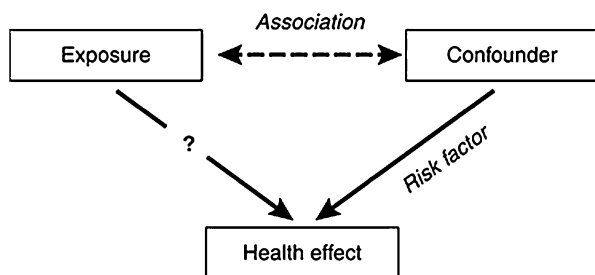

In contrast to experimental research, confounding is a major threat to validity in epidemiologic studies. *Confounding* {bias, confounding} can occur when one or more factors exist in the study population which are associated with both the outcome and the exposure, but are not caused by either the exposure or the outcome (Fig. 3). A known risk factor is a potential confounder and, if associated with the exposure in the study population, will become a *confounder*. Importantly, confounding can bias the health effect estimates either towards or away from the null hypothesis of no association.

The potential for confounding can be minimized through appropriate study design. For example, if sex is an important confounder (because it is associated with both exposure and disease but not caused by either), a study restricted to men only or women only would not be susceptible to confounding by sex. More commonly, analytic methods are used to reduce the potential for confounding. For instance, continuing the above example, if sex is an important confounder, we can stratify the analyses on sex, that is, consider the association between exposure and disease conditional on sex. More generally, one can use regression models to quantify the association between exposure and disease conditional on (or adjusting for) a number of potential confounders.

## Selection Bias

*Selection bias* {bias, selection} generally arises from the manner in which participants were selected for the study. A typical example of selection bias is the so-called

**Fig. 3** Confounding: relationship between exposure, health effect, and confounder

*nonresponder bias* {bias, non-responder} in which people that agree versus those who do not agree to participate in a study differ in terms of both exposure and their risk of the outcome. If the factors which potentially influence the selection are known and therefore measured, the selection bias can be controlled in the statistical analysis (see confounding).

Selection bias may also occur in the context of case–control studies (see below) where the controls are meant to represent the distribution of exposure among the source population from which the cases arose. *Selection bias in a case–control study* occurs when the controls are sampled in such a way that the exposure distribution among the controls does not estimate the exposure distribution in the source population.

Another common source of selection bias arises in the setting of missing data or when participants are *lost to follow-up*. If the risk of a subject missing data is related to both exposure and outcome, the missingness is said to be informative. Ignoring informative missing data can lead to selection bias. Similarly, loss to follow-up in a cohort study (see below) leads to missing data in some study participants. If the risk of being lost to follow-up is associated with both the exposure and outcome, selection bias may result.

### **Information Bias {Bias, Information}**

Exposures and outcomes in epidemiologic studies are always measured with error. Measurement error of dichotomous or categorical variables is often referred to as *misclassification*. Misclassification which depends on another variable is termed differential misclassification. Misclassification that does not depend on other variables is termed *non-differential misclassification*.

For example, differential misclassification of the exposure would occur if an exposure were measured with more error among those with the outcome of interest as compared to those not experiencing the outcome of interest. *Recall bias* {bias, recall} in the context of case–control studies is a well-known example of differential exposure misclassification; the health effect estimates are biased because those diagnosed with a specific disease (the cases) may recall their past exposures better than the controls without the disease. Differential misclassification can bias the estimated associations between exposure and disease either towards or away from the null hypothesis of no effect.

The impact of non-differential misclassification is sometimes predictable. Specifically, non-differential misclassification of a dichotomous exposure is expected to bias health effect estimates towards the null. This observation is often cited as a reason why one should not be overly concerned with measurement error of the exposure. However, non-differential misclassification of a categorical exposure with more than two categories, or a continuous exposure, can lead to bias either towards or away from the null, because in these cases the impact on study validity will depend on the pattern of classification and the measure of association.

## Effect Measure Modification and Interactions

*Effect measure modification* {modification, effect measure} (frequently simply referred to as *effect modification* or *interaction*) is present when the association between exposure and disease differs across levels of a third variable (the modifier). For example, the relative risk between exposure to asbestos and lung cancer is known to be greater among smokers than among nonsmokers. In this example, it would be tempting to conclude that smokers are more susceptible to the effects of this exposure. However, for any given exposure-disease relationship, the presence of effect measure modification will depend on the measure of association being used, hence the term *effect measure* modification. For example, for a truly harmful exposure and in the absence of any other biases, the absence of effect modification when considering the risk ratio guarantees that effect modification will be present when one instead considers the risk difference. Effect modification is equivalent to the concept of *statistical interaction* {interaction, statistical} and represents a departure from a multiplicative or additive model, depending on the measure of association being modeled. Thus, it is entirely possible that effect measure modification will exist only in multiplicative models, only in additive models, or in both. Thus, the presence of statistical interaction or effect measure modification must be distinguished from the concept of biological interaction.

Students of epidemiology often have trouble distinguishing the concepts of confounding and effect modification. To clarify, effect modification is present when the strength of the association differs (aside from random variation) across strata of the potential modifier. On the other hand, confounding represents a mixing of the effect of the exposure with effects of other factors (confounders) on the outcome. Furthermore, confounders, by definition, are associated with exposure and outcome, and need to be controlled for in analyses. In contrast, an effect modifier need not be associated with either exposure or disease and need not to be adjusted for in analyses. A given factor potentially can be a confounder, an effect modifier, both, or neither.

## Random Error and Precision

The precision of a health effect estimate (i.e., magnitude of the random error) in an epidemiologic study can be quantified and will depend on the *sample size*. This means the *precision* of study results can generally be improved by increasing the sample size of the study. In *study planning*, this is used to determine the sample size needed to answer a specific research question. Furthermore, it leads to the concept of *statistical power*, i.e., the ability of a study to demonstrate an association of a given magnitude between exposure and outcome, if such an association actually exists.

One can often increase the precision of estimates from an epidemiologic study by improving study efficiency. For example, for the same number of study participants, some epidemiologic study designs may be much more efficient than others. For instance, a case-control study with 1,000 cases and 1,000 control subjects is

**Table 3** Principles and elements of “Good Epidemiological Practice”

Accordance with ethical principles
Formulation of explicit and operationalizable research questions
Detailed and binding study protocol
Well-documented biological sample banks
Quality assurance
Data management and documentation
Analysis
Observance of applicable data protection regulations
Legally binding agreements between all stakeholders (researchers, sponsors, collaborators)
Publication and interpretation of results

expected to be more informative than a case–control study with 500 cases and 1,500 controls or a cohort study that follows 2,000 subjects, 100 of which develop the outcome of interest. In the above example, study efficiency can be assessed as the amount of information per subject with some study designs yielded more or less information per subject. However, depending on the resource constraints, one may wish to optimize the amount of information per research dollar spent rather than per subject. For example, if recruiting cases for a case–control study is much harder (i.e., more expensive) than recruiting control subjects, a study with fewer cases and relatively more control subjects may be the most cost-effective.

## Study Planning

A high *quality standard* in an epidemiologic study, usually conducted as a multi-disciplinary cooperation, is only achieved when a *study plan* is developed at the start of each study which follows the generally recognized *Good Epidemiological Practice (GEP)* guidelines. In the international technical literature, guidelines have been developed which have found broad recognition and which contribute significantly to quality assurance if they are carefully followed. Some of the important principles and elements of the GEP are listed in Table 3.

---

## Statistical Analysis

### Estimation, Confidence Intervals, and Testing

Statistical procedures and statistical inference are material parts of epidemiologic methodology. Since statistics is accorded its own chapter (see ► [Chap. 21, “Statistical Evaluation Methods in Toxicology”](#)), this section will merely address three important viewpoints, and in the following section, an introductory explanation of the regression models will be given.

The estimation of measures of association, such as a risk difference or odds ratio, is subject to random error. Virtually always, quantitative study results on the exposure-outcome association are given as a combination of an estimate of the strength of the association (*point estimate*) and an estimate of the uncertainty or precision associated with the point estimate. Depending on the target audience and the statistic being used, the uncertainty may be expressed using the *standard error* of the point estimate or the *95% confidence interval* around the point estimate. Since the confidence interval provides information on both the magnitude and the probability of a potential error, it is often the preferred method for quantifying estimate uncertainty in epidemiologic studies.

An important question in epidemiology relates to the significance of *testing hypotheses* {testing, hypotheses}. The purpose of testing a hypothesis is to come to a decision as whether to accept or to reject a hypothesis on the basis of the results of a trial which was carried out for this purpose. This methodological starting point of the statistical test theory does not, strictly speaking, apply to the problem of an epidemiologic study, which is to quantify the exposure-outcome relationship rather than to make a decision about whether or not the relationship exists. However, it is quite sensible to take the *p-value* from the hypothesis testing, which is a continuous evidence measure of the compatibility of a hypothesis with the data observed, but the *p-value* should not merely be used with a predetermined threshold value such as a 5% threshold to classify the results of the study as “significant” or “not significant.”

Another point which is often hotly debated is *multiple testing* {testing, multiple} or more specifically the simultaneous investigation of several relationships in a study. Whether or not using procedures for simultaneous testing is recommended depends on whether the problem actually requires the simultaneous testing of a whole list of relationships (exposure to several end points of effect) or whether the various exposure-effect combinations are based on independent problems and, for example, are only being investigated together in one study because of practicability. In this latter case, no multiple testing is carried out. If multiple testing with a few simultaneous hypotheses is necessary, simple methods such as the *Bonferroni* method are available. For the analysis of more extensive sets of related hypotheses, modern but more complex procedures have to be used.

## Regression Models

As discussed above, epidemiologic studies are susceptible to confounding, and potential confounders need to be considered either in the design of the study (through restriction) or in the analysis of the resulting data (through stratification or statistical adjustment). In very simple cases involving only a small number of key confounders, tabular analyses with simple hand calculations can be used to obtain valid point estimates and confidence intervals. However, as the number of potential confounders increases, tabular analyses become impractical and statistically inefficient and regression models are preferred. Choosing the most appropriate *statistical model* {model, statistical} is complex and requires advanced understanding of the

---

statistical issues, as well as a clear understanding of the hypotheses to be tested and the structure of all the relevant cause-effect relationships. Thus, *interdisciplinary cooperation* between epidemiologists, statisticians, and experts of all the affected specialties to create the model and evaluate and interpret the results is highly recommended.

and substantial information about the investigational medical product, particularly toxicology, in order to exclude potential risks for subjects/patients with the greatest probability. Early clinical trials aim to provide first evidence of safety of the investigational medical product. Regulatory and ethical aspects must be taken into account as closely as possible.

### Keywords

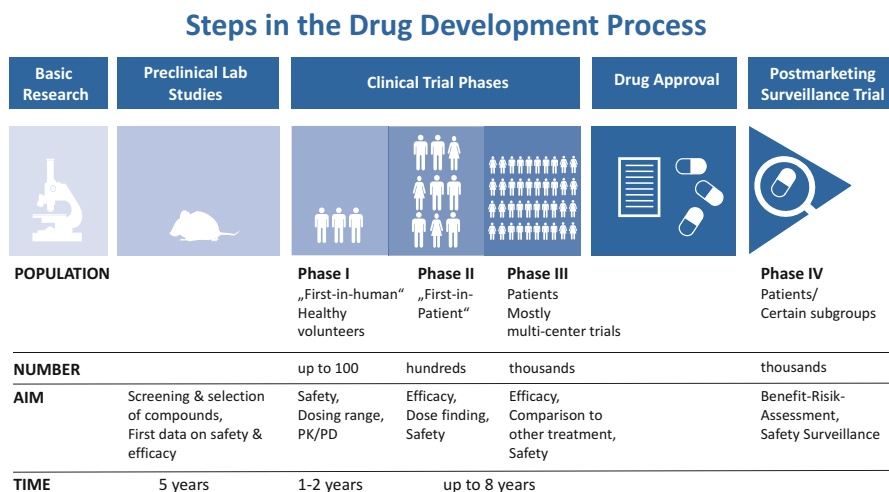

First-in-human · Phase I · Early clinical trials · Investigational medical product · Risk mitigation · Dose escalation · Multiple ascending dose

## Introduction

The transition from nonclinical to early clinical trials is a crucial phase in the development of new investigational products (IMP). Calculation of the starting dose, dose escalation, and the definition of the maximum dose requires adequate nonclinical (or preclinical) data and specific consideration of safety pharmacology, reproductive or genetic toxicity, and carcinogenetic potential of the IMP.

The subsequent clinical trials in humans are conducted in a series of *phases* (Phase I to phase IV) as depicted in Fig. 1.

The following chapter focusses on early clinical trials in humans. Here, most commonly cohorts of healthy volunteers (HV) are enrolled. Selecting HV allows for controlling important confounders that may change the pharmacokinetics and

**Fig. 1** Steps in the drug development process with focus on clinical trial phases. Clinical trials follow a rigorous series from early clinical trials (phase I/II studies) to late-stage, large scale, phase III studies. *PK* pharmacokinetics, *PD* pharmacodynamics

tolerability of the IMP, most importantly age, sex, or concomitant medication. Enrolment of HV also increases study accrual rates for the early dose-escalation studies.

Not least because study participants do not derive any health benefit, highest precautions to avoid any hazard for the participating HV must be guaranteed. Moreover, adequate compensation for time expenditure, discomfort, and inconvenience has to be ensured. All these aspects have to be approved by the institutional review board/ethics committee before a study can start.

Despite the advantages of a homogenous study population, IMPs with potential desirable toxic effects, particularly in the case of anticancer drugs, cannot be investigated in HV due to obvious ethical reasons. In these cases, phase I studies are conducted in the target population (i.e., actual patients). Yet, the employment of subtherapeutic doses in patients who suffer from the target disease raises legitimate ethical concerns on their own. Later studies (e.g., phase II), where clinical efficacy is a primary endpoint, may be more appropriate for patients (Karakunnel et al. 2018).

---

## Phase I Studies

In phase I studies – also called human pharmacology studies – a new IMP is evaluated for the first time in humans (Fig. 1). Phase I studies comprise several types of studies. First-in-human (FIH) studies are also called single ascending dose (SAD) studies and are randomized, placebo-controlled studies. Here, a single dose is given and escalated over 6–10 dose groups of around eight healthy volunteers. The pharmacokinetic profile, safety, and tolerability are key aspects. Usually, a multiple ascending dose (MAD) study will follow to evaluate these parameters when multiple doses of the IMP are given over a longer period of time. If a single or double blind study design is employed, preliminary data on pharmacodynamics can also be obtained.

IMPs that have shown effects on the cardiac conduction system in preclinical studies have to be evaluated in a so-called thorough-QT-study (TQT study) to rule out a significant QT-prolongation in humans. Such alterations noted in electrocardiograms (ECGs) are associated with fatal arrhythmias. TQT studies are complex, placebo-controlled, double-blind trials with around 50 healthy individuals.

Other types of phase I studies, performed in an open design, include bioavailability (how much and how fast does the IMP enter the systemic circulation) and bioequivalence studies (differences in formulation, e.g., powder versus tablet).

In addition, food-effect studies and ADME (Absorption, Distribution, Metabolism, Excretion) studies are important to further characterize the drug and discover relevant metabolites. Information on excretion in urine and feces is collected in so-called “mass balance” studies. Guidelines by EMA or FDA describe how drug-drug interactions (DDI, e.g., interaction of the IMP with expected comedication) have to be investigated in phase I study programs. DDI studies evaluate clinically relevant drug-metabolizing enzymes (e.g., cytochrome [CYP] P450 enzymes) and drug transporters (e.g., the efflux-transporter P-glycoprotein) and their impact on drug levels. As an example, comedication with contraceptive pills should be investigated in an IMP whose target-population includes women of child-bearing potential.

Dedicated pharmacokinetic analysis in hepatic or renal impairment is not possible in healthy volunteers. In this regard, phase I/IIa studies have to be set up in appropriate cohorts, in collaboration with academic medical centers or university hospitals. Crossover designs to show intraindividual effects are employed in bio-availability, food-effect, and TQT and DDI studies, while parallel-group designs are used in SAD and MAD studies.

Another specific study type is a so-called microdosing study where sub-pharmacological doses are administered to a low number of humans for a short period of time. These studies are carried out in advance of the traditional dose escalation, safety, and tolerance studies. Hereby, HV receive an IMP to allow for an investigation of its pharmacokinetic properties while maintaining an extremely low risk of toxicity (Marchetti und Schellens 2007).

---

## Safety and Toxicity in Nononcologic Phase I Trials

According to several analyses, phase I trials in HV with nononcology drugs are perceived to be safe. Emanuel et al. performed a meta-analysis of 394 Phase I studies conducted between 2004 and 2011 by a leading research-based pharmaceutical company. Of 11,028 HV, 36.3% experienced no adverse events and 63.7% experienced adverse events. Yet, 85% of adverse events were mild, and only 34 (0.31%) serious adverse events occurred, with no life-threatening events or deaths (Emanuel et al. 2015). Another systematic analysis included 25 phase I SAD and/or MAD studies and could not identify safety concerns involving laboratory parameters, ECGs, SAEs, or deaths (Young et al. 2017). Furthermore, a survey of phase I studies in Germany reported 1,250 subjects (950 active, 300 placebo), and 952 AEs occurred while 88.2% (840/952) of AEs were mild and 11.3% (108/952) were moderate. Only 0.4% (5/1,250) of subjects had active drug- or procedure-related serious AEs (Jung et al. 2020). These data are supported by previous analysis of AEs in phase I studies ( $n = 142$ ) in Germany, indicating that AEs in phase I trials are common, but usually of mild or moderate degree (Lutfullin et al. 2005).

Nonetheless, nononcology early phase studies are not exempt of serious complications. In March 2006, a novel agonist antibody (TGN1412) directed at CD28 was studied in the first phase I trial (6 verum, 2 placebo). The substance has been well tolerated by nonhuman primate species. Despite being administered at a supposedly subclinical dose, the compound led to sudden and rapid release of proinflammatory cytokines, causing catastrophic systemic organ failure in six subjects after 12–16 h of infusion (Suntharalingam et al. 2006; Brøsen et al. 2017).

Although all six HV in the TGN1412 study survived after intensive care treatment, in a phase I study conducted 10 years later with the fatty acid amide hydrolase (FAAH) inhibitor BIA10-2474, there was one fatality due to neurologic complications. FAAH breaks down neurotransmitters known as endocannabinoids, but the symptoms have been speculated to be unknown off-target

effects of BIA10-2474 (Butler und Callaway 2016). These tragic occurrences are reminders that utmost care and meticulous attention to results from nonclinical trials are essential for a safe conduct of first-in-human studies.

---

## Benefit-Risk Assessments

The assessment of risk of a phase I trial is a unique challenge. In the “Guideline on strategies to identify and mitigate risks for FIH and early clinical trials with IMPs,” the European Medicines Agency (EMA) mandates the identification of specific risks (European Medicines Agency 2017). The novelty and extent of knowledge of the supposed mode of action is particularly important. If an IMP may interfere with multiple signaling pathways or biological cascades (e.g., hemostasis), a greater risk for severe adverse events from off-target effects has to be anticipated. Similarly, a lack/scarcity of knowledge about the structure, tissue distribution, regulation, or biological function of the target increases risks. Additionally, the availability of relevant animal models and their extrapolability factor into the risk assessment. In line with the Declaration of Helsinki, the Good Clinical Practice Regulation and national medicine acts, a concise benefit-risk assessment, is an essential part of the study application at the competent authorities and ethic committees. The sponsor has to detail the substance-related risks in the investigator brochure and the study-specific risks in the study protocol.

---

## Phase II Studies

Phase II studies enroll actual patients and are usually conducted in medical centers with expertise in the particular target disease. Most commonly, they are managed by clinical research organizations (CRO) that specialize in the logistics of study conduct. Phase II studies are also called therapeutic explorative studies (Fig. 1). Their primary aims are efficacy assessment and dose finding, as well as safety and pharmacokinetics. A distinction between IIa and IIb studies, where IIa are proof-of-concept studies and phase IIb are dose-finding studies, can be made. Yet, studies incorporating both study questions in one design are common (IIa/b studies). There is also methodological discussion around phase II study designs. For example, designs that aim at an early validation of predictive biomarkers have been proposed. This would allow for timely decision if the drug should be developed for an unselected patient population or for a biomarker-defined subset of patients only (Mandrekar et al. 2013).

---

## Phase III Studies

Therapeutic confirmative trials, enrolling around 1,000 patients to show efficacy and safety, are referred to as phase III or “pivotal studies” (Fig. 1). Only compounds that have shown effects in phase II will enter the costly and logistically challenging

phase III. These studies are designed to establish superiority to placebo or non-inferiority to a comparator in large cohorts. This is prerequisite for a promising initial marketing authorization at the FDA or EMA. A so-called clinical development plan will have to specify how many phase III trials should be planned and conducted (Singh 2018). The choice of endpoints, comparator, number of subjects, study site, and location (e.g., EU, USA, and developing countries) will have a significant impact on the products' chances for marketing authorization. In 2009, Munos published an analysis of around 1200 drugs that have been approved by the FDA, since 1950, and pointed out that the probability of a new therapeutic molecule to enter such late phases is estimated to be only about 21.5 % or even 11.5 % only (Munos 2009).

---

### **Phase IV Studies (Postapproval Studies)**

Phase IV studies are conducted after marketing authorization. Hereby, information on the drug's effectiveness in various populations is gathered, and any adverse effects associated with long-term use can be investigated. Serious adverse effects, if rare, may emerge with large-scale use only, and continuous safety reassessment by regulatory authorities may, in some specific cases, necessitate the restriction of the use or the withdrawal of the drug. Furthermore, a drug may have been approved based on surrogate end points likely to predict clinical outcomes. After such an approval, a phase IV study can be conducted to demonstrate effects on clinical end points (European Medicines Agency 2019). In addition, phase IV studies are also suitable to refine dosing recommendations or assess outcomes relevant for health technology assessments.

---

### **Early Clinical Development of Vaccines**

Selected aspects and general principles of the clinical development of adjuvant or nonadjuvant vaccines will be reviewed in this paragraph, largely referring to the guideline on clinical evaluation of vaccines, issued by the EMA (European Medicines Agency 2018).

Before efficacy studies can be conducted, a careful characterization of the immune response elicited by the vaccine is necessary. This includes, for example, information on the functionality and nature of the induced antibody, the induction of memory cells, quantifying T cells specific for the vaccine antigen, etc. It has to be noted that the parameters which are of the highest significance for protection will not be known at this stage. Comparative immunogenicity trials commonly employ the seroconversion rate (i.e., rise in antibody concentration pre- and postvaccination) as a primary end point. Percentages of antigen-specific T cells, geometric means for antibody concentrations, and the postvaccination sero-positivity are accepted secondary end points.

In vaccine development, data from *in vivo* nonclinical studies are usually not helpful to determine the human dose. As it is not known what can be considered a protective immune response, the dose at which there is no further increment in immune response should be investigated. The differential effects in immune response to conjugated antigens and conjugative proteins have to be characterized as well.

An adjuvant formulation may allow for a reduction of the amount of the antigenic components of a vaccine. Yet, the employment of adjuvants (designed to augment the immune reaction) has to be corroborated by an adequate comparison between adjuvant versus nonadjuvant formulations. In inactivated vaccines, aluminum salts have been used for decades as adjuvants. Yet, although injection-site reactions are more common with vaccines containing aluminum, serious long-term hazards like increased rates of atopic diseases have not been confirmed by independent studies (Jefferson et al. 2004; Willhite et al. 2014).

Also, the safety of vaccines containing the organic mercury compound thiomersal has been a long-standing public concern, yet available data from large and well-conducted epidemiologic studies show no association with thiomersal-containing vaccines and neurodevelopmental defects (autism, speech disorders). It is used as an antimicrobial in early stages of manufacturing or as a preservative. Yet, reducing environmental exposure to mercury is a global concern. Therefore, reduction or removal of thiomersal has been achieved, and new vaccines without thiomersal are now available (European Medicines Agency 2004).

Regarding vaccines against SARS-CoV-2, multiple vaccine types, such as nucleic acid-, viral vector-, virus-, and protein subunits, are under investigations or have been approved. The attractiveness of RNA-based vaccines is the advantage of an easier and faster manufacturing in large quantities. Nevertheless, phases of vaccine development are subject to the same regulatory requirements comprising phase I to III trials (Mellet and Pepper 2021).

---

## Important Regulatory Aspects

Studies in humans are subject to legal regulations (national and supranational, e.g., the European Union) which include so-called Good Clinical Practice (GCP) directives and professional regulations (Declaration of Helsinki, evaluation by independent review boards (IRBs)). In addition, institutional regulations (e.g., standard operating procedures) usually apply also.

Since its inception in 1990, The International Council for Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) has become a pivotal organization, bringing together regulatory authorities and pharmaceutical industry (ICH 2021). It discusses scientific and technical aspects of pharmaceuticals and develops numerous guidelines, such as the ICH-GCP guideline (European Medicines Agency 2016; European Commission 2005). Those guidelines were also converted into German law as the “GCP regulation” (Federal Ministry of Justice and Consumer Protection 2012).

*GCP* is a standard for the design, conduct, performance, monitoring, auditing, recording, analysis, and reporting of clinical studies that provides assurance that the data and reported results are credible and accurate and that the rights, integrity, and confidentiality of study subjects are protected. It includes ethical and scientific quality standards for designing, conducting, recording, and reporting studies that involve participation of human subjects to ensure that the rights, safety, and well-being of the study subjects are protected. It is also to ensure the credibility of clinical study data.

---

## Study Responsibilities and Roles

The *sponsor* is an individual, company, institution, or organization which takes responsibility for the initiation, management, conduct and financing of a clinical study. The *investigator* is a person, usually a physician, responsible for the conduct of the clinical trial at a study site. The investigator delegates appropriately qualified persons (e.g., physician, study nurses) to trial-related duties.

---

## Trial Databases

According to the GCP-V regulation, all trials conducted in the European Union have to be entered into the *EudraCT* (European Union Drug Regulating Authorities Clinical Trials). EudraCT is the European Clinical Trials Database of all clinical trials commencing in the European Union from 1 May 2004 onward (<https://www.clinicaltrialsregister.eu/>). Internationally, the ClinicalTrials.gov registry (<https://clinicaltrials.gov/>), maintained by the US National Library of Medicine, is the largest database of privately and publicly funded clinical studies which are conducted worldwide. The “NCT numbers” are therefore the most common identifier found in scientific publications. Over the years, the entries have evolved to complete listings of study/start dates, inclusion and exclusion criteria, primary and secondary end points, and contact information. Recently, links to complete study protocols and statistical analysis plans as well as quick web links to pertinent publications have been added, further increasing transparency and usefulness of this free online resource.

---

## Institutional Review Board (IRB)/Independent Ethics Committee (IEC)

An *Independent Ethics Committee* (IEC) is an independent body (a review board or a committee, institutional, regional, national, or supranational), constituted of medical professionals and nonmedical members, whose responsibility is to ensure the protection of the rights, safety, and well-being of human subjects involved in a trial. IRB/IEC review and approve/provide a favorable opinion on the trial protocol, the

suitability of the investigator(s), facilities, and the methods and material to be used in obtaining and documenting informed *consent* of the trial subjects. The legal status, composition, function, operations, and regulatory requirements pertaining to IRB/IECs may differ among countries but should allow the IEC to act in agreement with GCP as described in the ICH-GCP Guideline (European Medicines Agency 2016). IRB/IEC also assure that the proposed clinical trials are conducted in accordance with the ethical principles that have their origin in the *Declaration of Helsinki*. The World Medical Association (WMA) has developed the Declaration of Helsinki as a statement of ethical principles for medical research involving human subjects, including research on identifiable human material and data (64th WMA General Assembly 2013).

---

## Important Documents

The most important documents to be submitted to and reviewed by the IEC include:

### The Study Protocol

The protocol is a document that describes the objective(s), design, methodology, statistical considerations, and organization of a trial. The protocol usually also gives the background and rationale for the trial, but these could be provided in other protocol referenced documents. Throughout the ICH-GCP Guideline, the term protocol refers to protocol and protocol amendments (European Medicines Agency 2016). The protocol also described the investigator's and sponsor's responsibilities. This is particularly important with the documentation, reporting, and assessment of adverse events.

### The Informed Consent Form

The informed consent is a process by which a subject voluntarily confirms his or her willingness to participate in a particular trial, after having been informed of all aspects of the trial that are relevant to the subject's decision to participate. Informed consent is documented by means of a written, signed, and dated informed consent form (European Medicines Agency 2016).

### The Investigator's Brochure (IB)

The IB is a compilation of the clinical and nonclinical data on the investigational product(s) that is relevant to the study of the product(s) in human subjects. Its purpose is to provide the investigators and others involved in the trial with the information to facilitate their understanding of the rationale for, and their compliance

with, many key features of the protocol, such as the dose, dose frequency/interval, methods of administration, and safety monitoring procedures. The IB also provides insight to support the clinical management of the study subjects during the course of the clinical trial (European Medicines Agency 2016). Obviously, the IB needs to include all the current knowledge about the investigational product(s).

---

## Testing of Other Substances

To assess the tolerability of working materials and chemicals, controlled studies are occasionally performed in volunteers. Examples are studies of ozone effects on lung function or the study of the neuropsychological effects of low doses of solvents. Special rooms and equipment allow the inhalation of defined substance concentrations. Such studies are important in toxicology as for the reevaluation of limit values for humans. The formalities required to perform such studies are usually similar to those of phase I clinical trials.

## Abstract

What is specific to the statistics in toxicology, and why not just use textbook statistics? The reason is the aim of regulatory toxicology: “be confident in negative results.” By toxicological studies, one would like to prove the harmlessness of new drugs. By means of the so-called proof of safety approach, the false-negative error rate (consumer’s risk) is directly controlled. Unfortunately, in most of the statistical textbooks and publications, the alternative proof of the efficacy of new drugs with the direct control of the false-positive error rate is used, denoted in toxicology as proof of hazard. Therefore, in this chapter, the basics of the falsification principle are presented simplistically. The commonly used proof of hazard approach is discussed hereinafter, focusing on testing a dose-related trend. Finally, the proof of safety methods for selected study types is explained by means of examples.

---

**Introduction**

In regulatory toxicology, statistical significance tests are used as standard for data evaluation. The difference between methods that directly control the more important false-negative error rates (proof of safety) and the common methods that directly control the false-positive rates (proof of hazard) is highlighted. Dunnett and Williams tests are recommended for the usual comparison of several dose groups versus the negative control, with simultaneous confidence intervals recommended for presentation and interpretation.

---

**The Falsification Principle**

Most of the tests used in biostatistics base on Popper's falsification principle, briefly "An effect can never be proved directly, only in that the probability of its opposite is very low." This very small probability is the  $p$  value of a test. It is a probability between 0% and 100%, where only very small levels, e.g., 0.01%, argue against the null hypothesis. As an arbitrary limit, 5% has been established; alternatively, for common tumors, a level of 1% was proposed as relevance criteria. Commonly, the decision for either the null hypothesis (harmless substance) or the alternative hypothesis (substance of concern) is usually performed by a statistical test, e.g., the Wilcoxon test (proof of hazard). Harmlessness is concluded if the  $p$ -value is greater than 5%, i.e. the null hypothesis of equal expected values is not rejected.

---

**Decision Scheme**

The type I error rate ( $\alpha$ ) is the false-positive rate, i.e., the probability of false rejection of  $H_0$ , while in "truth" no difference between treatment and control exists. The type II error rate ( $\beta$ ) is the false-negative rate, i.e., the probability of erroneous retention (i.e., non-rejection) of  $H_0$ , although in "truth" a difference between treatment and control exists; see the following decision scheme (Table 1):

---

**Proof of Hazard Approach**

The common design in regulatory toxicology includes a negative control, several (commonly 2–4) dose groups, and sometimes a positive control. For normal distributed endpoints, such as organ weights, the US National Toxicology

**Table 1** Error rates

		Computer output	Absolute, unknown truth	
			H <sub>0</sub> is true, i.e., no effect	H <sub>0</sub> is not true, i.e., effect
Test decision	H <sub>0</sub> not rejected	– (empty)	True	Type II error (β) false-negative rate
	H <sub>0</sub> rejected	*	Type I error (α) false-positive rate	True

This results in the two fundamental problems of the confirmatory test statistic: (i) only one of two errors –  $\alpha$  or  $\beta$  – is directly controlled, and (ii) the second error can only be controlled indirectly by a priori sample size determination (statistically) or definition (regulatory). It follows that the hypothesis is formulated in such a way that the content's more meaningful error was chosen as type I error. Thus, there are two test options: (i) tests of efficacy, in the case in screening research with the direct control of false-positive rate (proof of hazard), and (ii) tests of equivalence (two-sided hypotheses) respective test of non-inferiority (one-sided hypotheses) with the direct control of false-negative rate (proof of safety). For toxicological studies, therefore two concepts exist (see Tables 2 and 3)

**Table 2** Proof of hazard

Null hypothesis	$H_0^{\text{hazard}}: \mu_{\text{treatment}} - \mu_{\text{control}} \leq 0$ (substance harmless)
Alternative hypothesis	$H_A^{\text{hazard}}: \mu_{\text{treatment}} - \mu_{\text{control}} > 0$ (substance harmful)

**Table 3** Proof of safety

Null hypothesis	$H_0^{\text{safety}}: \mu_{\text{treatment}} - \mu_{\text{control}} \geq \delta$ (substance harmful)
Alternative hypothesis	$H_1^{\text{safety}}: \mu_{\text{treatment}} - \mu_{\text{control}} < \delta$ (substance harmless)

Here  $\delta > 0$  is minimal tolerable toxic effect, whereas we assume increasing values are toxic

Program recommends the use of either Dunnett (1955) or Williams (1972) procedure for pairwise comparisons between the dose group and the zero-dose control group. Both procedures control a familywise type I error (false-positive) rate. The first procedure tests chances against control, whereas the second tests a monotonic trend including control. As long as monotonicity can be assumed, the Williams test is the recommended test in the proof of hazard. When downturn effects at high doses are possible, the Dunnett test or a related Williams test modification robust against such specific non-monotonicity at high doses should be used. Through the multiplicity adjustment (control of familywise type I error rate), these tests however intensify the control of the actually less relevant false-positive rate substantially. For example, the false-negative rate increases from 17.6% to 34.4% when comparing three groups with a control by the Dunnett procedure compared with independent t-tests (endpoint body weight, to be detected difference  $\Delta = 10$  g,  $\sigma = 10$  g sample sizes 14,  $\alpha = 5\%$ , Bonferroni adjustment). Therefore, pairwise two-sample tests “control vs. dose,” each at level  $\alpha$ , may represent a compromise.

The evidence of a global trend represents a relevance criterion; on the other hand, the maximum safe dose (no observed effect level, NOEL) would be determined in toxicology also. The determination of a global trend appears as an easy task; nonlinear models or linear regression after data transformation is

used frequently. The dilemma is that these approaches much depend on the shape of the dose–response. But the shape is not an assumption; it is just an outcome of the experiment. Looking at data post hoc and selecting a particular model based on that impression is statistically incorrect. Therefore, it requires methods which are sensitive to all the possible shapes of the dose–response dependency. Tests with restriction order (trend test), based on the restricted alternative hypothesis,

$$\begin{aligned} H_0 : \mu_C &= \mu_{D_1} = \mu_{D_2} = \dots = \mu_{D_k} \\ H_A : \mu_C &\leq \mu_{D_1} \leq \mu_{D_2} \leq \dots \leq \mu_{D_k} \end{aligned}$$

can be used where (at least one  $\mu_C < \mu_{Dk}$ ) inequality in the alternative must hold true.

For this purpose, there are two principles: the likelihood ratio test and multiple contrast tests. Since the second approach is easier, numerically feasible confidence intervals are available, and power can be directly estimated; this should be shown here shortly. The Williams procedure is a special order-restricted test including the zero-dose control – an important argument for its use in toxicology. The idea will be illustrated with reference to the experimental design ( $[C, D_1, D_2]$ ).

Here, precisely, there are two possible dose–response profiles with respect to the control:

$$\begin{aligned} H_A^1 : \mu_C &= \mu_{D_1} < \mu_{D_2} \\ H_A^2 : \mu_C &< \mu_{D_1} = \mu_{D_2} \end{aligned}$$

For each profile, a contrast test can be used:

$$T_j = \frac{\sum_{i=C}^k c_i \bar{X}_i}{\sqrt{S^2 \sum_{i=C}^k \frac{c_i^2}{n_i}}}$$

The two sets of contrast coefficients  $c_i$  are (simplified for a design with equal sample sizes)

$$\begin{aligned} c_i^1 &= 1 \quad 0 \quad 1 \\ c_i^2 &= 1 \quad 0.5 \quad 0.5 \end{aligned}$$

The maximum test

$$T_{\max} = \max(T_1, \dots, T_q)$$

**Table 4** Ames assay data

I	Dose	Revertants	Mean
0	0	23, 22, 14	19.7
1	100	27, 23, 21	23.7
2	333	28, 37, 35	33.3
3	1000	41, 37, 43	40.3
4	3333	28, 21, 30	26.3
5	10,000	16, 19, 13	16.0

The following contrasts and their multiplicity adjusted p values result using the R code:

```
library(multcomp)
mymod<-lm(y~Dose, data=salmonellaTA98)
summary(glht(mymod, linfct=mcp(Dose="Williams"), alternative
="greater"))
See Table 5
```

**Table 5** Contrast coefficients and adjusted p values

Contrast	Coefficients' ci						p value
	1	2	3	4	5	6	
1	1	2	3	4	5	6	0.26
	-1	0	0	0	0	1	
2	1	2	3	4	5	6	0.095
	-1	0	0	0	0.5	0.5	
3	1	2	3	4	5	6	0.037
	-1	0	0	0.33	0.33	0.33	
4	1	2	3	4	5	6	0.069
	-1	0	0.25	0.25	0.25	0.25	
5	1	2	3	4	5	6	0.142
	-1	0.2	0.2	0.2	0.2	0.2	

For contrast 3, a slightly significant p value results, indicating a global significant trend, whereas a plateau including the doses 1000, 333, and 100  $\mu\text{g}$  (contrast 3 with a p value of 0.037) is most likely (Fig. 1)

(in our example  $q = 2$ ) is multivariate ( $q$ ) distributed with a correlation matrix defined by the contrast coefficients and the sample size (using R library multcomp) or can be calculated by resampling approach (SAS procedure MULTTEST).

This approach is demonstrated by Ames assay data (Table 4).

However, the boxplots indicate an increase up to doses 100  $\mu\text{g}$ ; hereafter a downturn effect occurs. Therefore, the modified Williams procedure protected against downturn effect at higher doses is used (Bretz and Hothorn 2003). The idea is to test the global Williams trend together with a trend up to dose 333  $\mu\text{g}$ , 100  $\mu\text{g}$ , and 10  $\mu\text{g}$ , i.e., for all possible peak points of the dose-response simultaneously (Table 6)

**Fig. 1** Boxplots for Ames assay data

## Proof of Safety Approach

The toxic response of most endpoints is either decreasing or increasing, such as declining numbers of offsprings in the *Daphnia* aquatic assay or rising number of micronuclei in the micronucleus assay. That is, the other direction is irrelevant for a toxicological perspective. Therefore, one-sided tests are appropriate for these assays. The harmlessness can be concluded by rejection of the null hypotheses that the difference between the treatment and dose effect is larger than an irrelevance threshold  $\delta$ . This decision can be achieved by so-called non-inferiority tests. However, the a priori definition of irrelevance threshold  $\delta$  is needed. Because this threshold is endpoint specific and scale dependent, a consensus is hard to find for different toxicological assays. For aquatic toxicity assays recently instead of difference to control, ratio-to-control tests were proposed (Denton et al. 2011) which allow a percentage, i.e., scale-independent definition of the threshold  $\eta$ . For chronic assays  $\eta = 75\%$  and acute assays  $\eta = 80\%$  were proposed. The approach provides several advantages: (i) the proof of safety concept controls the more important false-negative decision rate directly, (ii) it focuses on the toxicological relevant direction of decreasing effects, and (iii) it avoids the false claim of harmlessness when designs with insufficient small sample sizes are used (Hauschke et al. 1999).

The two-sample test for ratio-to-control comparison is a modification of the t-test (Fig. 2, Table 7):

**Table 6** Contrast coefficients and adjusted p values

Contrast	Peak dose							
1	1000	1	2	3	4	5	6	0.42
		-1	0	0	0	0	1	
2		1	2	3	4	5	6	0.17
		-1	0	0	0	0.5	0.5	
3		1	2	3	4	5	6	0.071
		-1	0	0	0.33	0.33	0.33	
4		1	2	3	4	5	6	0.13
		-1	0	0.25	0.25	0.25	0.25	
5		1	2	3	4	5	6	0.25
		-1	0.2	0.2	0.2	0.2	0.2	
6	333	1	2	3	4	5	6	0.12
		-1	0	0	0	1	<b>0</b>	
7		1	2	3	4	5	6	<b>0.038</b>
		-1	0	0	0.5	0.5	<b>0</b>	
8		1	2	3	4	5	6	0.104
		-1	0	0.33	0.33	0.33	<b>0</b>	
9		1	2	3	4	5	6	0.25
		-1	0.25	0.25	0.25	0.25	<b>0</b>	
10	100	1	2	3	4	5	6	0.04
		-1	0	0	1	<b>0</b>	<b>0</b>	
11		1	2	3	4	5	6	0.16
		-1	0	0.5	0.5	<b>0</b>	<b>0</b>	
12		1	2	3	4	5	6	0.39
		-1	0.3333	0.3333	0.3333	0	0	
13	33	1	2	3	4	5	6	0.68
		-1	0	1	<b>0</b>	<b>0</b>	<b>0</b>	
14		1	2	3	4	5	6	0.88
		-1	0.5	0.5	<b>0</b>	<b>0</b>	<b>0</b>	
15	10	1	2	3	4	5	6	0.93
		-1	1	<b>0</b>	<b>0</b>	<b>0</b>	<b>0</b>	

Contrast 7 reveals the smallest p value, i.e., the peak dose is 333  $\mu\text{g}$  (not the 100  $\mu\text{g}$  guessed from the boxplot), and a plateau including doses 333 and 100  $\mu\text{g}$  is most likely

A different objective is the estimation of the NOEL. Commonly it is estimated by step-down significant trend tests, whereas NOEL is the next lower dose after the last significant trend test. But this classic proof of hazard has the disadvantage that with small sample sizes, lower doses would be characterized as safe. An alternative concept of maximal safe dose (MAXSD) is described in the following section for the proof of safety

$$T^{\text{Ratio}} = \frac{\bar{X}_T - \bar{X}_C}{\sqrt{S^2 \left( \frac{1}{n_T} + \frac{2}{n_C} \right)}}$$

whereas the p values for the two-sample tests for the concentrations 1.56, 3.12, and 6.25 are very small, i.e., these concentrations are harmless; the p value for the concentration 6.25 is  $p = 0.99$ , i.e., this concentration is not harmless; see the R code:

**Fig. 2** Boxplots for Daphnia data

**Table 7** Reproduction data for the daphnid *Ceriodaphnia dubia* exposed to an effluent for 7 days

Concentration/%	No. young per adult
Control	27, 30, 29, 31, 16, 15, 18, 17, 14, 27
1.56	32, 35, 32, 26, 18, 29, 27, 16, 35, 13
3.12	39, 30, 33, 33, 36, 33, 33, 27, 38, 44
6.25	27, 34, 36, 34, 31, 27, 33, 21, 33, 31
12.5	10, 13, 7, 7, 7, 10, 10, 16, 12, 2
25.0	0, 0, 0, 0, 0, 0, 0, 0, 0, 0

```
library(mratios)
t.test.ratio(Number_Young~Conc, data=daph, rho=0.8, base=1,
alternative="greater," var.equal=TRUE)
The estimation of the maximally safe dose (MAXSD) can be
performed by step-up non-inferiority tests (Table 8)
```

### Impact of Sample Size

The sample size has a central position in decisions of tests, because the secondary error rate is determined only by an a priori estimation of the sample sizes. This will be illustrated for the proof of hazard and proof of safety on the basis of parametric tests (see Table 9).

**Table 8** Decision tree Daphnia example

Step	Comparison	p value	Decision
1	$\mu_{1.56}/\mu_{\text{control}}$	6.9e-04	Significant, i.e., harmless
			Go to step 2
2	$\mu_{3.12}/\mu_{\text{control}}$	2.5e-10	Significant, i.e., harmless
			Go to step 3
3	$\mu_{6.25}/\mu_{\text{control}}$	4.9e-07	Significant, i.e., harmless
			Go to step 4
4	$\mu_{12.5}/\mu_{\text{control}}$	0.99	Not significant, i.e., not harmless, i.e., dose 6.25 is MAXSD
-	$\mu_{25.0}/\mu_{\text{control}}$	Not tested	-

The related R code is the following:

```
library(mratios)
```

```
simstest.ratio(Number_Young~Conc, data=daphnia, type="Dunnett," alternative="greater,"
```

```
Margin.vec=c(0.8,0.8,0.8,0.8))
```

**Table 9** Estimated sample sizes

Proof of hazard		Proof of safety		
Detectable difference $\Delta$	Sample size	CV <sub>Control</sub>	k-fold threshold $\eta$	Sample size
2.5 g	199	10%	0.8	8
5 g	51		0.667	3
7.5 g	23		0.5	(1)
10 g	14	25%	0.8	28
12.5 g	9		0.667	10
15 g	7		0.5	5
17.5 g	5	50%	0.8	109
20 g	4		0.667	35
25 g	(1)		0.5	14

For example, for the terminal body weight, a standard deviation estimator from historical studies of  $\sigma = 10$  g and normal distribution can be derived

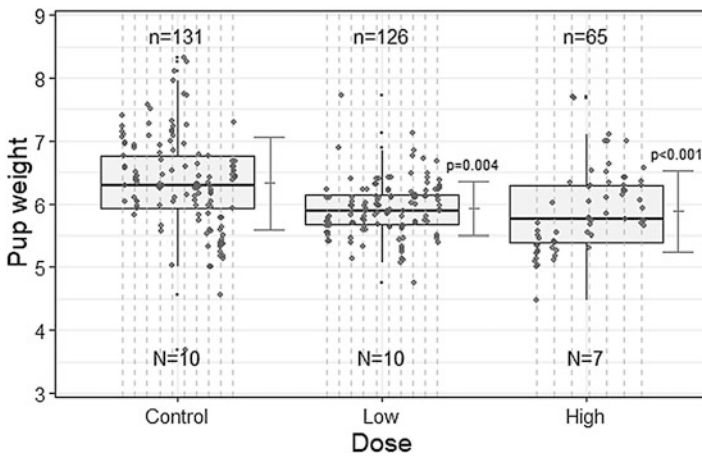

For the proof of hazard approach, the necessary sample size per group can be estimated for several detectable differences  $\Delta$  (one-sided *t*-test, design with equal sample sizes, type II error rate = 20%, type I error 5%); see Table 9

For the proof of safety using the ratio-to-control test, the sample sizes depend on the coefficient of variation of the control (CV<sub>Control</sub>) and the irrelevance threshold  $\eta$ . Sample size depends seriously on the accuracy requirements. Therefore, sample size should be chosen “per chance” but by either a statistical calculation or regulatory recommendation

## Presentation of Significances

The results of significance tests, such as the Dunnett test, are often represented by asterisks (\* . . .  $p < 0.05$ , \*\* . . .  $p < 0.01$ ) or directly by p values in tables or graphs, since it is highly condensed and clearly structured. With the common-used formal p value threshold of 0.05, a dichotomous decision is derived into “significant” and

“non-significant.” The p value is a probability that cannot illustrate the different influences of effect size (e.g., mean difference) and uncertainty (a function of variance, sample size, false-positive rate, and other factors). In risk assessment, “absence of evidence is no evidence of absence” (Altman and Bland 1995) is a further issue hereby. An alternative is confidence intervals, best used as compatibility intervals (Hothorn and Pirow 2020). No formal 95% level is used, and their compatibility with the data and model assumptions is considered. As an example, the analysis of the pup weights of a reproductive toxicology study is considered. On the one hand, the per-litter structure is represented by a mixed effect model, in which possible gender differences and litter sizes are also modelled. From this, adjusted p values of a Dunnett-type test (Hothorn 2015) can be integrated into a boxplot (Fig. 3) (Pallmann and Hothorn 2015), or 90% two-sided intervals can be used (Fig. 4), indicating that even at the low dose is a weight retardation, which becomes relevant at the high dose.

**Fig. 3** Boxplots for pup weight data visualizing the litter structure and the p values

**Fig. 4** Simultaneous, two-sided intervals for difference to control pup weights, adjusted for sex, litter structure, and litter size

## The Dunnett Test and Its Modifications

The Dunnett test is the standard test in regulatory toxicology. Initially, it is defined for normally distributed, variance homogeneous errors and offers both adjusted  $p$  values and confidence intervals compatible. It controls the familywise error rate and thus has an inherently higher false-negative rate than pairwise level alpha tests. Variance heterogeneity is rather the typical result of an assay, and therefore the use of modifications with a robust variance estimator (Herberich et al. 2010) or a reduced degree of freedom (Hasler and Hothorn 2008) is strongly recommended. Unfortunately, these show an increased false-negative rate, especially in unbalanced designs. Therefore, designs with approximately equal  $n_i$  are recommended. Sometimes a global analysis of variance and/or pretests for normal distribution, variance homogeneity, or outliers are performed before the Dunnett test. This is problematic, especially with the usual small  $n_i$ . Either one relies on the robustness of the test, or one uses the nonparametric variant (Konietschke and Hothorn 2012) or a robust modification based on most likely transformation models (Hothorn and Kluxen 2019). Different scales are typically in toxicology (Szoecs and Schaefer 2015). Therefore, appropriate modifications of the Dunnett test should be used, for proportions (such as rates) (Schaarschmidt et al. 2008), for counts (Hothorn et al. 2013; Jaki et al. 2014), for mortality adjusted poly-k estimators (tumor rates) (Schaarschmidt et al. 2008a), for survival functions (Herberich and Hothorn 2012), and for correlated multiple endpoints (Hasler and Hothorn 2011). The open-source project for statistical computing R, the packages multcomp, mratios, MCPAN, and SimComp simplify the calculation considerably.

## Introduction

Following the initial observation of a toxic effect of a substance in humans or animals “hazard identification,” step 1 of the National Academy of Sciences (NAS)-scheme (National Research Council, US 1983), the determination of the dose-effect relationship for the observed toxic effect represents the second step in the NAS-scheme. The toxicological threshold levels identified in this process (e.g., no-observed-adverse-effect level) are then used for a quantitative toxicological risk assessment (NAS step 4) on an individual and/or collective level, taking into account the available exposure data (NAS step 3).

---

## Toxic Effects on the Individual Level

### Interaction of Toxicants with Target Molecules in Living Organisms

Pharmaco-toxicological effects of chemical compounds, whether desired (e.g., in the case of therapeutic effects of medicinal products; see also Blumenthal 2011) or unwanted (e.g., in the case of detrimental effects of environmental toxicants), result in most cases from an interaction with specific target molecules in living organisms.

An important exemption from this rule are chemically reactive compounds or compounds from which reactive metabolites (e.g., free radicals) are formed, which modify biomolecules more or less unspecifically. In this case, the resulting toxicological effects are dependent on numerous factors, for example, the regenerative or repair capacity of the affected cell or organism, so that no simple model exists to describe the pharmaco-toxicological effects of such compounds.

However, usually defined macromolecules, for example, proteins or nucleic acids, are the specific targets of toxicants. The interaction of a toxicant/drug with its target(s) is in most cases mediated by binding to the target molecule, which is characterized by a specific affinity. In the case of toxic compounds, the normal

physiological function of the target molecule is usually affected by this process, whereby toxic (pathophysiological) consequences can be induced.

### Reversible and Irreversible Damage, Accumulation of Toxic Effects

A toxicant may bind to its target either in a reversible (e.g., by ionic or van der Waals binding) or irreversible (e.g., by covalent binding) way. However, whether a toxic effect is in the end reversible or irreversible does not only depend on the kind of interaction of the toxicant with its target molecule but also on the capacity of the respective target tissue for regeneration.

For example, the covalent, irreversible inactivation of the enzyme cholinesterase by a sublethal dose of the insecticide parathion (E605) may not necessarily lead to an irreversible damage, since new cholinesterase is continuously synthesized by the organism, whereby the toxic effect of parathion may be reversed. Also in the case of toxic effects on the liver, an organ with a high capacity for regeneration, tissue damage induced by toxicants is often reversible. On the other hand, a toxicant-induced damage of the peripheral or central nervous system is often irreversible, since differentiated nervous cells have no or only limited capacity for regeneration (e.g., irreversible damage of the sensory cells of the inner ear by aminoglycoside antibiotics with permanent deafness/hardness of hearing as consequence).

In the event of irreversible effects, not only the administered single dose is important but also the cumulative dose which is taken up during lifetime (summation toxicants). For example, for the anthracycline derivative doxorubicin (used as a cytostatic), the cumulative total lifetime dose should not exceed 450 mg/m<sup>2</sup> body surface, since for cumulative doses exceeding this empirically defined value, the risk of manifest heart damage is strongly increasing. In practice, threshold levels can be identified for many irreversible toxic effects.

### Receptor-Mediated Toxic Effects, Law of Mass Action, and K<sub>D</sub>-Value

Hormone and neurotransmitter receptors represent important targets for many toxicants. In case of receptor-mediated toxic effects, the intensity of these effects depends on the number of receptors that are affected by the toxicant. The receptor affinity of the toxicant (ligand) determines its potency. The higher the affinity, the higher the number of occupied receptors at a given concentration of the ligand. The affinity is quantitatively described by the so-called dissociation constant K<sub>D</sub>. This constant describes the disintegration of the receptor-ligand complex (RL) in case of reversible interactions:

This process is the reversion of the binding reaction of the ligand to its receptor (which is often easier to determine experimentally than the forward reaction of binding). Since the reaction obeys the law of mass action, the dissociation constant is given as

$$K_D = \frac{[R][L]}{[RL]} \quad (2)$$

where  $[L]$ ,  $[R]$ , and  $[RL]$  are the concentration of the free ligand, the receptor, and the ligand-receptor complex, respectively. The  $K_D$ -value indicates at which ligand concentration half of the receptors are occupied. The *smaller* the  $K_D$ , the *higher* the affinity of the ligand to its receptor.

## Sigmoid Shape of Toxicant-Receptor Binding Curves

The magnitude of the pharmaco-toxicological effect of a ligand depends on the amount of ligand-receptor complex formed, that is,  $[RL]$ , because usually only a receptor that carries a bound ligand is biologically active.  $[RL]$  depends on the ligand concentration  $[L]$  in a way that can be derived by transformation from Eq. 2:

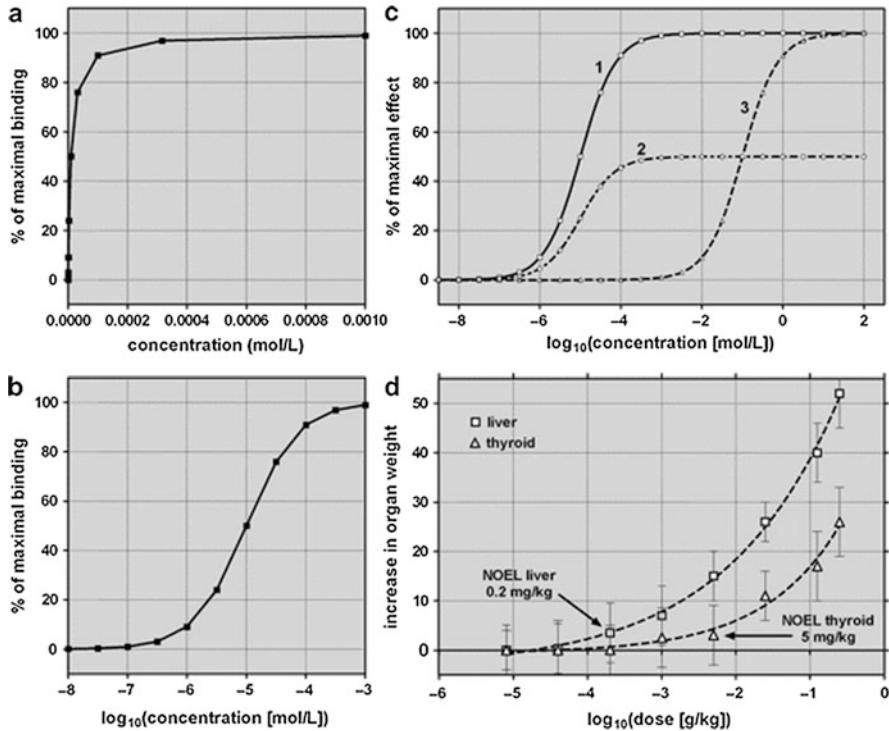

$$[RL] = \frac{[R]_t [L]}{K_D + [L]} \quad (3)$$

In this equation,  $[R]_t$  stands for the total receptor concentration, that is, for the sum of free receptor and receptor carrying ligand,  $[R] + [RL]$ . When  $[RL]$  is plotted against  $[L]$  according to the function provided in Eq. 3, then a hyperbolic curve results (Fig. 1a).

With a logarithmic scale of the x-axis, a sigmoid shape of the curve results (Fig. 1b). This logarithmic presentation more clearly indicates that a significant amount of ligand-receptor complex is only formed when the ligand concentration exceeds a certain limit (in the example of Fig. 1b a ligand concentration above around  $10^{-7}$  mol/L). For smaller ligand concentrations, formation of ligand-receptor complexes and therefore biological activity is virtually negligible. The  $K_D$ -value can be estimated by determining the concentration that elicits the half-maximal response. This concentration is called  $EC_{50}$  and is equal to  $K_D$  as long as the assumptions made above are valid, that is, that the effect size is only determined by  $[RL]$  and that  $[RL]$  only depends on the affinity of the ligand to its receptor. Derivations from this ideal case can occur, for example, if the receptor has additional binding sites for other ligands, leading to allosteric effects, or if there are more receptors than signaling molecules (so-called spare receptors) so that not every occupied receptor can contribute to the effect.

## Toxicant-Receptor Binding and Agonistic and Antagonistic Effects, Intrinsic Activity

A ligand, which is bound to its receptor, may activate (receptor agonist) or block (receptor antagonist) this receptor. Both processes may result in either desired or

**Fig. 1** Ligand binding, dose-response relationship, and toxicological threshold levels. (a) shows the relationship between the ligand concentration and the resulting extent of binding of the ligand (e.g., a toxin) to the receptor. The relationship follows the law of mass action. The graphical view on a linear x-axis scale yields a hyperbolic curve. (b) shows the same as (a) but now with a logarithmic display of the ligand concentration. A sigmoid curve results. (c) shows dose-response relationships for ligands with different potency (substance 1 = substance 2 > substance 3) and different efficacy (substance 1 = substance 3 > substance 2). In (d), the deduction of the NOEL level for the effects of a substance on the organ weights of liver and thyroid is visualized. Shown are mean values  $\pm$  95% confidence interval of replicated experiments. At the NOEL, the effect size is not significantly different from zero. See text for further explanations

unwanted effects for the organism. A classic example for a toxic agonistic effect is observed for the mushroom poison muscarine, which can result in an overstimulation of the parasympathetic nervous system by an activation of cholinergic receptors. Contrarily, atropine, an alkaloid contained in belladonna, can elicit severe toxic effects by an antagonistic interaction with cholinergic receptors. However, atropine, by virtue of its cholinergic receptor-blocking properties, can be used as an antidote in case of intoxication with muscarine.

While muscarine is designated as an *agonist* at certain cholinergic receptors, atropine is designated as an antagonist. More specifically, atropine is called a direct antagonist of muscarine, because it binds to the same receptors. On the other hand, atropine may indirectly abrogate, as a functional antagonist, the decrease in heart rate

induced by  $\beta$ -receptor antagonists, by blocking inhibitory effects of the parasympathetic nervous system on heart rate (for completion of definitions: a chemical antagonist can abrogate the effects of another substance by direct chemical inactivation, for example, dimercaptopropane sulfonic acid in the case of toxic effects of lead).

A receptor ligand may act as an agonist or as an antagonist. This behaviour is described by the so-called intrinsic activity, which quantifies the potential to activate, via binding to its receptor, downstream signal transduction mechanisms in the target cell (e.g., the cAMP system). It is possible to differentiate between “full agonists,” which result in a maximal activation (intrinsic activity = 1) and *partial agonists*, which only result in a submaximal activation of signal transduction mechanisms (intrinsic activity  $>0$  but  $<1$ ). Pure antagonists have an intrinsic activity of 0; the so-called inverse agonists have an intrinsic activity  $<0$ .

## Characterization of Toxicological Efficacy and Potency

The considerations outlined above assumed that the complete amount of administered ligand is directly available for receptor interaction, as it is the case in vitro. In vivo there is also usually a positive correlation between the total dose administered to the organism, the plasma concentration, and the concentration in the compartment where the receptor is located (often in a tissue outside the vasculature, either on the cell surface or intracellularly). Ideally, there is a linear relationship between the administered dose and the resulting ligand concentration [L] in the vicinity of the receptor. Therefore, the relationship between ligand concentration and response given in Eq. 3 can in principle also be applied to characterize the relation between administered dose and response.

The term efficacy describes the maximal effect ( $E_{\max}$ ) a substance can elicit if administered in sufficient dose. This situation is usually reached if all available receptor molecules have bound a ligand molecule, that is, in the case of maximal binding ( $B_{\max}$ ). A further increase of dose (and therefore of [L]) is not capable to increase the effect size further. In the graphical presentation of the dose-response relationship, this is reflected by the leveling off of the sigmoid curve at high ligand doses. Depending on the intrinsic activity of the ligand at its receptor, its efficacy may differ. By definition, full intrinsic activity is achieved with an agonist which activates the receptor to the highest extent possible. In the example of Fig. 1c, substance 2 shows a lower efficacy (intrinsic activity = 0.5, designated as partial agonism), whereas substances 1 and 3 display full agonistic activity (intrinsic activity = 1).

The potency of a ligand expresses how much (respectively how little) of this substance is needed to elicit a certain magnitude of response (usually the half-maximal response). The lower the required dose, the higher the potency. A higher potency manifests itself graphically as a shift to the left of the dose-response curve. In the example of Fig. 1c, substances 1 and 2 possess a higher potency than

substance 3 because the half-maximal effect ( $ED_{50}$ ) is already reached at a dose of  $10^{-5}$  mol/L, whereas for substance 3 the  $ED_{50}$  is  $10^{-1}$  mol/L.

## Identification of NOEL and LOEL as Toxicological Threshold Levels

Toxicants can have pharmaco-toxicological effects on different organs, for each of which a separate dose-response relationship can be established. This is illustrated in Fig. 1d, which shows the increase in organ weight of liver and thyroid in relation to the administered dose of a test substance. An increase in liver weight, often accompanied by histopathological signs of hyperplasia, is a relatively frequent toxicological finding.

This is because foreign substances often induce the expression of drug metabolizing enzymes in the liver, an effect that in turn may be associated with liver cell hypertrophy and hyperplasia in the long term. Thyroid hypertrophy on the other hand may be caused either by a direct thyrostatic effect of a test substance or may occur secondary to enzyme induction in the liver, because the induced enzymes may degrade thyroid hormones more intensively and the thyroid gland has to produce a higher amount of hormones to keep the thyroid hormone plasma levels constant. Nevertheless, even under these circumstances, liver and thyroid hypertrophy can display different dose-response relationships. This is because a considerable extent of enzyme induction in the liver is often necessary until first signs of secondary thyroid hypertrophy may become evident, and there may be toxicant/drug doses at which an increased liver weight is found but no effects on thyroid weight can yet be observed.

The lowest dose at which an effect is observed is called the LOEL (lowest-observed-effect level). In the example shown in Fig. 1d, a statistically significant effect (organ weight increase) was observed at a dose of 1 mg/kg or above in the liver but not until 25 mg/kg in the thyroid.

The NOEL (no-observed-effect level) is the tested dose level just below the LOEL. In the example provided in Fig. 1d, the NOEL was 0.2 mg/kg for liver and 5 mg/kg for thyroid. It should be emphasized that the LOEL (and therefore the NOEL) is usually defined by a statistically significant effect at this dose level although small, not statistically significant effects may be obvious already at lower dose levels. Furthermore, although in Fig. 1d a curve is fitted on the data points for clarity, fitted curves are usually disregarded for LOEL/NOEL determination and only the actual data points considered relevant. It should be pointed out that for statistical calculations, the number of replicates (animals per group in this case) and the statistical model used are important parameters. In the example shown in Fig. 1d, each dose level is regarded separately and statistical significance assumed if the 95% confidence interval (95% CI) no longer contains zero. Other approaches would also be conceivable, for example, a trend analysis. In any case, the selection of the statistical model used has to be justified.

## Problems in Determination of NOEL and LOEL Values

On basis of the aforementioned considerations, it is obvious that the calculated NOEL and LOEL values, respectively, will reflect the true “no effect level” and “lowest effect level” all the better if the number of dose levels evaluated and the number of measured values per tested dose level (i.e., in animal studies, the number of evaluated animals) is high, because then statistical significance can already be reached for small deviations from the control value. In case that only few measured values are available, statistical uncertainty may be so high, that a NOEL can only be assigned far in the ascending part of the curve. To avoid this, toxicity studies should be performed with a sufficient number of animals. For example, for performance of nonclinical chronic toxicity and carcinogenicity studies in rodents in context with marketing authorization of medicinal products, the use of at least 20, respectively, 50 animals per gender and dose level is recommended in OECD Guidelines 451 and 452 (see OECD 2020).

## Reporting of NOAEL and LOAEL Values

Particularly during assessment of nonclinical study data for medicinal products, it may, in certain circumstances, be a matter of discretion: which effects should be considered as unwanted (and therefore be avoided) and which effects can be tolerated with regard to the therapeutic benefit of the medicinal product. In the example shown in Fig. 1d, it would be conceivable to tolerate liver hyperplasia, if this is not related to irreversible liver damage, however, to consider impairment of thyroid function as being not tolerable.

For effects which are regarded as disadvantageous for the individual, instead of the NOEL value (which includes desirable effects), the NOAEL (no-observed-adverse-effect level) is given. Accordingly, the lowest dose level at which a significant adverse effect is observed is designated as LOAEL (lowest-observed-adverse-effect level). In the example presented in Fig. 1d, the NOAEL would be 5 mg/kg, if liver hyperplasia is considered as “not adverse,” and 0.2 mg/kg, if it is considered as “adverse.”

---

## Toxic Effects in Collectives

### Differences in the Individual Sensitivity

In the preceding paragraphs, the dose dependency of toxicant/drug effects was described, which should in principle be valid for each individual of the evaluated species. However, it should be considered that not each animal or human being will react in an exactly identical way to a given toxicant/drug. In practice, some individuals will react more sensitive and others will react less sensitive than the average. For

the more sensitive individuals, a given toxic effect will therefore occur already at a lower toxicant dose when compared with the less sensitive individuals.

## LD<sub>50</sub> and TD<sub>50</sub>

The dose-response relationship in collectives shall be exemplified for a long-known toxicological parameter, the LD<sub>50</sub> (LD stands for lethal dose), which indicates the dose of a test substance at which half of the treated animals die. The LD<sub>50</sub> is a first, orientating but rather crude measure for the toxicity of a substance. Ideally, differences in the individual sensitivity of the animals toward the substance result in a bell-shaped Gaussian curve for the lethal dose (see Fig. 2a). Few animals die already at a rather low dose. With increasing doses, the mortality rate reaches a maximum incidence (at the LD<sub>50</sub>), and again few animals survive until a rather high dose is given. Integration of the Gaussian distribution results in a function of cumulative mortality versus dose which expresses the fraction of animals that die *until* (instead of *at*) a given toxicant/drug dose. This integrated Gauss curve again has a sigmoid shape, and, in analogy to the determination of ED<sub>50</sub> from the dose-response curve, LD<sub>50</sub> can be determined (graphically or with the help of an adequate computer program) from this function (see Fig. 2b). In toxicological tests, usually different groups of animals are treated with different, ascending doses of the test substance, and the event rate (in case of LD<sub>50</sub> the event “death”) is counted in each group. This approach immediately yields the integrated Gauss function. Similar calculations can be performed for other parameters of interest, for example, organ toxicity, behavioral changes, etc. In this case, the resulting quantitative parameter is not called LD<sub>50</sub> but TD<sub>50</sub> (TD stands for *toxic dose*).

## Distribution of Individual Sensitivity, Therapeutic Range

The TD<sub>50</sub> is an orientating parameter which gives no information about the interindividual variability of the effect. In case of a large variability, unwanted effects can occur in a relatively large part of the population already at doses that are far below the TD<sub>50</sub>. This is visualized in Fig. 2c; there the distribution of the desired (therapeutic) effect and the unwanted (toxic) effect of a drug is plotted. For the toxic effect, a TD<sub>50</sub> of 10<sup>-3</sup> g/kg is identified, whereas the ED<sub>50</sub> lies at 10<sup>-7</sup> g/kg, which implies a large safety margin, with a therapeutic ratio (defined as quotient TD<sub>50</sub>/ED<sub>50</sub>) of 10<sup>4</sup>. However, a more detailed consideration of the dose-response relationships reveals that there is considerable overlap of the therapeutic and toxic effect curves and that a considerable fraction of the total population experiences toxic effects already at doses needed to elicit the full desired effect. Quantitatively spoken, the dose that elicits the desired effect in 95% of the population (ED<sub>95</sub>) also leads to toxic effects in more than 5% of the collective (shaded area in Fig. 2c), that is, is higher than the TD<sub>5</sub> value (Fig. 2d).

**Fig. 2 Dose-response relationship in groups (collectives).** (a) displays the statistical fluctuation of the individual lethal dose of a toxin within a collective. Ideally, as shown, a typical Gaussian distribution results. The maximum of the Gauss curve lies at the mean lethal dose ( $LD_{50}$ ); in (b) the curve of cumulative mortality is shown which was obtained by integrating the curve displayed in part (a). From this cumulative presentation, the  $LD_{50}$ -value can be derived. (c) shows the frequency distribution, in relation to the dose, for a desired therapeutic effect and for an unwanted toxic effect. From the large interindividual variability, an overlap results, so that in some individuals (*shaded area*) toxic effects already occur at doses in the therapeutic range (i.e., up to  $ED_{95}$ ). (d) provides the data shown in (c) in a cumulative, that is, integrated, manner with deduction of the parameters  $TD_5$  and  $ED_{95}$  together with the standard parameters  $TD_{50}$  and  $ED_{50}$ .

Thus, a more safety-related definition of the therapeutic ratio uses the  $TD_5/ED_{95}$  quotient instead of the  $TD_{50}/ED_{50}$  quotient. In the example shown in Fig. 2c, d the  $TD_5/ED_{95}$  ratio is about 0.25 and thus markedly below 1.

## Specific Dose-Effect Relationships

Dose-response curves with a U-shape (hormetic curves) can occur, for example, in the case of essential nutrients or trace elements. For example, vitamin A, when given in high doses, has a marked teratogenic effect. However, since vitamin A in a low dosage is essential for the correct embryo-fetal development, vitamin A deficiency may also result in the occurrence of malformations.

## Extrapolation of Threshold Levels to Application in Humans

NOAEL and other threshold levels determined in animal studies are valid at first only for animals of the investigated species. Extrapolation of these threshold levels to the human situation in context of a marketing authorization procedure for a medicinal product is shortly exemplified below.

### Use of More Than One Animal Species

According to the guidelines of the International Council for Harmonisation of Technical Requirements for Pharmaceuticals, ICH (ICH 2020), and European guidelines for evaluation of repeated dose toxicity of medicinal products, toxicological tests should usually be performed in more than one animal species, preferably both in a rodent and a non-rodent species. Hereby it is ensured that potential species-specific effects, that is, toxic effects that only occur in a specific animal species, are revealed. Often, such effects are not representative for human toxicology.

### Quantification of Exposure

Usually, dosage in toxicological studies makes reference to the bodyweight (mg/kg bodyweight) of the used laboratory animals. However, a direct extrapolation of these values to the human situation may be problematic, since in smaller animals, at the same weight-based dosage, often a considerably lower systemic exposure than in larger animals or in humans is achieved (see Fig. 3). In such cases, standardization of the dosage to body surface (mg/m<sup>2</sup>) often provides a better correlation (allometric scaling). However, instead of relying on data extrapolation to estimate exposure, it may be more favorable to measure the actual systemic exposure of experimental animals and of humans directly, for example, by determination of plasma levels following drug administration (see below).

### Toxic Threshold Levels and Safety Margin in Humans

For marketing authorization of medicinal products, it is recommended to collect pharmacokinetic data in humans and in laboratory animals for comparison. Under the assumption that at a systemic exposure at which toxic effects are observed in the animal study (LOAEL), toxic effects can also be expected to occur in humans, a safety margin can be estimated for drug application to humans. For this purpose, the ratio of the systemic exposure (*area under curve*, *AUC*) at the LOAEL (or alternatively the NOAEL) in the animal study and the systemic exposure at the (maximal) therapeutic dose level in humans is calculated. This quotient is called exposure multiple and indicates how far the dose range, to which humans are exposed during therapeutic dosing of a medicinal product and the dose range, at and above which

**Fig. 3 Measurement of plasma levels for determination of drug exposure.** The plasma levels (means) observed at different time points after single subcutaneous administration of a substance at a dose of 10 mg/kg at  $t = 0$  are shown for rats and monkeys. Note that the maximal plasma levels ( $C_{\max}$ ) and the area under curve (AUC), reflecting integration of plasma levels over time and hence total systemic exposure, are much larger in monkeys (AUC 26 ng h/mL) than in rats (AUC 1.4 ng h/mL) in this example

toxic effects have to be feared, are separated. In practice, often additional factors have to be taken into consideration, for example, the fact that pharmacokinetics may show dose dependency, may change after repeated administration (e.g., by induction of enzymes involved in drug degradation/metabolism), or may be influenced by the gender or by genetic polymorphisms.

By taking into account the aforementioned parameters, finally, a risk-benefit analysis is performed for the medicinal product in which the main toxicological findings, the calculated safety margin, the expected therapeutic benefit, and specific factors related to the exposed patient population, are taken into consideration. A more detailed description of the benefit-risk evaluation is provided in other chapters of this book.

## Abstract

One fundamental goal of regulatory toxicology is to establish safe levels of human exposure to toxic compounds. This is usually performed within the framework of risk assessment and risk management. Using both data of human exposure (*exposure assessment*) and from the characterization of the toxicity (*hazard characterization*), the risk of the investigated compound or agent can then be characterized (*risk characterization*) in a framed approach through health-based guidance values (HBGVs) or related measures. In the absence of information to establish dose–response relationships at exposure levels such low as they are generally experienced by humans, high-dose to low-dose extrapolation has been used. Whereas epidemiological findings of the agent’s toxicity are

e-mail: [lutzedler@gmx.de](mailto:lutzedler@gmx.de)

directly applicable to humans, toxicological results detected in experimental animals need in addition the extrapolation from the specific animal species to human (interspecies extrapolation). To estimate the magnitude of expected effects at lower doses associated with real human exposure or corresponding to acceptable risks for humans set by regulatory practices, appropriate extrapolation is required. This chapter focuses on the low-dose extrapolation of animal data but presents at the same time general methodology also applicable to human data to establish HBGVs for humans.

## Introduction

The fundament of the regulation of carcinogenic and noncarcinogenic compounds for human health protection is the toxicological and epidemiological knowledge base available when a specific agent or compound, often a chemical, is considered for risk assessment. Whereas epidemiological findings are directly applicable to humans they often are based on knowledge that was not obtained for the relevant dose range for the assessment. Toxicological data from the huge reservoir of experimental animals allow a designed approach to fill this gap, in principle. However, their results cannot directly be translated to humans because of systemic biological differences between the species. Well studied are differences in toxicokinetic and toxicodynamics. Furthermore, practical restrictions of the experiments (number of animals tested, duration of experiments, etc.) and the need to extrapolate between animals and humans may leave similar gaps regarding dose ranges as with epidemiological studies. Various extrapolation methods have been developed and applied to close the gaps and to estimate occurrence and size of adverse health effects expected at the low dose range relevant for humans. An outstanding organizing principle in the development of methods for extrapolation to low doses and decision making on exposure limits has been the distinction between thresholded and non-thresholded compounds.

---

## Study Types and Evaluation Principles

Studies in humans, epidemiological studies (see ► [Chap. 19, “Epidemiological Methods in Regulatory Toxicology”](#)) would be the gold standard for the risk assessment of compounds to which humans are exposed. Those studies are mostly of observational nature with retrospective elements, and the data may be confounded by other risk factors (e.g., personal, behavioral, environmental characteristics, co-exposure to other agents) and background exposure. Therefore, specialized statistical and epidemiological methods are required to analyze these data for risk

assessment. It should be noted that the most valuable human data are often obtained from highly exposed populations (e.g., occupational cohorts) and do not cover dose ranges relevant for regulatory practice. Therefore, effects observed mainly at high doses are extrapolated to low doses. Opposite to human data with their high variability and heterogeneity exhibit data from studies of usually inbred strains of experimental animals in general very low heterogeneity and only moderate variability. Furthermore, confounding can be efficiently controlled by prospective and randomized designs. Therefore, animal studies have been considered also as gold standard for human risk assessment, even when two steps of extrapolation – from high to low doses and from animals to humans – are required. Extrapolation from high to low doses can be performed only within the animal species or within the human population.

Although the nature of statistical methods is general enough to be applied to both carcinogenic and noncarcinogenic data, the statistical methods for risk extrapolation must account for risk management principles used in regulatory practice, for example, the biologically based paradigm that genotoxic and/or directly DNA reactive carcinogens does not show a threshold exposure level below which no biological/toxicological effect is possible. Even when the existence of a threshold could be assumed for noncarcinogenic compounds or carcinogens which do not directly react with DNA, estimating that threshold dose is not straightforward, requires the use of statistical methods and is impaired by scarcity of dose–response data near the threshold. In most cases extrapolation from high to low doses and between species might be unavoidable.

---

## A Road Map for Extrapolation

Risk extrapolation of both carcinogenic and noncarcinogenic compounds is preferably performed in a carefully planned investigation which should account for a number of critical check points listed in Table 1 as road map. Working through these points cannot be without considering the resources available for the assessment (e.g., available scientists and their profile of expertise, access to data, computational resources including software) and the time frame for delivering the low-dose extrapolation result. It should also be noted that this checklist may be applied iteratively for refining the assessment process.

---

## Choice of Risk Parameters

The critical effects which define the risk parameter for extrapolation should have been identified at an early step of risk assessment, preferably *hazard identification*, in the form of adverse health effects which are potentially relevant for risk characterization and which can be assessed quantitatively for extrapolation from high to low doses. Quantitative extrapolation distinguishes three major

**Table 1** Road map and checklist for extrapolation

1. <b>Data examination:</b> Screening and assessment of the available data on the compound, their quality, their relevance, and their suitability to construct dose–response relationships
a. When not only one but a whole class of compounds is assessed (e.g., dioxins), clarify how to proceed (lead compound, group risk index, toxic equivalence)
b. When more than one study and more than one endpoint are to be considered, check for pivotal studies and critical endpoints, respectively
2. <b>Risk parameters and measures:</b> Definition of risk parameters (the “risks”) by appropriate choice(s) of critical effects and of the type of risk measures used for characterizing the risk and for which an extrapolation to low(er) doses is planned
3. <b>Dose–response relationship:</b> Construction and critical evaluation of the presence and of the type (linear versus nonlinear, monotone versus non-monotone, steepness at low and/or saturation at high doses) of the dose–response relationship. Check for availability of data from step 1 and discuss (risk-based) effect sizes regarding the choices made in step 2
4. <b>Assumption of a threshold dose:</b> Decision about the biological nature of the critical effect on the basis of all available biological data (structure-activity relationship, in vitro and in vivo tests, short- and long-term animal studies, epidemiological studies). Assess available evidence for the existence of a threshold dose only when the substance is not a genotoxic carcinogen
5. <b>Extrapolation:</b> Determination of the data suitable data for a fitting dose–response models and choice of a set of models or model classes which may fit the regulatory purpose
a. Derive in a first step a <i>point of departure</i> (PoD) or <i>reference point</i> (RP) from the available dose–response data and assess its statistical quality (e.g., central estimate vs confidence bound) and the degree of extrapolation, i.e., location related to observed dose range
b. Establish in a second step a health-based guidance value (HBGV), e.g., an acceptable/tolerable daily intake value (ADI/TDI), or characterize the gap between the PoD/RP and the estimate of current human exposure, e.g., through a margin of safety or margin of exposure (MoE)
6. <b>Outcome assessment:</b> Critical evaluation of the uncertainty of the regulatory value established in step 5 (e.g., by means of probabilistic methods), determination of data gaps, and formulation of recommendations of further research and additional data if appropriate

statistical classes of data types which express increasing statistical (not necessarily biological) content of information:

- Quantal (e.g., the occurrence of a defined illness)
- Categorical-ordinal (e.g., severity of allergies)
- Continuous (e.g., concentration of a liver enzyme or biomarker such as beta-2-microglobulin for renal tubular effects, often also denoted as quantitative data)

Carcinogenic effects seen in animal studies usually fall into the class of *quantal data*, with the occurrence of cancer (*cancer incidence*) or death from cancer (*cancer mortality*) as the relevant endpoints for human cancer risk assessment. Incidence and mortality are still the most relevant indices for cancer risk assessment and the control of cancer diseases in a population. For time-to-tumor or genomic alterations, both the biological database and the statistical tools available for dose-response analysis are still not well developed. In contrast to the evaluation of quantal data of carcinogenic effects where a standard suite of approaches exists (USEPA 2005; Working group on risk derivation within the subcommittee “Gefährstoffbewertung” of the Committee

on Hazardous Substances 2005) the assessment of noncarcinogenic effects has been very diverse, in particular, regarding the specification of the relevant adverse events/effects and the identification of suitable parameters which describe effects best (Dourson et al. 2013). On the other hand, the database for noncarcinogenic endpoints is often larger and rich of *continuous data* which allow powerful dose–response analysis with smaller numbers of subjects than those needed for the quantal carcinogenic data. Data of the type *categorical-ordinal* were so far rarely analyzed for extrapolation purposes and require specialized analysis methods.

## Choice of Risk Measures

When critical adverse health effects (disease incidence or the change of a continuous quantitative marker) are identified a quantitative risk measure  $R$  is defined, that describes the risk as a mathematical function  $R(d)$  of the exposure dose  $d$ . In animal experiments the dose is usually expressed in units of mg/kg body weight administered per day. Alternatively, one may define the risk measure also in terms of the concentration of the substance, for example, as compound concentration in drinking water or in animal feed. In contrast to those external doses are concentrations of the compound in a target organ (e.g., blood, liver, kidney) considered as internal dose (see ► Chap. 29, “Toxicokinetic Models”).

In the case of quantal data,  $R(d)$  expresses the probability of the occurrence of the critical effect in the subject of investigation exposed to dose  $d$ :

$$R(d) = P(\text{Effect} | \text{Dose} = d). \quad (1)$$

The symbol  $P$  stands for *probability* (unfortunately, sometimes also denoted as risk). For many compounds one cannot neglect existing background exposure, either from exogenous or endogenous origin that adds to the total exposure (total exposure = background exposure + exposure through administered dose =  $d$ ). Denoting the risk due to background by  $R_0 = R(0)$ , one may distinguish between additional and extra risk:

- Additional/added risk (above background):  $R_{Add}^* = R(d) - R_0$
- Extra risk (of the substance):  $R_{Extra}^* = \frac{R(d) - R_0}{1 - R_0}$ .

Risk measures for continuous data where  $R(d)$  simply represents the effect size associated with the toxic compound can be defined accordingly as:

- Additional effect:  $R_{Add}^* = R(d) - R_0$
- Relative effect (size):  $R_{Relative}^* = \frac{R(d) - R_0}{R_0}$ .

In quantitative risk assessments of environmental contaminants, in particular, when chronic inhalation exposure is assessed in epidemiological studies on cancer

<sup>b</sup>Arsenic and its inorganic compounds

<sup>c</sup>Based on  $100 \text{ F}/\text{m}^3$  (F fibers)

<sup>d</sup>Cadmium and its compounds

incidence or mortality, the *unit risk (UR)* has been used as an international agreed risk measure, defined as the extra risk when a constant concentration of the toxic compound of  $1 \mu\text{g}/\text{m}^3$  exists in the inhaled air. Formally, this can be written:

$$\text{Unit risk} = P(C|\text{constant exposure } 1\text{g}/\text{m}^3) - P(C|\text{no exposure}) \quad (2)$$

where C represents the occurrence of the observed disease, for example, cancer. Similar as for the additional risk, the first term on the right describes the probability of disease due to the exposure ( $1 \mu\text{g}/\text{m}^3$ ) and the second the probability due to background, that is, the risk in absence of the compound. *UR* is then the excess lifetime cancer risk from continuous lifetime exposure to an agent at a concentration of  $1 \mu\text{g}/\text{m}^3$  in air.  $UR = 3 \times 10^{-6}$  per  $\mu\text{g}/\text{L}$  means that three excess cancer cases are expected to develop per 1000,000 people all exposed to the *unit dose (UD)*, that is, the daily exposure for a lifetime to  $1 \mu\text{g}$  of the substance in  $1 \text{m}^3$  in air; same when exposed to drinking water in units of  $1 \mu\text{g}/\text{L}$  water or through food in units of  $1 \mu\text{g}/\text{kg}$  food. *UR* is the preferred measure for comparing the carcinogenic potentials of different toxic compounds (see, e.g., Table 2). It should be noted that without additional specification, all these risk measures assume lifelong constant exposure to the substance, in the past often assuming life length of 70 years.

## Dose Extrapolation

Extrapolating from an established dose–response relationship available for the dose range

$$D_{\text{Experimental}} : d_{\min} < d < d_{\max} \quad (3)$$

to a lower dose range

**Table 3** Possible scenarios for extrapolation

Data source	Assumptions concerning the biological nature of action	
	No threshold	Threshold
Epidemiological studies	Dose–response model	Approximation of the threshold
	Extrapolation in the model	Determination of a PoD/RP and using safety factor for intra-species variation
Animal experiments	Dose–response model	Determination of a PoD/RP and using safety factors for intra-species variation and inter-species differences
	Extrapolation in the model	
	Extrapolation to humans	

$$D_{\text{Extrapolation}} : d_L < d < d_U, \text{ where } d_U < d_{\text{min}} \quad (4)$$

should distinguish between low-dose extrapolation with or without assuming the existence of a threshold dose. This distinction has guided risk assessment early on (WHO 1999; Boobis et al. 2009), although the question of the existence of biological thresholds has hardly been unequivocally resolved for any compound. Mainly three arguments question the existence of thresholds in general:

- “*additivity-to-background*”: Even small exposure can increase existing effect levels.
- “*heterogeneity in the population*”: Variation in sensitivity due to interindividual differences is not consistent with the assumption of a fixed break-point.
- “*missing evidence from epidemiology*”: Responses in humans can occur even at very low doses.

The discussion on the existence of a threshold dose should not be confused with the discussion of assuming *low-dose linearity* (NRC 2009; White et al. 2009). However, existence of low exposure linearity and the use of linear low-dose extrapolation for noncancer health effects have been questioned by Rhomberg et al. (2011), with arguments related to the three above. Low-dose linearity is not in the focus of this chapter nor is a discussion on the role of mode of action (see, e.g., Dourson et al. 2013). This section concentrates on the threshold concept as it has been introduced in regulatory toxicology as pragmatic mean. The concept may be applied even though lower doses may show a biological effect, as long as it is considered as irrelevant or is practically indistinguishable from background because of statistical variation and measurement error. An overview on possible extrapolation scenarios for human and animal data depending on the assumption on the existence of threshold doses is given in Table 3.

## Risk Assessment Under the Threshold Dose Assumption

When assuming the existence of a threshold below which no biologically relevant effect of the compound can be expected, regulation may start off to estimate that biological threshold, say  $D^*$ . That estimate should be as precise as possible and as close as possible to the “true” value (i.e., statistically unbiased). Accounting for the uncertainty of that estimate, a sufficiently large safety margin represented by a safety factor (SF) would establish an *intervention dose* (ID) below which no biologically significant effects would be expected:

$$ID = D^*/SF, \quad (5)$$

also referred as reference dose (RfD), defined by WHO (1999) as the maximum dose without significant or appreciable adverse effect on human health.

Traditional estimation of  $D^*$  identifies the largest applied experimental dose at which there is still sufficient evidence of no adverse health when assuming a monotone increasing dose–response relationship. Practically, this is pursued through statistical hypothesis testing of each dose group against the control group, stepwise, starting with the lowest dose until one finds the highest dose at which there is still no statistically significant difference of the effects compared with the control (significance usually defined by a P-value  $<0.05$ ). Consequently, the next higher must show a statistically significant difference in such a test procedure. The highest dose with no statistically significant effect is then denoted NOAEL (no observed adverse effect level) and serves as estimate of the biological threshold  $D^*$ . That NOAEL is then used as PoD/RP, Table 1 step 5a. When a NOAEL cannot be identified (e.g., when all doses tested were statistically significant different from the controls), the smallest dose that caused a statistically significant effect denoted LOAEL (lowest observed adverse effect level) serves as PoD/RP. Since the LOAEL would in general overestimate  $D^*$ , a higher safety factor (usually by a factor of ten higher) is used in that case. It should be noted that the estimation of the NOAEL may be significantly above or below the true threshold  $D^*$ . The use of the NOAEL has been criticized therefore (EFSA 2017), predominantly for three reasons:

- *Strongly depending on the number of cases tested per dose group.* The larger the number of the examined subjects per dose, the higher is the statistical sensitivity (power) of the testing approach and thus the chance that a statistically significant effect is found at a dose. In converse, the smaller the sample sizes have been chosen per dose group, the higher will be the NOAEL, eventually higher than the highest dose tested.
- *Depending on the sensitivity of the biological assay.* The higher the sensitivity of the experimental determination of the biological effect, the smaller will be the NOAEL.
- *Strongly depending on the choice of doses and dose range.* The selection of the doses in  $D_{\text{Experimental}}$  is crucial for the identification and localization of the NOAEL. If doses are widely spread in relation to true range where the

dose–response curve increases, the NOAEL can be determined only very vaguely and can be far above or below  $D^*$ .

Safety factors (SFs) are applied in the second step of the establishment of the PoD/RP, for example, by dividing the NOAEL by SFs representing different types of uncertainty. Therefore, published literature and regulatory agencies have used the term uncertainty factors for SFs (see ► [Chap. 26, “Benchmark Dose Approach in Regulatory Toxicology”](#)). Traditionally, two types of SFs have been used (cf. Edler et al. 2002) when extrapolating from animals to humans (Table 3):

- $SF_{\text{interspec}} = 10$  to take into account the interspecies variability between animals and humans. It allows for the possibility that the average exposed person is up to ten-fold more sensitive than the average exposed animal for which the NOAEL was derived.
- $SF_{\text{intraspec}} = 10$  to take into account the interindividual variability. This is to ensure that a ten-fold more sensitive individual than that for which the PoD/RP value was derived will still be protected by the PoD/RP.

For a refinement of these SFs accounting for toxicokinetic and toxicodynamic data, see, for example, Dorne and Renwick (2005). It should be noted that even then these SFs are default factors not accounting for specific toxicokinetic and toxicodynamic knowledge of the toxic compound. A biologically based extrapolation would transform the dose–response relationship from animals to humans using toxicokinetic information by applying physiologically based toxicokinetic (PBTK) models, one for the animal strain and another for humans permitting the calculation of concentrations in target organs. A precondition, however, is that sufficient biological information is available to construct both PBTK models. For the situation in toxicodynamic modeling see ► [Chap. 28, “Toxicodynamic Models.”](#)

If based on an animal experiment, dose has been converted from animal experiments to humans using interspecies extrapolation (USEPA 2005; ECHA 2012). For extrapolation from animals to humans, an allometric scaling is used where the administered doses are adjusted with body weights to the power of  $3/4 = 0.75$ .

---

## Risk Assessment Without Threshold Dose Assumption

For compounds for which no threshold dose is assumed (non-thresholded), there are basically two approaches (see Fig. 1). At first, one can expand the dose range  $D_{\text{Experimental}}$  to the entire dose range ranging from the “zero dose” (i.e., where only background exposure may exert an effect) to a maximum dose  $d_{\text{max}}$ , a practical limit beyond which an exposure is unrealistic. This dose interval  $D: 0 \leq d \leq d_{\text{max}}$  serves then as base of the dose–response assessment and risk estimation. However, this implies for the extrapolation to bridge several orders of magnitude, both in terms of response and in terms of dose. Although mathematical dose–response models can fit any dose range the biological database may not support such a wide range and the

**Fig. 1** (a) Dose–response curve  $F(d)$  in the observed range  $d_{\min} < d < d_{\max}$  and in the extrapolation range  $0 < d < d_{\min}$ . (b) Benchmark dose (BMD) approach restricted to a left truncated dose range combining that  $D_{\text{Experimental}}: d_{\min} < d < d_{\max}$  and a limited extrapolation range  $D_{\text{Extrapolation}}$  of the dose–response curve (copyright Annette Kopp-Schneider: the author thanks for providing the figure)

dose–response relationship  $F(d)$  fitted in the experimental range would only provide limited information on the relationship in the entire interval  $0 \leq d \leq d_{\max}$  or the extrapolation range  $D_{\text{Extrapolation}}$ . It was found that different mathematical models equally good fitting the data in  $D_{\text{Experimental}}$  provided largely diverging risk estimates when extrapolated to the low-dose range of interest, differing by several orders of magnitude. When, for example, the one-hit model, the multistage model, and the empirical models derived from the Weibull distribution and the log-normal distribution would all fit the data, one would obtain increasingly differing risk estimates when going to lower doses, in the order of

$$\text{One Hit} < \text{Multistage} < \text{Weibull} < \text{Lognormal}, \quad (6)$$

when excess risk is considered (see Krewski and van Ryzin 1981). This strong dependence of the risk estimates on the models selected and lack of biological justification for using a particular model has significantly compromised the use of these (and also other) models for regulatory purposes.

An alternative approach focuses on modeling dose–response for doses from  $D_{\text{Experimental}}$  allowing only a limited extrapolation to  $D_{\text{Extrapolation}}$ . The best investigated approach of this type is the benchmark dose (BMD) approach (EFSA 2017) described below. It should be noted that the NOAEL approach described in the previous section requires not the threshold dose assumption and can be applied as pragmatic rule when statistical dose–response modeling leads to inconclusive results or when critical adverse health effects are too complex for available modeling tools.

---

## The Limit Risk

A limit risk  $R_{\text{limit}}$ , interpreted as lifetime risk or lifetime cancer risk (LCR), is the probability that the exposure will cause cancer (incidence type of risk) or death from cancer (mortality type of risk) within average lifetime.

A first version of the limit risk approach stems from the second half of the last century known as the “virtually safe dose” (VSD) concept. It was at that time developed in response to difficulties of risk management in complying with US Food, Drug, and Cosmetic Act in the context of the Delaney Clause and when food additives found to induce cancer at any dose level were finally banned. The VSD was defined as dose associated with one additional tumor per one million subjects through lifetime exposure in the belief that a low LCR of  $10^{-6}$  would be acceptable for a population of several millions. Later on that level was alleviated to an LCR of  $10^{-5}$ . It should be noted that in a population of size 100 million about 500,000 persons might be diagnosed with cancer every year (IARC 2008). An LCR of  $10^{-5}$  would then result in 13 additional persons with cancer per year in that population exposed during whole lifetime assuming an average lifetime of 75 years. Setting the limit risk  $R_{\text{limit}}$  to an LCR of  $10^{-6}$  would allow only 1.3 additional cancer case per year in that population, see SCCS (2012).

The risk management of WHO, EPA, and US OSHA recommended an LCR of  $10^{-5}$  for carcinogenic compounds. ECHA (2012) stated that “based on experiences, cancer risk levels of  $10^{-5}$  and  $10^{-6}$  could be seen as indicative tolerable risk levels when setting DMELs (derived minimal effect levels) for workers and the general population, respectively.” Higher risks up to  $1/1000 = 0.001$  have been accepted in the regulation in the working environment. All these limit risks established for humans are much lower than the measurable risk in a test group of animals tested for carcinogenesis which is generally not smaller than  $1/20 = 0.05$ ; in large experiments at best  $1/50 = 0.02$ .

The most extensively used model for calculating an LCR has been the so-called linearized multistage (LMS) model (USEPA 1986). Based on the multistage mutation model of Armitage and Doll (see ► Chap. 28, “Toxicodynamic Models”) the LMS is in essence a linear approximation of the multistage carcinogenesis dose–response model. Prominent model parameter is the slope factor (SF) used by the USEPA (USEPA 2005) as convenient descriptor of cancer potency in EPA’s Integrated Risk Information System (IRIS) (see <http://www.epa.gov/iris/>). The LMS model is also a member of the set of models recommended for the BMD by EPA (USEPA 2012).

---

## PoD Based on Benchmark Dose

The benchmark dose (BMD) approach is a general method of fitting dose–response models applicable for any dose–response data and basically it is built up by five steps:

1. Specification of type of dose–response data
2. Specification of the Benchmark Response (BMR) level
3. Selection of candidate dose–response model(s) for model fitting the data
4. Identification of acceptable models for modeling
5. BMD modeling and calculation of the PoD.

The BMD approach aims at determining a PoD/RP on an empirically and objectively verifiable basis and is applicable for all four scenarios described in Table 3. The BMD-based PoD was introduced into regulatory practice as the benchmark lower confidence limit (BMDL) of the dose at which response above background would not exceed a defined level, the BMR (Fig. 1b). Therefore, at the modeling step (5) above one determines one or a family of models which fit the observed dose–response data best in terms of a chosen statistical criterion (goodness-of-fit measure). From a best fitting model – or best fitting family of models – one obtains then a statistical estimate of the benchmark dose (BMD) as the dose level that is associated with the change in the response defined through the numerical value of the BMR.

Simultaneously, one calculates during statistical estimation the confidence interval (BMD-CI) of the BMD corresponding to a specific confidence level

which has been traditionally defined as 10%. The BMD-CI is then an interval (BMDL – BMDU) on the dose scale where BMDL is the lower and BMDU the upper confidence bound covering with probability 10% the BMD of the best fitting model(s) given the data. The lower confidence bound BMDL is then a limiting dose which allows a statistical conclusion: “the BMD is with probability 95% not smaller than this BMDL.” Choosing the BMDL as PoD allows then to say: “With 95% probability is the adverse health effect at the dose equal to this PoD not larger than the chosen BMR.”

Note that in this set up the BMD-CI and BMDL are not necessarily within  $D_{\text{Experimental}}$  nor within  $D_{\text{Extrapolation}}$ . The size and location of the BMD-CI and the location of the BMDL are a function of the dose–response data and depend strongly on wealth and precision of the available toxicity data. Various approaches ranging from pragmatic proposals to model averaging and other Bayesian approaches have been developed and discussed, in particular, by regulatory agencies such as FAO and WHO, US EPA, and EFSA. The most appropriate use of the BMD approach in risk assessment has been a topic of intense and controversial discussion since its introduction to low-dose extrapolation in the early 1980s and numerous efforts on guidance were launched to position the approach in regulatory toxicology. For details and more recent guidance see ► [Chap. 26, “Benchmark Dose Approach in Regulatory Toxicology”](#)) The most relevant issues are as follows:

- The BMD approach uses all available dose–response data from a study and fits a set of mathematical models. It accounts for the statistical variability of the dose–response data by calculating the confidence interval of the BMD ranging from the lower bound (the BMDL) to the upper bound (the BMDU).
- The lower one-sided confidence bound BMDL (e.g., the  $\text{BMDL}_{10}$  when setting  $\text{BMR} = 10\%$ ) accounts for the statistical uncertainty in the data (with the statistical certainty level of 95%) and is used as PoD/RP.
- The estimate of the BMD and therefore also the size of the PoD depend via the fitted model(s) strongly on the definition of the size of the BMR.
- General advice on how to define the BMR requests consideration of a low but measurable response level, reflecting an effect that is negligible or nonadverse.
- Choosing the BMR very low might well comply with that advice but it would normally result in an extrapolation outside the range of the observed data and could induce severe model dependence of the BMDL: different models might return drastically different BMD and BMDL values, such that the risk assessment would be driven by the models fitted to the data and not by the observed data.
- Choosing the BMR high enough to avoid extrapolation could easily violate the advice and question the aim of regulation to protect human health.
- For quantal data a  $\text{BMR} = 10\%$  of extra risk over background has been set as a default level in literature and in guidance of regulatory agencies for quantal data such as tumor incidence in animal experiments.
- For continuous data a  $\text{BMR} = 5\%$  of change relative to background was proposed. Default values are helpful for orientation but cannot circumvent a

thorough scientific analysis of biological and toxicological consequences of different choices.

- Suites of models were recommended and used in practice. When different models are fitted to the data and when some models fit equally well but result in different BMDs and BMDLs, selecting the BMDL of the best-fitting model is likely to underestimate the uncertainty in the BMD approach, while selecting the model with the lowest BMDL generally results in an overestimate of the risk.

---

## Other PoDs

Depending on the dose–response data available, two other methods concur with the BMD approach in practice:

**T25:** Defined as the chronic dose with 25% of the animals with tumors (at a specific tissue site after correction for spontaneous incidence and within the standard lifetime) the T25 is likely within the range of the experimental data (Dybing et al. 1997). An adjusted T25 is obtained as

$$HT25 = T25 / (b_{w_{human}} / b_{w_{animal}})^{0.25} \quad (7)$$

and an LCR can be calculated as

$$LCR = exposure \ dose / (HT25 / 0.25) \quad (8)$$

In contrast to BMD a T25 can be clearly identified even when besides the control group, only one dose group is available.

**TD50:** The TD50 value was introduced primarily for ranking of carcinogens in the Carcinogenic Potency Database (CPDB).

It characterizes the dose which, if administered chronically for the standard lifespan, will halve the probability of remaining tumor free (Sawyer et al. 1984; Gold et al. 1999). The determination of the TD50 value is complicated by intercurrent deaths due to causes other than tumorigenesis and the non-observability of the time of onset. The TD50 has been used as PoD when the toxic substance was administered chronically for the standard lifespan of the species, but is not recommended for low-dose extrapolation.

---

## Margin of Exposure (MoE)

Risk assessment of compounds that are both genotoxic and carcinogenic presents particular difficulties, since the effects of such compounds are normally regarded as being without a threshold such that no safe level can be postulated. Therefore, low-dose extrapolation has been found inappropriate for genotoxic carcinogens. Pragmatic risk management approaches such as the application of the ALARA (As Low as Reasonably Achievable) and the TTC (Threshold of Toxicological

Concern), which establishes exposure thresholds for chemicals present in food, dependent on chemical structure, have been discussed and occasionally applied as possible rescue. However, such approaches cannot inform risk managers on urgency and extent of the risk reduction measures needed.

More recently the margin of exposure (MoE) approach has been applied by both the European Food Safety Authority (EFSA) and the Joint FAO/WHO Expert Committee on Food Additives (JECFA) not to bridge the gap between the PoD/RP and human exposure but to describe the extension of that gap (Barlow et al. 2006). The MoE is numerically defined as the ratio of the point of departure (PoD/RP) of the critical effect to the predicted or estimated exposure level (WHO 2009). The magnitude of the MoE gives an indication of the level of concern without extrapolation to the substantially lower exposure levels usually encountered in human situations: the larger the MoE, the smaller the potential risk through exposure. The MoE should, however, not be used for a numerical quantification of risk but stay as qualitative advice for risk management. Therefore, the MoE is not recommended for extrapolation and the calculation of actual risks in the exposed population (Barlow et al. 2006). However, an MoE of 10,000 or more, based on animal cancer bioassay data, would be considered as of low concern (EFSA 2005). An MoE higher than 10,000 based on BMDL<sub>10</sub> can, in cases of lifelong exposure, be associated with an LCR lower than  $3.5 \times 10^{-5}$  if based on a male rat experiment and lower than  $7 \times 10^{-5}$  if based on a male mice experiment and using linear extrapolation (ECHA 2012; USEPA 2005).

## Abstract

The concepts of “variability” and “uncertainty” play a central role in exposure and risk assessment. Traditionally applied worst-case scenarios do not adequately reflect the requirements of modern practice. Methods of probabilistic analysis, such as Monte Carlo simulations, are promising developments for sound consideration of these aspects.

## Background

Regardless of the topic in question, variability and uncertainty are aspects of modeling and assessing health risks which need to be taken into account (Bogen et al. 2009; Mekel and Fehr 2000; US-EPA 2011; Schendel et al. 2018). “Variability” refers to the (statistical) distribution of the studied phenomena, while “uncertainty” refers to those parameters, factors, and models which are lacking or incomplete. This chapter will expand upon the concept of uncertainty and variability, describe methods of probabilistic estimation and sensitivity analysis, and provide an overview of suitable software.

**Variability** refers to real heterogeneity with respect to space, time, or persons and represents a feature of the system studied. Subdividing sources of variability according to space, time, and population provides a useful means for their understanding. Examples of temporal variability include, for instance, seasonal food consumption patterns or patterns of activities varying on a weekly basis. Both small and wide-area variations are observed in environmental pollution. Examples of intraindividual variability concern behavioral and personal features (Table 1).

In practice, variability can be taken into account through subdividing the studied system into a number of subgroups which are then analyzed separately. In research design and classical statistics, this is called “stratification.” The phenomenon of variability cannot be resolved by additional studies, these can serve solely to characterize the degree of variability more precisely. This results in a need for political–administrative decision-making on the desired level of safety in environmental policy.

**Uncertainty**, in contrast, is a researcher’s feature. It results from incomplete or lacking knowledge on aspects of the studied system. Uncertainty, just as variability, contributes to variation of analytical results. Types of uncertainty include scenario, parameter, and model uncertainties. The former concerns, e.g., an exposure pathway which was overlooked. Parameter uncertainty can result from samples lacking representativeness. The third type of uncertainty regards the modeling quality, as, e.g., inclusion or exclusion of a relevant model parameter. In principle, uncertainty can be reduced by doing additional research (Table 2).

**Table 1** Sources for variability. (Based on US-EPA 2011)

Category	Variability source concerning...	Examples
Time	Long-term resp. short-term variation	Concentration level
		Weather
		Dietary intake
		Seasonal variation
		Long-term trends
Space	Regional; small scale	Weekly interval of activity patterns
		Spatial variable concentration
Population	Interindividual variability	Regional dietary habits
		Personal characteristics: e.g., bodyweight, age
		Behavior: e.g., time budget, activity pattern

**Table 2** Sources for uncertainty. (Based on US-EPA 2011)

Category	Uncertainty source concerning . . .	Examples
Scenario uncertainty	Descriptive errors	Incorrect or incomplete information
	Aggregation errors	Spatial and temporal approximations
	Judgments errors	Selection of a wrong model
	Incomplete analysis	Overlooking important exposure pathways
Parameter uncertainty	Measurement error	Imprecise or biased measurements
	Sample uncertainty	Small or nonrepresentative sample size
	Variability	In time, space, or activity
	Surrogate data	Chemicals with similar structure
Model uncertainty	Relation error	Incorrect conclusions from correlations
	Modeling error	Non-consideration of relevant parameter

Both phenomena, variability and uncertainty, are relevant to each step of risk assessment. Distinguishing between sources of variability and uncertainty is important regarding two aspects: Firstly, with respect to interpreting the results, when assessing toxicity, for instance, it is important to know which variability exists within the population in question. Additionally, the reliability of this toxicity assessment matters: How sure are we that the toxicity and its variability was estimated correctly?

Secondly, the distinction between variability and uncertainty is important for the following reason: While variability impacts on the assessment's precision and its generalizability, uncertainty can lead to incorrect statements.

Variability and uncertainty of variables often occur together. If certain aspects of variability are unknown and stratification therefore is not possible, this lack of knowledge contributes to the uncertainty of the analysis. The quantification of soil ingestion from mouthing behavior of small children can serve as an example: It is well-known that there are large differences between children concerning the daily soil ingestion. The study design and methods of most recent studies still leave many open questions. For instance, it is questionable to which extent the soil ingestion was determined correctly; what is the variance between children; which type of statistical distribution can best describe the variability; and how do seasonal factors influence these values.

---

## Methods for Quantifying Variability and Uncertainty in Risk Assessment

### Point Estimates

In traditional risk assessment, single values or point estimates are commonly being used for representing the input model variables. In order to describe the typical conditions, for model variables having an empirically describable variability, measures of central tendency, i.e., mean or median, are being used. Such an estimate is

referred to as “typical case.” For the purpose of considering variability and uncertainty adequately, especially with respect to sufficient health protection, assumptions are mostly conservative or “unfavorable.” So far, upper percentiles like 90th or 95th percentiles of variables or – if such measures were not available – the worst conceivable assumptions were used for exposure assessment. This results in the so-called worst-case approach. Worst-case assumptions are usually a combination of variability and uncertainty concerning model variables. It is problematic that worst-case estimates often do not describe realistic exposure situations.

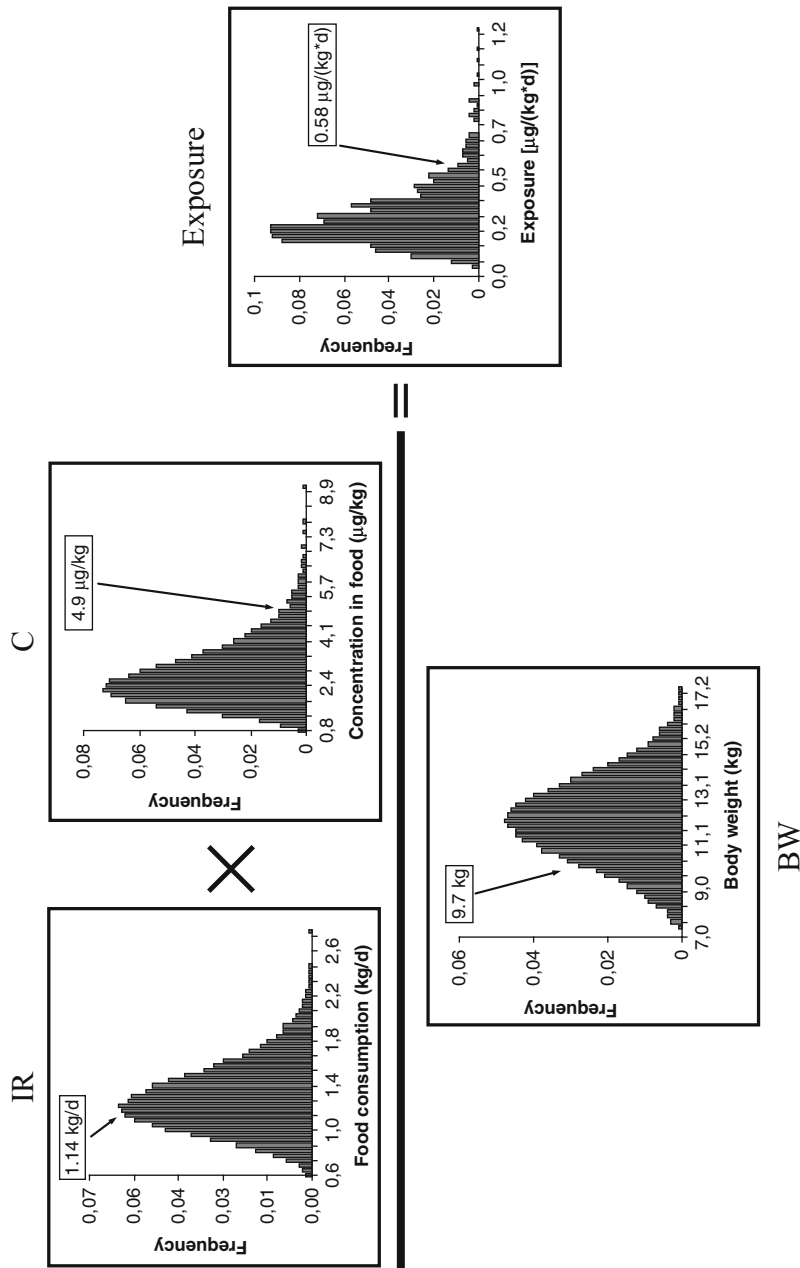

## Probabilistic Estimates

Probabilistic assessments make use of the entire distribution of all or several model variables (Cullen and Frey 1999). Simulated values are randomly chosen from these distributions according to their statistical parameters and then linked to other randomly chosen values according to the model’s algorithms. An example of this principle using the “nutrition” pathway in probabilistic exposure assessment is illustrated in Fig. 1. From the distribution of each of the three input variables, randomly chosen simulation values are being selected, e.g., 1.14 kg/day for food consumption, 4.9 ng/kg for pollutant concentration, and 9.7 kg for body weight. According to the model equation, the resulting exposure is 0.58 µg/kg body weight-day. This procedure is repeated through Monte Carlo simulation many times. The results of these simulations, in turn, can be displayed in a distribution, too. This distribution then represents the exposure assessment’s results and can be described by its statistical parameters such as mean, standard deviation, and percentiles.

By using entire distributions for estimation, each possible feature of a variable, including the “tails” of the distribution, is combined with other model variables according to its respective probability. This results in better insights about the populations’ exposure and more meaningful information regarding the spread and confidence interval of the calculated exposure or risk. Additionally, probabilistic methods provide the possibility to include all available information into the assessment, as opposed to an arbitrary selection of percentiles.

## Sensitivity Analysis

By conducting sensitivity analysis, model variables that contribute most to the spread of the results can be isolated (WHO/IPCS 2008): If, e.g., the distribution of input variables that are identified as being influential to the final results relies on sound data, the estimation can be considered sound. Body weight, for instance, could have strong influence on the final results. If the probability distribution of body weight applied is based on a representative population sample, the calculated variation can be considered reliable. If, in contrast, the input variables that are identified as influential to the final results rely on a relatively weak data basis, the results, correspondingly, are unreliable. Such findings can also point at further need

**Fig. 1** Exemplification of a Monte Carlo simulation for the example of dietary exposure of children ( $IR$  = food consumption [kg/day],  $C$  = concentration in food [ $\mu\text{g}/\text{kg}$ ],  $BW$  = body weight [kg])

for research regarding that variable. From this background, variables, which rely on a weak data basis but are identified as not significantly impacting the final results, will not necessarily require an effort to improve the data basis.

The simplest type of sensitivity analyses are *What-if*-analyses: The size of each input variable is modified (e.g., in steps of 10%), respectively, while the other variables are kept constant, studying the respective influence on the final result. Itemizing for input values, the most sensitive variables can be identified.

Meaningful sensitivity analysis requires data on variation that usually cannot be obtained from point estimates, but are easily available from probability distributions. Sensitivity analysis is not meaningful when using worst-case point estimates, because the maximum value is used for several input variables (e.g., 100% resorption). The combination of probabilistic estimates and sensitivity analysis provides information about the reliability of the estimates and its possible consequences regarding risk management.

---

## Application Potential in Dose–Response Assessment

Research and development in the area of probabilistic modeling so far have focused on exposure assessment (Mekel et al. 2007; Lindtner 2014). In recent years only, efforts were made to investigate their application potential in dose–response assessment as an alternative or addition to the application of so-called uncertainty factors that traditionally have been used when transferring data from animal studies to humans. In the Netherlands, these methods are applied in parallel to traditional, deterministic risk assessment of new and existing chemicals and pesticides (Vermeire et al. 2001). Similar developments can be observed in other countries (Chiu et al. 2018) but often have not become part of regulatory practice yet.

---

## Software for Probabilistic Exposure and Risk Assessment

Faster computers have enabled the application of computationally intensive probabilistic modeling in recent years. Specific commercial software tools for conducting probabilistic simulations are available. These software tools are not specifically designed for use in areas like toxicology or environmental health, but are used in a variety of disciplines where risk and decision analysis is an issue, in particular, in areas like economy and finance.

For performing a probabilistic exposure and risk assessment, the two most popular commercial systems are @Risk (<http://www.palisade.com>) and Crystal Ball (<http://www.oracle.com>). Both systems work directly as add-ins for spreadsheet software like Excel. @Risk is now available in seven different languages.

Both systems work in similar ways: Both require (i) a user-defined model to be implemented in a spreadsheet and (ii) the specification of the probability distributions for the model input variables. Differences exist in performance, e.g., in terms of clarity, provision of (partly) automatic functions, graphs, etc. Both systems offer a

large amount of different options for performing probabilistic analysis, necessitating, however, considerable intensity of training. Standard statistical software like SAS, SPSS, or R can be used for probabilistic assessment, too, but all simulation steps need to be programmed. Again, this requires extensive knowledge of the statistical packages.

## Abstract

Due to changes in living and working habits, most individuals spend about 80–90% of their time in public and private indoor environments. Those offer a broad diversity of pollution situations. Several hundred of very volatile, volatile, semi-volatile, and particular organic matter (VVOCs, VOCs, SVOCs, and POMs) can be detected in indoor air. Emitting from construction materials (e.g., floorings, paints, furniture, joints), consumer products (electrical and electronic devices), as well as cleaning products, they are one of the determining factors for indoor air quality (IAQ). The wide variety of pollutants, exposure levels, differences in sensitivity, as well as different cultural habits and ways of living

G. Volland (✉)

Material Testing Institute (MPA)-Otto-Graf-Institute Pfaffenwaldring, Schwäbisch Gmünd, Germany

complicate the assessment of risk. In a variety of reports, indoor air pollutants have been associated with health problems. Therefore, it must be of special interest to obtain reliable data to assess the IAQ. The basis for reliable and comparable data is given by a series of international and national standards for the sampling and determination of volatile (VOC) and semi-volatile (SVOC) organic compounds in indoor air.

## **Objectives and Purpose for the Determination of Volatile and Semi-volatile Organic Compounds in Indoor Air**

Indoor air, as dynamic system, is generally characterized by a wide variety of organic pollutants in differing concentrations (Salthammer 1999; Uhde and Salthammer 2007; Edwards et al. 2005; Schleibinger et al. 2001; Hofmann and Plieninger 2008). **Measurements of indoor air pollution are carried out for different reasons.** However in most cases, occupants **complain about poor air quality**, which often is correlated with complaints about odor and/or unspecific health problems such as headache, sleeplessness, lack of concentration, and fatigue (WHO 2000, 2010; COMEAP 2004; Anses 2011; EPA). Based on the results of a first measurement or a previous survey of a building, it might be necessary to **determine if a specified limit or guideline value is maintained.** Last but not least, the effectiveness of a remedial treatment has to be proven. A special task is to correlate observed or suspected effects on occupant health with indoor pollution. Due to these different questions, **individual sampling and determination strategies have to be applied.** Complaints from occupants in public buildings (e.g., offices, schools, and kindergartens) are often characterized/accompanied by the presence of different complaints and differing health problems. As normally, only few information on possible pollutants and their sources exists, these cases regularly require an extended search for the possible causes of the complaints. In general, it is advisable to use questionnaires to obtain a systematic record of complaints as well as a systematic record of the affected building (e.g., ISO/DIS 16000-32 – Investigations of constructions and pollutants and other injurious factors – inspection). Based on the obtained information, an individual sampling strategy has to be developed. In the ISO Guides 16000-1 (general aspects) and 16000-5 (volatile organic compounds – VOCs), the general rules for different sampling strategies are specified. In addition to these general aspects, ISO Guides 1600-2 and 1600-12 describe the sampling strategies for formaldehyde and polychlorinated biphenyls and dibenzo-dioxins/furans (PCB, PCDD/F), respectively. In cases of complaints about “bad” indoor air, it is often useful to know the average level and the range of the concentration of organic pollutants in indoor air (Krause et al. 1991; Schleibinger et al. 2001; Hofmann and Plieninger 2008).

**Table 1** Development of the average concentrations of typical volatile organic compounds in indoor air (median) within the period from 1985 to 2008 in indoor air in Germany

Compound	1985/1986 (Krause et al. 1991)	1999 (Schleibinger et al. 2001)	2006 (Hofmann and Plieninger 2008)
	Median in $\mu\text{g}/\text{m}^3$		
Toluene	62	28	12
Sum of C9 aromatic hydrocarbons	23	8	10
1-Butanol	<1	27	11
Limonene	13	8	6
Formaldehyde	55	38	32
Hexanal	<1	34	21

In this context, it must be noted that due to regulations and technical progress, new building and consumer products have been implemented on the market. These products are in general characterized by lower emission rates and the substitution of critical ingredients, e.g., solvents. This influences the average composition of indoor air. The reduction of the average concentration of aromatic hydrocarbons in indoor air is an example for this development (see Table 1).

Based on first investigations, often the question occurs whether threshold or guideline values are exceeded in the indoor air. Besides formaldehyde, **most threshold or guideline values for VOC and SVOC are long-term guidelines**, regarding an **average concentration** in indoor air over a longer period (e.g., annual average). Depending on the definition of the guideline value, short-term sampling and/or long-term sampling methods have to be applied. Guideline values for indoor air quality are published by the World Health Organization (WHO 2000, 2010), for the United States (EPA 2007; OEHHA 2012), France (Anses 2011), the United Kingdom (COMEAP 2004), and Germany (Umweltbundesamt 2007). Table 2 gives an overview of existing guideline values in different countries.

## Screening Methods

Besides the given low concentrations of organic pollutants in indoor air, which normally prevents the use of screening methods, these methods just detected a “sum” of volatile compounds in indoor air. In principle, gas chromatography with flame ionization detector (FID), photo-ionization detector (PID), and photo-acoustic sensor (PAS) is applicable for screening methods. These methods may give a quick overview of possible indoor air pollution. In practice, however, these results often show substantial deviations from the real concentration of VOC in indoor air. Generally not suitable are commercially available short-term tubes used for air examination at the workplace in the range of workplace-related limit values. For special indoor air pollutants, e.g., formaldehyde, commercial enzyme-based screening systems (e.g., “Bio-Check”) are available and suitable for pretesting.

**Table 2** Indoor air guideline values for selected indoor air pollutants in different countries compared with the median in indoor air in Germany

Organic compound	Median (P50) indoor air Germany (Hofmann and Plieninger 2008) Concentration in $\mu\text{g}/\text{m}^3$	WHO (2010)	USA (chRELs) (EPA 2007; OEHHA 2012)	Germany (recommended concentration RW I) (UBA 2007)	France (Anses 2011)	UK (COMEAP 2004)
Formaldehyde	32.5	100 (30 min)	< 20 (EPA) 9 (OEHHA)	120 (30 min)	10	100 (30 min)
Naphthalene	1	10	9	2	–	–
Toluene	1	–	300	300	–	–
Trichloroethene	1	–	600	–	20	–
Tetrachloroethene	1	250	–	–	250	–

## Sampling

Generally, the sampling strategy has to be adapted to the individual case. Sampling of indoor air should be carried out **at room temperatures between 19 °C and 24 °C** and a **relative humidity in the range of 30% and 70%** (comfort level see ISO 7730). Besides that, other **important parameters** like the **ventilation**, the nature of the **sources**, and the type of indoor environment have to be paid attention in choosing the conditions for sampling indoor air. Two basic sampling systems are applicable for the determination of VOC and SVOC in indoor air. Active short-term sampling is characterized by drawing the air through defined absorption systems, e.g., charcoal, polyurethane foam, or different sorts of silica gel.

The short-term sampling strategy for formaldehyde and VOC, for example, in natural ventilated rooms, demands intensive ventilation as a first step. After this, ventilation doors and windows have to be closed for about 8 h (preferably overnight). The sampling starts after this period (preferably next morning) without further ventilation (see ISO 16000-2 and ISO 16000-5). The sampling volume varies according to sampling method and the interesting compound between 1 and 10 l (thermal desorption and gas chromatography/mass spectrometry) up to 400 m<sup>3</sup> (determination of dioxins and furans). The hourly sampling rate should be less than 10% of the room volume or less than 10% of the ventilation rate (see ISO 16000-1). The disadvantage of the short-term sampling technique is that the result only represents the composition of indoor air during the sampling time. Normal differences in indoor air, effected by different air exchange rates or temperature-influenced changes in the emission rate, are not detected by active sampling methods. To detect these influences, a series of sampling are necessary.

To determine the average concentration of an indoor air pollutant, long-term sampling strategies should to be applied. If passive sampling systems for the interesting pollutants are available, this method offers the chance to determine the average indoor air concentration. Passive sampling systems are available and tested for aldehydes (see ISO 16000-4) and VOC (see ISO 16017-2 and EN 14412). For long-term measurements, generally no preconditioning is necessary. Sampling is carried out under actual living conditions. Occupants maintain their usual ventilation habits. It is recommendable to request and document these habits before the sampling starts. Deviations during the sampling period should be documented as well. For long-term measurements in offices, schools, and kindergartens, it is recommendable to determine the room temperature, the humidity, and especially the concentration of CO<sub>2</sub> continuously parallel to the sampling. Disadvantage of the passive sampling method is that concentration peaks and concentration gradients are not detectable. Figure 1 gives an example of the results for toluene in indoor air in different indoor environments obtained by active short-term and passive long-term sampling method (Bruno et al. 2008).

Aspects of the sampling and measurement strategy as well as examples and limitations of the different sampling techniques are given in the ISO standards 16000-1, 16000-2, 16000-5, and 16000-12 and ISO 16017-1 and 16017-2.

**Fig. 1** Weekly trend of toluene concentration in various indoor environments (Bruno et al. 2008)

## Determination of Organic Pollutants in Indoor Air

After sampling volatile and semi-volatile compounds in indoor air on solid-phase sorbents, several detection methods are applicable. For **VOC and SVOC, chromatography/mass spectrometry (GC/MS low and high resolution)** combined with either thermal desorption or solvent extraction is an appropriate method. ISO 16017-1 gives an overview of suitable sorbent tubes and the related accuracy. For common concentrations of VOC in indoor air, the standard deviation using thermal desorption and GC/MS is in the range of 1–5% (see ISO 16017-1). Using charcoal sorbent tubes combined with solvent extraction, comparable standard deviation can be obtained (see VDI 2001-2). For semi-volatile organic compounds like biocides or polychlorinated biphenyls, absorbed on polyurethane foam (PUF), standard deviations in the range between 10% and 25% are frequent (see Table 3).

Formaldehyde and other **carbonyl compounds (aldehydes and ketones)** can be absorbed on **silica gel cartridges coated with 2,4-dinitrophenylhydrazine (DNPH)**. The formed DNPH derivatives are analyzed utilizing high-performance liquid chromatography (see ISO 16000-3). The average random error (standard deviation for duplicate samples) for the determination of formaldehyde in indoor air is about 12% (see ISO 16000-3). This proves that the available methods for sampling and detection of organic compounds in indoor provide sufficiently accurate results:

**Table 3** Selected dioxin-like PCB – an example for the accuracy of the determination of toxic semi-volatile organic compounds in indoor air (Volland 2006)

PCB congener	Laboratory A		Laboratory B
	Sorbent PUF method EPA TO-4A GC/MS (HR)		Sorbent PUF method ISO 16000– 14 GC/MS (LR)
	Arithmetic mean ( <i>n</i> = 4)	Standard deviation (abs.)	Separate operation
	Concentration in ng/m <sup>3</sup>		
PCB 77	0.68	0.05	0.67
PCB 118	12.7	1.52	17.00
PCB 156	2.60	0.14	2.46
PCB 167	1.0	0.11	1.34
WHO-TE (max.) in pg/m <sup>3</sup>	5.0	0.59	5.4

Detailed information for the determination of VOC and SVOC is given with ISO 16000-3, -4, -6, -13, -14, -31; ISO 16017-1 and -2; EN 14412; VDI 2100; VDI 2464, VDI 3498 and EPA Compendium Methods for the Determination of Air pollutants in indoor air and EPA Compendium Methods for the Determination of Toxic Organic Compounds in Ambient Air (EPA 1990, 1999).

The detection sensitivity of the applied methods ranges from few pg/m<sup>3</sup> (e.g., PCDD/F method ISO 16000-14) to several hundred micrograms/m<sup>3</sup> for the detection of organic pollutants.

## Limits and Errors of the Determination of Organic Indoor Air Pollutants

Despite existing guidelines and standards for sampling and determination of organic pollutants in indoor air, very often, differing results for the same building are reported. Indoor air is a dynamic system, and thus, the concentration of organic pollutants in indoor air is influenced by a set of parameters. Besides the wide range of the contamination within a building (see Table 4), those differences are mainly caused by three parameters.

**Strength and emission characteristic of the source:** Depending on the room temperature, the temperature of the building element, and the air humidity, the emission characteristics of the sources change.

**Ventilation:** In most cases, the concentration of volatile organic pollutants in ambient air is significantly lower than in indoor air. Thus, different ventilation rates influence the obtained results. Depending on the tightness of a building envelope, the wind speed influences the ventilation even if the windows are closed.

**Absorbing effects and secondary sources:** Depending on the vapor pressure, organic compounds can absorb at the surfaces of, e.g., walls, floors, as well as on dust particles (see Table 3). In particular, SVOCs generate relevant secondary sources based on absorbing effects.

**Table 4** Examples of the concentration range of phthalate-based softeners [Di-ethylhexyl-phthalate (DEHP)] and organophosphorous-based flame retardants [Tris-chloro-ethylphosphate (TCEP)] in indoor air and house dust in German schools (Hansen et al. 2001; Volland et al. 2010)

	Living area and sleeping rooms	Classrooms	Community area (e.g., dining room)
<b>Softener (DEHP) (Volland et al. 2010)</b>			
House dust	Range and arithmetic mean ( $\bar{O}$ ) in mg/kg		
Boarding school A	300–2,300	500–2,600	<50
	$\bar{O}$ 1,200	$\bar{O}$ 1,880	
Boarding school B	110–740	350–575	<50
	$\bar{O}$ 400	$\bar{O}$ 450	
Indoor air	Range and arithmetic mean ( $\bar{O}$ ) in $\mu\text{g}/\text{m}^3$

School D		770–2,190	
School E		410–1,450	
Indoor air in $\mu\text{g}/\text{m}^3$		Range in $\mu\text{g}/\text{m}^3$	
School C	Nonexistent in this building	0.36–0.43	Nonexistent in this building
School D		1.2–3.9	
School E		0.3–2.0	

## Influence of Emission Characteristics and Ventilation

The **emission rate** of VOC and SVOC is commonly determined by the diffusion potential and the **vapor pressure** of the organic compound. Figure 2 points out how different vapor pressures resp. boiling points of solvents in coatings influence the emission characteristics of volatile compounds (Zellweger et al. 1997). In general, VOC with boiling points between 60 °C and 150 °C will lead to short and high concentration of VOC in indoor air immediately after application of the product. The emission of products containing organic compounds (e.g., solvents) with high boiling points (>180 °C) resp. low vapor pressure is characterized by long-term emission of those compounds combined with a low concentration in indoor air. Regarding the influence of the temperature, it is obvious that **higher temperatures will increase the emission rate**. The concentration of dioxin-like PCB in indoor air in buildings with PCB-coated ceiling slabs, for example, increases from 3.5 up to 13.6 pg WHO/TE/m<sup>3</sup> (Volland et al. 2006). At the first glance, normally, the room temperature is taken in account. Due to **structural conditions of a building**, parts of this building may have **different temperatures**. Depending on the season and the

**Fig. 2** Development of the concentration of n-propyl-benzene and diethylene glycol in test chamber air within the period after application of different products (Zellweger et al. 1997)

actual weather conditions, the temperature of these building materials ranges from 10 °C to 60 °C. Longer periods of sunshine, for example, will increase the temperature of building components. Experience shows that this effect is relevant for components containing indoor air pollutants. Influences caused by different temperatures of the building itself can be shown, regarding the season of sampling. Figure 3 gives an example of the influence of the room temperature and the season, when sampling was conducted.

Depending on the definition of a long-term guideline value, the interesting average concentration of indoor air pollutants also depends on the ventilation. The effects of sampling carried out according to ISO 16000-1 (see short-term sampling above) or when sampling is carried out during actual living conditions are shown in Fig. 4. In most cases, the PCB concentration obtained during actual living conditions is less than results obtained by sampling according to ISO 16000-1.

The emission characteristic of steam volatile organic compounds like aldehydes is additionally influenced by the humidity of the indoor air. Increasing humidity increases the emission. Figure 5 shows the influence of room temperature, air humidity, and ventilation for formaldehyde in indoor air.

## The Effect of Absorbing Effects (Sinks)

Due to specific physical characteristics of indoor air pollutants, longer-lasting indoor air contamination leads to relevant concentration on secondary areas in the room. One of the consequences is that these contaminated areas affect as a secondary source. Besides walls and floors, house dust is an important sink. Table 4 shows the

**Fig. 3** Influence of room temperature and season on the concentration of PCB 118 and the sum of 12 dioxin-like PCB in indoor air (Volland et al. 2006)

contamination of house dust in buildings contaminated with softeners or flame retardants. Both sources, secondary contaminated building materials and contaminated house dust, may raise the indoor air concentration.

## Conclusion

The given examples illustrate the influence of the indoor environment (temperature, humidity, season, ventilation) as well as the specific physical characteristics of indoor air pollutants on obtained measurement results. In the most cases, the methods to determine organic pollutants in indoor air deliver accurate and comparable results. For determination methods of VOC and SVOC in indoor air, if sampling is carried out under comparable conditions, the **usual accuracy is in the range of 10–30%**:

The complex correlation of the given structural situation in a building and the variety of the indoor climate normally overlaps the analytical errors of the determination step. The sampling strategy, the time of sampling as well as the parameters influencing the emission rate of the source are dominating the quality of results measuring the indoor air quality. Reported results without detailed information about the sampling condition cannot be assessed.

**Fig. 4** Comparison of the concentration of PCB (sum of 6) in indoor air depending on sampling according to ISO 16000-1 (short time sampling) and sampling under actual living conditions, regarding the season, when sampling was carried out (Volland et al. 2006)

**Fig. 5** Influence of room temperature, air humidity, and ventilation rate on the indoor air concentration of formaldehyde (calculated based on results reported by ISO 16000-3)

**Higher differences** between two measurement results are mostly **caused by differences of relevant parameters in the room during sampling.** These

differences in indoor environment can cause deviations of more than 100%. Thus, the assessment of results of the determination of VOC and SVOC in indoor air without the knowledge of the conditions during the sampling is fairly impossible. In the praxis often an exceeding of a guideline value is detected based on one single measurement. If the guideline value is based on a long-term average concentration, **the state of the art bans an assessment based on a single measurement.**

## Abstract

The Benchmark-Dose (BMD) approach aims at determining an exposure level/dose corresponding to a predefined change in response, the Benchmark Response (BMR), usually defined over background using all available dose–response (DR)

L. Edler (✉)

Dudenhofen, Germany

Formerly: Division of Biostatistics, German Cancer Research Center-DKFZ, Heidelberg, Germany

information by fitting mathematical models to the dose–response data. The statistical confidence interval of the BMD (BMD-CI) accounts for the statistical uncertainty and the lower (one-sided) confidence limit, denoted BMDL, is used as reference point (RP) or point-of-departure (PoD) for the characterization of the risk of hazardous compounds replacing the no-observed-adverse-effect level (NOAEL) when sufficient DR data are available. Concept, scope of application, prerequisites for conduct, and key check points of the application of the BMD approach are presented and guidance is given for regulatory practice. The use of the BMD-CI for establishing a Health Based Guidance Value (HBGV) or a Margin of Exposure (MoE) is outlined.

**Introduction**

The assessment of human health risk from the exposure to hazardous compounds has been omnipresent for scientists, regulators, and legislators in modern societies. Next to exposure assessment is dose–response assessment, a critical step for the risk characterization, and its outcome is a unanimously agreed base for decision making to protect human health. Measurement of doses and identification and description of adverse and toxic effects have challenged many scientific disciplines, in particular, toxicology, biology, and medicine. Ranging wide into the last century, the dominant focus was risk elimination and the definition of a “safe” dose below which no adverse/toxic health effect would exist. A long used concept has been the assumption of a threshold dose below which, theoretically or practically, no toxic effect would exist or might occur. From this concept evolved the NOAEL approach. Another early concept was low-dose extrapolation and the identification of doses at which none or no appreciable risk would exist.

Conceptual problems with the existence of such limits and practical limitations of measuring doses and responses initiated a more holistic view on dose–response data from toxicity studies in the second part of the last century, and methodological research on dose–response modeling became part of risk assessment, supported by the increasing availability of computational and statistical methods and data bases of toxicity data, for example, from the US National Toxicology Program (NTP). Initiatives of the US Environment Protection Agency (EPA), European Food Safety Authority (EFSA) and joint action of the Food and Agriculture Organization (FAO) and the World Health Organization (WHO) through its Joint FAO/WHO Expert Committee on Food Additives (JECFA) have fostered comprehensive dose–response assessment for risk assessment for all relevant hazardous compounds. These international regulatory bodies and many national bodies apply Benchmark-Dose approach since about 2000. A search in PubMed in March 2021 resulted in

almost 1200 hits for “benchmark dose” and more than 900 hits for “benchmark dose” and almost 700 hits when restricting the search by adding “risk assessment.” The BMD approach has meanwhile evolved to a state-of-the art for the extrapolation to low doses, the characterization of dose–response, the derivation of risk estimates, and the establishment of health-based guidance values (HBGV).

This development was supported strongly by methodological research in published literature, comprising mathematical modeling and statistical inference to identify reference doses that can be used for the risk characterization of hazardous compounds. Statistical software has been developed which could be applied by regulatory bodies, contract research companies, and individual researchers.

Although the BMD approach is based on a rather simple concept and proceeds in few well defined steps, as outlined below, all these steps allow for specific assumptions and modifications, often tailored for the risk assessment problem given by risk management and accounting for the type and amount of dose–response data available. Choices between options by groups of researchers and expert groups led occasionally to diverting results and decisions for the same compound. This chapter informs on the relevant elements of the BMD approach and its application. A systematic outline of the approach and explanations of dose–response modeling methodology might sharpen the view on individual BMD calculations and help judging quality of the method and judgment of both validity and uncertainty. It should also be noted that the establishment of the BMD approach for regulatory toxicology has by now not reached its final status. Matter in fact, all three bodies mentioned above (FAO/WHO, EFSA, and US EPA) are currently, often jointly, engaged to improve and refine the use of the BMD approach. This chapter presents the current status and risk assessors should be alert for future news about the BMD.

---

## **Benchmark-Dose (BMD) Approach**

The BMD approach has been introduced by Crump (1984) following discussions within US-NIH and US EPA when the paradigm of risk assessment was established by the US National Research Council (NRC 1983) as “A new method for determining Allowable Daily Intakes” with the explicit motivation for replacing the no-observed-adverse-effect-level (NOAEL) approach because of its potential shortcomings in risk assessment, see also Dourson et al. (1985) and Murrell et al. (1998). The shortcomings of the NOAEL, as well as the NOEL (no-observed-effect-level), have been reiterated and confirmed since then in numerous investigations and reviews, for example, U.S. EPA (1995, 2012), Edler et al. (2002), FAO/WHO (2009), and EFSA (2009). Methodological research on the BMD approach and initiatives for regulating human health and environmental risk assessment has boosted the use of the BMD approach during the past two decades when risk indices based on the BMD were used for food risk assessment, see, for example, the Food Safety in Europe (FOSIE) project (Barlow et al. 2002), the update of EFSA (EFSA et al. 2017b), guidance provided by U.S. EPA Davis et al. (2010), U.S.EPA (2021), and the update of

Chap. 5, “Dose-Response Assessment and Derivation of Health-Based Guidance Values” of FOA/WHO (2009).

The BMD approach was constructed to determine an exposure level or dose (the benchmark dose BMD) which produces a small but measurable adverse health effect in individuals of the exposed population. The allowed size of that effect is usually related to the background effect attributed to no exposure and it should be small enough to represent a relevant adverse effect and large enough for not critically depending on the mathematical models applied on selected dose–response data. To account for the statistical variation of the toxicity data, the statistical lower one-sided confidence bound of the BMD (the benchmark dose lower confidence limit BMDL) is calculated and used as Reference Point (RP) or Point-of-Departure (PoD) for the risk characterization (EFSA 2005).

The BMD approach controls the response level at the dose equal to the BMDL. This is in contrast to the NOAEL where the response level at the NOAEL is not controlled and can be rather high, in particular, when the sample size at the dose value equal to the NOAEL is small. The imprecision and the size of the response level at the NOAEL can therefore be large. A second advantage of the BMD approach over the NOAEL is that it attempts to use all available dose–response information by fitting mathematical models to all data. The NOAEL is somehow locked at one dose level of the toxicity study.

The BMD approach does not claim to be without uncertainty, but it makes the intrinsic uncertainty of empirical dose–response data more transparent. It investigates and describes the risk at or near a dose range where risk can be characterized and it allows extrapolation to dose ranges relevant for the assessment of human health risks, in particular for the range of human exposure. Therefore, the BMD approach is more transparent than previous approaches and requires a thorough analysis of available dose–response data.

The methods addressed in this chapter apply to the risk assessment of many types of contaminants, additives, etc., for various consumer products (food, drinking water, cosmetics, etc.) as well as for hazardous agents in the environment. However, the methods presented below differ from those applied for other risks such as radiation risk and from pharmaceutical medicines or risk of technical origin where the type of exposure is of different quality. A short overview on the BMD approach with a generic figure explaining the main features is given in ► [Chap. 23, “Extrapolation Procedures for Carcinogenic and Noncarcinogenic Compounds.”](#)

## **Dose–Response Assessment for Risk Characterization**

In basic and applied research for risk assessment, toxicity studies are performed to identify sources of hazards and risks for human health and human environment. This research applies also for plant and animal health and the preservation of eco-systems. In the sequel of those studies, additional biological and toxicological investigations collect information to proceed from risk identification to risk characterization and further to risk management. Quantification of the risk is therefore essential and risk

indices such as the HBGV derived from dose–response data have evolved as gold standard for risk management. A HBGV provides quantitative information for risk managers and enables decision making to protect human health, for example, by defining a range of oral exposure that would be expected without appreciable health risk. This general approach applies to many types of human exposure and is applicable to many species and biological systems. It applies also to direct genotoxic and DNA-reactive carcinogens where not the HBGV but the margin of exposure (MoE) is the preferred risk index. Dose–response methods for the establishment of HBGV apply also to the MoE, see FAO/WHO (2009).

The link between hazard identification and establishment of HBGVs is the determination of a RP or PoD on a dose–response curve derived from toxicity experiments. The RP/PoD is a dose that corresponds to a specified adverse health effect, considered as response associated with a predefined risk. The preferred source of information for deriving an RP/PoD would be experiments or observational studies which have been prospectively designed for the specific dose–response assessment accounting for scenarios of the exposure of interest, possibly including the most vulnerable subpopulations. However, those studies are rare. On the other hand, many toxicity studies designed for the hazard identification provide sufficient data to quantify the risk and to determine a RP/PoD.

Note that in contrast to quantifying the risk for a given exposure, the determination of a RP/PoD is a sort of “inverse” estimation task: for a given risk level, say  $R^*$ , is an exposure level, say  $D^*$ , determined which assures with sufficient confidence that this risk level  $R^*$  is not surpassed when exposure does not exceed the level  $D^*$ . The establishment of a HBGV for risk management and regulation is based on that level  $D^*$  or levels derived therefrom. The HBGV is such anchored on the  $R^*$  and therefore  $R^*$  should have societal acceptance.

For an overview of approaches for the risk assessment of hazardous compounds see, e.g., Edler et al. (2002). The BMD approach differs from assessments which extrapolate from high to low doses (see also ► Chap. 23, “Extrapolation Procedures for Carcinogenic and Noncarcinogenic Compounds”).

## Dose–Response Data Types

Dose–response (DR) data for hazard characterization originate almost exclusively from studies in humans or experimental animals. The focus here is on the assessment of risks of chemicals and compounds in food and diet. The relevance of food and diet as source of human exposure explains the abundance of quantitative risk assessment in that area. For the use of dose–response assessment for *in vitro* and genomic data, see e.g., Crump et al. (2010), Yang et al. (2007), and Long et al. (2018). The biggest challenge for the latter data sources is the construction of a robust qualitative relationship between the *in vitro* effects and the genomic alterations and the adversity on human health.

A clear concept of what is meant by dose and how dose is quantified is part of exposure assessment and crucial for the dose–response evaluation. Both, aspects of

toxicokinetic (TK)/toxicodynamic (TD) nature of the compound and statistical aspects of data should be considered (see also ► [Chap. 28, “Toxicodynamic Models”](#)). Regarding TK/TD and TD, one distinguishes in dose–response assessment between the *administered dose*, also called external dose and the *absorbed dose*, also called internal dose. The latter may be further specified as tissue concentration or concentration reaching the relevant target of adversity. Target doses can be obtained by case-specific biomonitoring. Most common candidates are concentrations of the toxic substance in blood or tissue or biochemical components (e.g., lymphocytes). The temporal nature of exposure is relevant when duration and frequency of exposure are factors to be considered. The field of food risk assessment distinguishes between acute and chronic exposure and separate HBGVs are established for the two types of exposure. Acute exposure can be quantified by the amount of toxins (e.g., mg toxin once given or mg toxic substance per kg body weight (BW) given once or several times within a short period of time, often 1 day only). The HBGV is then the acute reference dose (ARfD). In contrast, chronic exposure is usually quantified by the amount of toxin per kg BW and per day and hazard characterization assumes in general life-time exposure when establishing an acceptable daily intake (ADI) or a tolerable daily intake (TDI) as HBGV. Preferably, one would use individual body weight data for the analysis when the dose is in units of mg per kg BW per day. A special case of chronic exposure has been noted for toxic substances in drinking water where the dose is always presented as concentration, preferably as part per million or trillion (ppb or ppt). Concentration has been used as dose metric for animal health assessment in agriculture when the amount of toxin is related to the amount of daily feed consumption, for example, mg toxin/kg feed; see e.g., EFSA et al. (2017a) for the risk assessment of deoxynivalenol for humans and farm animals.

Transformation of doses into equivalent human doses (e.g., using allometric scaling) has been used in the past mainly when the NOAEL approach was applied or when the focus was on low-dose extrapolation. It has hardly been used with the BMD approach where the establishment of the link between the RP/PoD and the HBGV is constructed using uncertainty factors (FAO/WHO (2009)). Most toxicity experiments report the dose as measured in the study. However, the dose response data are often illustrated in graphics and, accounting for wide dose ranges, the original dose  $d$  is plotted often on log-scale with a graph of the response (on the vertical, say  $y$ -axis) versus  $\log(d)$  on the horizontal, say,  $x$ -axis. This occurs preferably when the doses were administered over several orders of magnitude (e.g., 0, 1, 50, 100, 500, 1000) or when the experiment was designed by purpose on logarithmic dose scale (e.g., 0, 1, 5, 25, 125, 625). It should be noted that the BMD approach has been developed for doses on the original scale and not the log scale and data analysis and graphical data presentation should always be separated. The fact that some model equations do have the term  $\log(d)$  in their definition formula should not be confused with the specification of dose at first place.

Essential for BMD modeling is the specification of the response related to observable toxicological effects identified as relevant for hazard characterization.

Whereas a toxic outcome informs usually on a wide spectrum of toxic endpoints, only those endpoints suit modeling that express adverse health effects or can be sufficiently associated with human health effects. Although a causal relation between an identified endpoint and exposure would increase its relevance for human hazard characterization, this relation should not be postulated as requirement since it might exclude informative relevant endpoints from a full risk characterization, besides conceptual and practical problems of the definition of causality. As a rule “only effects that link to adverse responses should be chosen for dose–response assessment” (FAO/WHO (2009)). Since the BMD approach is indispensably based on statistical methods, it is the statistical quality of the endpoint, in particular, its statistical scale that counts for DR modeling. This chapter will focus on the most prevalent categories of response data, the quantal and the continuous endpoints.

- **Quantal endpoints** (also denoted as dichotomous or binary) describe individual responses that inform exclusively on absence or presence of an effect, for example, assigning a 0 to absence and a 1 to presence. When considering several subjects exposed to the same dose, one summarizes the results of a group as the proportion of subjects with effect, the incidence of the effect. Is cancer the endpoint it is the cancer incidence.
- **Continuous endpoints** describe responses that are measured on a numerical scale, often as nonnegative values where 0 denotes absence of any measurable effect and where any positive value might occur under exposure. When considering several subjects exposed to the same dose, one may summarize again the response per group by the mean and the standard deviation (SD). It should be noted that from a statistical view the continuous endpoints can be subdivided further as of having an additive scale (i.e., differences of effects carry the relevant toxicological information, called interval scale) or a multiplicative scale (i.e., ratios of effects carry the relevant toxicological information, called relational scale). This distinction has possible consequences for the specification of the BMD model.

For other data types such as count data, ordinal categories of response, hierarchical nested endpoints (e.g., litter clusters) and multivariate endpoints see FAO/WHO (2009).

Except for data of human studies where a continuum of exposure doses could prevail, one usually faces a set of doses,  $d_1, d_2, \dots, d_I$  and a control group denoted by the “dose”  $d_0$ . These are ordered by their amount as  $d_0 = 0 < d_1 < d_2 < \dots < d_I$ . The  $I + 1$  groups are juxtaposed to the responses in the same order where, say  $n_i$ , subjects are exposed to dose  $d_i$  with  $n_i$  responses  $Y_{ij}, j = 1, \dots, n_i, i = 0, 1, \dots, I$ . When considering tumor incidence in a carcinogenesis experiment the quantal response would be either  $Y_{ij} = 1$  (for tumor) or  $Y_{ij} = 0$  (for no tumor) in the  $j$ th animal of the  $i$ th group and the data are then summarized as  $\{(d_i, n_i, p_i), i = 0, 1, \dots, I\}$  with  $p_i = r_i/n_i$  the proportion of tumor bearing individuals and if  $r_i$  denotes the number of tumors in group  $i$ . The continuous responses  $Y_{ij}$  represent usually measurements of a

biologically relevant effect, usually ranging between the value  $0$  and a maximum nonnegative value, say  $Y_{max}$  observed in the experiment. Such a maximum is difficult to fix because of heterogeneity between experiments.

## Dose–Response Model (DRM)

Modeling DR data translates an anticipated relationship between the response  $R$  and the dose  $D$  into a mathematical and statistical framework to identify a DRM that describes the observed DR data and allows statistical inference and determination of risk indices such as a RP/PoD. The BMD approach is based on a two level concept where at first a mathematical function is defined that describes the expected functional dependence of response on dose. This mathematical function  $\mu(dose)$  is an average or mean response function, a monotone increasing curve of *dose*. To account for the variation of response between the individuals of the population describes the second level the variation by a statistical distribution that may depend on dose. The distribution of the response, say  $P_R$ , is statistically defined by a density function  $f(y)$  or a cumulative distribution function  $Cf(y)$ ,  $y$  denoting the response. The  $f(y)$  can be interpreted as probability of response equal to  $y$  and  $Cf(y)$  as the probability that response is not larger than  $y$ . This statistical part of modeling is the stochastic element of a DRM and is the prerequisite of any statistical inference. Both parts, the mathematical mean function  $\mu(dose)$  and the statistical distribution  $P_R$ , constitute the DRM. If one knows the biological mechanism and the statistical variation one can put the two parts together in one model. In such an ideal situation one would just fit this model as the “true” model and estimate the true BMD statistically. The statistical fit to the observed data allows the calculation of the statistical confidence bounds such as the BMDL to be used as RP/PoD. However, this ideal situation is not the reality of risk assessment and both, the available knowledge about the dose–response relationship and in most cases, also about the response distribution is too limited to identify one single model and one single distribution as true. In contrast, the options for mathematical models and statistical distributions are literally infinite and therefore also for the BMD approach. DR modeling in risk assessment needs beyond mathematical and statistical means the input from biology and toxicology to accomplish model building. The more biological and toxicological information is available about the adverse health effects and their distribution the less uncertain is model building and the value of the RP/PoD. The sections below introduce sets of mean functions and distributions of response for building DRMs.

---

## Before Starting the BMD Approach

Increasing practice with the BMD approach and discussions of diverging conclusions of regulatory agencies sharpened the awareness of risk assessors to control and to communicate their assumptions in BMD modeling. The most critical preparations are addressed in this section. Before starting a DR analysis of toxicity data, the risk

assessor is advised to identify the kinds of data available on dose and response, select the response and dose metric for the assessment, present and discuss the data of the study, for example, using graphical presentations, and the results of preliminary descriptive analyses, and judge the quality of data; all in front of the assessment. There have been ongoing discussions on the framework of the risk analysis within which DR modeling is embedded. At that interface between risk characterization and risk management, the latter might be consulted (Renwick et al. 2003; Abt et al. 2010).

## Data Selection

Data selection for the BMD approach is an important first step of the BMD approach when the risk assessment problem has been formulated (Barlow et al. 2002; Renwick et al. 2003). Important issues include the human relevance of the data; however, also the quality of the original toxicity studies. General criteria for rating the quality of toxicity studies have been proposed by Klimisch et al. (1997) and were further specified by Schneider et al. (2009). When selecting DR data, one should consider, in particular, species, strain, and sex differences and their impact on the sensitivity of the test substance in target organs. Data requirements for mathematical modeling and quantitative methods have been formulated for eight approaches of food safety and food risk assessment by Edler et al. (2002) and for dose–response assessment and mathematical modeling in general by Barlow et al. (2002) including the BMD approach; for further notes on the selection of data see Edler et al. (2014):

- The observed shape of the DR curve alone is not a sufficient criterion for selecting DR data. The biological relevance of effects, for example, a deviation from monotonicity, must be weighed against the statistical significance of model fitting. Statistical model selection may not overrule available biological DR information.
- Attempts to qualify data through prescreening DR data for their suitability for the BMD approach may not be without arbitrariness due to the multiplicity of testing and the absence of statistical rules of how to set the significance level for a sequence of goodness-of-fit tests.
- Testing for the presence of a DR relationship, for example, using a trend test, could be misleading, when all effects remain below the primary chosen level of the BMR.
- An in-depth examination of the utility of studies is recommended before a DR analysis is performed.
- Most relevant for the size and precision of the BMD and BMDL are number and range of dose levels.

It was also emphasized that suitability of data for the BMD approach should not be separated from the quality of the toxicity study itself. Although agreed criteria to judge the quality of a study for a BMD analysis are difficult to establish and at

present not available, existing quality standards of regulatory toxicology regarding the test material used in the bioassays of the studies and guidance available for the conduct and reporting of bioassays (including, for example, genetic origin, housing, and health status of the animals) might be used for BMD analysis.

Statistical expertise should inform on the practicality of DRMs in view of the available data; this refers in particular to the design of the toxicity study and its influence on the modeling. Notice, however, that precise statistical methods for defining optimal designs for BMD modeling do hardly exist because of the statistical complexity of nonlinear regression. However, it has been noted that studies with more dose levels and less animals per dose would be preferred over studies with only few dose groups and a large number of animals in each (EFSA et al. 2017b). Deficiencies of a study design usually lower the BMDL, in striking contrast to the behavior of the NOAEL which tends to increase with inferior designs and gets such less protective. DR modeling using the BMD approach challenges the overall quality of the toxicity database. Some researchers suggested running the BMD analysis over all data sets of toxicity studies identified for risk assessment questions as a sort of screening for good quality DR data.

The above points referred primarily to data from animal experiments. Recommendations for the selection of human dose–response data are less developed; however, some guidance for the use of epidemiological data for dose–response assessment can be found in Herz-Piccioto (1995), Steenland and Deddens (2004) and van den Brandt et al. (2002).

## Model Selection and Specification

A standard set of mathematical models of the mean response evolved for the use of the BMD approach in particular, for quantal and continuous data. Prominently to mention are the models of the software packages BMDS (U.S. EPA 2021) and PROAST (2020), see also Varewyck and Verbeke (2017). Table 1 lists by name single models for quantal and continuous data which have been repeatedly used so far (EFSA et al. 2017b; FAO/WHO (2009), Shao and Shapiro 2018). This lists single models (e.g., Logistic and LogLogistic model) and single models from model families (e.g., the Multistage family for quantal data and the Exponential and the Hill family for continuous data). Publications and guidance of different agencies vary in the reporting and handling of the models and model families. Although a tailored selection and definition of models can be a preferred option, there has been agreement among modelers to consider at least the models listed in Table 1 as default set for routine BMD analyses. The set of models has been proved flexible enough to cover a wide range of dose–response relationships. The newest version of U.S. EPA (2021) extended this list, in particular, for continuous data by variants of polynomial models, including the linear model, and a set of models evaluated by Bayesian models.

For the mathematical expression of the single models, see their presentation in the various guidance documents and related publications. The mean models are

**Table 1** List of most used mathematical models of the mean response for quantal and continuous data

Quantal data	Continuous data
Probit	Linear
LogProbit	Power
Logistic	Exponential family
LogLogistic	M2
Weibull	M3
Gamma multi hit	M4
Multistage family <sup>a</sup>	M5
1-stage (QuantalLinear)	Michaelis-Menten
Multistage Cancer	General Hill
2-stage	Hill family
General Multistage	M2
Dichotomous Hill	M3
LVM <sup>b</sup> Exponential	M4
LVM <sup>b</sup> Hill	M5

<sup>a</sup>The multistage models is a general family of models from which only models assuming very few stages have been used for BMD

<sup>b</sup>LVM: Models used in PROAST (2020) which assume a continuous latent variable that describes the adverse health effect for a quantal data

given by mathematical equations for  $\mu(dose)$  as function of the dose. The values of the model parameters are determined by fitting the model to the DR data. As important as the mathematical equation are the basic constraints of the model parameters. They locate and shape the function such that it fits the DR data in the observable ranges of the doses and the responses and they are an essential element of the model.

For illustration, see the mathematical expression of the Logistic and LogLogistic model for quantal data:

$$\text{Logistic : } \mu(dose) = \frac{1}{1 + \exp(-a - bdose)}, \quad 0 \leq dose < \infty \quad (1)$$

with  $-\infty < a < \infty$  and  $b > 0$

$$\text{LogLogistic : } \mu(dose) = c + \frac{1 - c}{1 + \exp(-a - b \log(dose))}, \quad 0 < dose < \infty \quad (2)$$

with  $-\infty < a < \infty, b > 0$  and  $0 \leq c < 1$ .

All models and members of model families are defined by their structural form and the model parameters with the basic constraints. This allows doses and responses to range over a large range of values limited only by monotonicity and avoidance of artifacts (such as negative incidences). The slope parameter, that is, the parameter  $b$  in Eqs. (1) and (2) above, is always positive for quantal data. For continuous data, primarily, two model families of the mean have dominated dose-response

assessment in regulatory toxicology: the Exponential and the Hill family. From a mathematical view, the mean models resemble those for quantal data. However, the response range is completely different. It ranges usually between 0 and any value with no fixed maximum. Depending on how effects and effect sizes are defined, a response can also be negative. As consequence, the definition of the adverse health effect and the specification of the BMR are for quantitative responses much more demanding. For convenience, a quantitative response is throughout this chapter represented by nonnegative values indicating an increase of severity with increasing values. The most general four-parameter exponential model is given here for illustration (Exponential M 5):

$$\mu(dose) = c + a \exp(-b \text{dose}^k) \text{ for } 0 \leq \text{dose} < \infty \quad (3)$$

with  $b > 0, k > 0$  and case dependent restrictions on  $a$  and  $c$

The presentation of the mean models has been extremely inconsistent in published literature and, unfortunately, also in regulatory guidance. The formats presented in EFSA et al. (2017b), U.S.EPA (2021), and update of Chap, 5 in FAO/WHO (2009) are not identical. The crucial point is, however, not the form of an equation in a guidance document. Decisive is only the way how the model and the distribution is implemented in the software and how the computational fitting algorithm is constructed. This requires statistical and computational expertise for understanding. Unfortunately, the code of software is rarely available and changes with versions of the software.

Note that the LogLogistic model for the mean response given by Eq. (2) cannot model incidences at the  $dose = 0$  directly:  $\log(dose) = \log(0)$  is no real number; mathematically  $\log(0) = -\infty$ , minus infinity. Therefore, when this model and any other model with  $\log(dose)$  is used the software implementation uses instead of the dose  $d = 0$  a very small positive number, for example,  $0.00001 = 10^{-5}$  to avoid minus infinity. In other words, the dose-interval  $0 < dose < \infty$  is replaced by  $10^{-5} < dose < \infty$ .

For models for continuous data is the slope parameter positive. However, the curve can turn upwards or downwards depending on direction of the effects of the toxic substance. As noted above this chapter considers increasing severity. Basic constraints of the parameter  $a$  and  $c$  serve for that. Each single model for the mean response of the suite of models displayed in Table 1 is defined by the values of 3–4 parameters. Parameter  $k$  is often denoted as potency in case of quantal and shape in case of continuous data. For further interpretations of parameters and their combination, see, for example, EFSA et al. (2017b).

By imposing additional constraints on model parameters, one can restrict the possible range of modeling. This is still an option in the BMDS software of U.S. EPA (2021) and has to be used with caution since it restricts modeling such that results of the same models applied to the same data produce different BMDs and/or BMD-CIs and therefore different RP/PoDs. Differences of established HBGVs up to an order of magnitude could be traced back to the use of additional constraints during modeling. An often used constraint excludes dose–response curves which

have a steep (up to infinite slope) at the origin (i.e., at  $dose = 0$ ). Those curves can be excluded by restricting the slope at  $d = 0$  to be not larger than a fixed value, say 1, U.S.EPA (2012). However, it has also been argued that this option should be avoided and that the full range of model parameters should be allowed for each model (EFSA et al. 2017b). It has also been recommended to examine visually the shape of the fitted DR curve and check how the values of the parameters in a model and the BMD and the BMDL values react on constraints made during model fit. As a default, it was recommended not to constrain the model parameters as long as there are no convincing biological arguments (EFSA et al. 2017b). From a statistical point of view, keeping the space of the model parameters as wide as possible is fortunate, since it reduces the chance that model parameters hit boundaries in the parameter space with all subsequent computational difficulties. Despite intense discussions at various rounds of harmonization of dose–response modeling for hazardous chemical compounds, there is still no agreement on the use constraints to guide risk assessors in the use of constraints when fitting single models. It was only recently, when model averaging (MA) and Bayesian approaches became available for the BMD approach, that the concerns on the use of constraints diminished when those statistically more complex methods replaced single model fitting.

The update of FAO/WHO (2009) attempts also to generalize model building for mean response by defining a hyper-family of models that includes almost all single models of Table 1 by requesting for continuous data the format

$$\mu(dose) = c + a F(dose^k, b) \quad \text{for } 0 \leq dose < \infty \quad (4)$$

with the four parameters  $a, b, c$ , and  $k$  and a general function  $F$  where the effect of the dose is strictly modeled as a power of the dose with exponent  $k > 0$ , mainly responsible for the shape of the mean response curve. This general format holds also for quantal data given a minor modification: the set of parameters is reduced to  $a, b$ , and  $k$  when setting  $c = 1 - a$ . In strict mathematical sense, it does, however, not cover the quantal models that depend on  $\log(dose)$ . Therefore, for quantal data one should use two formats:

$$\begin{aligned} \mu(dose) &= a + (1 - a) F(dose^k, b) \quad \text{for } 0 \leq dose < \infty. \\ \mu(dose) &= a + (1 - a) F((\log(dose))^k, b) \quad \text{for } 0 < dose < \infty. \end{aligned} \quad (5)$$

In order to select a DRM, one has also to specify the distributional part of the model as the second component of the model building of the BMD approach. It defines the statistical distribution of the response,  $P_R$ . For individual quantal response, the distribution, depending on  $dose = d$ , is the Bernoulli distribution. The probability of a response is  $p(d)$  and for nonresponse  $1 - p(d)$ . The number of responders in a group of  $n$  individuals has then a Binomial distribution with two parameters  $(n, p(d))$  and the (theoretical) mean is  $np(d)$ . This term is modeled by the mathematical mean function. The BMD approach can therefore be restricted to the

summary data, that is, to the incidences, of the groups of the experiment using the data triplets  $(d_i, n_i, p(d_i))$ , for  $i = 0, 1, \dots, I$ .

For human data where each individual is exposed to a unique dose this distributional assumption works only when the data can be aggregated into a set of  $I$  categories where  $I = 0$  would represent the background. Otherwise, when modeling individual data, there exists usually additional information for humans in the form of covariates describing relevant characteristics of each individual. This calls for more sophisticated epidemiological model building, see below.

The BMD approach used historically for individual continuous response the Gaussian Normal distribution  $N(\mu(d), \sigma(d))$  as the default with mean  $\mu(d)$ , depending on dose  $d$  and a standard deviation (SD)  $\sigma(d)$  that may depend on  $d$ . Were the DR data available in  $I$  dose groups and a control ( $I = 0$ ) with  $n_i$  subjects exposed to dose  $d_i$  and the responses  $y_{ij}$ ,  $j = 1, \dots, n_i$ ,  $i = 0, 1, \dots, I$ , the individual responses are modeled as

$$y_{ij} = \mu(d_i) + e_i \quad \text{for each group } i = 0, 1, \dots, I \quad (6)$$

where  $e_i$  is an additive statistical error term describing the statistical variation of the responses at dose  $d_i$ . The observed means are denoted as  $m_i$  and their observed standard deviations as  $s_i^2$ . The quadruplets  $(d_i, n_i, m_i, s_i^2)$  summarize then data and are the input for the software.

The assumption of the Gaussian Normal distribution has two handicaps when being applied to biological data. One stems from its mathematical property to be defined on a response range  $-\infty < \text{response} < \infty$ , the other is due to its symmetric distributional shape around the mean. Both properties do not fit toxicological responses when they are nonnegative or positive and when they exhibit a skewed distribution with a large portion of low responses sticking together and a relative small portion of the large responses reaching far out to high values. Very high responses were sometimes denoted as “outlier” and were discarded from the dose–response analysis. A deletion of data is, however, not recommend since even the Gaussian Normal distribution would allow for high values and it is hard to decide whether a high value still belongs to a single statistical distribution or to a component of a mixture of several distributions. Whereas one may neglect the first handicap of the response range  $-\infty < \text{response} < \infty$ , by assuming that the Gaussian Normal may still serve as a good approximation, when the observed means are all positive, skewness causes a problem and needs to be accounted in modeling, in particular, when it is biologically plausible. The log-normal distribution was therefore introduced rather early (Slob 2002) for the BMD approach as a second default distribution for continuous data. It is a distribution with nonnegative values skewed to the right, allowing relative high values without the suspicion that they are erroneous measurement or belong not to the assumed distribution. The lognormal distribution is for sure not the only statistical option for nonnegative right skewed data; however, it is a simple one and mathematically easy to handle because of its direct relationship with the Gaussian Normal:

The distribution of the response  $Y$  is lognormal if the logarithm of  $Y$  is Gaussian Normal. (7)

In other words, would we use instead of the response  $Y$  as observed the logarithm  $\log(Y)$ , we could analyze these transformed responses  $\log(Y)$  with the methods we do have for the Gaussian Normally distributed data. This has been often used as an option in statistical inference when the consequence of the statistical computation was qualitative, for example, in statistical testing using the analyses of variance (ANOVA) or other regression methods. Unfortunately, this does not apply for the quantitative analysis of the BMD approach where the size of the response or its changes, the BMR, is the quantity of interest; see U.S.EPA (2021) for concerns of using  $\log(Y)$  data. When assuming the lognormal distribution, one should be aware of the properties of this distribution and the specific forms of their mean and SD. It follows from Eq (7), then

$$\text{mean of lognormal} = \exp(\mu + 0.5\sigma^2) \quad (8)$$

$$\text{SD of lognormal} = \exp(\mu) (w(w-1))^{0.5} \text{ with } w = \exp(\sigma^2). \quad (9)$$

Accounting for the more complex form of the mean of the log-normal distribution, the BMD modeling uses in place of the mean of the distribution as the center (average) of the statistical distribution the median:

$$\text{median of lognormal} = \exp(\mu) \quad (10)$$

which depends on  $\mu$  only. This is concordant with Eq. (7) since  $\log(\exp(\mu)) = \mu$ . The median of the lognormal is identical to geometric mean and reflects such the multiplicative background of the lognormal distribution (Slob 2017). The geometric SD of the log normal distribution is equal to  $\exp(\sigma)$ . These mathematical relationships have been obscured when using the terms normal scale and lognormal scale without explicit mathematical detail.

Another method of the BMD approach used for continuous data has been the so-called hybrid approach where the originally available continuous response data are transformed into quantal responses by introducing a critical cut-off for the effect, see Crump (1995), Gaylor and Slikker (1990), Falk Filipsson et al. (2003), and U.S. EPA (2021).

## Specification of the Benchmark Response (BMR)

The specification of the BMR constitutes the most essential step in the BMD approach since it quantifies the size of an effect for response evaluation, at which a RP or PoD is anchored in the dose-response relationship. The value of the BMR links the DR modeling quantitatively with the adverse health effects for quantitative hazard characterization. In contrast to other means of hazard characterization, for

example, the NOAEL approach or other semi-quantitative approaches, the BMD approach is fully quantitative and specific for an effect size.

Therefore, before analyzing, DR data type and the size of BMR must be specified. In the short history of the BMD approach has this been the most important but also most controversial decision to be made. It links toxicological and statistical reasoning and needs the cooperation of both disciplines. Toxicological expert knowledge should drive the choice of the critical endpoint and should elaborate possible quantitative sizes of changes over background that account for biological and optionally also medical relevance and for public health consequences. Statistical expert knowledge is challenged to translate toxicological facts into statistical entities and response metrics to be used in the BMD modeling accounting for the statistical quality of the data. It has been advocated that the BMR should be set equal to a low but measurable response level reflecting an effect that is negligible or nonadverse. Obviously, a too low BMR would normally result in an extrapolation outside the range of the observed data and induce severe model dependence of the RP/Pod. Therefore, a practically useful BMR cannot be set too low and it may in some real life dose-response assessment be associated with substantial risk. The BMR specification could therefore only be feasible as a compromise between the ideal property of reflecting nonadverse or negligible effects on the one side and the practical needs of statistical valid estimation of the BMD and the BMD-CI that avoids bias.

For quantal response data is the critical endpoint the incidence expressed as proportion or probability. This probability of the occurrence of the event is denoted  $R(d)$ , indicating its dependence on dose  $d$ . The response is defined by an expression that compares  $R(d)$  with the risk at background  $R(0)$  on an additive or multiplicative scale:

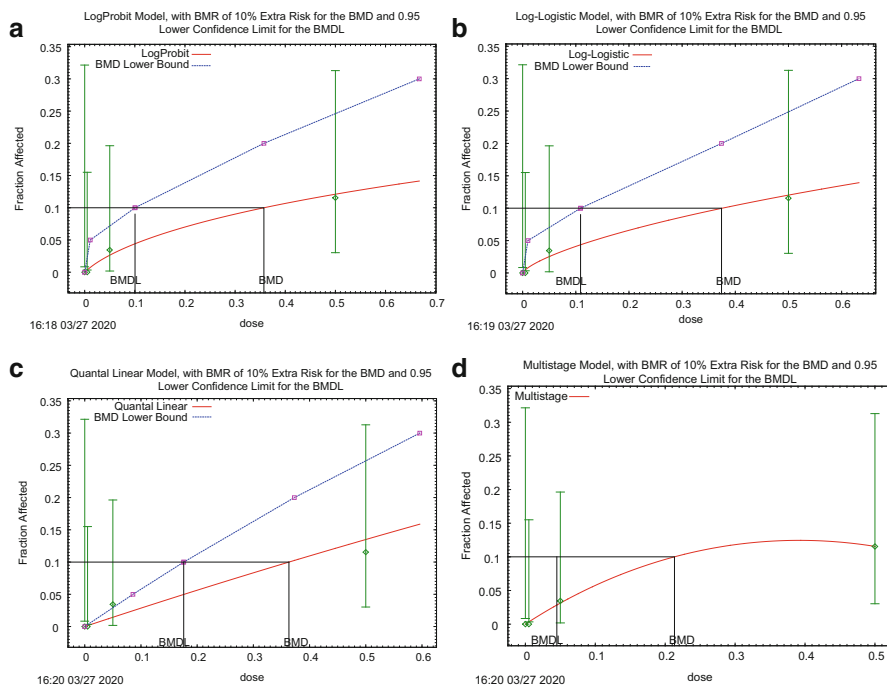

$$\text{added risk } R(d) - R(0) \quad (11)$$

$$\text{extra risk } [R(d) - R(0)]/[1 - R(0)] \quad (12)$$

The extra risk is standardized by the maximum possible risk added to background  $1 - R(0)$ . Note that for quantal data the mean function  $\mu(d)$  is trivially related with the risk  $R(d)$  via  $R(d) = p(d) = \mu(d)/n$ . Extra risk has been widely used as default metric of response for quantal data and is given on a percentage scale, theoretically, ranging between 0% and 100%. A BMR for extra risk  $p$ ,  $0\% < p < 100\%$  defines a  $BMD_p$  as

$$[R(BMD_p) - R(0)]/[1 - R(0)] = p = BMR_p \quad (13)$$

indicating the chosen BMR level  $p$  as subscript, usually also expressed on the % scale. For example, the BMR = 10% is denoted  $BMR_{10}$  and its BMD and BMDL as  $BMD_{10}$  and  $BMDL_{10}$ , respectively. The BMR of 10% has been the default critical effect size for tumor incidence over background. It is the dose where the incidence is not larger than 10% and the  $BMDL_{10}$  is therefore the dose where the incidence is (statistically) unlikely larger than 10%. In precise statistical wording, the  $BMDL_{10}$  is the lower (one-sided) statistical 95% confidence level of the  $BMD_{10}$  and the (extra)

**Fig. 1** The Log-probit (a), LogLogistic (b), QuantalLinear (c), and Multistage-2 (d) model fitted to the incidence of haemangiosarcomas in rats after exposure to sterigmatocystin reported by Maekawa et al. (1979). Each graph shows the incidences with 95% confidence intervals, the fitted model curve (red) and above that the (pointwise) 95% confidence bound of the fitted model used for calculation of the BMDL using U.S. EPA BMDs software

risk at a dose equal to  $BMDL_{10}$  is with a probability of 5% not larger than 10%. It should be noted that the BMR (additive or multiplicative) is not defined as a change of the *observed risk* (observed mean response  $\mu$ ), but of the *predicted risk*, predicted by fitting the model  $\mu(d)$  to the data. This distinction is important since the fitted model does not hit the observed background response (the observed incidence of the control group) exactly. Simply adding the chosen BMR value to the observed background response on y-axis of a BMD plot is therefore not identical with the intersection of the fitted curve with the y-axis at dose = 0, see Fig. 1 in EFSA et al. (2017b).

The default choice of 10% as BMR for an extra risk BMR has been criticized as of being too large as an acceptable human risk level for carcinogenic compounds. Indeed is a BMR of 10% too large for the assessment of human cancer risk. Acceptable risk levels ranged between  $10^{-4}$  and  $10^{-6}$  corresponding to BMRs of 0.01% and 0.0001%, respectively. However, setting the BMR much lower than 10% does not account for the sensitivity of most cancer bioassays, and therefore, the default value of  $BMR = 10\%$  for quantal data must be viewed as a compromise between measurability and relevance of effects.

The specification of a BMR for continuous data is conceptually similar, but more difficult since the scale of the endpoint is no more bounded and the nature of the continuous effects is much. On the other hand, BMRs defined for continuous data do have the potential to better reflect effects that are negligible or nonadverse. There exist again the two options of an additive and a multiplicative metric for the effect size in comparison with the background effect  $Y(0)$ . With  $Y$  denoting the critical endpoint for the BMD modeling, one defines

$$\text{added effect } Y(d) - Y(0). \quad (14)$$

and

$$\text{relative effect } [Y(d) - Y(0)]/[Y(0)] \quad (15)$$

where BMR is again a portion  $p > 0\%$ . For the multiplicative scale, standardization is versus background effect  $Y(0)$  only, since a maximum effect is difficult to precise for quantitative effects.

A third definition of the BMR relates the added effect size  $Y(d) - Y(0)$  to the variation of the data observed for the controls, that is, the standard deviation of  $Y(0)$ , say SD-control (variation standardized effect):

$$[Y(d) - Y(0)]/SD_{\text{control}}. \quad (16)$$

The choice between an additive and a relative metric for the effect size should be made on a thorough examination of the scale of the continuous endpoint. The relative effect has been the most chosen BMR definition in practice using for the mean function  $\mu(d)$  a relation between BMD and BMR that is similar as for quantal data. In contrast to quantal data, there is no more an upper bound for  $p$  and it is prudent to choose small percentages for the relative effect with  $p$  as subscript when defining the  $BMD_p$  by.

$$[\mu(BMD_p) - \mu(0)]/\mu(0) = p = BMR_p \quad (17)$$

For example, a BMR =5% is denoted  $BMR_{0.05}$  and has been a default critical relative effect size over background in many BMD approaches for continuous data resulting in  $BMD_{0.05}$  and  $BMDL_{0.05}$  values. The  $BMD_{0.05}$  is then the dose where the relative effect is not larger than 5% and the  $BMDL_{0.05}$  is a dose where the relative effect is (statistically) unlikely larger than 5%. Recent guidance has criticized this default and requested justification of any BMR value chosen (EFSA et al. 2017a).

When using the variation standardized effect as metric the  $BMD_p$  is defined by

$$[\mu(BMD_p) - \mu(0)]/SD_{\text{control}} = p = BMR_p \quad (18)$$

This metric can be generalized by replacing the calculated standard deviation of the control in the denominator by other variation estimates, for example, 2SD

instead of 1SD. The 1SD has been the preferred use of US-EPA and is a default in BMDS software (U.S.EPA 2021). The standardization by the SD was justified by the argument that it allows a better comparison of BMDLs from different experiments. However, the dependency of the RP/POD on the variation of single experiments has also been considered as a weakness since the RP/PoD values would then depend not only on the quality of the data but also on all other study-specific factors that may increase or decrease that variation. It was also noted that the extrapolation of RP/PoD for humans in the risk characterization step would be more dependent on the animal data than when using the relative effect metric (EFSA et al. 2017b).

It should be noted that US-EPA guidance for the BMDS software uses instead of the term BMR the term “Benchmark Response Factor” (BMRF) with the defining eq.

$$\mu(BMD_p) = \mu(0) + BMRF_p \mu(0) \quad (19)$$

This presentation may have advantages for understanding the software.

The update of FAO/WHO (2009) integrates the specification of the BMR for continuous data into a tiered approach with “consideration of biological and statistical significance, human relevance and the existence or absence of a dose–response relationship”:

1. At first, one should clarify whether a biologically relevant adverse effect size can be defined for the critical endpoint. Therefore, historical data may be used. If a cut-point can be defined, such as in the hybrid approach, a BMR similar as for a quantal response data may be used.
2. If tier 1 does not work, an expert decision can be made “involving risk assessor (s), statistician(s), toxicologist(s) and/or clinician(s) who all collaborate to define the quantitative definition of adversity and consider type and severity of the effect, the background variability and the mode of action leading to the effect.” One might use a range of BMR values in place of a fixed numerical value.
3. If tiers 1 and 2 would not lead to a definite BMR level, the BMR approach itself might not be an option at all and dose–response assessment might proceed with modeling the data to extract dose–response information such as “investigating fold changes, looking at differences from background estimating response from the DR curve” to obtain eventually a range of quantitative values useful to derive some reference values that characterize the hazard, for an ad hoc judgment or a MoE type assessment. It was stressed that those values should not be used to establish a HBGV.

There have been tendencies, in particular for continuous data to use BMRs larger than the 5% or 10%, for example, response levels of 25% and even 50%. The use of such more “central” indicators of dose response may be indicated for the comparison of the toxic potency of compounds but hardly for risk characterization and they are not recommended for the establishment of HBGVs and MoEs.

## Model Fitting and Model Acceptance

In principle, model fitting is a method to find those values of the model parameters that result in a DR curve which is over the whole observed dose range as close as possible near the observed data points. This is easy when fitting a straight line to data where the two parameters, background (value at dose = 0) and the slope of the curve are the only model parameters. They are estimated best in linear regression with an explicit mathematical function. This is directly related to the Gaussian least squares method. Note, however, that the optimality of straight line as the best fit of the linear regression and the interpretation of the estimates depends on the Gaussian normality assumption for the statistical distribution of the response. The complexity of curve fitting increases with the number of parameters, the nonlinearity of the model, and the choice of the response distribution.

If the BMR and the dose–response model (or a suite of models) have been specified, fitting model(s) uses established statistical and computational mathematical methods. Three model fitting options are currently available for the BMD approach, two frequentist approaches and the Bayesian approach including model averaging (MA):

- (a) The frequentist approach results in a fully specified model often denoted as the “best fitting model” from which the BMD can be estimated and the BMD-CI calculated. The fitting can be described as statistical search method for parameter values which lead to a dose–response curve that fits best the observed data points.
- (b) The modified frequentist approach identifies a small set of fully specified models by searching for those parameter values which lead to a dose–response curve that fits the observed data points reasonably good. Models of reasonable fit are identified by prespecified acceptance criteria. In a second step, the BMDs and BMD-CIs of those “acceptable models” are combined to derive a RP/PoD.
- (c) The Bayesian approach is a statistical demanding machinery which determines a RP/PoD using all the selected models. This statistical methodology makes use of prior information on unknown elements in modeling using biological and toxicological reasoning. A special Bayesian approach is the so-called Bayesian MA which uses a weighing of models and allows an interpretation somehow similar to the modified frequentist approach.

The modified frequentist approach accounts for the practical experience of hazard characterization that the BMD approach should not aim to find the single statistically best fitting models but rather to identify all plausible models and their BMD/BMDL values that are compatible with the observed data and constitute a set of “acceptable” RP/PoDs.

Different from the frequentist approach, inform the methods of MA and the full Bayesian approach on the model uncertainty of the BMD estimates and the derived RP/PoD. For further details of all three fitting approaches, see EFSA et al. (2017b). For computational details, contact U.S.EPA (2021).

All model fitting approaches use statistical acceptance criteria which allow assessing the quality of the fit; in common language: How good do the chosen models fit the observed data? Software implemented for the BMD approach uses its way to find solutions for the estimation of the model parameters, the derivation of a BMD confidence interval, and the presentations of results, including a graphical illustration of what is called the best fitting curve. Details of occasionally complex fitting using mathematical modeling and computationally sophisticated computational procedures are often hidden in BMD analysis software. Recommended BMD software informs on the used statistical criteria for fit and reports key indices of the “goodness-of-fit” in its output. Users should be familiar with basic model acceptance criteria to understand and interpret uncertainty and validity of the BMD estimate, the BMD-CI, and the derived RP/PoD. It is important to get familiar with those criteria before the computational execution of BMD analysis such that appropriate software options can be set and the key quality indices are calculated. The concept of those criteria is shortly described next.

*Visual inspection* can be used to compare the quality of the fit of the final “best fitting curve” (or any equivalent graph) with the observed dose–response data in a graphic. This is a highly subjective procedure which depends on the experience and attitude of the risk assessor and their “angle of view” but also on the presentation of the final model and the data through the software. It is the distance in the vertical direction, that is, parallel to the y-axis in a coordinate plot which informs on the quality of a fit. It would be misleading to judge a perpendicular or horizontal distance. The maximum likelihood method reduces to a least squares fit when assuming a Gaussian Normal distribution where the squares of the difference between fitted and observed values (the residuals) count; related to the fact that for this distribution the maximum likelihood method reduces to a least square fit. The visual assessment is more complicated when assuming a lognormal distribution for the response. Visual inspection may fail when curve and data are transformed either by purpose to ease the construction of the methodology and software or by intention to ease presentation. Log-transformations of dose and/or response can distort to visual impression seriously.

The statistical standard for acceptance of a fit based on the (maximum) *likelihood approach* for the BMD analysis is the likelihood of the parameter estimates. Likelihoods are given in the scale of probabilities and have values between 0 and 1, mostly reported as logarithms  $L = \log(\text{likelihood})$ , the log-likelihood value of the fit. For a more detailed discussion and numerical examples of the log-likelihood values and their role for comparing models, see the first version of the EFSA Opinion (EFSA 2009).

BMD software reports L values for each model, often together with a CHI-square statistic value as an another index of “goodness-of-fit.” Statistical P-values are reported for a likelihood ratio test and the chi-square test, by testing the null-hypothesis that the model fits the data versus the alternative that it does not fit. This P-value controls the error probability of rejecting the fit, given the fit was correct (type 1 error) and not the probability of main interest in fitting models, namely, the error probability of accepting the fit, given it was incorrect, that is, of no good fit (type 2 error). Therefore, the P-value of the “goodness-of-fit” testing can only be used as an indicator for the goodness-of-fit. A high P-value indicates good fit and a

small one a bad fit. Note, however, that the numerical size of this P-value depends on sample size and number of parameters estimated and in the case of grouped data on the number of experimental groups. A level of  $P > 0.1$  (10%) or  $P > 0.2$  (20%) has been used in model fitting to accept a model. Smaller levels indicate inferior fits and very small ones, say  $P < 0.01$ , indicate an unacceptable fit.

When models are nested, for example, when using the Exponential and the Hill model family for the continuous or the multistage model family for quantal data, the log-likelihood criterion can be used to find the “best” model within the model family.

The limitations of log-likelihood initiated about 50 years ago the construction of the *Akaike Information Criterion (AIC)* which accounts for the number of parameters, usually denoted as  $p$ , estimated during model fitting. The AIC is defined as  $AIC = (-2L) + 2p$ . It is a positive value indicating a good fit when being small and a bad one when being large, however, only as long as the calculation is in the same modeling context: The numerical value of the AIC cannot be used to assess an overall or absolute quality of a fit. The AIC corrects somehow for parsimony of model selection when it increases its value with the second term  $2p$  and punishes overfitting when using models with too many parameters. The AIC has been used in the revised version of EFSA (EFSA et al. 2017b) to build a flow-chart for the modified frequentist approach.

---

## BMD Modeling in Practice

Dose–response assessment with BMD approach is determined by the availability of informative toxicity studies for hazard characterization. The quality of the data and the endpoints of adverse health effects determine depth and extent of BMD modeling. A prospective evaluation plan should be set up involving all parties which are interested in the outcome of the assessment (bodies of the regulatory agency, modelers and risk assessors, risk managers, and if available, risk communicators). This would help straight modeling and increase reproducibility of the approach and transparency of the assessment. First of all, a well-designed strategy for handling the data and the potential critical effects of the selected studies is needed.

### One Data Set

It is not unusual in risk assessment that hazard identification supports the evaluation of one critical endpoint of one data set only. An example is cancer incidence when one set of pivotal dose–response data has been identified as most relevant and sufficiently informative for example, a NTP study performed according to an established design and published transparently with public access to all relevant data. BMD modeling for one data set and one critical endpoint is illustrated next for the incidence of hemangiosarcomas in rats as critical endpoint in a data set identified as pivotal for the risk assessment of the mycotoxin sterigmatocystin EFSA (2013). The data were obtained from Maekawa et al. (1979) who exposed rats to

sterigmatocystin (STX) at doses 0, 0.005, 0.05, and 0.5 mg STX/kg b.w. per day and observed hemangiosarcomas at the incidences of 0/11, 0/27, 1/29, and 3/26, respectively.

The incidence in the three dose groups was very low and indicated an increasing trend with dose. The Cochran-Armitage test for a linear trend showed with a P-value of 0.23 of no statistical significance. This should, however, not prohibit a detailed dose–response analysis using models for quantal response as shown in Table 1. This subsection illustrates the BMD approach in practice by discussing the basic steps of the BMD modeling when fitting of a single model and then a suite of models.

Since the doses were logarithmically spaced between 0.005 and 0.5 mg/kg BW per day, the fit of the LogProbit model as simple model with a mean function depending on  $\log(\text{dose})$  appears reasonable. Using BMDS software (Version 2.60), the  $\text{BMD}_{10}$  was estimated as 0.36 mg/kg BW per day for the  $\text{BMR}_{10}$ , corresponding to 10% cancer incidence, noting that the highest observed incidence was 12% at the highest dose. The lower one-sided 95% confidence bound  $\text{BMDL}_{10}$  was calculated as 0.10 mg/kg BW per day ranging between the second and third dose. Figure 1a shows the fitted curve of the LogProbit model and Table 2a the details of the fit, with  $\text{BMD}_{10}$  and  $\text{BMDL}_{10}$  at the right together with the log-likelihood value of  $-13.7786$  and the  $\text{AIC} = (-2 \log \text{lik}) + 2 p = 31.5573$ . The number of model parameters was  $p = 2$ . Both the GoF test and the CHI-square test indicated with their rather large P-value of 0.88 and 0.92, respectively, a good fit, visualized in Fig. 1a. The difference between the observed incidences of 0, 0, 1, and 3 in the four groups and the estimated incidences of 0, 0.093, 0.765, and 3.148, respectively, of the fitted curve (the so-called expected incidence) was small supporting the quality of the fit.

Acceptability of a model can also be assessed by comparing the fit of a selected model with the fit of the so-called *FULL model*. The full model simply consists of the observed (mean) responses at each applied dose and it is point-wise mean function where the fitted curve takes the value of the observed response at the respective dose. It “interpolates” the observed DR curve and the number of parameters equals the number of groups. If a model’s fit is not significantly worse than that of the *FULL model*, for example, when  $P > 0.05$  one may accept the specific model. In addition, an acceptable model should also explain substantial dose–response information by being statistically significant ( $P < 0.05$ ) different from the *NULL model*. The *NULL model* stands for the nonexistence of a DR relationship, that is, the mean responses of control and dose groups are all on a straight line parallel to the dose axis. In summary, the statistical fit of an acceptable model should be statistically significantly better than the *NULL model* ( $P < 0.05$ ) and not significantly worse than the *FULL model* ( $P > 0.05$ ). In cases where none of the models pass the tests, visual inspection of the data may show that some models still adequately describe the observed DR. In that case, the decision to accept a particular model needs to acknowledge the high level of uncertainty of BMD estimate and the BMDL value. Note also that the choice of the significance levels is not stringent and nothing more than statistical defaults.

Table 1a informs on the fit of the *NULL* and the *FULL model*. The *NULL model* has the log-likelihood value of  $-16.4979$  and the  $\text{AIC} = 34.9958$  and the goodness-of-fit is rather weak with a  $P = 0.13$ , in concordance with the outcome of the trend

**Table 2** BMD approach detailed by the dose-response assessment of the incidence of haemangiosarcomas observed in rats after exposure to sterigmatocystin reported by Maekawa et al. (1979). BMDs and BMDLs were determined for a BMR of 10 using US-EPA BMD5 software

test. The *FULL model* as model with “perfect” fit of the observation has likelihood value of  $-13.6482$  and the  $AIC = 35.2964$  to be compared with those of the fitted model. Compared with the *NULL*, the Log-probit model can be considered as acceptable for this example of rather sparse dose–response information. For the use of the AIC criterion, see the section on “Frequentist Combining” below.

## A Suite of Models

The identification of one BMDL out of the fit of a suite of models has been a discussion point since the first uses of the BMD approach for the hazard characterization of toxic compounds (U.S.EPA 2012; EFSA 2009; EFSA et al. 2017b), in particular, when the BMDL values of the accepted models varied over a substantial dose range and induced large uncertainty in the determination of the RP/PoD, uncertainty which directly turns into uncertainty of the HBGV. However, in the views of risk managers, a seemingly small difference in HBGVs may have a large impact and might question the applicability of the BMD approach. Whereas a variation of the BMDLs by a factor of 2–3 might be expected from a statistical viewpoint, such a difference could be unacceptable for a HBGV, in particular, when the compound is highly toxic, economically relevant, and/or prevalent in food or environment at nonnegligible concentrations. Model uncertainty, for example, when given by a range of BMDLs, may question selection of models, the specification of acceptance and the procedure of the determination of a final BMDL. Several proposals and concepts have been developed to cope with model uncertainty.

## Pragmatic Proposals

The first reactions on the model uncertainty were pragmatic and considered the type and information content of the dose–response data, the type of models judged as acceptable, the degree of variation among the BMD estimates and the BMDL values, and the differences between BMDs and BMDLs. Three aspects were of concern: (i) BMDs and/or BMDLs of acceptable models differ by at least one order of magnitude, (ii) some BMDLs are practical zero or below current detection limits of the toxin, and (iii) the BMDL is substantially lower than the BMD, for example, when the BMD/BMDL ratio is larger than by a factor 5–10 corresponding to a difference of about one order of magnitude. A further discussion point was the width of the BMD-CI for different model.

It was suggested to check each acceptable model by visual inspection of the fit and to assess the shape of the fitted curves in relation to what is expected from biological reasoning. Guidance of US-EPA for BMDs software (U.S.EPA 2012) suggested that a concave shape of the fitted curve at low dose or models with infinite slope at dose = 0 would contradict toxicological knowledge at low doses. Therefore, models with concave shape should be modified by avoiding a steep decline of the response curve when dose tends to 0. Therefore, the model fit was constrained by limiting the range of the slope or other parameters in order to control the shape of the curve for most quantal models (LogProbit, LogLogistic, Weibull, Gamma, and the Multistage- 2) The constraint model replaces so the unconstrained one in situations (i)–(iii).

Another modification of the set of models would be to enlarge the list of Table 1 by allowing both, constraint and unconstraint models for model fitting and define on that extended set a subset of acceptable models, for example, with maximum limits on the allowed differences either among the BMDs or among the BMDLs or between the BMDs and the BMDLs or the distance of the BMDL to the lowest dose tested, see EFSA (2011), Edler et al. (2014), and Davis et al. (2010). Early guidance of EFSA (2009) suggested that BMDLs and BMD/BMDL ratios should not vary by more than one order of magnitude. Otherwise, further examination of the DR data would be recommended and further measures taken, for example, fitting constraint models, changing the size of the BMR. At the extreme, the overall quality of a study would be put on stake and its suitability for dose–response assessment denied. For continuous data, a stepwise decision tree has been proposed by Davis et al. (2010), iterated in the guidance document of U.S.EPA (2012).

It is the Multistage-2 model in the example of sterigmatocystin above where the BMDL<sub>10</sub> of 0.045 mg/kg b.w. per day was 2–4 times lower than that of other acceptable models. Visual inspection showed a concave curve (Fig. 1d). The constraint model would give a BMD<sub>10</sub> = 0.36 and a BMDL<sub>10</sub> = 0.18 mg STX/kg b.w. per day and fit better to the suite of other BMDLs (Table 1b).

At some instances, it was also argued that a BMDL value should only be used for hazard characterization when it is “within the observed dose-range” by adopting an argument which had been extensively used in the discussion of statistical regression when fitted curves  $f(x)$  derived on a bounded region of the independent variable  $a \leq x \leq b$  were extrapolated to  $x < a$  or  $x > b$ . Although extrapolation should be handled with caution for hazard characterization, declaring a BMD approach as invalid, when the BMDL is lower than the lowest dose tested, is neither supported by sound statistics nor does it suit the aim of risk assessment to investigate response at low doses – at least as long as the extrapolation does not extend over orders of magnitude. It should be noted that

- With a control group available, the experimental range is from 0 to the largest dose tested and such the BMDL is always in that range.
- As long as the BMD estimate is larger than lowest dose one can hardly claim extrapolation. The BMDL is a lower confidence bound at the statistical confidence level of 95% and depends strongly on that level choice, in addition to dependence on the choice of the BMR value. Both settings might be reconsidered in a discussion of extrapolation.
- Hazard characterization aims for information at the low dose range and can be considered as an attempt for extrapolation by definition. In fact, the regulation problems with cancer risk extrapolation to a risk as low as  $10^{-6}$  and  $10^{-5}$  were one of the reasons to establish the BMD approach.

The limitations of the pragmatic proposals and their different usage by regulatory agencies have stressed harmonization and development of transparent and reproducible approaches as outlined in the next two subsections.

## Frequentist Combining

Noting that the BMD approach “does not aim to find the single statistically best estimate of the BMD but rather all plausible values that are compatible with the data” and recognizing the promising results of “multimodel estimation and inference using model averaging” (EFSA et al. 2017b) guidance recognized model averaging (MA) as a method to cope better with model uncertainty. MA has been developed to a useful statistical methodology (e.g., Wheeler and Bailer (2007, 2008, 2009)) such that the revised EFSA opinion from 2017 promoted the use of MA to overcome the diversity of RP/PoD values. Since MA tools were not always available at that time, elements of MA were implemented in a flow chart to determine a BMD-CI. Deviating from previous practice to check acceptability by GoF testing based on the log-likelihood, the AIC values of the single models guided the determination of a BMD-CI, see Fig. 8 in EFSA et al. (2017b). The advice is to fit all models including the *NULL*- and the *FULL*-model and to calculate their AICs for a decision tree. An absolute value of 2 was used to differentiate between AICs and a few decisions guide to a PR/PoD:

- If the all AICs of the suite of models are less than by 2 different from AIC-NULL, the data are rejected, because of no reasonable dose–response relation.
- The model with the lowest AIC is identified and labeled as AIC<sub>MIN</sub> model. All models with AIC less than by 2 different from AIC<sub>MIN</sub> (i.e.,  $AIC \leq AIC_{MIN} + 2$ ) constitute the final acceptable models.
- Use the set of models to calculate the BMD-CI and use the smallest BMDL of these models as RP/PoD for the data set and endpoint. Note, however, that small AICs indicate a good fit.
- A criterion for caution checks for  $AIC_{MIN} > AIC_{FULL} + 2$  and would stop for seeking further statistical advice when the “best” model might be not good enough compared with the *FULL*-model.
- Identify within a nested model family using log-likelihood method at first the best model and use only this one as acceptable model.

In the example of sterigmatocystin, above was  $AIC_{NULL} = 35.30$ ,  $AIC_{FULL} = 35.00$  and  $AIC_{MIN} = 30.06$ . The critical boundary for the models suitable for the BMD-CI is therefore  $AIC_{MIN} + 2 = 32.06$  such that all models except the Probit and Logit model are suitable, including the Multistage2-model with the very low BMDL<sub>10</sub> of 0.045 mg STX/kg b.w. per day. This model poses therefore still a problem, also in this frequentist approach. It can be resolved when using frequentist MA or Bayesian MA approach that would give a very low weight to this single model.

## Model Averaging

The stepwise procedure outlined above is transparent and uses with the AIC an established statistical criterion for model selection. However, it is only a substitute for MA and may be over-conservative by selecting the minimum BMDL. MA combines

the estimates of the different models, not distinguishing between acceptable and non-acceptable models, through a weighted average of the DR models where the weights reflect the relation of the fitted curves to the observed data. The method assumes that the true model is one of the models in the family of models being averaged and it reflects both the sampling variability and model uncertainty. It is expected to yield an RP/PoD higher than the lowest BMDL. A detailed example of MA for quantal data is given in EFSA et al. (2017b). MA has been recommended also in the updated Chap. 5 of FAO/WHO (2009). Even when MA would not yield an acceptable RP/PoD, one can extent the MA to a full Bayesian approach with so-called “soft constraints.”

The application of MA for continuous data is less developed than that for quantal data. EFSA et al. (2017b) has only two nested model families in use, the Exponential and the Hill. This and the two options for the distribution of the response (Normal vs. Lognormal) indicate the need for more research on MA for continuous data including means to involve expert knowledge. Note that expert knowledge would also play a role when applying a full Bayesian approach with the need of prior information to run it.

## **BMD Confidence Interval**

The BMD approach accounts for the statistical variability of the dose–response data by calculating statistical confidence bounds. This is an important difference compared with the NOAEL approach. Primarily, statistical uncertainty of the BMD is addressed through its confidence interval ranging from the one-sided lower bound (the BMDL) to the one-sided upper bound (the BMDU). With the default confidence level at 90% (one-sided 95%), the interval (BMDL, BMDU) is a two-sided confidence interval. The lower bound BMDL has been the key descriptor of the BMD approach because of its clear statistical interpretation: When accepting the BMD approach as admissible dose–response assessment method with the BMD as model characteristic (expressible in terms of the model parameters), the specification of a BMR, and when accepting the assumptions made for modeling, the response at the BMDL is with probability 95% not larger than the BMR. The BMDL is therefore in a direct relation with the level of risk specified by the BMR. The BMD estimation is such a basic statistical procedure of dose–response modeling to reach this statement. If the aim is the determination of the BMD, often denoted as the true BMD behind the modeling (i.e. the BMD of the true but unknown model), the BMD-CI is the preferred outcome since it exhibits the complete variability of the BMD and allows a comparison of the uncertainty across models. The BMD-CI covers therefore more uncertainty than the BMDL alone and to some extent it informs on the quality of the design of a study.

---

## **BMD Modeling with Several Data Sets**

Hazard characterization uses often more than one set of dose–response data for the assessment one critical endpoint of adverse health effects. Most promising for a joint BMD analysis are data based on the same or a similar design such as studies of both

sexes of experimental animals or a sequence of substudies investigating different dose ranges or different generations of experimental animals in studies of reproductive and developmental toxicology. Those data may be found in a sequence of publications of the same group of researchers. Occasionally, dose–response data across species on the same endpoint can be considered together, when they are similar regarding quality and shape of dose–response. A joint BMD analysis of several data sets is possible when a joint common value of the BMR is specified and the same distribution of the response is assumed. The joint analysis of continuous data is simpler when also a common SD is assumed. Different SDs can also be handled, eventually with extra programming.

Two evaluation strategies are possible when several data sets are used:

- (a) Perform a separate BMD analysis for each data set as described above, resulting in a corresponding set of BMDs and BMDLs from which an overall RP/POD is determined. Since the BMDLs are numerical values any type of statistical averaging can be used, for example, means, medians, or means weighted by a study quality (e.g., width of the BMD-CI). Following the precautionary principle of risk assessment, a low BMDL or the minimum of the BMDLs would be the candidate for the RP/PoD. This precautionary choice is recommended in the case of doubts with combining BMD analyses.
- (b) Perform a combined BMD analysis of all selected data sets stratified (i.e., strata are generated) by the factor(s) of the combination such as substudy, sex, etc.

Different from option (a) would (b) perform for each model a joint evaluation of the combined data set with the different strata. For example, the factor sex or other subpopulations can be included as a covariate in the DR analysis (Slob 2002). The statistical analysis checks then whether males and females show significant different DRs or whether the DR data are similar enough to combine both sexes. In practice, one generates, at first, a combined data set with all the available data (doses, number of subjects per groups, incidences if quantal, means and SDs if continuous) and one additional item in the data set for the strata. Next, this combined data set is analyzed accounting for the stratification factor, also called covariate. The statistical analysis is then a general regression with covariates. The methodological advantage of this combination lies in the possibility to have a freedom to define common parameters across data sets when a model is fitted, for example, when a preinspection of the data allows for a common background or a common slope. This reduces the number of parameters and increases the statistical precision of the remaining parameters. Note that the AIC with the number of parameters estimated as one of the two summand decreases with a decrease of the number of free parameters.

Option (b) may be used to combine only a subset of BMD analyses, for example, when using identical parameters. Although there are then less data available, the statistical power of a combined analysis may outweigh that loss by a more precise overall BMDL. Notice that the combined BMD analysis of (b) is different from pooling the data and neglecting the covariate. Pooling data from different data sets

would erroneously ignore the variation across study and could underestimate the risk. Only in the ideal situation when different studies would not differ at all the results should be the same. Overall, covariate adjusted BMD analysis should not be based on statistical reasons only but accompanied by thorough biological and toxicological reasons allowing for the combination of the data sets.

---

## **BMD for Human Data and Presence of Covariate Information**

The methodology described in the previous section applies equally to human data. More specific guidance for human data has been rare and is mostly available in connections with example data (EFSA 2009; EFSA et al. 2017b). Experimental human data on toxic substances hardly exist because of ethical restrictions, except for few chemicals which had been tested in past for potential therapeutic effects. Hazard characterization with human data is essential for the regulation of many chemical compounds, for example, polychlorinated dibenzodioxins and polycyclic aromatic hydrocarbons (PAHs), methylmercury, cadmium and lead, acrylamide or aflatoxins. However, statistical methods of epidemiology have often been tailored to few pivotal data sets from observational epidemiological studies often addressing a large number of potential endpoints. Those studies are often complex and exposure is usually a continuum from background to occasionally very large doses. Observed doses can also be concentrated within a very narrow range giving not much “room” for the estimation of a dose–response function. Differentiation between possible shapes (e.g., linear vs nonlinear) of the dose–response curve is then difficult or impossible. In addition, human doses have to be estimated, for example, from dietary surveys for food risks in contrast to administered doses in animal experiments. Doses are not under control and may carry substantial error. Human response data do have a large population variation and they are usually confounded by many factors related to personal traits, constitution, behavior, and they may depend on different histories of life–time environment such that competing risk and causality play a big role in the assessment of human data. Recent guidance of FAO/WHO (2009) accounts for the complexity of the modeling of human observational data and addressed as key conditions for the application of the BMD approach:

- Exchangeability
- Positivity
- Consistency

It was noted that the BMD approach as outlined in the previous section needs to be adapted for the lack of a well-defined control group and covariates which may act as confounders. There are also situations, where co-exposure can take the role of a covariate, see, for example, the cadmium and methyl-mercury risk assessment.

A serious restriction of modeling human data is the almost ubiquitous lack of individual data for reasons of privacy and data protection issues up to commercial interests of the data owners. Most data are available for risk assessment only in

aggregated format, for example, percentiles (terciles, quartiles, quintiles, or deciles). This typical granularity raises questions of power and bias compared with the ideal situation of individual data. The BMD approach applied to those aggregated data has to overcome two major hurdles: (i) summary data need adjustment for covariate information and (ii) the specification of a BMR at control is mostly prohibited. A BMR would need to be defined at the background exposure available, for example, at the lowest percentile of aggregated data, possibly including historical information.

---

## BMD Modeling for Different Endpoints

Risk assessment may be based on more than one critical endpoint, and therefore, a multiplicity of endpoints, data sets, and studies may be available for the BMD approach. A prospective planning of the dose–response assessment is therefore recommended to organize the determination of a RP/PoD for the risk characterization. That plan should provide a road map comprising (i) the studies selected (ii) their data sets suitable for modeling, (iii) the various relevant endpoints for the adverse health effect to which (i) and (ii) can be associated, and finally (iv) a prioritization of modeling that accounts for the variety of critical endpoints and data sets available. If possible, a ranking of endpoints by degree of adversity may be helpful. An ordering by size of BMDL or location of the BMD-CI may identify the most critical endpoints if no toxicological arguments would contradict. An exception are genotoxic or directly DNA reactive carcinogens. The BMD approach is then applied separately to cancer incidence as quantal endpoint and MoEs are calculated (EFSA 2005) (see also ► Chap. 23, “Extrapolation Procedures for Carcinogenic and Noncarcinogenic Compounds”).

If several endpoints are judged as equally relevant, one may proceed similarly as in the case of several data sets above and summarize them statistically, for example, by a (weighted) mean, median, or the minimum.

---

## Reporting the Results of the BMD Approach

A comprehensive scheme for reporting the outcome of a BMD analysis has been compiled in EFSA (2009) and iterated in EFSA et al. (2017b) with a list of seven items to consider:

1. Summary table of endpoints and their data bases
2. Choice of BMR
3. Software used
4. Assumptions and settings used for modeling
5. Tabulation of the results including all relevant modeling characteristics
6. Graphical presentations of single models and/or outcome of model averaging
7. Conclusion on RP/PoD.

Reporting so-called study BMDLs for all studies identified for the BMD approach, similar as study NOAELs, may apply in special situations but hardly in

complex assessments. In most cases, it might be prudent not to summarize the numerical values into one final RP/PoD for each endpoint, but to report the outcome of all BMD analyses transparently, informing on the quality of the studies from which the data were taken as possible source of variation.

Besides providing information on all endpoints and data sets, it is advisable to justify any decisions made during the BMD analysis, in particular, the specification of the BMR, the model selection, and the specification of the response distribution. Both adherence to and deviation from default assumptions should be justified. Compliance with rules on reproducibility and transparencies ask for complete documentation of code and output of the BMD software, usually published electronically as supplementary information.

---

## Use of the BMDL for Risk Characterization

The use of the BMDL as RP/PoD depends on the nature of the critical effect and the mode of action of the effects considered for hazard characterization including also related toxicity endpoints, see ► [Chap. 23, “Extrapolation Procedures for Carcinogenic and Noncarcinogenic Compounds.”](#) Characterizing the risk of compounds which are both genotoxic and carcinogenic are based on the margin of exposure MOE, the ratio of RP (or PoD) over the estimated exposure dose ED

$$MOE = RP/ED \quad (20)$$

When establishing an HBGV (e.g., an ADI or TDI), uncertainty factors (UFs) are applied to the BMDL in the same way as it was done for the NOAEL approach, see [FAO/WHO \(2009\)](#).

DR data from observational epidemiological studies differ from typical animal toxicity data; however, the BMD approach still applies. A more careful check for the appropriateness of the data is indicated and the influences of confounders on the DR relationship should be addressed for modeling and the interpretation of the HBGV or MoE. The overall UF for human data is usually simpler and smaller since the interspecies extrapolation is dismissed.

The uncertainties of the BMD approach have been addressed above at several instances. Most vulnerable is the preparation of the approach, that is, the selection of the studies, data sets and endpoints and the specification of the BMR. Uncertainty can be reduced by MA techniques or Bayesian procedures, see e.g. the section “Dealing with uncertainty” in [Edler et al. \(2014\)](#). For general guidance on the handling and reporting uncertainty in risk assessment see [EFSA \(2018\)](#).

## Abstract

Human biomonitoring (HBM) aims to determine internal exposure to chemicals and related effects. Similar to environmental monitoring, HBM is a basic method for the protection of human health in case of exposure to chemical substances. About 200 chemicals can be analyzed by HBM. In many countries broad general population HBM programs have been established. HBM data are evaluated by

reference values and health-based values. Interpretation of HBM data in exposure assessment and health risk context increases its utility and input into risk assessment and risk management.

---

## Introduction

*Human biomonitoring* (HBM) is defined as the measurement of concentrations of chemicals or their metabolites in human biological media such as blood, urine, or breast milk. Application of hair, pulmonary air, teeth, nails, and saliva in HBM is limited to specific issues. HBM also includes chemical and biological parameters (biochemical effect monitoring, biological effect monitoring) which allow inferences about the pollutants' biological effect. HBM is considered the method of choice for determining internal exposures in the population, population groups, or individuals. Similar to environmental monitoring (EM), HBM is a basic method for the protection of human health in case of exposure to chemical substances. HBM of dose and biochemical effect is an efficient and cost-effective tool to assess human exposure to chemical substances. HBM considers all routes of uptake and all sources which are relevant. HBM is an ideal instrument for risk assessment and risk management. HBM can identify new chemical exposures (merging chemicals), trends, and changes in exposure, establish distribution of exposure among the general population, identify vulnerable groups and populations with higher exposures, and identify environmental risks at specific contaminated sites. The focus of this chapter is on HBM related to environmental and not to occupational exposures. Several overviews on HBM are available (e.g., Angerer et al. 2007, 2011; Needham et al. 2007; Schulz et al. 2011). Figure 1 shows the relation between exposure and health impairment and how EM and HBM are integrated in the scheme.

---

## Environmental Monitoring

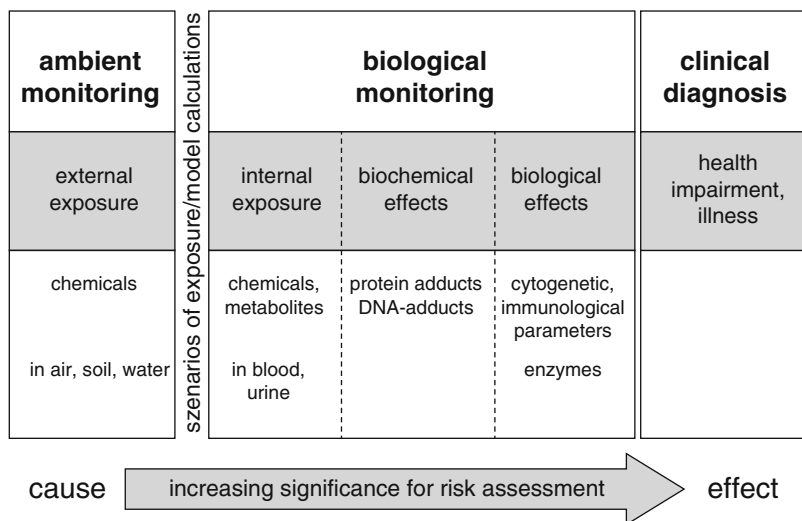

Environmental monitoring (EM), also called ambient monitoring, is the determination of chemical substances in environmental samples such as water, air, soil, indoor air, dust, or food (food monitoring). HBM is considered to supplement EM. EM is especially necessary to identify the sources of exposure and to facilitate measures for minimizing emissions. The purpose of EM is similar to HBM to show how well environmental objectives are met and to help detect new environmental issues. The results are also of fundamental importance to environmental management in general, as the drafting and prioritization of environmental policies are based on the findings of EM.

---

## Chemicals (Biomarkers of Internal Exposure)

Nowadays, about 200 chemicals can be analyzed by HBM (Table 1). The number is steadily increasing.

**Fig. 1** Relation between exposure and health impairment. (Modified from Angerer et al. 2007)

## Biochemical Effect Monitoring

### DNA Adducts

*DNA adducts* are markers of exposure to carcinogenic substances showing the intake of carcinogens and metabolic activation by forming an ultimate carcinogen which can covalently interact with cellular DNA (details in Angerer et al. 2007). DNA adducts represent key events in mutagenesis and carcinogenesis. For the determination of adducted nucleosides, mostly white blood cells and lymphocytes, in some cases sputum and exfoliated urothelial cells, have been used as surrogate tissues. DNA adduct monitoring has been performed in relation to substances like PAH, aromatic amines, dietary heterocyclic amines, and others. Though there are very sensitive techniques for DNA adduct monitoring available, they lack specificity. DNA adducts seem to be a promising tool within molecular epidemiology in population studies; interpretation on an individual level is currently not possible.

### 8-Hydroxy-2'-deoxyguanosine (8-OHdG)

Besides substance-specific DNA adducts, biomarkers of DNA oxidation are increasingly used in HBM (details in Angerer et al. 2007). Free radicals and other reactive species are constantly generated *in vivo* and cause oxidative damage to DNA. Oxidative DNA damage is always present and can be physiologically compensated. Additionally, oxidative DNA damage occurs due to exogenous causes, such as inorganic and organic pollutants or their metabolites.

**Table 1** Biomarkers of internal exposure in environmental health

Classes of chemical exposure	Chemical, metabolites
Aromatic amines	Aniline, <i>o</i> -toluidine, <i>m</i> -toluidine, <i>p</i> -toluidine, <i>o</i> -anisidine, 3-chloroaniline, 4-chloroaniline, 3,5-dichloroaniline, 4-dichloroaniline, 2-aminonaphthalene, 4-aminobiphenyl
Carbamates	Carbofuranphenol, 2-isopropoxyphenol
Chlorophenols	2-Monochlorophenol, 4-monochlorophenol, 2,4-dichlorophenol, 2,5-dichlorophenol, 2,6-dichlorophenol, 2,3,4-trichlorophenol, 2,4,5-trichlorophenol, 2,4,6-trichlorophenol, 2,3,4,6-tetrachlorophenol, pentachlorophenol (PCP)
Disinfection by-products	Bromodichloromethane, dibromochloromethane, tribromomethane (bromofom), trichloromethane (chloroform)
Fungicides	Ortho-phenylphenol, ethylene thiourea, pentachlorophenol, propylene thiourea
Herbicides	2,4-Dichlorophenol, 2,4-dichlorophenoxyacetic acid, 2,4,5-trichlorophenoxyacetic acid, various sulfonylurea herbicides
Metals/metalloids	Aluminum, antimony, arsenic and arsenic compounds/species, barium, beryllium, cadmium, cesium, cobalt, chromium, copper, lead, mercury and mercury compounds/species, molybdenum, nickel, platinum, selenium, thallium, tungsten, vanadium, uranium, zinc
Organochlorine pesticides	Aldrin and dieldrin, oxychlordan, heptachlor epoxide, <i>trans</i> -nonachlor, dichlorodiphenyltrichloroethane (DDT), <i>p,p'</i> -dichlorodiphenyltrichloroethane (DDT), <i>p,p'</i> -dichlorodiphenyldichloroethylene (DDE), <i>o,p'</i> -dichlorodiphenyltrichloroethane, endrin, hexachlorobenzene, hexachlorocyclohexane, beta-hexachlorocyclohexane, gamma-hexachlorocyclohexane (lindane), 2,4,5-trichlorophenol, 2,4,6-trichlorophenol, and other pesticide metabolites
Organophosphorus insecticides, dialkyl phosphate metabolites	Diethylphosphate, dimethyl phosphate, diethylthiophosphate, dimethylthiophosphate, diethyldithiophosphate, dimethyldithiophosphate, and specific metabolites: urinary acephate, urinary dimethoate, urinary omethoate, urinary methamidophos
Parabens	Butylparaben, ethylparaben, methylparaben, <i>n</i> -propylparaben
Perchlorate and other anions	Nitrate, perchlorate, thiocyanate
Perfluorinated compounds	Perfluorobutanesulfonic acid, perfluorodecanoic acid, perfluorodecanoic acid, perfluoroheptanoic acid, perfluorohexane sulfonic acid, perfluorononanoic acid, perfluorooctanoic acid, perfluorooctanesulfonic acid, perfluorooctanesulfonamide, 2-( <i>N</i> -ethyl-perfluorooctane sulfonamido) acetic acid, 2-( <i>N</i> -methyl-perfluorooctane sulfonamido) acetic acid, perfluoroundecanoic acid

(continued)

**Table 1** (continued)

Classes of chemical exposure	Chemical, metabolites
Phenols	Benzophenone-3, bisphenol A, 4-tert-octylphenol, triclosan
Phthalates	Monobenzyl phthalate, monoisobutyl phthalate, mono- <i>n</i> -butyl phthalate, mono-cyclohexyl phthalate, mono-ethyl phthalate, mono-2-ethylhexyl phthalate, mono-(2-ethyl-5-hydroxyhexyl) phthalate, mono-(2-ethyl-5-oxohexyl) phthalate, mono-(2-ethyl-5-carboxypentyl) phthalate, mono-(carboxynonyl) phthalate, monoisononyl phthalate, mono-(carboxyoctyl) phthalate, mono-methyl phthalate, mono-(3-carboxypropyl) phthalate, mono- <i>n</i> -octyl phthalate
Phytoestrogens	Daidzein, enterodiol, enterolactone, equol, genistein, <i>o</i> -desmethylangolensin
Polyaromatic hydrocarbons	1-,3-,9-Hydroxybenz[ <i>a</i> ]anthracene; 1-,2-,3-hydroxybenzo[ <i>c</i> ]phenanthrene, 1-,2-,3-,4-,6-hydroxychrysene, 3-hydroxyfluoranthene, 2-,3-,9-hydroxyfluorene, 1-,2-,3-,4-,9-hydroxy-phenanthrene, 1-hydroxypyrene, 3-hydroxybenzo[ <i>a</i> ]pyrene, 1-,2-hydroxynaphthalene
Polybrominated diphenyl ethers	2,2',4,4',5,5'-Hexabromobiphenyl (BB-153), 2,2',4-tribromodiphenyl ether (BDE 17), 2,4,4'-tribromodiphenyl ether (BDE 28), 2,2',4,4'-tetrabromodiphenyl ether (BDE 47), 2,3',4,4'-tetrabromodiphenyl ether (BDE 66), 2,2',3,4,4'-pentabromodiphenyl ether (BDE 85), 2,2',4,4',5-pentabromodiphenyl ether (BDE 99), 2,2',4,4',6-pentabromodiphenyl ether (BDE 100), 2,2',4,4',5,5'-hexabromodiphenyl ether (BDE 153), 2,2',4,4',5,6'-hexabromodiphenyl ether (BDE 154), 2,2',3,4,4',5',6'-heptabromodiphenyl ether (BDE 183), 2,2',4,4',5,5'-hexabromobiphenyl (BB 153)
Polychlorinated biphenyls, non-dioxin-like	2,4,4'-Trichlorobiphenyl (PCB 28), 2,2',3,5'-tetrachlorobiphenyl (PCB 44), 2,2',4,5'-tetrachlorobiphenyl (PCB 49), 2,2',5,5'-tetrachlorobiphenyl (PCB 52), 2,3',4,4'-tetrachlorobiphenyl (PCB 66), 2,4,4',5-tetrachlorobiphenyl (PCB 74), 2,2',3,4,5'-pentachlorobiphenyl (PCB 87), 2,2',4,4',5-pentachlorobiphenyl (PCB 99), 2,2',4,5,5'-pentachlorobiphenyl (PCB 101), 2,3,3',4',6-pentachlorobiphenyl (PCB 110), 2,2',3,3',4,4'-hexachlorobiphenyl (PCB 128), 2,2',3,4,4',5' and 2,3,3',4,4',6-hexachlorobiphenyl (PCB 138 and 158), 2,2',3,4',5,5'-hexachlorobiphenyl (PCB 146), 2,2',3,4',5',6-hexachlorobiphenyl (PCB 149), 2,2',3,5,5',6-hexachlorobiphenyl (PCB 151), 2,2',4,4',5,5',-hexachlorobiphenyl (PCB 153), 2,2',3,3',4,4',5-heptachlorobiphenyl (PCB 170), 2,2',3,3',4,5,5'-heptachlorobiphenyl (PCB 172), 2,2',3,3',4,5,6'-heptachlorobiphenyl (PCB 177),

(continued)

**Table 1** (continued)

Classes of chemical exposure	Chemical, metabolites
	2,2',3,3',5,5',6-heptachlorobiphenyl (PCB 178), 2,2',3,4,4',5,5'-heptachlorobiphenyl (PCB 180), 2,2',3,4,4',5',6-heptachlorobiphenyl (PCB 183), 2,2',3,4',5,5',6-heptachlorobiphenyl (PCB 187), 2,2',3,3',4,4',5,5'-octachlorobiphenyl (PCB 194), 2,2',3,3',4,4',5,6-octachlorobiphenyl (PCB 195), 2,2',3,3',4,4',5,6' and 2,2',3,4,4',5,5',6- octachlorobiphenyl (PCB 196 and 203), 2,2',3,3',4,5,5',6-octachlorobiphenyl (PCB 199), 2,2',3,3',4,4',5,5',6-nonachlorobiphenyl (PCB 206), 2,2',3,3',4,4',5,5',6,6'-decachlorobiphenyl (PCB 209)
Polychlorinated dibenzo- <i>p</i> -dioxins	1,2,3,4,6,7,8-Heptachlorodibenzo- <i>p</i> -dioxin (HpCDD), 1,2,3,4,7,8-hexachlorodibenzo- <i>p</i> -dioxin (HxCDD), 1,2,3,6,7,8-hexachlorodibenzo- <i>p</i> -dioxin (HxCDD), 1,2,3,7,8,9-hexachlorodibenzo- <i>p</i> -dioxin (HxCDD), 1,2,3,4,6,7,8,9-octachlorodibenzo- <i>p</i> -dioxin (OCDD), 1,2,3,7,8-pentachlorodibenzo- <i>p</i> -dioxin (PeCDD), 2,3,7,8-tetrachlorodibenzo- <i>p</i> -dioxin (TCDD)
Polychlorinated dibenzofurans	1,2,3,4,6,7,8-Heptachlorodibenzofuran (HpCDF), 1,2,3,4,7,8,9-heptachlorodibenzofuran (HxCDF), 1,2,3,4,7,8-hexachlorodibenzofuran (HxCDF), 1,2,3,6,7,8-hexachlorodibenzofuran (HxCDF), 1,2,3,7,8,9-hexachlorodibenzofuran (HxCDF), 2,3,4,6,7,8-hexachlorodibenzofuran (HxCDF), 1,2,3,4,6,7,8,9-octachlorodibenzofuran (OCDF), 1,2,3,7,8-pentachlorodibenzofuran (PeCDF), 2,3,4,7,8-pentachlorodibenzofuran (PeCDF), 2,3,7,8-tetrachlorodibenzofuran (TCDF)
Polychlorinated biphenyls, coplanar	3,4,4',5-Tetrachlorobiphenyl (PCB 81), 3,3',4,4',5-pentachlorobiphenyl (PCB 126), 3,3',4,4',5,5'-hexachlorobiphenyl (PCB 169)
Polychlorinated biphenyls, mono-ortho-substituted	2,3,3',4,4'-Pentachlorobiphenyl (PCB 105), 2,3',4,4',5-pentachlorobiphenyl (PCB 118), 2,3,3',4,4',5-hexachlorobiphenyl (PCB 156), 2,3,3',4,4',5'-hexachlorobiphenyl (PCB 157), 2,3',4,4',5,5'-hexachlorobiphenyl (PCB 167), 2,3,3',4,4',5,5'-heptachlorobiphenyl (PCB 189)
Pyrethroid pesticides	4-Fluoro-3-phenoxybenzoic acid, <i>cis</i> -3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane carboxylic acid, <i>trans</i> -3-(2,2-dichlorovinyl)- 2,2-dimethylcyclopropane carboxylic acid, <i>cis</i> -3-(2,2-dibromovinyl)-2,2-dimethylcyclopropane carboxylic acid, 3-phenoxybenzoic acid
Tobacco smoke	Cotinine, (4-(methylnitrosamino)-1-(3-pyridyl)- 1-butanol)
UV filters, benzophenone-type	2-Hydroxy-4-methoxybenzophenone (2OH-4MeO-BP), 2,4-dihydroxybenzophenone (2,4 OH-BP), 2,2'-dihydroxy-4-methoxybenzophenone (2,2'OH-

(continued)

**Table 1** (continued)

Classes of chemical exposure	Chemical, metabolites
	4MeO-BP), 2,2',4,4'-tetrahydroxybenzophenone (2,2',4,4'OH-BP), 4-hydroxybenzophenone (4OH-BP)
Volatile organic compounds	1,1,1-Trichloroethane (methyl chloroform), 1,1,2,2-tetrachloroethane, 1,1,2-trichloroethane, 1,1-dichloroethane, 1,1-dichloroethene (vinylidene chloride), 1,2-dibromo-3-chloropropane, 1,2-dichlorobenzene, 1,2-dichloroethane (ethylene dichloride), <i>cis</i> -1,2-dichloroethene, <i>trans</i> -1,2-dichloroethene, 1,2-dichloropropane, 1,3-dichlorobenzene, 1,4-dichlorobenzene (para-dichlorobenzene), 2,5-dimethylfuran, benzene, chlorobenzene, dibromomethane, dichloromethane (methylene chloride), ethylbenzene, hexachloroethane, methyl tert-butyl ether (MTBE), nitrobenzene, styrene, tetrachloroethene (perchloroethylene), tetrachloromethane (carbon tetrachloride), toluene, trichloroethene (trichloroethylene), <i>m</i> -/ <i>p</i> -xylene, <i>o</i> -xylene

8-OHdG levels in blood and urine are used in HBM as a biomarker of oxidative stress in relation to exposures to chemicals, physical stress, or tobacco smoking. However, though valid methods for the determination of 8-OHdG are available, diagnostic reliability of this marker is still in debate. It is a marker which is unspecific for the substance taken up. Furthermore, there is a lack of well-established dose–response relations between environmental exposures and the induction of 8-OHdG. Thus, interpretation has to be undertaken with caution, and the biomarker is not suitable for individuals.

### Hemoglobin Adducts (Hb Adducts)

Many reactive electrophilic intermediates of mutagenic substances bind to nucleophilic sites of proteins forming protein adducts. The preferred sites are the sulfhydryl group of cysteine, nitrogen of histidine, and N-terminal valine (Angerer et al. 2007). Hemoglobin (Hb) and serum albumin are the preferred monitor molecules because they are readily accessible in large amounts. Considering the life span of Hb (120 days), Hb adducts cumulate in the body. The reaction products of chemical substances with Hb indicate genotoxic properties of that special substance. Since protein adducts are stable and are not removed by active repair processes, they are a more precise HBM tool when compared with DNA adducts. The level of Hb adducts in blood enables the estimation of internal exposure as well as biochemical effects. Examples for chemicals and their adducts are:

- Alkylating agents: ethylene, -oxide → -hydroxyethylvaline, butadiene, -oxide → *N*-(2-hydroxy-3-butenyl)valine, acrylonitrile → cyanoethylvaline, *acrylamide* → *N*-2-carbamoylethylvaline, glycidamide → *N*-(*R,S*)-2-hydroxy-carbamoylethylvaline
- Nitro aromatic compounds: 2,6-dinitrotoluene → 2-amino-6-nitrotoluene, 2,4,6-trinitrotoluene → 2-amino-4,6-dinitrotoluene, 1-nitropyrene → 1-aminopyrene
- Further examples are Hb adducts for aromatic amines: aniline *o*-toluidine, *m*-toluidine, *p*-toluidine, *o*-anisidine, 2-aminonaphthalene, and 4-aminobiphenyl

---

## Biological Effects (Biomarker of Effect)

Markers for nephrotoxic effects, such as proteins in urine of subjects exposed to solvents or metals, have been well established. In HBM studies with exposure to genotoxic chemicals, especially the measurement of DNA strand breaks (comet assay) in lymphocytes in white blood cells has become very popular (Angerer et al. 2007). The *comet assay* may be effective in distinguishing exposed from nonexposed groups at high exposure. As with 8-OHdG, the biomarker is not specific; there is still a lack of well-established dose–response relations between exposures and the formation of strand breaks which limits the applicability of this marker in HBM. It may be useful as group indicators, but not for interpretation on an individual level.

Cytogenetic biomarkers currently applied in molecular epidemiologic studies include chromosomal aberrations, micronuclei, and sister chromatid exchange. This important group of genotoxicity biomarkers has been developed in animals, even *in vitro*, and is now increasingly applied to exposed populations. However, these biomarkers are currently inadequate to HBM purposes, especially for interpretation in individuals.

---

## Other Markers

The concept of individual variability has led to discuss the suitability of *biomarkers of susceptibility*. Of special interest is polymorphism in enzymes such as cytochrome P450 families and the glutathione transferases. Despite the intense work ongoing and the promising results achieved on the pharmacological and toxicological significance of polymorphic metabolizing enzymes, their routine use as HBM biomarkers in environmental health is yet not validated.

“Omic” technologies include genomics, transcriptomics (gene expression profiling), proteomics, and metabolomics. These new techniques are increasingly utilized in an effort to develop novel biomarkers of exposure, susceptibility, and response to chemicals. The application in the prediction of risks and the prevention of diseases related to chemical exposures is promising, but yet not established in HBM.

## General Population HBM Programs

Broad general population HBM programs are established or planned by international, national, and state organizations in a number of countries. One of the most recognized programs is the US *National Health and Nutrition Examination Survey* (NHANES, <http://www.cdc.gov/nchs/nhanes.htm>). Four surveys have been conducted between 1971 and 1994. In 1999, NHANES became a continuous survey. NHANES includes a physical examination and collecting of biological specimen and a detailed medical history. Approximately 7,000 residents participate each year. Biological specimen is used for clinical and nutritional testing as well as to assess exposure of the noninstitutionalized civilian US population to environmental chemicals. In Germany (Kolossa-Gehring et al. 2012), the nationwide population representative study on exposure to environmental chemicals and its sources comprises of four surveys (*German Environmental Surveys*, GerES I–IV) conducted since 1985 (<http://www.umweltbundesamt.de/gesundheit-e/survey/index.htm>). GerES IV (2003–2006) was the first survey exclusively on children. A further HBM tool in Germany is the *German Environmental Specimen Bank* (ESB). The ESB is a permanent monitoring instrument and an archive for human species specimens (<https://www.umweltbundesamt.de/en/topics/health/assessing-environmentally-related-healthrisks/environmental-specimen-bank>). The German HBM activities include the *German Human Biomonitoring Commission* (<https://www.umweltbundesamt.de/en/topics/health/commissions-working-groups/human-biomonitoring-commission-hbm-commission>). The commission provides general HBM concepts and derives values for interpretation of HBM data since 1992 (Schulz et al. 2011). Other countries with HBM programs include Belgium, Canada, the Czech Republic, Denmark, France, Israel, Japan, and South Korea (for overview see Special Issue, Berlin International Conference on Human Biomonitoring. *Int J Hyg Environ Health* 215 2012). A more broadly harmonized HBM program has been started throughout the European Union in 2011 (COPHES, <http://www.eu-hbm.info/>).

---

## Evaluation of HBM Results (Internal Exposures)

Leading concepts for the evaluation of HBM data in the general population have been given by the German HBM Commission (Schulz et al. 2011) as well as by Hays and Aylward (2012).

---

## Reference Values

The German HBM Commission has established the concept of *reference values*. The reference values (RV<sub>95</sub>) are statistical descriptions of the ranges of concentrations typically seen in a specified reference population but which have no direct

relationship to health effects or risk assessment. They are based on the 95th percentile. The reference values derived by the German HBM Commission for various substances are summarized in Tables 2, 3, 4, 5, 6, 7, 8, 9, 10, and 11. Many data for adults are based on the GerES III performed in 1997–1999. The exposure to most of the substances shown in the following tables has been decreased since then. Striking examples are lead in blood and PCB in blood.

For describing background exposure in the nonsmoking general population to acrylamide (AA) through the acrylamide hemoglobin adduct (*N*-2-carbamoyl-ethylvaline: AAVal) in the blood, the following levels were derived:

- 1.8 µg AAVal/l for nonsmoking children
- 1.2 µg AAVal/l for nonsmoking adults (Schulz et al. 2011).

Hb adduct of acrylamide (AAVal) reflects the acrylamide dose taken up in the previous 4 months.

## Reference Value and Risk Assessment

RV<sub>95</sub> is a strictly statistically derived value and has per se no health relevance. However, RV<sub>95</sub> is an important tool for prevention to assess whether populations or individuals are more exposed when compared to the environmental background exposure. In case of exposures above RV<sub>95</sub>, the recommendation is to clarify whether a conspicuous source exists and if it can be avoided. From the perspective of environmental hygiene and preventive medicine, it should be considered whether

**Table 2** Gives an overview on HBM guidance values in environmental (nonoccupational) exposures

Value	Basis	Reference
Reference value RV <sub>95</sub>	Population studies (not always strictly representative)	German HBM Commission
Human biomonitoring value I HBM I	Epidemiological data	German HBM Commission
	Toxicological data	
	Tolerable daily intake (TDI)	
Human biomonitoring value II HBM II	Epidemiological data	German HBM Commission
	Toxicological data	
Biomonitoring equivalent BE	Reference dose (RfD)	Summit Toxicology
	Reference concentration (RfC)	
	Tolerable daily intake (TDI)	
	Acceptable daily intake (ADI)	
	Minimal risk level (MRL)	
	Risk-specific doses (cancer)	

**Table 3** Reference values (RV<sub>95</sub>) for antimony, arsenic, cadmium, lead, mercury, nickel, thallium, platinum, and uranium in urine or blood (Schulz et al. 2011)

Parameter and matrix	Population group (age range)	Study period	RV <sub>95</sub>
Antimony in urine	Children (3–14 years)	2003–2006	0.3 µg/l
Arsenic in urine	Children (3–14 years)	2003–2006	15.0 µg/l
	Adults (18–69 years)	1997–1999	
Cadmium in urine	Nonsmoking children (3–14 years)	2003–2006	0.2 µg/l
	Nonsmoking adults (18–69 years)	1997–1999	0.8 µg/l
Cadmium in blood	Nonsmoking children (3–14 years)	2003–2006	<0.3 µg/l
	Nonsmoking adults (18–69 years)	1997–1999	1.0 µg/l

<sup>a</sup>Background exposure values, no strict reference value

this exposure can be reduced as far as reasonably possible. Furthermore, for substances which are considered carcinogenic (genotoxic), no health-based HBM values can be derived; RV<sub>95</sub> may be also used for risk assessment and risk management. This also applies for other substances for which no threshold is known. For

**Table 8** Reference values ( $RV_{95}$ ) for polychlorinated biphenyls (PCB), alpha-hexachlorocyclohexane ( $\alpha$ -HCH), beta-hexachlorocyclohexane ( $\beta$ -HCH), hexachlorobenzene (HCB), and 1,1-dichloro-2,2-bis(p-chlorophenyl)ethylene (DDE) in whole blood (Schulz et al. 2011)

Parameter	Population group (age range)	Study period	$RV_{95}$
PCB 28	Children (7–14 years)	2003–2006	0.01–0.1 $\mu\text{g/l}^{\text{a}}$
PCB 52	Children (7–14 years)	2003–2006	0.01–0.1 $\mu\text{g/l}^{\text{a}}$
PCB 101	Children (7–14 years)	2003–2006	0.01–0.1 $\mu\text{g/l}^{\text{a}}$
PCB 138	Children (7–14 years)	2003–2006	0.4 $\mu\text{g/l}$
	Adults (18–69 years)	1997–1999	0.4–2.2 $\mu\text{g/l}^{\text{b}}$
PCB 153	Children (3–14 years)	2003–2006	0.6–3.3 $\mu\text{g/l}^{\text{b}}$
	Adults (18–69 years)	1997–1999	
PCB 180	Children (3–14 years)	2003–2006	0.3–2.4 $\mu\text{g/l}^{\text{b}}$
	Adults (18–69 years)	1997–1999	
$\Sigma$ PCB (138 + 153 + 180)	Children (3–14 years)	2003–2006	1.0 $\mu\text{g/l}$
	Adults (18–69 years)	1997–1999	1.1–7.8 $\mu\text{g/l}^{\text{b}}$
$\alpha$ -HCH	Children (7–14 years)	2003–2006	<0.1 $\mu\text{g/l}$
	Adults (18–69 years)	1997–1999	
$\beta$ -HCH	Children (7–14 years)	2003–2006	0.3 $\mu\text{g/l}$
	Adults (18–69 years)	1997–1999	0.3–0.9 $\mu\text{g/l}^{\text{b}}$
HCB	Children (7–14 years)	2003–2006	0.3 $\mu\text{g/l}$
	Adults (18–69 years)	1997–1999	0.4–5.8 $\mu\text{g/l}^{\text{b}}$
DDE	Children (7–14 years)	2003–2006	0.7–1.4 $\mu\text{g/l}^{\text{c}}$
	Adults (18–69 years)	1997–1999	1.5–31 $\mu\text{g/l}^{\text{c}}$

Reference values for PCBs, HCB,  $\beta$ -HCH, and DDT in breast milk (sampled 2003–2005) are 0.5 mg/kg fat for total DDT and  $\Sigma$ PCB ( $1.64 \times (138 + 153 + 180)$ ), 0.06 mg/kg fat for HCB, and 0.07 mg/kg fat for  $\beta$ -HCH

<sup>a</sup>Reference values had been originally derived related to the detection limit of 0.1  $\mu\text{g/l}$ . Meanwhile, detection limit for PCB 28, 52, and 101 is about 0.01  $\mu\text{g/l}$ . Levels above 0.01  $\mu\text{g/l}$  may indicate an exposure above background exposure

<sup>b</sup>Levels increase between age groups 18 and 69 years continuously. Due to the general decrease of PCB exposure and considering that samples were collected in 1997–1999, the current reference values should be lower at least by a factor of 0.5

<sup>c</sup>Levels increase between age groups 18 and 69 years continuously. Furthermore, data include the comparison between samples collected in West and East Germany. Levels of participants from East Germany were 2–3 times higher compared to those from West Germany

**Table 9** Reference values ( $RV_{95}$ ) for the perfluorinated compounds – perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) in plasma (Schulz et al. 2011)

Parameter	Population group (age range)	Study period	$RV_{95}$
PFOA	Women, men, children <10 years	2003–2007	10 $\mu\text{g/l}$
PFOS	Women (not strictly representative)	2003–2007	20 $\mu\text{g/l}$
	Men (not strictly representative)	2003–2007	25 $\mu\text{g/l}$
	Children <10 years (not strictly representative)	2003–2007	10 $\mu\text{g/l}$

**Table 10** Reference values ( $RV_{95}$ ) for aromatic amines in urine of nonsmoking adults (Schulz et al. 2011). The data are based on samples which are not strictly representative. Study period was 2003–2004

Parameter	$RV_{95}$
Aniline	14.5 $\mu\text{g/l}$
<i>o</i> -Toluidine	0.20 $\mu\text{g/l}$
<i>m</i> -Toluidine	0.25 $\mu\text{g/l}$
<i>p</i> -Toluidine	1.25 $\mu\text{g/l}$
<i>o</i> -Anisidine	1.10 $\mu\text{g/l}$
3-Chloroaniline	0.25 $\mu\text{g/l}$
4-Chloroaniline	1.00 $\mu\text{g/l}$

3,5-Dichloroaniline	4.30 $\mu\text{g/l}$

example, the German HBM Commission recently rescinded the HBM values for lead in blood of children and adults (Wilhelm et al. 2010). For reasons of preventive health protection, the Commission recommends using the  $RV_{95}$  for the assessment of lead exposure.

For occupational health purposes, BAR values (Biologischer Arbeitsstoff-Referenzwert) are established by the German Commission for the Investigation of Health Hazards of Chemical Compounds in the Work Area (MAK Commission). These BAR values are similar to the reference values of the German HBM Commission. However, in risk communication two kinds of values with the same meaning may contribute to confusion.

---

## Health-Based Values

### HBM Values

The health-related biological exposure limits established by the German Human Biomonitoring Commission are called the *HBM values*. Two levels were defined: the HBM-I value and the HBM-II value. The HBM-I value is a control value, while the HBM-II value is defined as an action level. The HBM-I value describes the concentration in the body matrix of a substance below which no adverse health effect should be expected. At a concentration level higher than the HBM-I and lower than the HBM-II value, an investigation of potential sources of exposure should be undertaken. Exposure to such sources should be minimized, or relevant sources should be eliminated where necessary and achievable with an acceptable level of input. HBM values are derived from toxicological and epidemiological data as well from existing health-based exposure guidance values such as the tolerable daily intake (Table 2). The protection levels intended by the tolerable intake values described above correspond to the protection level intended by the HBM-I value. The HBM-II value describes the concentration in the body matrix of a substance above which relevant adverse health effects may

**Table 11** Reference values ( $RV_{95}$ ) for metabolites of phthalates in urine of children and adults (Schulz et al. 2011). Adults were students from Münster, West Germany

Phthalate	Metabolite	Population group (age range)	Study period	$RV_{95}$
DnBP	MnBP	Children (3–14 years)	2003–2006	300 µg/l
		Adults (20–29 years)	2006 and 2008	70 µg/l

occur, and hence, immediate action to reduce exposure must be taken and expert care in environmental medicine will be required. HBM values are summarized in Table 12.

**Table 12** Human biomonitoring (HBM) values derived by the German HBM Commission

Parameter and medium	Population group/age groups	HBM-I value	HBM-II value
Bisphenol A in urine	Children	1.5 mg/l	
	Adults	2.5 mg/l	
Cadmium in urine	Children and adolescence	0.5 µg/l	2 µg/l
	Adults	1 µg/l	4 µg/l
ΣMetabolites of di(2-ethylhexyl)phthalate DEHP: 5oxo- and 5OH-MEHP in urine	Children (6–13 years)	500 µg/l	
	Women of reproductive age	300 µg/l	
	Men ≥ 14 years, general population	750 µg/l	
Mercury in urine	Children and adults	7 µg/l	25 µg/l
		5 µg/g creatinine	20 µg/g creatinine
Mercury in blood	Children and adults	5 µg/l	15 µg/l
Pentachlorophenol in serum	General population	40 µg/l	70 µg/l
Pentachlorophenol in urine	General population	25 µg/l	40 µg/l
		20 µg/g creatinine	30 µg/g creatinine
Thallium in urine	General population	5 µg/l	
ΣPCB (138 + 153 + 180) in serum × 2	Infants, children, women of reproductive age	3.5 µg/l	7 µg/l

## Biological Equivalents (BEs)

*Biomonitoring equivalents* (BEs) are defined as the concentration of a chemical or metabolite in a biological medium (blood, urine, human milk, etc.) consistent with defined exposure guidance values or toxicity criteria, including reference doses and reference concentrations (RfD and RfCs), minimal risk levels (MRLs), and tolerable daily intakes (TDIs) (Hays and Aylward 2012). Thus, the definition of BE is functionally similar to the HBM-I value of the German HBM Commission (Angerer et al. 2011). BE values have been derived for more than 80 chemicals (Table 13).

A second BE level has also been defined, the BE<sub>POD</sub>. This is the BE value corresponding to an exposure level which incorporates uncertainty factors associated with NOAEL or LOAEL, duration adjustment, as well as interspecies extrapolation but which omits uncertainty factors which address intraspecies factors or other database uncertainty factors.

The various HBM guidance values used in occupational health will not be mentioned here.

**Table 13** Chemicals for which BE values corresponding to current risk assessment-based exposure guidance values have been derived (Hays and Aylward 2012)

Cadmium	2,4-Dichlorophenoxyacetic acid
Arsenic, inorganic	1,2,3-Trichloropropane
2,4-D Cyfluthrin	Styrene
Deltamethrin	Ethylbenzene
DDT/DDE/DDD	1,2-Dibromoethane
Dioxin TEQ (dioxin, furan, and coplanar PCB compounds)	1,2-Dichloroethane
	Acrylonitrile
Carbon tetrachloride	Toluene
Chloroform	Methyl isobutyl ketone (MIBK)
Hexachloroethane	Furan
1,1,1-Trichloroethane	Tetrahydrofuran
Benzene	<i>n</i> -Hexane
Dibromomethane	<i>n</i> -Octane
Bromoform	<i>n</i> -Nonane
Bromodichloromethane	Hexachlorobenzene
Methylene chloride	1,4-Dioxane
1,1-Dichloroethane	Dibromochloromethane
1,1-Dichloroethene	<i>n</i> -Decane
Acrylamide	Tetrachloroethene
1,1,2-Trichloroethane	<i>cis</i> -1,2-Dichloroethene
1,1,2,2-Tetrachloroethane	<i>trans</i> -1,2-Dichloroethene
Trichloroethene	<i>n</i> -Heptane
Bisphenol A	1,1,1,2-Tetrachloroethane
Di(2-ethylhexyl)phthalate	Xylenes, mixed
Diethyl phthalate	Methyl tert-butyl ether (MTBE)
Dibutyl phthalate	Triclosan
Benzyl butyl phthalate	Hexabromocyclododecane
Diisononyl phthalate	PBDE 99

## Risk Assessment in Context with Surveys/Tool in Risk Management

Using BEs, hazard quotients are calculated as the ratio of the biomarker concentration to the BE as proposed by Hays and Aylward (2012). *Hazard quotients* <1 indicate that the measured concentration of a chemical in a biological medium is below BE. In this case the exposure is expected to be below the corresponding exposure guidance value. Applying health-based guidance values (HBM-I, HBM-II, BEs) to the NHANES data (geometric mean and 95th percentile population biomarker concentrations) from the report 2012, Aylward et al. (2012) calculated hazard quotients. Most analytes showed hazard quotients below 1. Hazard quotients approaching or exceeding 1 or cancer risks greater than  $1 \times 10^{-4}$  were found for

acrylamide, dioxin-like chemicals, benzene, xylene, several metals, di-(2-ethylhexyl) phthalate, and some legacy organochlorine pesticides suggesting that exposure levels may exceed published human health benchmarks. This approach is very useful to assist risk managers in the prioritization of chemicals for more detailed chemical-specific evaluation and risk assessment follow-up.

## Abstract

A toxicodynamic model (TDM) is used to describe a concentration–response relationship primarily for predicting effects at certain concentrations and as explanatory tool for investigating mechanisms of action (MOA) of toxic substances or explaining sensitivity differences between exposed subjects and between species. All such information can specifically contribute to the risk assessment of such substances. Suitable mathematical models and statistical analysis methods have to be applied for the toxicodynamic modeling.

## Introduction

TDMs describe the relationship between toxic effects (response) attributed or related to exposure to the toxic substances under investigation or its metabolites and the circulating concentration in the body (or a target organ). Therefore, toxicodynamic modeling is often based on statistical models that relate concentration to adverse effects accounting for biological mechanisms at the site of action (mode of action, MOA) and tissue/cell dynamics. Table 1 informs on the major areas of the application of TDMs and methodological aspects of modeling.

## Requirements for Toxicodynamic Modeling

In order to provide information on the MOA of the toxic substance and/or to establish a concentration–response relationship, toxicodynamic (TD) modeling requires careful planning and performing of studies. In general, TD studies may proceed as follows:

- Formulation of the TD issue or question (problem formulation)
- Collection of available preliminary information on MOA and toxicological parameters
- Choice of one or a class of TDMs which appear to fit the purpose
- Selection of the available and appropriate experimental (or observational) data required for modeling
- Identification of model parameters (e.g., known from previous experience) with the potential to inform on the relevant TD characteristic (e.g., maxima or steepness). If applicable screen available data to identify a range of possibly realistic numerical values of the model parameters, when the model fit requires iterative computational procedures and needs such values (so-called initial values) to start the calculation

**Table 1** Overview on functions, application areas, and procedures of toxicodynamic models

Function	Application areas	Methods
<b>Describe</b>	Concentration–response curve	Parametric curve fitting
	Toxicodynamic potency	Model fit
	Hypothesis generation	Statistical estimation of concentration (dose) descriptors
<b>Explain</b>	Complex biological and toxicological mechanisms	Biologically based models
	Check or reject hypotheses	Model selection
<b>Predict</b>	Extrapolation to low concentrations	(Non-)parametric curve fitting
	Interspecies extrapolation	Model fit
	Intra-species differences in sensitivity	Model fit

- Fit of the TDMs to the concentration–response data and determination (using statistical estimation procedures) of previously unknown model parameters
- Assessing the quality of the model fit
- Interpretation of the estimated parameter values and application of the modeling outcome to the TD question
- Assessing the robustness and the uncertainty of the modeling

An important part of the TD problem formulation is the definition of the TD endpoint (target) and a consideration of its statistical quality in terms of scale of measurement. Three main classes of effect (response) data can be distinguished:

- Quantal measures (e.g., presence/absence of liver toxicity/liver tumors)
- Categorical (ordinal) measures (e.g., degree of impairment of an organ function)
- Continuous (metric, quantitative) measures (e.g., number of tumors in animal experiments, values of an enzyme measured in the blood serum, indices of reproduction).

Besides the statistical information content of a TD endpoint, one should also address the biological information content and toxicological meaning of the TD endpoint. This is, in particular, relevant for the ultimate interpretation of the outcome of the TDM. Therefore, it is important to distinguish between a direct and an indirect target. A direct target would accurately exhibit the effect to be tested in the TD study. Indirect targets (e.g., biomarkers) are applicable when only a surrogate of the target can be measured.

---

## Description and Application of Toxicodynamic Models (TDMs)

### Toxicodynamic Potency

Measures of toxicodynamic potency are obtained mainly from descriptive parametric TDMs and their adaptation to concentration–effect curves. Three common TDMs for continuous and two for quantal measures are presented below. All five models allow the determination of a quantity which can be interpreted as TD potency of a substance which expresses an activity often as a descriptor of concentration related to a certain size or degree of a toxic effect.

**The Linear Concentration–Effect Model.** In cases where a direct proportional relationship between the concentration of the toxic substance  $C$  and the effect  $E$  can be assumed, the linear model

$$E = E_0 + mC \quad (1)$$

is the simplest model to be applied.  $E_0$  denotes the base effect (background) and  $m$  the proportionality of the effect relative to the concentration (slope). The two model

parameters ( $E_0, m$ ) are statistically determined from concentration–effect data usually available as  $n$  data pairs

$$\{(C_i, E_i), i = 1, \dots, n\}$$

where  $E_i$  denotes the effect observed at concentration  $C_i$  in a total of  $n$  observational units (samples) investigated in the TD study. The statistical analysis method is linear regression (see, e.g., Draper and Smith 1998). In practice, this model plays only a minor role since a direct linear relationship rarely applies for TD data. However, the linear model can be used for an interpolation of the concentration–response curve over a few concentrations when only a part of the concentration–effect course is considered, and if linearity can be assumed for that part. Moreover, linear regression is ideal for teaching purposes and for the presentation of the basic concepts of statistical regression and model fitting as sort of statistical reference standard.

**The Log-Linear Concentration–Response Model.** When the range of concentrations of the TD study is large, covering, for example, several orders of magnitude, one often uses a logarithmic transformation of the concentration in order to visualize the concentration–effect relationship in a graphic when plotting the  $E_i$  values versus the  $\ln(C_i)$  values ( $\ln$  denotes natural logarithm to the base  $e$ ). If this results in a graph where  $E$  is proportional to  $\ln C$ , then the log-linear model

$$E = E_0 + m \ln C \quad (2)$$

with the base effect value  $E_0$  and the slope parameter  $m$  can be fitted using the same statistical methods as for Eq. (1). Although the log-linear model is analyzed as the linear model, it should be noted that fitting a log-linear model to data where effects at concentration 0 are included is mathematically more complex. Since the transformed concentration  $\ln(0)$  is for mathematical reasons no more a real number and located outside the range of the plot, at “minus infinity” the fit of Eq. (2) to the TD data can graphically be inspected only at a restricted concentration range. For this reason, the data and the fit are usually retransformed to a linear plot with a logarithmic scale of the abscissa (“x-axis”). It should also be noted that a logarithmic transformation of the concentration may not remove nonlinearity from the concentration–effect relationship. Therefore, one cannot compare the slopes of linear and nonlinear models directly and other nonlinear models (see below) may be investigated. Model fit is obtained again by standard linear regression where for computational reasons the concentration  $\ln(0)$  is replaced by a large negative value to mimic “minus infinity.” The choice of this substitute adds uncertainty to the slope estimate. Note that the statistical uncertainty is characterized by a statistical confidence interval with a lower and an upper bound referring to a level of confidence, usually for 90% or 95%.

**The Emax Model.** Concentration–effect curves, which show a saturation of the effect at high concentrations, exhibit a similarity with curves known from enzyme kinetics and receptor-binding relationships for a long time. They are often evaluated with a model related to the Michaelis-Menten equation. In its simplest form, this so-called Emax model takes the form

$$E = \frac{E_{max} \cdot C}{E_{50} + C} \quad (3)$$

with the two model parameters ( $E_{max}$ ,  $E_{50}$ ). Herein,  $E_{max}$  is the maximum effect, achieved at the maximum concentration, theoretically at  $C = \infty$ .  $E_{50}$  is the “half-maximum” concentration at which 50% of the maximum effect  $E_{max}$  is reached (Yu et al. 2019).

By definition, the effect at background (i.e., at concentration equal to 0) is  $E_0$ . In the model Eq. (3),  $E_0 = 0$  and such comparable with a linear regression through the origin (0,0) where one is interested in the slope  $m$  only. There are two options if the TD study must account for a positive effect at background: (1) one adds a third model parameter  $E_0$  for the background effect such that the model Eq. (3), changes to  $E = E_0 + (E_{max} C)/(E_{50} + C)$  (response-additive background) or (2) one postulates a virtual background concentration  $C_0$  and replaces on the right side of Eq. (3) the concentration  $C$  by  $C + C_0$  (concentration-additive background). Practically more important is, however, the extension of the  $E_{max}$  model to the of *Hill type* model, where the concentration  $C$  on the right side of Eq. (2) is replaced by an exponentiated expression  $C^n$  (the  $n$ th power of  $C$ ) which leads to a sigmoidal shape of the concentration–effect curve. Methods of non-linear curve fitting (regression) are available in standard statistical software packages for the calculation of the model parameters; see, for example, Gabrielsson and Weiner (2016).

Note that the models of Eq. (3) are by one more parameter more complex than the linear and log-linear models since they have two parameters for the shape of the curve compared to only one slope parameter in the linear model. It is obvious that the same class of models can be applied when the toxic effect is also presented on a logarithmic scale. However, the effects will be interpreted on a multiplicative scale in that case.

**The Probit Model and Logit Model.** Concentration–effect data available as quantal data in a form, where the number of responders  $r_i$  and the number of non-responders  $s_i$  at the different concentrations ( $C_i$ ,  $i = 1, \dots, n$ ) have been analyzed traditionally using parametric models. Therefore, the data are prepared as a set of pairs

$$\{(C_i, p_i), i = 1, \dots, n\}$$

where  $p_i = r_i / (r_i + s_i)$  describes the effect as proportion (also called effect rate) at concentration  $C_i$ . The *probit model* describes the proportion  $P$  as a function of the concentration  $C$  by

$$P(C) = \Phi(E_0 + m \ln C) \quad (4)$$

with the base effect parameter  $E_0$  and the proportionality (slope)  $m$  and where  $\Phi$  denotes the Gaussian (“Normal”) distribution function. A somehow more flexible partner of the *probit model* is the *logit model* which models the likelihood of an effect at concentration  $C$  as

**Fig. 1** The probit (solid line) and the logit model (dashed line) as descriptive TD models. (© Annette Kopp-Schneider, the author thanks for providing the figure)

$$P(C) = \frac{\exp(E_0 + mC)}{1 + \exp(E_0 + mC)}. \quad (5)$$

Applying the linearizing logit transformation one obtains the linear relationship

$$\text{logit } P(C) = \ln \frac{P(C)}{1 - P(C)} = E_0 + mC$$

and when the concentration is analyzed on logarithmic scale,

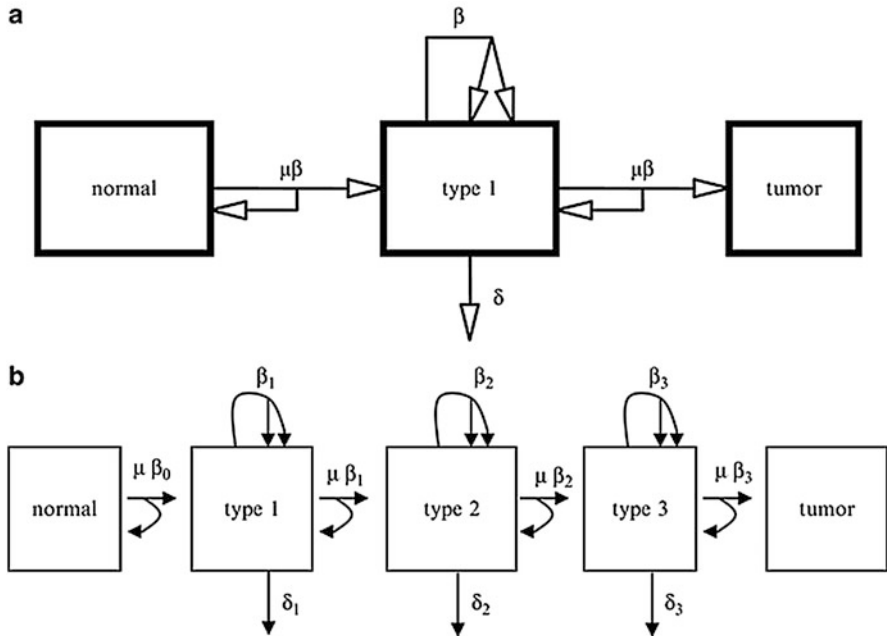

$$\text{logit } P(C) = \ln \frac{P(C)}{1 - P(C)} = E_0 + m \ln C \quad (6)$$

with  $E_0$  as basal effect and parameter  $m$  as proportionality factor (see Fig. 1).

## Explanatory and Biologically Based TDMs

The model parameters used above express primarily statistical properties of the concentration–effect relationship and therefore these TDMs are often denoted as empirical in contrast to models that integrate biological knowledge of the MOA of a substance in the modeling process, denoted as named biologically based. The latter contain (at least some) model parameters with a physiological or toxicological interpretation and require as consequence, more reliable foreknowledge on the chemical, the biological nature of the toxic substance and its physiological and toxic mechanisms. Consequently, more complex computational modeling is needed for biologically based TDMs, including use of special software when the underlying biological or toxicological features exhibit a higher order of nonlinearity than what is expected for empirical models. On the other hand, fitting a biologically based TD model should always be accompanied with a sensitivity and uncertainty analysis. In

**Fig. 2** The two-stage model of clonal evolution of tumors (a) and the multistage mutation model of carcinogenesis (b, shown here with three intermediates) represent explanatory toxicodynamic models. In the models,  $\mu$  describes the mutation rates,  $\beta$  the birth rates, and  $\delta$  the death rates of the cells. (© Annette Kopp-Schneider, the author thanks for providing the figure)

the field of carcinogenesis, the two-stage model of clonal expansion of tumors (initiation-promotion model) and the multistage mutation model (Armitage-Doll model) have been a prominent example of biologically based TDMs (see Fig. 2 and Kopp-Schneider (1997)).

Biologically based TDMs constitute an essential part of biologically based dose–response models (BBDRs) that describe the dose–response from external dose to internal dose and to tissue response. Whereas toxicokinetic-toxicodynamic (TK-TD) models, sketched in the section below, are a subclass of BBDR that has been repeatedly applied in risk assessment, the use of fully developed BBDRs has been rare and limited so far in regulatory context because of their needs in resources and time.

## TDMs for Risk Characterization in Regulatory Toxicology

In the context of in regulatory toxicology, risk characterization serves risk managers in decision making (e.g., when deriving regulatory limits). It informs, preferably, in quantitative terms, on the magnitude of risk associated with different exposure levels and helps to establish health-based guidance values (HBGVs). Therefore, risk

characterization synthesizes the two basic lines of risk assessment namely exposure assessment on the one hand and hazard identification and characterization on the other (see ► [Chap. 6, “Toxicological Risk Assessment”](#)). Thereby the assessments of toxicokinetic and toxicodynamic variability are two relevant steps for establishing a HBGV.

## Toxicokinetic-Toxicodynamic Models

TK-TD models combine dose–time relationships of toxicokinetics (TK) with concentration–activity relationships of TD and allow a holistic view of dose-dependent toxic effects over time. TK-TD models are therefore particularly well suited to represent causal relationships between exposure and the toxic effects and thus contribute to a better understanding of the chronologic sequence of toxic effects. Simple TK models can be replaced by physiologically based TK models (PB-TK models) to calculate concentrations in organs and target tissues. From a methodological statistical point of view TK-TD models are directly connected to Pharmacokinetic-Pharmacodynamic (PK-PD) models used in drug research and regulation (Derendorf and Hochhaus 1995; Yu et al. 2019).

A further extension of TK-TD models are the TK-TD population models which characterize dose/time–response relationships in populations and combine individual relationships in a comprehensive modeling. They are applicable even to sparse and irregularly sampled individual exposure data, if the sample size is large enough. The statistical analysis is challenging, for example, when using nonlinear mixed effect models or Bayesian hierarchical models. For more details on Bayesian statistical methods and software, see, for example, Lunn et al. (2002).

## Chemical-Specific Adjustment Factors

When characterizing the hazard of a toxic substance risk assessors have usually been forced to use dose–response data from experimental animals to derive a Point of Departure (PoD or reference value/reference point RP) using statistical methods (see ► [Chap. 23, “Extrapolation Procedures for Carcinogenic and Noncarcinogenic Compounds”](#)). To establish a HBGV for humans exposed to the toxin one needs to extrapolate at first the PoD derived for animals to humans accounting for interspecies differences. Secondly, one has to account for interindividual differences in the human population. Both types of variations (inter-species and intra-species) are accounted using a so-called uncertainty factor UF, formally:  $HBGV = PoD/UF$ . A default UF of 100 has been used to convert a PoD derived from an animal study into a HBGV for humans where inter-species and inter-individual differences contributed each the factor of 10. Principles for applying UFs and alternatives allowing data-derived UFs are outlined in FAO/WHO (2009). A specific alternative to default UFs are chemical-specific adjustment factors for substances when sufficient toxicokinetic and toxicodynamic data allow differentiation of sources of uncertainty

such that each of the two factors of 10 is subdivided into a product of two subfactors, one for toxicokinetics and another for toxicodynamics. Defaults were 4.0 and 2.5 for the interspecies differences and 3.2 each for human inter-individual differences for toxicokinetics and toxicodynamics, respectively (Edler et al. 2002). Deviations from those defaults depend on quantity and quality of relevant data. Deviation from the two default TD factors 2.5 and 3.2 can be based on the outcome of TDMs where the factor may reduce or enlarged depending on available data.

## Abstract

Toxicokinetics describes by means of mathematical functions the time- and dose-dependent processes of absorption, distribution, and elimination of a chemical substance and metabolites thereof in animals and humans. For this purpose, classical compartment open models and physiologically based toxicokinetic models are used. Both are applied to fit concentration-time data and to predict concentration-time courses of a parent chemical and metabolites usually in blood or plasma for repeated or continuous exposures; the latter models enable additionally to predict such time courses in various tissues and organs. An introduction is given into toxicokinetic modeling exemplified by two classical compartment open models and a physiologically based toxicokinetic model.

## Introduction

Pharmacokinetics and toxicokinetics deal with the mathematical description of absorption, distribution, and elimination of chemicals in animals and humans. Pharmacokinetics focuses preferably on low doses of drugs, and toxicokinetics on both low and high doses at toxicologically relevant levels (Welling 1995). However, there is no strict separation between pharmacokinetics and toxicokinetics in the literature.

Already in 1847, A. Buchanan did some pharmacokinetic calculations on inhalation and exhalation of vaporous diethyl ether. In 1913, L. Michaelis and M. Menten published an equation that described the saturation kinetics of sucrose-invertase activity. This equation is often used in toxicokinetic modeling of enzyme-mediated processes. The origins of pharmacokinetics are generally attributed to the work of E. Widmark and J. Tandberg, who in 1924 described concentration-time courses of “indifferent” narcotics in plasma by means of a one-compartment open model, and to the development of the first physiologically based pharmacokinetic model (PBPK model, also called physiological pharmacokinetic model) published in two papers in 1937 by T. Teorell. In contrast to “classical” compartment open models, PBPK models require physiological and anatomical as well as chemical-specific physicochemical and biochemical data. Since the early 70s of the last century, the development of PBPK models increased continuously with the advances in analytical technologies and in computer software allowing to solve the numerous differential equations that describe these models. Toxicokinetics originated in 1976–1977, when P.J. Gehring and coworkers reported the essential relevance of “pharmacokinetics” in evaluating the results of chronic toxicity/carcinogenicity studies in laboratory animals (Gehring et al. 1976; Watanabe et al. 1977). Physiologically based toxicokinetic (PBTk) models (also named PBT models or physiological toxicokinetic (PT) models) are particularly suitable for such purposes. In the following, the relevance of toxicokinetics for quantitative risk assessment will be shortly elucidated, and the principles of toxicokinetic modeling will be shown on two classical compartment open models and a PBTk model.

---

## The Relevance of Toxicokinetics

Toxicology studies of chemicals in laboratory animals are generally conducted using high doses in order to obtain statistically significant adverse or carcinogenic effects. Often, such an effect is not caused by the chemical itself but by a metabolite. Because the fate of a chemical and its metabolites in the exposed organism is usually characterized by saturable processes, a meaningful extrapolation of the dose-effect relationship to low doses, relevant for human exposure, requires knowledge of the relationship between the external dose (administered amount and exposure concentration, respectively, of the chemical) and the resulting internal dose (body and tissue burdens) of the biologically active toxicant (parent chemical, a metabolite, or both) in laboratory animals and humans. It is obtained by means of toxicokinetic studies. This is why accurate information on chemical-specific toxicokinetics is of utmost

importance for the quantitative assessment of the dose-dependent human health risk arising from the exposure to a chemical when it is based on the results of animal studies. Quantitative risk assessment for a chemical (e.g., the probability of developing cancer for a given scenario of exposure) is generally carried out by national and international agencies responsible for regulating health and safety.

---

## Toxicokinetic Modeling

Toxicokinetics describes by means of mathematical functions the time- and dose-dependent processes of absorption, distribution, and elimination via metabolism and excretion (ADME) of a chemical and of the biologically active toxicant in animals and humans. The required toxicokinetic data are generated in animal studies and, if ethically acceptable, in low dose exposed humans by recording, at diverse doses of the chemical, the resulting concentration-time courses of the chemical and of the toxicant in body fluids and, if a gaseous chemical is dealt with, in the inhaled and exhaled air.

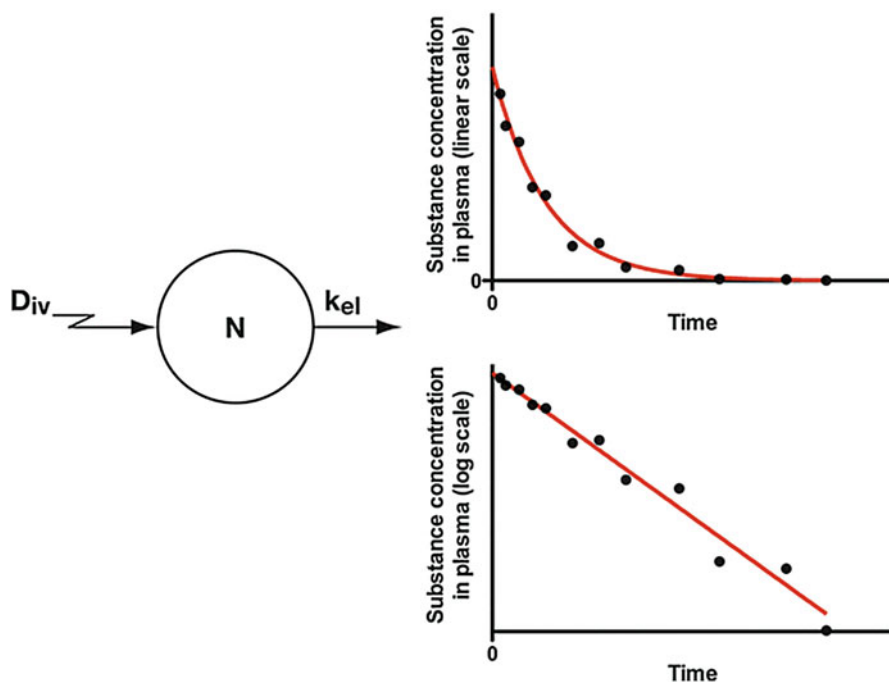

In order to gain species specifically enzyme-related kinetic parameters, dose-dependent concentration-time courses of the chemical and of the toxicant, respectively, are determined in perfused organs, and in an incubation medium, respectively, containing suitable biological material, such as cellular, microsomal, or cytosolic suspensions.

The ADME characteristic parameters are then obtained from fits of a toxicokinetic model to *in vivo* data or from predictions made by a toxicokinetic model that uses *in vitro* data. The most frequently used toxicokinetic models are compartment models. A compartment is defined by its volume. It is well-stirred, which means that the chemical within it is uniformly distributed. The compartments of both classical and PBTK models are open because the chemical enters (input) and leaves (output) them.

---

## Classical Compartment Open Models

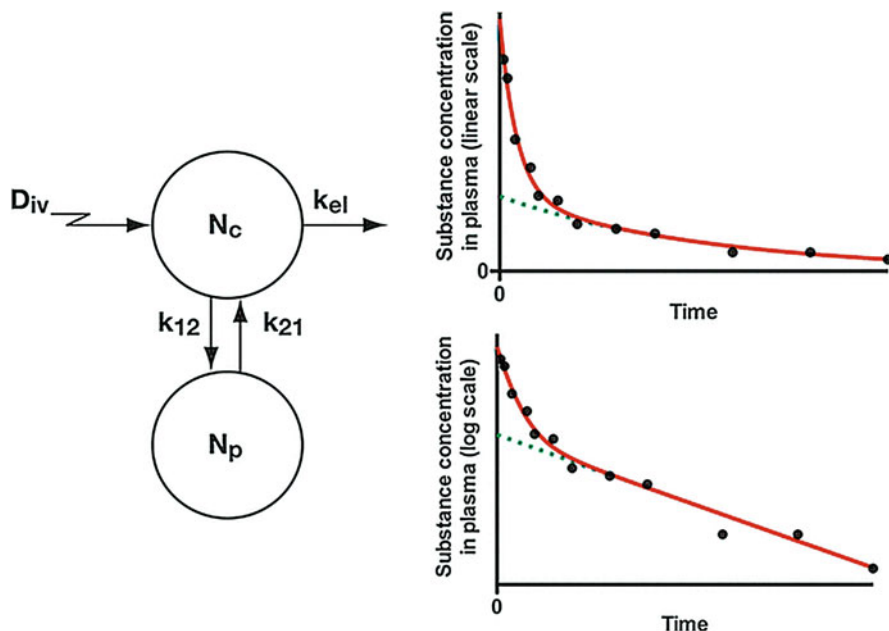

Classical compartment open models generally consist of not more than three compartments. The models are data-based: measured concentration-time courses of a chemical in plasma or blood define the number of the compartments to be chosen. For instance, if the distribution of a chemical in the organism occurs too fast for experimental measurement (instant homogenous distribution within the whole organism), a one-compartment open model will be chosen (Fig. 1). If the distribution processes can be observed experimentally, a two- or even a three-compartment open model might be required to fit the data adequately. In most cases, it is sufficient to use a two-compartment open model (Fig. 2). The first compartment, called central compartment, summarizes those organs and tissues that are rapidly perfused (e.g., blood, spleen, heart, brain, kidneys, liver). The chemical concentrations in them are considered to be always in equilibrium with the chemical concentration in the circulating blood. The second, “peripheral”, and the third, “deep”, compartment combine the slowly perfused tissues (e.g., muscles, adipose tissue, skin). They

**Fig. 1** One-compartment open model for a single intravenous injection of a low dose of a chemical substance that distributes too fast to be experimentally observed, and curve fitted to the measured concentration-time course of the substance in plasma (plotted linearly and semi-logarithmically). Symbols and abbreviations: filled circles, measured data; lines, fitted first-order decay curves;  $D_{iv}$ , intravenously administered amount of a substance (dose) at time point zero;  $k_{el}$ , first-order elimination rate constant;  $N$ , amount of substance at any time point in the compartment. The fitted concentration-time curve is given by  $y = y_{(0)} \cdot e^{-k_{el} \cdot t}$ . The substance concentration at any time point  $t$  is given as  $y$  and at  $t = 0$  as  $y_{(0)}$ . The slope of the linear curve in the semi-logarithmic plot represents  $k_{el}$ .

require certain periods of time until reaching a kind of distribution equilibrium with the concentration in blood or plasma. The volume of distribution is defined as the ratio of the actual amount of the chemical in the whole organism (except that in the bladder and in the gastrointestinal tract) to its actual concentration in blood and plasma, respectively. Generally, the volume of distribution represents not a physiological space but a fictitious one. Therefore, it is also known as apparent volume of distribution. It is the constant compartment volume in the one-compartment open model. In the two- or three-compartment open models, however, it increases until the end of the distribution phase (see Fig. 2).

At low chemical concentrations, the rates of elimination of a chemical follow first-order kinetics, and the concentration-time course of the chemical in the central compartment is given by an explicit function (see legends to Figs. 1 and 2). By using the rate constants ( $k_{el}$ ,  $k_{12}$ ,  $k_{21}$ ; see Figs. 1 and 2) determined after single intravenous administration of the chemical, predictions of its concentration-time course in

**Fig. 2** Two-compartment open model for a single intravenous injection of a low dose of a chemical substance that distributes from the central into the peripheral compartment, and curve fitted to the measured concentration-time course of the substance in plasma (plotted linearly and semi-logarithmically). Symbols and abbreviations: filled circles, measured data; lines, fitted curves;  $D_{iv}$ , intravenously administered dose at time point zero;  $k_{el}$ , first-order elimination rate constant;  $k_{12}$  and  $k_{21}$ , first-order rate constants of substance transport from the central compartment to the peripheral compartment and vice versa, respectively;  $N_c$  and  $N_p$ , amounts of substance at any time point in the central and the peripheral compartment, respectively. The fitted concentration-time curve is given by a function that is composed of two exponential terms:  $y = A \cdot e^{-\alpha \cdot t} + B \cdot e^{-\beta \cdot t}$ . The substance concentration in plasma (the central compartment) at any time point  $t$  is given as  $y$ . The green dotted lines showing the second exponential term of the fitted function have the y-axis intercept  $B$ . The constant  $A$  is the difference between the initial concentration in the central compartment  $y(0)$  and  $B$ . The constants  $\alpha$  and  $\beta$  consist of the rate constants  $k_{12}$ ,  $k_{21}$ , and  $k_{el}$ . The distribution phase is reflected by the first part of the red curve until it meets the green dotted one

blood and plasma, respectively, can be done for repeated or continuous intravenous administrations. With increasing concentration of the chemical, saturation kinetics (e.g., according to Michaelis and Menten) will become evident. Under such conditions, no explicit solution exists for the mass balance differential equations describing the rates of change in the amount of the chemical in each compartment (not shown). A numerical solution has to be used for this purpose.

The disadvantages of the classical models for toxicokinetic issues are evident. No information can be obtained on the target tissue burden of the toxicant. Also, an extrapolation of toxicokinetic parameters between different mammalian species including human (interspecies scaling) is highly problematic because the kinetic information gained by such models has no biological or physiological meaning. These shortcomings are drastically reduced when using PBTK models.

### Physiologically Based Toxicokinetic (PBTK) Models

In PBTK models, the compartments correspond to organs, tissues, or lumped groups of tissues with actual, well-defined species- and body weight-specific anatomical volumes. The processes of input and output are driven by the physiological organ- or tissue-specific blood flows and depend on physicochemical parameters (e.g., tissue-to-blood partition coefficients) and additionally on biochemical parameters in metabolizing organs (e.g., a chemical- and organ-specific maximum metabolic rate  $V_{max}$  together with the corresponding apparent Michaelis constant  $K_{map}$  that is related to the whole organ). Figure 3 shows a flow diagram of a PBTK model for inhalation exposure of a mammal to a gaseous lipophilic chemical that is metabolized in the liver to an amphiphilic, non-volatile metabolite, which is eliminated by metabolism

$$(g) \quad \frac{dc_{mL}}{dt} \cdot V_L = Q_L \cdot \left( c_{mart} - \frac{c_{mL}}{P_{mLB}} \right) - \frac{V_{mmax} \cdot c_{mL}}{K_{mmap} + c_{mL}} + \frac{V_{max} \cdot c_L}{K_{map} + c_L}$$

Fig. 3 (continued)

in the liver and by first-order excretion in the kidneys. The organism is subdivided into several compartments representing those organs and tissues that are relevant to describe the fate of the chemical and its metabolite. The lung, adipose tissue, liver, and kidneys are represented by their own compartments. The compartment “richly perfused organs” primarily summarizes the brain, spleen, heart, and intestines; the compartment “moderately perfused tissues” mainly represents the muscle and skin. The scarcely perfused bones and cartilage are not taken into account. The model is flow- or perfusion-limited. This means that the rate at which the chemical is transported away from a tissue compartment is limited by the blood flow through it and that the concentration of the chemical in the compartment is in equilibrium with that in the blood leaving it. The mass balance differential equations that describe compartment specifically the rates of change in the quantity of the chemical and its metabolite, respectively, were solved by means of a matching computer software (Berkeley Madonna); tissue-characteristic concentration-time curves of the inhaled chemical and its metabolite were predicted for a short-term exposure during which steady state (the situation in which input and output rates are equal) is not reached yet (Fig. 4).

Many PBTK models for inhalation exposure to gaseous chemicals are more complex, e.g., the model of Filser and Klein (2018), which simulates inhalation exposures of mice, rats, and humans to ethylene, the largest production volume organic chemical worldwide, or to ethylene oxide, a mutagenic and carcinogenic epoxide, which is also of high industrial relevance. The model consists of the compartments lung, richly perfused tissues, kidneys, muscle, adipose tissue, arterial blood, venous blood, and liver. In the liver, ethylene is metabolized to the

**Fig. 3** Physiologically based toxicokinetic model for inhalation exposure of a mammal to a gaseous lipophilic chemical substance that is metabolized in the liver to an amphiphilic, non-volatile metabolite (marked by the suffix “m”) which in turn is excreted via the kidneys and metabolically eliminated in the liver. Also shown are the equations that describe uptake and elimination processes in each of the physiological compartments. Steady-state equations: concentrations of the substance or of the metabolite (a) in oxygen-poor “venous” blood and (b) in oxygen-rich “arterial” blood. Mass balance differential equations for: (c) the richly-perfused organs, (d) the kidneys, (e) the moderately perfused tissues, (f) the adipose tissue, and (g) the liver. Symbols:  $c_{air}$ , concentration of the substance in the air at time  $t$ ;  $c_{art}$  ( $c_{mart}$ ),  $c_{ven}$  ( $c_{mven}$ ), concentrations of the substance (the metabolite) in the arterial blood leaving the lung and in the venous blood entering the lung at time  $t$ ;  $c_R$  ( $c_{mR}$ ),  $c_K$  ( $c_{mK}$ ),  $c_M$  ( $c_{mM}$ ),  $c_A$  ( $c_{mA}$ ),  $c_L$  ( $c_{mL}$ ), concentrations of the substance (the metabolite) in the richly perfused organs, kidneys, moderately perfused tissues, adipose tissue, and liver at time  $t$ ;  $K_{mapp}$  ( $K_{mmapp}$ ), apparent Michaelis constants for the concentration of the substance (the metabolite) in the liver;  $V_{max}$  ( $V_{mmax}$ ), maximum rate of metabolic elimination of the substance (the metabolite) in the liver;  $\lambda$ , substance-specific partition coefficient blood/air;  $k_{me1}$ , first-order rate constant of urinary metabolite excretion from kidneys;  $P_{RB}$  ( $P_{mRB}$ ),  $P_{KB}$  ( $P_{mKB}$ ),  $P_{MB}$  ( $P_{mMB}$ ),  $P_{AB}$  ( $P_{mAB}$ ),  $P_{LB}$  ( $P_{mLB}$ ), substance-specific (metabolite-specific) partition coefficients richly perfused organs/blood, kidney/blood, moderately perfused tissues/blood, adipose tissue/blood, and liver/blood;  $Q_{alv}$ , alveolar ventilation;  $Q_{card}$ , cardiac output (equals the blood flow through the lung);  $Q_R$ ,  $Q_K$ ,  $Q_M$ ,  $Q_A$ ,  $Q_L$ , blood flows through the richly perfused organs, the kidneys, the moderately perfused tissues, the adipose tissue, and the liver;  $V_R$ ,  $V_K$ ,  $V_M$ ,  $V_A$ ,  $V_L$ , volumes of richly perfused organs, kidneys, moderately perfused tissues, and liver

**Fig. 4** Predicted concentration-time curves of an inhaled lipophilic gaseous chemical substance and its amphiphilic, non-volatile metabolite in selected tissues of a mammalian organism, generated by means of the physiologically based toxicokinetic model described in Fig. 3. The exposure duration is modeled to be too short to reach steady state. During exposure, the substance is first distributed in the richly perfused organs. The accumulation in the poorly perfused adipose tissue takes place more slowly and is still continuing when the substance concentrations in the blood, liver, and richly perfused organs are already declining due to the end of exposure. The metabolite picture is similar, with the exception that the concentration of the metabolite is high in the liver, the organ in which it is formed. Most of the metabolite peaks are reached after the end of exposure, the latest one in the adipose tissue. The final decreases of substance and metabolite concentrations in the adipose tissue are not shown

biologically active toxicant ethylene oxide by cytochrome P450 2E1, and ethylene oxide is hydrolyzed by epoxide hydrolase to ethylene glycol. In various tissue compartments, including the liver, ethylene oxide is also spontaneously hydrolyzed or is conjugated with glutathione, either spontaneously, or mediated by glutathione S-transferase. For validation of the model, simulated concentration-time courses of ethylene or ethylene oxide in inhaled or exhaled air, and of ethylene oxide in blood as well as predicted levels of ethylene oxide-induced 2-hydroxyethyl adducts in hemoglobin and DNA, were compared with experimental data. The publication contains all the differential equations that describe the model.

PBTK models have the advantage over classical compartment models that they permit knowledge of the fate of a chemical and the biologically active toxicant, respectively, not only in blood or plasma but also in the target tissue of toxicity and in other tissues. They are useful for interspecies scaling of the toxicokinetic parameters of a chemical because sufficient species-specific anatomical and physiological information is usually available. Additionally, the chemical-specific physicochemical and biochemical parameters can be obtained from measurements *in vitro* using animal and human tissues. This is why the use of such models for risk assessment purposes is continuously growing. However, it has to be stressed that interspecies scaling easily results in erroneous predictions on the blood and tissue burdens of metabolites. Model predictions should always be treated with caution as long as they are not validated by a comparison of predicted data with species-specific experimental *in vivo* data.

## Abstract

Exposure assessment represents, besides hazard identification, the second pillar that is needed for risk characterization. Exposure assessment attempts to quantify human exposures to potentially toxic substances by considering the relevant parameters: source, amount, site/place, frequency/duration, pathway/route, and

human activity. The external exposure of the pulmonary, dermal, or gastrointestinal surfaces will – when absorption takes place – result in respective internal exposure of the organism. Exposure scenarios use the best available parameter information and apply it to a specific problem, e.g., an increased indoor air concentration of a solvent, to estimate the potential risk for different populations, such as children or aged people, taking behavior and anthropometric data into account. Deterministic and probabilistic models for quantitative exposure estimates are in use. Variability and uncertainty should be taken into account. The basics of this methodology and regulatory aspects are described in this contribution.

## Introduction

Exposure is defined as the

concentration or the amount of a particular agent that reaches a target organism, system, or (sub)population in a specific frequency for a defined duration. (WHO/IPCS 2004)

Exposure can be understood as dose estimation, by the oral, dermal, or inhalation route and is normally characterized by means of exposure scenarios. The information from the exposure scenario is needed for building up an exposure model. Exposure models can be understood as a translation of an exposure scenario to a mathematical algorithm to yield a qualitative and a quantitative estimate of exposure.

Exposure assessment is based on three basic elements: (i) the exposure scenario, (ii) the exposure model, and (iii) the exposure parameters<sup>1</sup> (WHO/IPCS 2005). The basic characterization of the exposure is made by the exposure scenario (ES). The ES describes the circumstances of exposure, covering all situations and corresponding information needed to perform an exposure estimate. The WHO (2004) defines the term exposure scenario as

a combination of facts, assumptions, and interferences that define a discrete situation where potential exposures may occur. These may include the source, the exposed population, the time frame of exposure, microenvironment(s), and the activities. Scenarios are often created to aid exposure assessors in estimating exposure.

This definition should be used as a basic concept for exposure estimation.

Since 2006, an additional definition of exposure scenario must be taken into consideration regarding to the European Chemicals Regulation (REACH; European Commission 2006). In the regulation, the exposure scenario is defined as

...the set of conditions that describe how the substance is manufactured or used during its life-cycle and how the manufacturer or importer controls, or recommends others to control, exposures of humans and the environment.

This definition is basically not different to the above one, but its focus is the characterization of the measures to control the exposure and the measures to reduce it, where needed.

This chapter is explaining the exposure scenario on the basis of the WHO definition, with hints of the particularities of the REACH regulation.

Similar to drug treatment, an exposure estimate can be understood as the dose of a contaminant or hazardous substance that can be taken in by an individual or a population.

## Structure of Exposure Scenarios

Exposure scenarios describe the complex characteristics of the external exposure from any substance that can be released from a variety of sources, e.g., the environment, consumer products, food, and other sources. The resulting external “dose” will be systemically absorbed and results in the toxicologically relevant “internal” exposure. The characterization of the exposure scenario describing external exposure should be divided into several parts to be combined with each other yielding the complete scenario. The different elements of an exposure scenario are broadly characterized in Heinemeyer (2019a) as shown in Fig. 1.

In the REACH regulation (European Commission 2006), the scenario contains basically the same information. However, its focus is on the information which measures are considered by the producer of the product to control the exposure to an extent that will not exceed the derived no-effect level (DNEL). If, for example, in an

Source	<ul style="list-style-type: none"> <li>Chemical product, food, cosmetic, toy, furniture, cloth</li> </ul>
Amount	<ul style="list-style-type: none"> <li>The amount or concentration of an agent in the product. Includes recommendations for use by the manufacturer</li> </ul>
Site/Place	<ul style="list-style-type: none"> <li>The place where the product is used or consumed (e.g. at home, public place etc.)</li> </ul>
Frequency/Duration	<ul style="list-style-type: none"> <li>Time budgets, characterisation how often, how regular and how long a product is used or consumed</li> </ul>
Pathway	<ul style="list-style-type: none"> <li>The transfer of the agent from the source to the target</li> </ul>
Route	<ul style="list-style-type: none"> <li>Oral intake, dermal absorption or inhalation</li> </ul>
Activity/Behaviour	<ul style="list-style-type: none"> <li>Description of the use, due to habits and behaviors of the exposed population and its further characteristics e.g. age, gender etc.</li> </ul>

**Fig. 1** Elements of an exposure scenario

exposure calculation, the DNEL is exceeded, the registrant<sup>1</sup> must implement measures to reduce the exposure by risk management measures (Bruinen de Bruin et al. 2007). Examples for RMM are reduction of the concentration of a substance in a product, hindrance of migration of a substance from an article, or release reduction by special dispensers. Non-exceedance of the DNEL indicates that a product is safe.

A scenario can be characterized by three parts (subscenarios). There may be an overlap of the above-shown elements of the scenario.

*The first part of the exposure scenario describes the source of the substance of interest. This source may be a chemical product, food or any other products used by consumers or workers. Water, air, and soil may also serve as source. This sub-scenario covers information about the amount of an agent in that source that will be potentially released. The kind of the source also determines frequency and the duration of the release.*

**Example**

A certain household cleaner (source) containing a substance in a particular concentration will be applied to a bigger area (e.g., the ground of a room) and released during and after application.

*The second part of the exposure scenario describes the release and transfer from the source (pathway of exposure) and its contact and with the exposed person and the following intake/absorption (route of exposure).*

**Example**

The substance, due to its vapor pressure and molecular weight, will be released and evaporated to room air to yield a certain concentration. The concentration will increase and continue over time and can be inhaled by persons in that room. Due to air exchange, the concentrations in room air will decrease. Substances having low volatility will be distributed mostly via the house dust path.

*The third part of the exposure scenario describes the use, due to habits and behaviors of the exposed individual or population. This includes the information about activities of people using that products. The frequency and duration of the actual use (working with a product, eating food, etc.) is considered. The information is often scarce and thus is mostly characterized by default values.*

---

<sup>1</sup>Registrant: The company that prepares the chemical safety report for notification to ECHA (European Chemicals Agency)

**Example 1**

The exposed person stays in that room for a certain time and will inhale the air. The time an exposed person is spending in a room may account for, e.g., 4 h.

**Example 2**

An individual or a population eats a combination of food over a certain time period and with different frequencies.

**Characterization of the Source and the Use of the Substance in a Product**

This subscenario is used to characterize the source of the substance and the amount that is potentially released during the use of the product. The limitations of these processes are determined by the product itself that contains the substance, its physicochemical properties, its concentration, and the mode of use.

**Categories of Use**

A substance may appear as an ingredient in many different products and product types (Heinemeyer and Hahn 2005). An approach that characterizes product use categories can therefore be very helpful to identify the sources of substances. Product categories have been used on the national and international level. Some of the documents became “official” due to their use in technical guidance documents (ECHA 2010) or from use and recommendations by international agencies (EFSA 2009) and organizations (WHO 2005). Therefore, they have some standardizing character, although the details are differing. Major importance is due to the guidance documents and classifications used in international databases, such as the *industrial categories* and *product and article categories* described in the ECHA guidance R12 *use descriptor system* (ECHA 2010) (Table 1).

The impact of classification of products has recently been described by Heiland (2019). Also, poison centers around the world are using product use classification systems for documentation of cases and to prepare annual reports. In most of the classification systems, a differentiation is made according to the use of the products, e.g., paints, household cleaners, pesticides, cosmetics, and others. Due to these documentations, it can be checked how close exposure scenarios are close to reality (Heinemeyer and Hahn 2005). The identification of use of a substance and the description of manufacturing and the use process is an important part in defining exposure scenarios under REACH (van Engelen et al. 2007; Heinemeyer 2008).

The development of classification systems available for foods is more advanced than those for other products mentioned above. Food classification was developed since longer times for systematic characterization and for nutrition evaluation, e.g.,

for food consumption surveys. The data are also used for exposure assessments. In the EU, the European Food Safety Agency (EFSA) has introduced a harmonized food classification characterization in its *Comprehensive Food Consumption Database* (EFSA 2012), which comprises data on food consumption from nearly all EU member states. In Germany, the *Bundeslebensmittelschlüssel* (BVL 2012a; Max-Rubner-Institut 2012b) is used to classify food. The Max-Rubner Institute is responsible to maintain this classification system up to date which is close to the *LanguaL* (Møller and Ireland 2010). The latter combines a fixed three-level thesaurus with relational and dynamic tables, so-called facets. Product/use categories can be transferred and expressed as subscenarios on different levels of aggregation to apply a standardized approach (use model) with respective exposure (model) parameters. Food classification is also extensively described by Fabiansson (2019).

---

## Release, Distribution, and Disappearance

As in pharmacokinetics, this part of the exposure scenario describes the appearance, distribution, and disappearance of a substance in an environment. This subscenario regards mainly for exposures via the air and inhalation. It includes:

1. The description of the concentration of the substance (as described above) in the product and its release, by migration, evaporation, or emission.
2. The distribution of the substance in the surrounding environment to which emission occurs, either bound to particles, e.g., house dust, or in the gas phase.
3. The disappearance of the substance from the environment.

Source, (micro)environment, and substance characteristics are limiting the release of the substance. In combination with the use, the route of exposure will be oral, dermal, or by inhalation. In some exposure scenarios, source, pathway and route are characterized by one process, e.g., exposure via food consumption.

## Exposure by Inhalation

The scenario characterizing the exposure by inhalation normally describes the concentration – time course of a volatile substance in the indoor air, either in one or multiple rooms. The concentration can be used for comparison with toxic concentrations.

It is recommended to use the concentration in air to estimate the uptake of a substance via the lungs to the systemic circulation by using the inhaled air volume and an absorption factor. Internal exposure evaluation enables risk assessors to

estimate total body burden, e.g., in children or other particular populations. To perform these estimates, the respiratory volumes per time and pulmonary absorption rates are needed.

In addition to inhalation of substances in the gas phase, the inhalation of small particles should be also taken into account. Dust is a vehicle for nonvolatile substances that can be adsorbed and desorbed from the particles, absorbed through the alveolus, and thus enter the human body.

Exposure parameters needed to estimate exposure from inhalation

- Concentration of the substance in room air
- Concentration of the substance associated with fine dust particles
- Migration rates (release rate per time)
- Vapor pressure
- Molecular mass
- Density
- Product amount used in the application
- Concentration of the substance in the product
- Duration of the application
- Room volume
- Air exchange rate
- Inhalation volume per time
- Absorption factor

## Typical Scenarios of Inhalation Exposure

### 1. Use of volatile substance, e.g., solvents in paints, laquers, or cleaners

A certain amount of a product (e.g., a paint or cleaner) will be applied to a surface. A volatile substance will be evaporated and produces indoor room concentrations. The substance distributes in the room and disappears after some time, according to the air exchange rate. This type of scenario has been considered, e.g., in the computer tool ConsExpo (RIVM 2017) and the wall paint emission model published by the US EPA (2001).

### 2. Emission from solid bodies

A constant amount will be evaporated over a longer time period from, e.g., furniture and textiles. This may lead to constant (steady state) concentrations of the substance in indoor air. The extent of this concentration depends on the air exchange rate, temperature, and other factors, e.g., whether the substance can be adsorbed to particles. This scenario may be applicable for exposures from inhalation due to solvent contaminated residual wastes.

### 3. Inhalation of dust

Dust inhalation represents a special form of exposure by inhalation. By this pathway, inhalable fine particles from the microenvironment that can adsorb substances enter the lungs and alveolus. After desorption from the particles, the substance can be absorbed to the systemic circulation. Sometimes, they can remain in the alveolar cells and lead to local effects, as particles as well. The concentrations in the dust cannot be estimated and have to be measured.

The example shown below represents an estimation of exposure for a child (bodyweight (BW) 8.10 kg). This estimate is characterized by its conservatism, taking low body weight (fifth percentile), a respiratory volume (RV) that considers (partly) activity *and* rest, as well a maximal contact time (CT) and a high pulmonary absorption rate (RPA; 100%). This approach is often called “worst case.”

#### Example: Conservative Estimation of Exposure by Inhalation

- Concentration in room air (estimated or measured, C) –  $10 \mu\text{g}/\text{m}^3$
- Body weight (BW) – 8.1 kg
- Respiratory volume per time (RV) –  $2.9 \text{ m}^3/\text{day}$
- Contact time (TC) – 1 day
- Pulmonal absorption rate (RPA) – 1
- Inhalation exposure (absorbed amount)  $[C*RV*RPA*TC/BW] - 3.5 \mu\text{g}/\text{kg}/\text{day}$

---

## Dermal Route of Exposure

The dermal exposure estimation characterizes the amount of a substance which is on the skin and can be absorbed through the skin.

### Typical Scenarios of Dermal Exposure

#### 1. Use of cosmetic products

A product will be applied to skin; one or more substances in the product can be absorbed through the skin. In dermal exposure assessment, products that can remain on skin (nonrinse) will be differentiated from those that will be removed by washing (rinse off).

## 2. Use of household cleaners

The hands will be shortly put into the water that contains the washing product. Substances in that diluted product can be adsorbed to and remain on skin and may be dermally absorbed. When taking a bath, the whole body surface will be exposed.

## 3. Dermal exposure via air

Volatile substances in the air can come into contact with the skin and are dermally absorbed. Normally, the extent of this exposure is small.

## 4. Wearing textiles and contact with leisure and hobby products

Direct contact of substances from textiles or leisure and hobby products with the skin is possible by migration to the skin. The exposure surface is the part of skin that is covered by the textile or contacting the leisure and hobby product.

## 5. Contact with pets

Ingredients from, e.g., pesticides used for domestic animals to treat against pest may lead to dermal contact when touching pets. Children may have oral exposure after licking hands (mouthing behavior) after touching the animals.

A basic rule for estimating dermal exposure has been described in the EU technical guidance document for existing chemicals and has been taken over by ECETOC (2005) as well as in the ECHA technical guidance documents (2015, 2016a, 2016b). The *amount* (AM) that can lead to exposure can be estimated from the *area* (A) of exposure times an estimated *thickness of the layer* (TL) of 0.01 cm (default value) and from the *concentration* (C) of the substance in the *product* ( $AM = A * TL * C$ ). In some documents, additional *absorption rates* given as percentages are used. However, it must be considered that dermal absorption is a time-dependent process. Taking percentages as rates can lead to errors and should only be applied as a default assumption, e.g., a conservative concept assuming 100% of absorption through the skin. For short contact times (e.g., shortly applied cosmetics), correction factors have been introduced that reduces the absorption rate. In general, values from 1 – (10) – 50% are used as default assumptions, with different justifications, depending on the purpose of the evaluation. For some substances, absorption constants and coefficients have been derived, due to lipid solubility (octanol/water coefficient) and molecular weight. Respective models have been established by Wilschut et al. (1995) and have been integrated into the ConsExpo tool (RIVM 2017).

Exposure parameters needed to estimate dermal exposure.

- Exposed skin area (e.g., 840 cm<sup>2</sup> for hands)
- (Theoretical) thickness of layer (0.01 cm; mixtures; 0.001: articles)
- Concentration of substance in the product
- Migration rates of the substance (measured)
- Absorption coefficient (derived by model evaluation), alternative: absorption rates (conservative estimates, percentages)

## Oral Route of Exposure

Oral exposure characterizes the oral intake of a substance by mouth and the amount that is absorbed in the gastrointestinal tract. Oral intake is possible with food, drinking water, house dust, the mouthing behavior, and some personal care products (e.g., tooth paste). House dust and related paths are particularly important in small children. In general oral exposure estimation requires knowledge of the concentration of the substance in and the amount of the medium that is taken in.

### Typical Scenarios

#### 1. Intake of food and drinking water

A number of different sources have to be distinguished to estimate the dietary exposure to contaminants in the food chain, pesticide residues, food additives, process contaminants, substances in food packaging, and bacterial toxins and metabolic products. Process contaminants, e.g., acrylamide or MCPD, (3-Chlor-1,2-propandiol) can be formed during heating of foods.

Dietary exposure estimation is normally performed by multiplying concentration data in the food and the respective food consumption data and correction factors, e.g., for storage and preparation. Concentrations in food can be obtained from, e.g., market control measurements. However, as these data are risk oriented, there is a reason for expecting high concentrations. Systematic and representative evaluations of concentrations in food are more adequate to study dietary exposure in a population. Such data are available from, e.g., the German food monitoring system (BVL 2012). The European Food Safety Agency is establishing a system to regularly collect data of concentrations of substances in food, collected from the member states (EFSA 2011). Due to the immense number of samples needed to describe concentrations in food, approaches have been developed to reduce numbers of sample by, e.g., pooling, for example, by the concept of total diet study (TDS; Blume and Lindtner 2019).

The identification of food consumption data normally is performed by means of questionnaire studies. On the national levels, food consumption surveys have been performed in many countries, for example, the “Nationale Verzehrsstudie II” (Max-Rubner-Institut 2012a) in Germany. There are several methodological approaches by which consumption studies can be performed (24-h recall, dietary history, food frequency study, diary studies, with and without weighing the food) (Straßburg 2019). It should be mentioned that these study types have advantages and disadvantages for the particular questions asked in risk assessment, e.g., acute or chronic hazards (Lindtner and Heinemeyer 2019).

To perform food consumption studies, foods will be characterized by a food basket that contains a significant part (normally >90%) of all foods eaten. The particular foods should be classified by a systematic food group classification system (see respective chapter).

Food exposure estimation is in general performed for the general population and normal food consumers (eaters), by taking concentration and consumption data describing a central tendency (means and medians). To describe high consumers, EFSA (2008) has proposed to identify those foods that have the highest contribution to exposure and exchange the means by 95th percentiles in the estimation equation.

## 2. Ingestion of substances via the house dust and soil path

House dust and soil represent an important vehicle for nonvolatile substances. House dust consists of particles from several sources, e.g., soil dust, and from pollution. It contains a lot of different materials, e.g., plant pollen, mites, human and animal skin cells (dander), fibers, soil, and vapors. Substances migrate from the different materials (textiles, floor coverings, furniture, etc.) and, after release due to mechanical or thermic influence, adsorb to house dust. Partly, bigger particles may become a part of dust themselves.

The daily intake of house dust is unknown. Extrapolations from soil intake studies are normally used to estimate exposure from house dust intake. The intake of soil has been identified by means of tracer studies, taking substances that are poorly absorbed in the gut and comparing the concentrations measured in the stool with those in the soil. The AUH report (1995) recommends to take an estimate of 16 mg (median) and 110 mg (95th percentile) as standard values for house dust intake. The US EPA (2009) employs 60 mg per day as an estimate for central tendency. The extrapolation of soil to house dust may introduce uncertainties into the assessment; overestimation of exposure by house dust should be assumed. An actual overview about house dust exposure is given by Klenow (2019).

Exposure parameters needed to estimate oral exposure

- Concentrations of the substance in food and drinking water
- Consumption values for the food or drinking water, preferably related to individual body weight
- Weight
- Concentrations of substances in house dust/soil
- Default – values of house dust intake

---

## Behavior of Populations and Individuals

Many exposed people are limiting their exposure by themselves and by their particular behavior. Studying the behavior in certain populations is essential and plays an increasing role in exposure assessment. The instructions of use will as well as the behavior of individuals and populations will influence the variability of the use and consumption of products. Two different types can be distinguished: (i) the active exposure where a person actively uses a product and (ii) the passive exposure where the exposed person is a bystander. In case of inhalation exposure, for example, the major difference between active and passive exposure is that the active person

may be closer to the source of exposure. An older version (3.0) of the ConsExpo tool is using a fictive room volume that is considerably smaller than the room to consider that situation. The indirect exposure via the environment is a particular form of passive exposure. From this perspective, eating food is passive exposure as well as being in a room and inhaling a substance that is released from furniture, while painting that furniture is active exposure.

Active and passive exposure can also be differentiated in terms of the degree of activity having impact for, e.g., exposure by inhalation. For example, the respiratory volume over time can vary from 15 m<sup>3</sup>/day (at rest) up to 100 m<sup>3</sup>/day (heavy work). This may lead to considerable variability in the exposure estimate and thus having impact for the risk characterization. When estimating exposure from inhalation, it is appropriate to assume a well-balanced ratio of activity and resting times.

## Exposure Estimate

The aggregated (external) exposure is estimated from all external sources and via all pathways and routes of exposure.

If several agents are involved in the exposure scenario, the estimation is called cumulated exposure. Cumulated exposure is well characterized, for example, some pesticides or chlorinated dibenzo-dioxins, substance groups having some related toxicological features. Meek et al. (2011) also discuss combined exposures a situation where agents are involved having different toxic actions.

## Time Budgets

As an important element of behavior scenarios, time budgets characterize the contact times of an exposed person. In case of exposure by inhalation, this is the time a person is staying in the room where the exposure takes place. Small children have normally longer contact times as adults because they may stay at home for longer time while adults are at work, outside, or at other business. This will change with school age. It is therefore of great importance to relate the time budgets to age. Data sources for time budget are, e.g., the US-EPA exposure factors handbook, the AUH (1995) report, and the RIVM general factsheet (Bremmer et al. 2006a).

## Particular Age-Related Behaviors

The evaluation of behavior can be used to characterize important differences between adults and children. For example, the ingestion of soil and house dust may account for an important amount of oral exposure in small children. This occurs primarily in the toddlers, by crawling on the ground, as well as in the kindergarten, becoming less importance in the school age. Children frequently put their hand into the mouth, which is called the *mouthing behavior*. The latter has particular importance for exposure from

insecticides after treatment of pets against insects (lice, flies). Migrating substances from toys may also be relevant for mouthing. Therefore, migration rates are very important to estimate exposure. The mouthing time may vary over a big range (Groot et al. 1998; Juberg et al. 2001; Smith and Norris 2003). House dust evaluations represent an essential part of exposure assessment in children.

Exposure parameters needed to characterize a behavior scenario

- Duration of stay
- Frequency of staying
- Air ventilation
- Activities of “daily life”
- Exposure as active user or bystander
- Hand to mouth activities

### **Anthropometric Data**

Exposure estimation needs anthropometric data that characterize the exposed person or population. Estimation of exposure by inhalation needs, according to the exposure scenario and the respective model, data about respiration rates and the lung surface. Dermal exposure evaluation requires information about body surfaces. However, estimation results are normally related to body weight. Relation to body surface is more appropriate, because body surface is correlating better with the extracellular fluid. Many substances distribute into body water, and there is also correlation between body surface and the basic metabolic rate. This is in particular of relevance when comparing results in children and adults.

Most important anthropometric data.

- Body surface and parts of body surface, e.g., hands and arms
- Body height
- Body weight
- Respiration time volume and related to activity
- Lung surface

### **Single-Point-Based (Deterministic) Exposure Assessments**

Exposure factors can be characterized as single numerical values (deterministic approach) or as distributions (probabilistic approach). Therefore, every deterministic value represents a certain value from the distribution. An adequate exposure estimate must take into account all possible sources, pathways and routes which may result in very complex scenarios. The estimation is performed by separated estimations of the particular pathways with subsequent summation. Possible correlations of exposure paths must be considered. Also, summarizing exposure results should only be made for central tendency estimations. Results from individual conservative estimations, e.g., by using 95th percentiles or default values, should not be summarized. Consideration of conservative estimates must be performed very carefully, possibly by

addition of one conservative estimate with other averages. The European Food Safety Agency (EFSA 2008) has proposed to take the 95th percentiles of exposures contributing most to exposure, exchange them with the averages, and sum all up.

In many exposure calculations, arbitrary high values are used, in order to end up with an overestimation, without knowing the real situation. Such approaches are often lacking from reality.

## **Distribution-Based (Probabilistic) Exposure Assessment**

When presenting exposure parameters as distributions, the bounds of that distribution may represent the entire estimation range. It is appropriate to use well characterized distributions and their statistical descriptors as a basis for exposure estimations. A check whether or not the used value can be matched with other representative values is needed. This approach will be facilitated considerably by use of modern computer tools. The total range and variability of the individual distributions will be weighted out and ends up with a distribution as result.

Probabilistic exposure modeling can be used as an alternative that considers the variability and uncertainty of the assessment that can be demonstrated by use of a probabilistic approach (Schümann 2019). Variability is characterizing the natural variation of parameters, while the uncertainty is determined by the lack of knowledge, which is often depending on data quality. For example, the body weight in the population participating in, e.g., the German food consumption study is described mostly by variability, because it is based on a representative sample from the entire population. On the other hand, the basis of data characterizing, e.g., concentrations of substances in products or food is often very poor. Therefore, these data must be considered uncertain.

Probabilistic models are formed by taking a similar general algorithm in the model but characterizing the model variables (parameters) as distributions. If the distributions are appropriately formed, i.e., the data basis is sufficient large and the values are representative for a population, the probabilistic distributions are describing the variability of the parameters. The less the number of data is and their representativeness, the more will distributions represent a mixture of variability and increasing degree of uncertainty.

## **Impact of Exposure Assessment**

Exposure assessment represents, besides hazard identification, the second pillar that is needed for risk characterization. The margin between the quantitative estimate exposure and the N(L)OAEI is characterizing the risk (risk characterization). It is called the margin of exposure (MOE), in earlier times the margin of safety (MOS), but both are meaning the same. The larger the MOS/MOE is, the more can the probability of risk be denied. A concern for risk is assumed if the exposure is exceeding the NOAEI. Risk can also be expressed as a ratio of the exposure dose

and the NOAEL (see resp. chapters in this book). Uncertainty factors are used in this formula to consider uncertainties, e.g., the lack of knowledge of the intraindividual and interindividual variation between animals and humans. Using the approach of tolerable/acceptable daily dose (TDI/ADI) or the acute reference dose (ARfD) the ratio should be lower than 1.

In the REACH regulation, the DNEL will be used instead of the NOAEL (compare the resp. chapter).

For these reasons it is of great importance to estimate the exposure as exact as possible. Estimates taking exposure scenarios and models are having sometimes considerable uncertainties, leading to partly extreme ranges of the exposure estimates which depend on the exactness of the description of the exposure scenario. It is essential to describe the exposure factors as exactly as possible. The approach of using conservative scenarios may lead to overestimations, resulting from rough models or taking defaults or other conservative values as model parameters. Due to the precaution principle, there is an intention to overestimate the exposure; it should, however, not result in unrealistic results. Distribution-based (probabilistic) modeling can be taken as an appropriate alternative because it considers the range of exposure factors and reveals a distribution of exposure. Taking distributions allows to consider extremes that characterize the skewness of a distribution. Ninety-fifth and higher percentiles are therefore appropriate descriptors of conservative assumptions and estimates and thus reflect “reality.”

Measurements can be taken into account for exposure estimations, if they are representative for the population of interest. On the other hand, they are showing a *shot* of a particular event or situation which can hardly be transferred to a general scenario. Measurements available for, e.g., contaminants in food, in house dust, and indoor air should therefore be given attention, but they are not necessarily representative for the scenario of interest. Although there is a lot of data available for some substances, they often lack from representability and thus can be used for risk assessment only with great caution.

## Abstract

Toxicological evaluations are based on the information derived from scientific studies. Understanding the quality of data is crucial for that purpose. Definition of evaluation criteria allows for a transparent and harmonized examination of the quality of toxicological studies.

## Keywords

Toxicological studies · Study quality · Study reliability · Transparency · Evaluation criteria

## Introduction

Using toxicological studies of high quality and reliability for toxicological risk assessment is a prerequisite for reliable and trustworthy results of the assessment process. Current approaches for evaluating the quality and reliability of toxicological studies are presented.

---

## Data and Data Sources

The OECD Test Guidelines and European Council Regulation (EC) 440/2008 for the testing of chemicals (see **Resources**) provide standardized, internationally agreed test method procedures used by government, industry, and independent laboratories to determine the safety/toxicity of chemicals and chemical mixtures, including pesticides and industrial chemicals. Standards of *Good Laboratory Practice* (GLP) set up rules for an adequate conduct of chemical nonclinical safety tests to ensure uniformity, consistency, reliability, reproducibility and contribute to the quality of the experimental procedures and data reporting (Borgert et al. 2016).

However, despite these standardization efforts, a large number of toxicological studies that can be found in the published literature have not been performed according to recent guidelines and/or GLP standards. This holds especially true for older studies and for scientific investigations, often conducted by academic research groups, aimed at answering specific questions.

Studies published in scientific journals (*primary literature*) are one of the main sources of information on toxicological properties of chemical compounds. The peer-review process should in principle implicate high quality standards of the published data. Depending on the regulatory area, nonpublished data from industry study reports constitute another important source of information for toxicological evaluations. Recent industry studies are generally performed according to the current guidelines and under GLP conditions.

*Secondary literature* (scientific reviews, or evaluations and reports from authorities or scientific organizations, which are increasingly available via internet portals such as eChemPortal, see **Resources**) allow for a quick data overview and may help identifying relevant studies. Nevertheless, the final evaluation of a certain substance should be performed on the basis of primary literature and original studies.

---

## Evaluation of the Reliability of Studies

Comprehensive reporting of methodological details and results is a prerequisite for the evaluation of the reliability and thus quality of any toxicological study (Przybylak et al. 2012). Klimisch et al. (1997) proposed a system for categorizing the quality of experimental toxicological and ecotoxicological studies, which is now widely used in several regulatory schemes (e.g., the EU's REACH Regulation). In this system, studies are assigned one of the four categories as presented in Table 1.

**Table 1** Klimisch categories for assessing reliability of toxicological studies

Klimisch category	Explanation
1	Reliable without restriction
2	Reliable with restriction
3	Not reliable
4	Not assignable

In order to conclude on a specific reliability category of published *in vivo* studies, the following criteria concerning the documentation of methodology and presentation of data should be assessed (summarized from Klimisch et al. 1997):

- Information on experimental animals (species, strain, gender, numbers, age)
- Information on the test substance (identity, purity, composition, source)
- Information on route of administration, dosage, and test conditions (e.g., methods for analytical verification of test concentrations)
- Information on performed examinations (endpoints investigated) and description of methods used (including statistical analysis)
- Description of observed effects and lesions
- Corresponding data of control group or historical controls of the laboratory
- Description of dose-response relationship, if applicable.

Nevertheless, the assessment of study reliability is often not straightforward, for example, when effects sizes are small, and may be influenced by subjective views and the experience of the assessor and biased by circumstances. In recent years, the issue of study quality has gained in interest, not at least triggered by the call for evidence-based approaches, such as systematic reviews (Stephens et al. 2016). Samuel et al. (2016) published a comprehensive review on existing guidance for assessing the methodological and reporting quality of toxicological data of various kinds (*in vivo*, *in vitro*, structure-activity relationships, physico-chemical, and human observational studies).

In order to support a harmonized and transparent evaluation of reliability of published *in vivo* and *in vitro* toxicological studies, a tool (“ToxRTool,” see **Resources**) has been developed, which provides more detailed criteria for assigning Klimisch categories, and a way for transparent documentation of this evaluation (Schneider et al. 2009). Since its publication, ToxRTool was used for assessing the quality of toxicological studies for various purposes and topics, especially in the context of performing systematic reviews (e.g., Fewtrell et al. 2017; Nagy et al. 2020).

Science in Risk Assessment and Policy (SciRAP) is another data evaluation tool for toxicological and ecotoxicological studies. SciRAP (see **Resources**) was developed by Molander et al. (2015) and, rather than using a scoring system as in the ToxRTool, the evaluation relies on qualitative responses to the evaluation criteria, visualized by a color system. Recently, SciRAP was further evaluated by external experts and refined (Beronius et al. 2018).

With the advent of omics techniques new types of toxicological data are produced, for which the concept of quality assessment needs to be expanded. Vachon et al. (2018) developed a set of key criteria for such kind of data.

---

## Plausibility of Study Design and Results

Besides reliability, further considerations are necessary to judge on the suitability of a study to be used in a substance safety evaluation. The comprehensive reporting of experimental designs and procedures for data evaluation allows for the examination of the consistency of the observations in relation to following aspects:

- Is the chosen design of the study (e.g., animal strain, cell line, route of administration, methods for statistical evaluation, etc.) appropriate for the question to be answered?
- Are the study results mechanistically plausible?
- Is the interpretation presented by the authors supported by the study results?

---

## Plausibility of Results in Relation to the Overall Knowledge on a Given Substance

A final evaluation of a toxicological study should take into consideration how the presented results are related to the already existing knowledge on this substance. Contradictions between different studies have to be discussed taking into account possible explanations (e.g., differences in study design, animal strains, exposure route, etc.). Only then, a final conclusion on the adequacy of the study results for risk assessment purposes can be drawn. Often consideration of study reliability (as discussed here) is mixed with judging on the relevance or suitability of a study for a specific assessment purpose. Roth and Ciffroy (2016) emphasize the importance of keeping these two aspects separate.

---

## Weighting of Borderline Cases

Toxicological evaluations and subsequent regulatory decisions on a given substance should be based on the entirety of available data, in accordance to the concept of *Evidence-Based Toxicology* (see **Resources**).

In cases where a toxicological study is of impaired quality, the weight or confidence attributed to this study should be determined in the context with other available evidence and the mechanistic plausibility. As an example: Should a study of restricted quality, which points out a much higher effect compared to similar studies be disregarded? This can only be decided on a case-by-case basis in the context the specific regulatory decision framework taking other evidence and potential explanations into account.

A *weight-of-evidence approach* can be used to integrate available information from various sources to draw conclusions. This weighting process requires various experiences, for example, in the evaluation of study quality, in the specific scientific domain, and in risk assessment in general. However, albeit being a quantitative method for combining evidence in support of a hypothesis, it is based on opinions that are influenced by individual expert's knowledge and personal backgrounds, which might lead to divergent decisions (Weed 2005). Therefore, the decision making process with respect to the study evaluation should be presented in a transparent, objective, and systematic manner.

---

## Conclusions

Specified criteria for a formal evaluation of the reliability of toxicological studies have been developed and are well established. A comprehensive evaluation of quality of a primary source and its reliability for safety evaluation focuses on a consistent study design and the comprehensive documentation of methods and results. Furthermore, the internal plausibility of study design (e.g., appropriateness of the study design to address a specific question), as well as the plausibility of observations in view of existing information on the investigated substance should be evaluated to judge on the adequacy of study results for risk assessment. In equivocal cases, it is necessary to assess the weight of a specific study on a case-by-case basis, taking other evidence and potential explanations into account in a weight-of-evidence approach. This process of decision making has to be presented in a transparent and reproducible way.

## Abstract

Literature searches are necessary to find answers to many toxicological issues. Fortunately, today we are no longer reliant on time-consuming searches in reference books, but can make use of the Internet as an important tool for gathering information. A lot of information including complete substance assessments is easily available and free of charge. Because of the large variety of possible data sources, however, literature searches are difficult to undertake and in addition can take a lot of time. Depending on the particular issue of research, different searching strategies should be used.

**Introduction**

In the early 1960s, information on exposures to toxicants and toxins and their adverse effects was still restricted. Those who evaluated such information had to look it up in printed journals and reference books. At the same time, the number of synthetic chemicals increased continuously and there was a need for faster and sorted information for many professions including poison centers, forensic experts, food toxicologists, drug developers, and chemical safety experts in general.

Rapid advances in toxicological knowledge in the 1970s and 1980s were possible due to novel *in vitro* test systems (Ames et al. 1975; Greim et al. 1986), sensitive detection methods in histopathology and chemical analysis, and related developments. The first generation of small scientific calculators for laboratory use became available and personal computers were introduced. Thus it was possible for researchers to systematically collect toxicological information and evaluate laboratory data with statistical methods. This was also the beginning of databases and search systems used in toxicology (Kazyak 1974; Oxman et al. 1976; McGill et al. 1978). These became widely accessible after 1990 (Ludl et al. 1996; Gardner and Spangler 2000; Wexler 2001; Wukovitz 2001; Brinkhuis 2001).

Today huge databases and information systems are available for toxicology in general (see Wexler et al. 2020) and for subtopics like toxicological test guidelines (OECD 2020; ICH 2020) or glossaries like those of IUPAC (International Union of Pure and Applied Chemistry, see Duffus et al. 2017; Templeton et al. 2020). These together provide rapid access to the desired information and constitute an important tool for toxicologists and those involved in toxicological regulation.

---

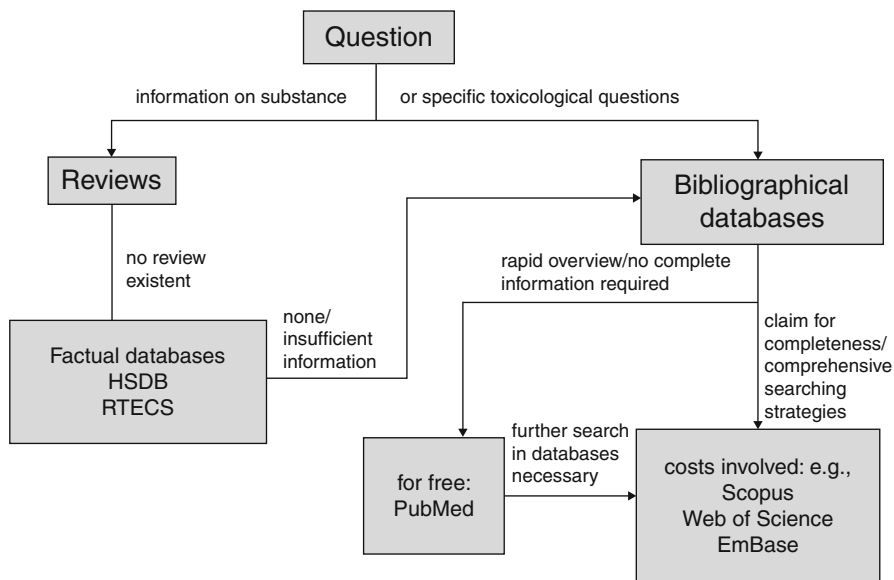

**Overview of Data Search Methods**

Figure 1 gives an overview of different searching methods. The individual steps are described as follows.

---

**Using Online Search Engines**

The easiest way of performing a data search is searching in the Internet. Proven search engines include Google, Bing, Yahoo, and Google Scholar. If adequate search terms are entered, relevant Internet sites can often be found.

**Fig. 1** Overview of possible data searching methods (example)

## Portals of Publishing Companies

Meanwhile many publishing companies offer their journals and books online. As a result they provide the possibility to systematically search for specific literature on their homepages. Good online search tools for journals and e-books are offered, for example, by SpringerLink, ScienceDirect, and Wiley Online Library. For the download of articles a fee has to be paid in most cases.

## Assessment by a National or International Committee

If the assessment of a particular substance is of interest, reports by expert committees can be helpful. The problem is that there exists no up-to-date collection of all reports available. The most comprehensive collection is offered by the OECD eChemPortal. It includes, for example, information and reports from the search portal INCHEM of the International Programme on Chemical Safety (IPCS) but also reports of the World Health Organization (WHO), the International Agency for Research on Cancer (IARC), and the Joint FAO/WHO Expert Committee on Food Additives (JECFA). Furthermore it provides access to reports of the United States Environmental Protection Agency (US-EPA), datasets of the International Uniform Chemical Information Database (IUCLID), and the registration dossiers submitted to the European Chemicals Agency (ECHA) under the European program for reevaluation of existing chemicals (REACH).

Reports of the United States National Toxicology Program (NTP) and the US Agency for Toxic Substances and Disease Registry (ATSDR) can be searched via the respective homepages of these organizations. Reports on chemicals that are consumer-relevant (e.g., fragrances, preservatives) can be found via the homepage of the Scientific Committee on Consumer Products (SCCP) of the European Union. Other important sources of information are documents justifying occupational exposure limits. Besides the German documents in this regard (MAK), also those of the English Health and Safety Executive (HSE), the Dutch Expert Committee on Occupational Standards (DECOS), the US Occupational Safety and Health Administration (OSHA), American Conference of Industrial Hygienists (ACGIH), and National Institute for Occupational Safety and Health (NIOSH) as well as the European Scientific Committee on Occupational Exposure Limits (SCOEL) and the Nordic Expert Group (NEG) are worth mentioning.

---

## Review Articles

Furthermore, there are journals publishing exclusively review articles, such as *Critical Reviews in Toxicology*. These articles will be found by searching through the relevant bibliographical databases (see below).

---

## Factual Databases

A good overview can also be obtained by querying fact databases. As the name indicates, these databases—in contrast to bibliographic databases (see below)—contain the relevant information about a substance and also provide references to the literature that was used as source of this information. Meanwhile the NLM (National Library of Medicine) has merged databases that have been established over years to existing databases. The best example for this is TOXNET which contains Toxline, HSDB, and CCRIS among others. Toxline has been completely absorbed into PubMed. HSDB (collection of referenced data derived from a core set of books, reports, and other literature) and CCRIS (carcinogenicity data from individual case studies) can be searched via PubChem. Access is still free of charge. Another frequently used factual database is RTECS, whose current data sets can be accessed free of charge via the homepage of the NIOSH Pocket Guide to Chemical Hazards.

---

## Comprehensive Data Searches and Analyses

The search becomes a lot more complicated, if no assessments by expert committees and no review articles are available, or if preparation of such an assessment is actually the reason for the search. In this case, a comprehensive search in bibliographical databases becomes necessary.

## Bibliographical Databases

Bibliographical databases, as the name indicates, provide the bibliographic information by which an article published in a journal (*primary literature*) or book can be found. In addition, most of these databases also include the abstracts of the publications.

Searches in bibliographical databases will yield journal articles but also book chapters, doctoral theses, and reports by research institutions. In toxicology in particular it is important to find also the so-called grey literature, meaning papers that have not been published in journals.

---

## Selection of the Database

Important databases include MEDLINE, EMBASE, Chemical Abstracts (CA), BIOSIS, Web of Science, and Scopus. Furthermore, there are a few smaller databases tailored to specific subject areas. The databases differ in their thematic orientation. MEDLINE and EMBASE, for example, are focused on medicine, BIOSIS on biology, CA on chemistry. But there are also geographical differences. For example, European publications are taken into consideration much more in EMBASE than in MEDLINE.

For some years already, free access to MEDLINE (PubMed) has been offered in the Internet via the US National Library of Medicine (NLM). As the search and query options are limited there, they are not suitable for complicated issues. However, these databases can also be queried at a charge (e.g., via the providers DIMDI and STN). The search and query options are much better there but access is limited to trained staff and with costs.

For a very thorough and comprehensive search, several databases, therefore, have to be queried. But the problem is that most articles will be found more than once. Table 1 shows that, for the example of 2-butoxyethanol (CAS: 111-76-2) 645, citations were found in the SCOPUS database and that 216 of these will also be found, for example, in the PubMed database.

This is due to the fact that the different databases partly access the same publications. The major commercial database providers, therefore, offer the possibility to eliminate duplicates across different databases. Because of the more professional searching possibilities and the possibility to eliminate duplicates, it is

**Table 1** Number of hits for the substance 2-butoxyethanol in the databases PubMed, Web of Science and Scopus, and number of overlaps

	PubMed	WoS	Scopus
PubMed	<b>282</b>	204	216
WoS	204	<b>720</b>	444
Scopus	216	444	<b>645</b>

971 hits overall, 188 hits common in the 3 databases

recommendable to make use of an online database provider for comprehensive searches. The cost of a complex search, however, may then easily amount to several thousand euros. Alternatively, you can perform your own check for duplicates using the so-called reference management systems (see below). Citavi, EndNote, or Zotero are only a few, and there are many others available.

The search results depend on the substance being searched for. For poorly studied substances it is possible that not a single citation is found, while for well-studied substances such as polychlorinated biphenyls, there may be well over 30,000 hits in the available literature depending on the database.

---

## Searching Strategies

Searches in factual databases are easy to perform, as they address a particular substance. Searches in bibliographical databases are more complicated, and you have to distinguish between a search for a particular substance name and a search for certain toxicological effects in this case. A chemical substance can be queried preferably via its CAS number, which unambiguously identifies the substance, alternatively by the international nonproprietary name (INN), chemical name according to IUPAC nomenclature, or the InChI identifier. Even CAS numbers cannot be queried in all databases. A small number of additional documents can be found by using synonyms, but many databases already include synonyms automatically. On the other hand, this may also result in related substances being found that are not actually being queried.

A search for toxicological effects is performed using specific search terms. Some databases (e.g., MEDLINE) offer structured lists of search terms (thesauri) that make it possible to search also for superordinate and subordinate terms. The database provider DIMDI offers a very helpful tool in this context, in the form of comprehensive search term lists in “preprocessed searches” (pps). Searches of this kind, however, often return a multitude of hits that are not really useful. The general rule is as follows: The more specific the search terms, the more appropriate the identified articles, but also the greater the risk of missing important publications. This means that the sensitivity of a search is adversely affected by high specificity and vice versa.

---

## Reference Management

Helpful tools for managing large amounts of literature are commercially or non-commercially available software tools such as “EndNote,” “Citavi,” “Zotero,” or “Faust.” Most of these programs store not only the bibliographic information but also abstracts and key words. They allow systematic searches for specific search terms in fields like title, authors, year, journal, and more. Reference lists can be automatically generated in different formats. The access to individual databases and import of searched/found data into reference management systems is state of the art

now. This saves a lot of writing. However, the quality of the data is not the same with all databases, and if data have been imported from different databases, some manual post-editing is necessary in most cases.

---

**Abstract**

In the first section, a historical summary of analytical chemistry is presented. In ancient history, one function of an analytical chemist was to confirm the identity of noble metals, especially gold. In later times, important inventions and their discoverer were named. Now, in the twenty-first century, analytical chemistry is an interdisciplinary scientific field.

Next, the aim and means of analytical chemistry are discussed. For analytical tasks, the chemist has available over 6,000 experimental procedures (including sub-specifications). The most important procedures are summarized. Moreover analytical problems, such as analyte(s) from complex matrixes, and the necessary purification as well as determination steps are discussed. Quantification measures, such as parts per trillion, are considered. The three analytical phases (pre-analysis, analysis, post-analysis) are presented, and recently developed analytical procedures such as “lab on a chip” and the “omics” sciences are introduced.

In the section “Pre-analysis,” different techniques of sample preparation prior to analytical measurement are described. Apart from classic methods, such as crushing and homogenization, extraction techniques such as solid-phase extraction, liquid-liquid extraction and solid-phase micro-extraction are reviewed.

The analytical section is divided into three parts, plus subparts: (i) separation techniques are presented followed by (ii) atomic spectroscopy and (iii) selective analytical chemistry. Each (sub)part begins with a short historical overview. For separation techniques, first the principles of chromatography are described followed by the principles of electrophoresis and capillary electrophoresis. The chromatographic and atomic spectroscopy classifications and techniques are not presented in isolation, as in many analytical textbooks. They are described along with associated coupled techniques.

Such coupled techniques are liquid chromatography (LC), gas chromatography (GC), thin-layer chromatography, and ion exchange chromatography (IEC). LC is often coupled with mass spectrometry (MS; including different ionization techniques such as thermospray, fast atom bombardment, particle beam). GC is also often coupled with MS. Moreover derivatization techniques and headspace GC are presented.

In the case of atomic spectroscopy, atomic absorption spectroscopy (AAS) and inductively coupled plasma mass spectrometry (ICP-MS) are presented in more detail. In the section “Selective Analytical Chemistry,” sensor techniques with ion-selective electrodes and the principles of immunoassays are described. These techniques are primarily for routine and fast analysis of known components in a sample. In most cases, the sample preparation steps are easy and rapid compared to, say, the sample preparation steps for gas chromatography.

Special types of mass spectrometers such as mass matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF-MS) and Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR-MS) and their usage will be described. These mass spectrometers can be coupled with LC.

**Introduction: Historical Summary**

As an applied science, the history of analytical chemistry dates back to ancient history. Initially, analytical chemistry was a regulatory method to detect forgery of noble metals (Volke 2004). This was important because noble metals, especially gold, had an important function in the monetary system. In the early study of alchemy, which aimed to transform base metals to gold, analytical chemistry was necessary to check for any success.

Analytical chemistry is as old as chemistry itself because after any preparation steps, the result has to be verified. Normally, the desired molecule or compound was extracted, distilled, or precipitated from the reaction solution. In a further step, the separated component reacted with a second component to yield a substance that was then characterized by some distinctive physicochemical attribute. These could include its color, its melting or boiling point, its solubility in a series of solvent media, its smell, its optical activity, or its refractive index. Further quantitative analysis was achieved by gravimetric or titrimetric measurements. Many of the greatest discoveries in chemistry could fairly be described as classic examples of successful analyses, including the discovery of oxygen, the halogens, and several other elements. Discovering a new chemical element was regarded as the highest and most prestigious achievement possible for an academic chemist.

Parallel to the development of various chemical synthetic methods, special techniques were developed in the field of analytical chemistry. About 1660, R. Boyle (1627–1962) used litmus for the detection of acids and alkaline solutions. A. Lavoisier (1743–1794) investigated the composition of water (previously it was believed that water was an element) and published the law of conservation of mass. About 1800, J. Dalton (1766–1844) published his atomic theory and the law of multiple proportions (Dalton's law), and A. Avogadro (1776–1856) published his theory of gases. In 1817, J. Gay-Lussac (1778–1850) presented a volumetric procedure to determine the amount of silver in solution. He also accelerated the development of titrimetry.

In the nineteenth century, analysis became a recognized subdomain of chemistry. J. Berzelius (1779–1848) was one of its famous representatives (qualitative analysis,

law of definite proportions, chemical notation, discovery of elements. . .). In 1821/22, the German scientist C. H. Pfaff (1773–1852) published his two-volume book *Handbuch der analytischen Chemie für Chemiker, Staatsärzte, Apotheker, Oekonomen und Bergwerks Kundige* (Handbook of analytical chemistry for chemist, physician, pharmacist, economists and mining engineers (Pfaff 1821, 1822)). In 1861, R. Bunsen (1811–1899) and G. Kirchhoff (1824–1887) developed emission spectroscopy. In 1898, M. Curie (1867–1934) and her husband Pierre (1859–1906) discovered the elements polonium and radium. In 1894, the chemist W. Ostwald (1853–1932) published his book *Die wissenschaftlichen Grundlagen der analytischen Chemie* (The scientific basics of analytical chemistry (Ostwald 1894)). He explained many phenomena seen in analytical chemistry by the newly developing physical chemistry. Thus analytical chemistry has been jointly responsible for many central contributions to our understanding of nature (e.g., the existence of the various elements, gas theory, stoichiometry, atomic theory, the law of mass action, nuclear fission. . .).

In the twentieth century, with the knowledge transferred from other scientific areas, especially physics and engineering, new methods such as chromatography and spectroscopy were applied. About 1920, instrumental methods were introduced into analytical chemistry to support the classic methods of precipitation, extraction, and distillation. Several Nobel Prizes were awarded in the field of analytical chemistry, including W. Ostwald (1909; catalysis, chemical equilibria, and reaction velocities), F. Pregl (1923; quantitative organic microanalysis), A. Tiselius (1948; electrophoresis and adsorption in analytical chemistry, especially in the identification of blood serum proteins), A. Martin and R. Synge (1952; partition chromatography), J. Heyrovský (1959; polarography), R. Ernst (1991; Fourier transform nuclear magnetic resonance (NMR) spectroscopy), and J. Fenn and K. Tanaka (2002; both for their work in mass spectrometric analyses of biological macromolecules) as well as K. Wüthrich (for his development of NMR spectroscopy for determining the three-dimensional structure of biological macromolecules in solution). Further aspects of the history of analytical chemistry are presented in the book by F. Szabadvary (Szabadvary 1966).

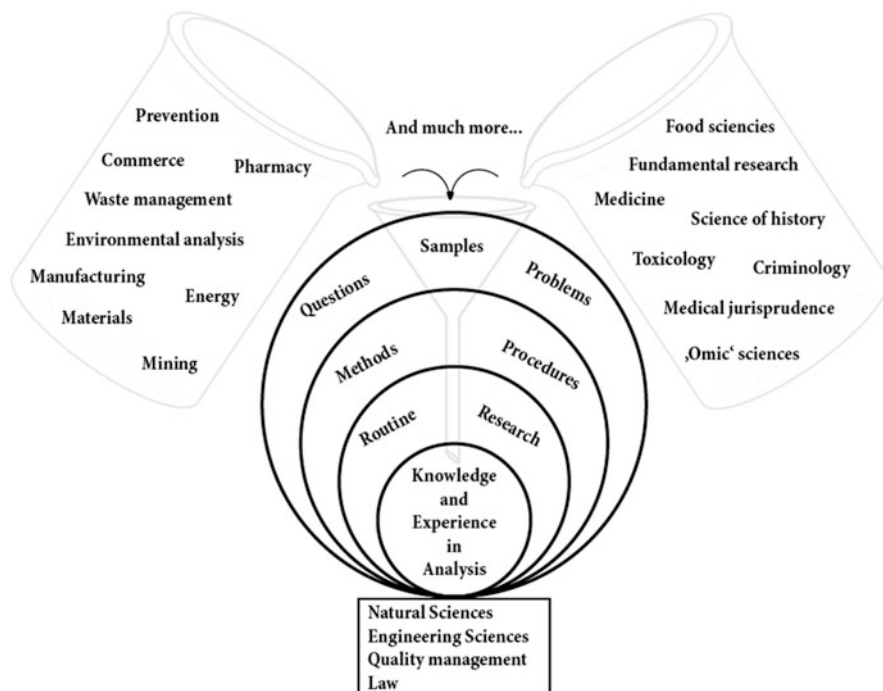

Analytical chemistry thus developed as an interdisciplinary scientific field spanning physics, biology, gene technology, toxicology, material sciences, engineering sciences, informatics, and (forensic) medicine.

---

## The Aim and Means of Analytical Chemistry

C. R. Fresenius stated in his classic *Introduction to Qualitative Chemical Analysis* (Fresenius 1866):

Chemical analysis is based directly on general chemistry, and it cannot be practiced without a knowledge thereof. At the same time it must be regarded as one of the fundamental pillars upon which the entire scientific edifice rests; for analysis is of almost equal importance with respect to all the branches of chemistry, the theoretical as well as the applied, and its

**Fig. 1 Challenges for the analytical chemistry.** Samples from all areas are brought to the analyzer. With his spectrum of methods and – last but not least – his experience and knowledge, he analyzes the samples. Moreover the analyst has to take into account current laws, quality management standards, and new technical developments in his field. (Modified after Tölg et al. (2000))

usefulness to doctors, pharmacists, mineralogists, enlightened farmers, technologists, and others requires no discussion.

Analytical chemistry (often also called analysis – the word is a transcription of the ancient Greek *αναλυσις* meaning “resolution”) penetrates all areas of live and working (Fig. 1).

It is normally divided into different subspecies, depending on the field of application, such as environmental analysis, biological analysis, geological sciences, online process analysis, food analysis, and instrumental analysis as well as forensic science and materials characterization. Analytical chemistry is not only concerned with trace analysis but also analysis of bulk substances or ingredients, as in the food industry.

In more general terms, analytical chemistry is concerned with methods to determine the chemical composition of different samples, including trace or bulk analysis. Basic issues in analytical chemistry are sensitivity, selectivity, and accuracy. The speed of determination is now especially important in clinical chemistry and forensic science. The analytical chemist is normally confronted with two questions: (1) What

substances or chemical groups are present in the sample (*qualitative* chemical analysis, molecular structure analysis)? and (2) What is their content in the sample (*quantitative* chemical analysis)? In the most cases, it is unnecessary to know the full chemical composition of the sample but only the most important compounds of interest.

In practice, qualifying and quantifying an analyte in a complex sample becomes an exercise in problem-solving. The sample can be regarded as the sum of two parts: the *matrix* and the *analyte(s)*. To be efficient and effective, an analytical chemist must know the appropriate tools to tackle a wide variety of problems. Therefore analytical chemistry requires a broad education in chemical and physical concepts. Advanced separation and spectroscopic techniques, as well as data analysis (“chemometrics”), play an important role in this field.

For the analytical task, over 6,000 experimental procedures including sub-specifications are available. A selection of the most important methods are listed in Table 1 (Durner 2010).

To isolate the analyte from a complex matrix, two further questions arise for the chemical analyst in practice:

1. Which steps of purification and isolation are necessary for the determination (qualitative and/or quantitative) of the analyte(s)?
2. Which method of determination is suitable for my analyte(s)?

To accomplish these goals, a sample is prepared by traditional methods like dissolution, homogenization, extraction, filtration, evaporation, separation, chemical derivatization, as well as newer methods like solid-phase extraction. Traditional and new methods are often combined to reduce the number of (time consuming) preparation steps; and the degree of automation is increasing. The achievements of analytical chemistry, especially in inorganic or organic trace analysis, can be shown by the amounts that can now be detected. To emphasize what **ppm** (parts per million), **ppb** (parts per billion), **ppt** (parts per trillion), or **ppq** (part per quadrillion) mean, we can use mass or volume units:

ppm is comparable to mg/kg,  $\mu\text{g/g}$  or  $\text{mL/m}^3$ ,  $\mu\text{L/L}$ .

ppb means  $\mu\text{g/kg}$ ,  $\text{pg/g}$  or  $\mu\text{l/m}^3$ , nL/L.

ppt is the same as  $\text{ng/kg}$ ,  $\text{pg/g}$  or  $\text{nL/m}^3$ , nL/L.

ppq means  $\text{pg/kg}$ ,  $\text{fg/g}$  or  $\text{pL/m}^3$ , fL/L.

For such trace analysis, as well as for normal analysis, quality management plays a very important role. To guarantee cross-border equivalence in the field of analytical chemistry, international rules for laboratory working such as “good laboratory practice (GLP)” or European and International Standards like EN ISO 17025 were introduced.

In analytical chemistry, three phases can be distinguished.

**Table 1** Selection of the most important methods in analytical chemistry (Durner 2010)

<b>Spectrometry</b>	
Absorption spectroscopy/photometry	Nephelometry/immunonephelometry
UV-/VIS-/NIR-/IR-spectroscopy	Turbidimetry/immunturbidimetry
Atomic absorption spectroscopy (AAS)	Atomic emission spectroscopy (AES)
Atomic fluorescence spectroscopy (AFS)	Flame emission spectroscopy
Nuclear magnetic resonance (NMR) spectroscopy	Inductively coupled plasma mass spectrometry (ICP-MS)
Luminescence spectroscopy: bioluminescence measurement, chemiluminescence, fluorescence, time-resolved fluorescence, fluorescence polarization, and phosphorescence spectroscopy	Matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF-MS)
<b>Ligand assays</b>	
Enzyme immunoassay	Fluorescence polarization enzyme immunoassay
Fluorescence immunoassay	Radioimmunoassay
Immunoblot (Western blot)	Receptor assay
Luminescence und electrochemiluminescence-immunoassay (CLIA/ECLIA)	
<b>Chromatography</b>	
Thin-layer chromatography (TLC)	Gas chromatography (GC) and GC-MS
Liquid chromatography (LC)	High-performance liquid chromatography (HPLC) and HPLC-MS
<b>Electrophoresis</b>	
Zone electrophoresis: cellulose acetate electrophoresis	Rocket electrophoresis
Immunoelectrophoresis/Immunofixation	Isotachopheresis
Isoelectric focusing	Capillary electrophoresis
Pulse-field gel electrophoresis	Counterimmune electrophoresis (countercurrent electrophoresis)
<b>Blood cell counts</b>	
Impedance measurement	Immunophenotyping of hematopoetic cells (flow cytometry)
Flow cytometric cell count determination with cytometric or cytochemical-cytometric cell classification particle property determination with automated processing (particle counting and particle size determination of blood cells)	
<b>Electrochemical studies</b>	
Amperometry: O <sub>2</sub> partial pressure (Clark electrode)	Coulometry
Potentiometry: pH, ion-selective electrodes	Voltammetry

(continued)

**Table 1** (continued)

<b>Molecular biological methods</b>	
(Real-time) polymerase chain reaction (PCR)	Fluorescence in situ hybridization(FISH)
Southern blot	Evidence for single-nucleotide polymorphisms (SNPs) with, e.g., restriction fragment length polymorphisms (RFLPs), fluorescence resonance energy transfer (FRET)-probes, density gradient gel electrophoresis (DGGE), denaturing HPLC (DHPLC)
<b>Additional procedures</b>	
Aggregometry	Areometry
Filtration (adsorption filtration, membrane filtration, ultrafiltration)	X-ray diffraction
Immunohistochemistry	Coagulometry
Microscopy (light and dark field, fluorescence, and phase-contrast microscopy)	Osmometry: cryoscopy, vapor-pressure osmometry
Qualitative studies with visual evaluation (e.g., osmotic erythrocyte resistance)	Sedimentation studies (erythrocyte sedimentation rate)
Reflectometry/carrier-bonded methods of analysis	Radioactivity measurement
Rheology, viscosimetry	Centrifugation: analytical ultracentrifugation, density-gradient centrifugation

1. Pre-analysis
2. Analysis
3. Post-analysis

The term “pre-analysis” or “pre-analytical phase” encompasses all the administrative and functional factors and processes that occur prior to laboratory analysis. These include preparation, isolation, work-up by centrifugation, storage, and transport. The term “analysis” or “analytical phase” covers taking aliquots and the general preparation of an analytical sample, the analysis itself, and acquisition of the appropriate data value(s). In this phase precision, accuracy, detection limit, method specificity, analytical sensitivity, and statistical quality control play an important role. The term “post-analysis” or “post-analytical phase” covers the analytical assessment of analytical results and the recorded set of definitive findings. Keywords in this context are plausibility, trend analysis, abnormal values, status assessment, diagnostic sensitivity, diagnostic specificity, and predicted value (O’Kane et al. 2008).

A few years ago, a new technology was introduced which has started to change classical laboratory chemistry in some areas. It uses “lab on a chip” devices that have the size of a credit card or even a fingernail. A “lab on a chip” allows determination of multiple analytes without further matrix purification. Fixed capture molecules on

the chip sensor array bind molecules, such as nucleic acids or blood proteins, from the fluid matrix (a few femtoliters of which are normally sufficient). The sensor array may incorporate electrochemical sensors that recognize the binding of a substance by the change in potential or current flow. As this chip technology is derived from the field of electronics, the chips are rather expensive. Therefore inexpensive alternatives, such as paper-based “chips,” are in development (Yehya and Wael 2010; Trietsch et al. 2011; Deisingh and Thompson 2004; Palchetti and Mascini 2008).

This new micro-fluidic technology is important for medical analysis as well as for basic “omics” sciences (proteomics, metabolomics, etc.). This technology has been praised as offering “devices suitable for every purpose” to find the proverbial “needle in the haystack” (Schneider and Orchard 2011; Saleem and Reddy 2011; Singh et al. 2010; Suter-Dick and Singer 2008).

## Important Techniques of Pre-analysis

For the (trace) analysis of different substances from complex matrices, special treatments are necessary to determine the analyte(s) with sensitive analytical methods (Peters and Remane 2012). This field of pre-analytics involves different techniques of sample taking and especially different possibilities of sample preparation prior to the analytical measurement (Persoon et al. 2006). Examples of pre-analytical methods, for “working up” a sample, are crushing, homogenization, solubilizing, chemical exploration, and extraction techniques. In toxicology, extraction techniques play an important role. Some long-established extraction techniques are based on the principle of two non-mixable phases in close contact (Hennion 2000). An overview of common extraction techniques is shown in Table 2.

**Table 2** Overview of widely used extraction techniques. (Modified after Gey (2008))

Phase 1	Phase 2	Extraction technique
Solid	Liquid	Solvent extraction techniques, e.g., Soxhlet extraction, ultrasonic or microwave-assisted extraction, accelerated solvent extraction
Solid	Supercritical	Supercritical fluid extraction
Solid	Gas	Gas extraction techniques, e.g., headspace extraction
Fluid	Solid	Adsorptive extraction techniques like solid-phase extraction (SPE), solid-phase microextraction (SPME), or adsorptive microextraction techniques as well as dispersive extraction techniques
Liquid	Liquid	Liquid-liquid extraction techniques, e.g., liquid-phase extraction, liquid-phase microextraction (incl. hollow fiber techniques), ion pair extraction
Liquid	Gas	Purge and trap techniques (PT techniques)
Gas	Liquid	SPME
Gas	Solid	SPME

## Solid-Phase Extraction

Solid-phase extraction (SPE) is a chromatographic technique known for over 60 years (Liska 2000). It is a physical extraction process to enrich, isolate, and/or cleanup the analyte(s) from a complex liquid matrix onto a stationary phase from the SPE material. This technique can be very effective, even when the solutes are present in extremely dilute concentrations (e.g., ppb). The extraction tube is usually packed with an appropriate bonded phase that is reproducible in activity, selectivity, and retention properties. In the first step, an adsorption on the solid phase takes place that means that the interaction of the analyte(s) and the solid state is stronger compared to the liquid phase. In the second step, an extraction from the solid phase takes place. In other words, the interaction of the analyte(s) and the liquid phase is now stronger compared to the solid phase. Therefore it is possible to retain and enrich the analyte (s) in the first step and to elute it in the second step by rejecting the matrix. Because it is widely used, the SPE technique is discussed in more detail. The principal setup of a SPE tube is shown in Fig. 2. The I.D. of a tube is in the range 2–10 mm, and it is 2–4 cm long and is usually made from an inert polymer or, occasionally, from stainless steel or other materials. Normally the first step in using SPE tubes is conditioning. This means that the solid phase (sometimes also called the adsorbent) is pretreated with an (organic) solvent. This is necessary to activate the side chains from the solid phase to get a high and reproducible recovery. After conditioning, the sample can be placed. With the help of a vacuum, the sample is drawn through the solid phase of the tube. Afterwards, the solid phase is washed. In the next step, the solid phase is dried and then the analyte(s) are eluted by a solvent or a series of solvents/solvent mixtures of successively increasing elution strength (an elutropic series) (see Fig. 3).

Effective separation by SPE depends primarily on the proper choice of sorbent and eluting solvents depending on the chemical and physical properties of the components in the sample. SPE tubes are available incorporating a wide variety of chemistries, adsorbents, and sizes. The most commonly used phases for the solid state are reversed phase, normal phase, ion exchange, and adsorption (Camel 2003; Majors 2010; Zwir-Ferenc and Biziuk 2006).

**Fig. 2** General setup of a solid-phase extraction (SPE) tube

**Fig. 3** Working principle and general steps in using solid-phase extraction (SPE) tubes. The first step is conditioning: i.e., the cleaning and activating of the solid phase of SPE. The second step is normally the sample application. Only the desired analyte(s) should be adsorbed, and these can be enriched. The third step is a washing step and in the fourth step the analyte(s) are eluted

## Liquid-Liquid Extraction

Liquid-liquid extraction (LLE) is a tool for separating and isolating the favored analyte(s) of a liquid mixture by contacting it with a second, immiscible liquid in which one or more of the favored analyte(s) are preferentially soluble. Normally one of the two phases is an organic phase, while the other is an aqueous phase. Under equilibrium conditions, the distribution of analyte(s) over the two phases is determined by a distribution law. In practice, it is not always possible to find the optimum conditions that provide both high recovery and high purity of the analyte(s) in one extraction step. Therefore it is not unusual that a second extraction procedure, with a different solvent or other extraction conditions (e.g., pH value), is necessary. Moreover multiple extraction steps with the same solvent can also be required. In the case of a large extraction volume, the solvent must be evaporated to enrich the analyte(s) (Hii and Lee 2010; McConvey and Nancarrow 2011; Silvestre et al. 2009; Tedder 2009; Testard et al. 2010).

## Solid-Phase Microextraction

Solid-phase microextraction (SPME) is a common, solventless, fast, and field-compatible technique for extraction and concentration of volatile and semi-volatile analyte(s). It was invented in 1990 by Dr. J. Pawliszyn and colleagues. The physical basics are adsorption and desorption of the analyte(s) from a polymer-coated fused fiber (Pawliszyn 1997). In SPME, analyte(s) establish equilibrium between the sample

**Fig. 4 Adsorption phase.** First, the SPME needle pierces the septum on the sample container. Second, the SPME fiber is incubated in with the analyte(s). Third, after incubation from minutes to hours independent from, e.g., the concentration of the analyte(s), the SPME fiber is retracted and the needle is withdrawn

matrix, the headspace above the sample, and a polymer-coated fused fiber (SPME adsorptive layer; see Fig. 4). After the sampling period, during which extraction has ideally reached equilibrium, the adsorbed analyte(s) is/are transferred into an inlet system that desorbs the analyte(s) from the SPME adsorptive layer into a gas (for GC) or liquid (for LC) mobile phase (see Fig. 5). Because analyte(s) is/are concentrated on the SPME fiber, and is/are rapidly delivered to the column, minimum detection limits are improved and resolution is maintained. SPME provides linear responses for wide concentrations of analyte(s). By controlling the polarity and thickness of the coating on the fiber, maintaining consistent sampling time, and adjusting several other extraction parameters, an analyst can ensure highly consistent, quantifiable results from low concentrations of analyte(s) (Chen and Pawliszyn 2007). Sometimes a secondary trapping and release of desorbed solutes after SPME is necessary when desorption from the SPME adsorption layer is too slow. This trapping and release can be accomplished using a discrete thermal trap or, in the case of column stationary-phase trapping, by injection onto a cold column and subsequently temperature programming for solute elution (Duan et al. 2011; Risticvic et al. 2009; Risticvic et al. 2010; Vuckovic et al. 2010).

**Fig. 5 Desorption phase.** First, the SPME needle pierces the GC inlet or the needle is introduced into the SPME/HPLC interface. Second, the analyte(s) on the SPME fiber are desorbed, e.g., by heating the inlet. Third, the SPME fiber is retracted and the needle withdrawn

## Separation Techniques

### Chromatography

Chromatographic methods have been used for a long time. In ancient Greece, Aristotle used alumina for the cleaning of seawater. In 1859, the German scientist F. Runge made experiments that were a precursor to paper chromatography (Runge capillary pictures). In 1901, the Russian botanist M. Tswett initially described the method to separate plant pigments such as chlorophyll and carotenes (Furr 2004). Since 1906, the term “chromatography” was used, derived from the Greek words “χρωμος, chromos” “color” and “γραφειν, graphein” “to write,” meaning “color writing.”

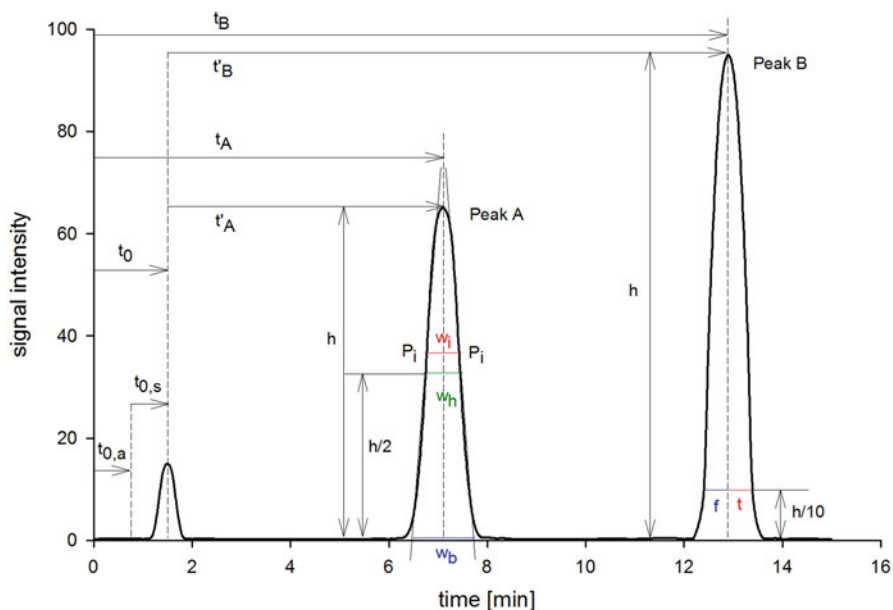

The physical bases of chromatography are the chemical and/or physical interactions of the analytes from the sample, present in the mobile phase, with the particles of a stationary phase – resulting in a temporal and spatial separation of the analytes (retention of the analytes; see Fig. 6). The greater the affinity of the analyte to the stationary phase, the greater the delay period during chromatography. The separated analytes are detected at the exit of the column by a flow-through detector that

**Fig. 6 Principles of chromatography.** The sample with the analyte(s) is applied to the chromatographic system. The analyte(s) in the mobile phase interact with the stationary phase. Thereby the separation takes place. After leaving the chromatographic system, the analyte(s) can be detected by different analyzing systems

measures their quantity. The result of the separation is a chromatogram (see Fig. 7), where the signal intensity is shown as the ordinate and the retention time as the abscissa. The different retention times are characteristic for the substance. The height of the signal/peak, or the area under the signal/peak, can be used for quantification of the analytes' concentration (Guiochon and Trapp 2000).

One possible classification of chromatographic techniques considers the following points (see also Fig. 8):

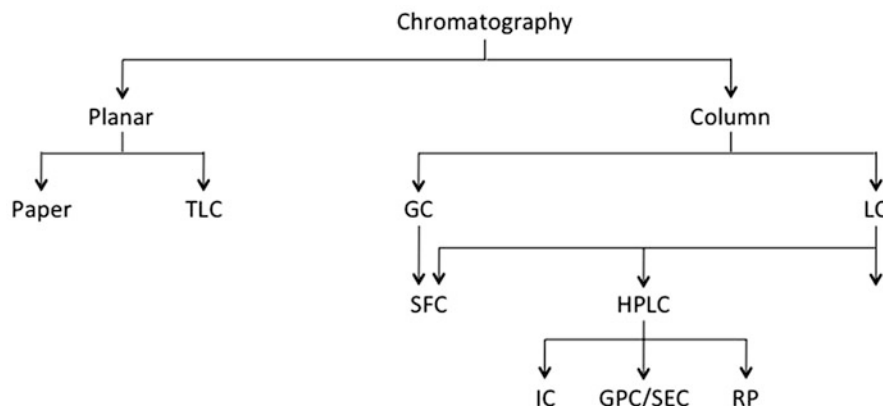

**Fig. 7 Example of a chromatogram**  $t_{0,a}$ : Time delay of the apparatus. This is the time the eluent needs to reach the detection system from the injector. It should be as low as possible ( $t_{0,a} \approx 0$ )  $t_{0,c}$ : Time delay of the column. This is the time the eluent needs to pass the column.  $t_0$ : Dead time. This is the time the eluent needs to pass the distance from the injector through the column to the detector.  $t_0 = t_{0,a} + t_{0,c} \approx t_{0,c}$   $t$  Retention time of the components. This is the time required for the components to pass the distance from the injector through the column (including interaction) to the detector.  $t'$  Net retention time for a component. This is the time the component is in the stationary phase.  $t' = t - t_0$   $k'$  Retention factor (formerly called as capacity factor).  $k'$  is a characteristic parameter of a component in the phase system.  $k' = \frac{t'}{t_{0,c}} = \frac{(t-t_0)}{t_{0,c}} \approx \frac{(t-t_0)}{t_0}$   $T$  Tailing factor. This is a measure for the symmetry of a peak. It is measured at 10% peak height after the International Union of Pure and Applied Chemistry (IUPAC) or 5% peak height after the US Pharmacopeia (USP).  $T = \frac{f}{t}$   $\alpha$  Separation factor (formerly called the selectivity).  $\alpha$  characterizes the potential of a phase system to separate two components. In the numerator the data of the later eluted substances are named. Therefore  $\alpha$  is  $\geq 1$ .  $\alpha = \frac{t'_B}{t'_A} = \frac{k'_B}{k'_A}$   $R$  Resolution. Considering the width of a peak it characterizes the separation of two neighboring peaks.  $\Delta t_{B,A} = t_b - t_a$ ;  $R = 2 \cdot \frac{\Delta t_{B,A}}{w_{b,A} + w_{b,B}} = 1,177 \cdot \frac{\Delta t_{B,A}}{w_{h,A} + w_{h,B}}$

- Selection of the separation distance, as in column or layer chromatography
- Selection of the phases:

Normally, the mobile phase is liquid or gaseous, and the stationary phase is solid or liquid. So four combinations can result: liquid-solid and liquid-liquid as used in liquid chromatography (LC); gaseous-solid and gaseous-liquid as used in gas chromatography (GC).

- Selection of the separation mechanisms, such as separation by adsorption, distribution, ion exchange, and cavity diffusion (molecular sieve chromatography, gel permeation chromatography).

**Fig. 8 One possible classification of chromatographic techniques.** TLC = Thin-layer chromatography; GC = gas chromatography; LC = liquid chromatography; SFC = supercritical fluid chromatography; HPLC = high-performance liquid chromatography; IC = ion chromatography; GPC = gel permeation chromatography; SEC Size exclusion chromatography; RP = Reversed phase chromatography

In the following, important chromatographic techniques will be presented together with a widely used coupled technique: mass spectrometry.

### HPLC: Including Coupled Techniques

High-performance liquid chromatography (HPLC; formerly also called high-*pressure* liquid chromatography) is a technique of liquid chromatography and a highly improved form of column chromatography. In comparison to traditionally chromatography, a solvent is not allowed to drip through the column under gravity; instead it is forced through under high pressure – up to 400 atmospheres. The HPLC instrument consists of a solvent reservoir, degasser, pump, injector, detector, integrator, and column, the last of which is a temperature-controlled oven. Advantages of HPLC techniques compared with traditional chromatography are:

- The analysis time is shorter.
- It is possible to use much smaller particles as the stationary phase in the column that gives a greater surface area for the interaction between the analytes and the stationary phase. In consequence, the separation of a multicomponent mixture is better, the reproducibility is higher and the detection limit is lower.

Depending upon the interaction between the particles of the stationary phase and the analytes in the liquid phase, the following kinds of liquid chromatography are distinguishable:

- Exclusion chromatography
- Ion chromatography

- Adsorption chromatography
- Chromatography of optical isomers.

Adsorption chromatography is widely used. Depending upon the stationary phase, “normal phase” and “reversed phase” chromatography can be distinguished. The stationary phase in normal phase chromatography is made of unmodified silica gel and in rare cases of  $\text{Al}_2\text{O}_3$ . Because of the polar character of the stationary phase, the components (eluent) of the mobile phase are nonpolar like hexane. Normal-phase chromatography is used in about 5–10% of routine measurements.

In reversed phase chromatography, the stationary phase is more nonpolar (hydrophobic) compared to the mobile phase (“reversed phase”). The free silanol groups of the silica gel have been reacted with alkyl chlorosilane to form siloxane groups. One common stationary phase uses the n-octadecylsilane (OSD) modification of the silica gel. For reversed phase chromatography, mixtures of water, methanol, tetrahydrofuran (THF), or acetonitrile (ACN) are used as mobile phases. The most polar analytes of the sample will be eluted first because their interaction with the hydrophobic groups of the stationary phase is weak, whereas the most nonpolar analytes will be eluted at longer retention times because their interaction with the stationary phase is greater (whereas, in the case of normal phase chromatography, the elution sequence is inverted).

Another important factor in chromatography is the temperature. It influences the interaction between mobile and stationary phases as well as the viscosity of the liquid phase. For high reproducibility and robustness, it is important to use a constant temperature (Meyer 2010).

The composition of the liquid phase (often also called the elution phase) can be either constant or varying. The first case is named *isocratic elution* and the second case *gradient elution*. The gradients can be linear, concave, convex, or in steps. Besides binary gradients also ternary or quaternary gradients can be used, involving three or four different elution media.

The correct flow rate of the liquid phase also depends on factors such as the internal diameter of the column. At high flow rates, the interaction of the analytes with the stationary phase is insufficient. It is advisable to choose a constant velocity (that a linear flow pattern results) when attempting to reproduce chromatography results obtained with columns of differing internal diameters.

In HPLC, the analytes can be detected using different detector types. The detectors are classified into two groups: The first group uses certain characteristics of the total elution flow (depending on the dissolved analytes therein) such as density, refractive index, capacitance. The second group uses certain characteristics of the dissolved analytes such as UV-absorption, fluorescence, redox behavior. The choice of the detector type depends on the analytes. In some cases, multiple detection systems are used. Typical detector types use the principles of UV/VIS, (FT)-IR, fluorescence, electrochemical, conductivity, refractive index detectors, evaporative light scattering detectors, and mass spectrometric detectors (LC-MS; see section “LC-MS (Thermospray, Fast Atom Bombardment, Particle Beam)”).

Many substances of current interest cannot be detected by HPLC because they do not contain the necessary chromophoric, or fluorophoric, groups. In this case, it is possible to add a chromophoric group by a derivatization reaction (the derivatization process is discussed in section “GC: Including Coupled Techniques”). Derivatization can be done in a pre-column mode (that means before analytical separation) or in post-column mode (after separation). Typical chromophoric groups for UV/VIS detection are, e.g., 4-dimethylaminoazobenzene-4'-sulfonyl chloride, 1-fluoro-2,4-dinitro-benzene (Sanger's reagent), and 4-(dimethylamino)benzaldehyde (Ehrlich's reagent), and for fluorimetric detection fluorecamine, 4-(dimethylamino-sulfonyl)-7-fluoro-2,1,3-benzoxadiazole, and 3,4-dihydro-3,4-dioxo-1-naphthalenesulfonic acid sodium salt (Folin's reagent). HPLC derivatization plays an important role in the determination of many pharmaceutical compounds (amino acids, antibiotics), in agrochemistry (proteins, peptides, toxins), in the environment (pollutants), and in food sciences (biogenic amines as indicators of proteolytical process) (Kaushal et al. 2011; Milroy et al. 2012; Gianotti et al. 2011; Poletini 2011).

This chapter will only describe selected methods with practical use in the field of toxicology. Therefore molecular spectroscopic techniques like mass spectrometry (MS), matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF) will be presented as coupled technique with the chromatographic methods and not separately, as in textbooks of analytical chemistry. Atomic spectroscopic techniques that are widely used in the field of toxicology are considered in section “Atomic Spectroscopy.”

### LC-MS (Thermospray, Fast Atom Bombardment, Particle Beam)

In 1898, the scientists E. Goldstein and W. Wien showed that a beam of positive ions is deflected by electric and magnetic fields. The development of mass spectrometry (MS) goes back to the work of J. J. Thomson in the year 1910. He demonstrated that the noble gas neon consists of two stable isotopes with mass 20 and 22. Fifty years later, this technique was used in organic chemistry for structure determination, determination of the relative molecular mass, and analysis of small amounts of a sample. The fundamental principle of MS is to produce ions from inorganic and organic substances (without destroying them by ionization). Major components of a mass spectrometer are the ion source for the generation of ions, an analyzer for the ion separation/mass selection by electric and/or magnetic fields and the ion detectors of different types such as electron multipliers, Faraday cups, ion-to-photon detectors or scintillation counters (Miller 2009).

#### Ionization Techniques

The ionization of analytes can be realized thermally, with an electric field or by bombardment with electrons, ions, and photons. The resulting ions from the analytes can be single ions or clusters, ionized molecules, as well as fragments or associates from the ionized molecules. During thermospray ionization (TSI), the analytes within the liquid sample are contained in a capillary, with the end at a temperature of about 200 °C, under pressure in a heated atomizing chamber. Widely used solvents are CH<sub>3</sub>CN/H<sub>2</sub>O or CH<sub>3</sub>OH/H<sub>2</sub>O, with an evaporable electrolyte additive

such as 0.1 M  $\text{CH}_3\text{COONH}_4$ . As the liquid leaves the capillary, a nebula of fine drops is formed. Because of the high temperature in the atomizing chamber, the solution media vaporizes. Ions are formed, by the agency of the electrolyte additive, which reach the mass analyzer by a small leak (called a skimmer) in the atomizing chamber. Furthermore, an electric potential is maintained between the skimmer and the repeller (a further component of the atomizing chamber). One main advantage of this technique is that polar and thermolabile substances can attain the gas phase without a direct vaporization process. Problems can arise when the sample is insoluble in the solvent and/or only few solvents are suitable.

Fast atom bombardment (FAB; also called liquid secondary ion mass spectrometry (LSIMS)) belongs to the group of desorption methods. The analytes of the sample are dissolved in a thin, liquid, nonvolatile matrix (e.g., glycerol, 3-nitrobenzyl alcohol, thioglycerol, diethanolamine) that is placed onto a metal plate. The matrix is brought into the ion source and is bombarded with accelerated primary particles in the keV energy range. For this desorption process, inert gases like Xe or Ar are used. During this process, secondary ions are formed which can be accelerated, focused, and analyzed by common methods. Cluster ions from the liquid matrix are also desorbed and produce a chemical background that varies with the matrix used. The FAB technique is gentle and can therefore be used for analysis of proteins and peptides.

Particle beam (also called monodisperse aerosol generator-based interface for liquid chromatography (MAGIC)): the solved analytes are separated with a chromatography column. At the end of the capillary, a helium flow, in combination with TSI or other pneumatic techniques, generates aerosols. The aerosol is sprayed (after focusing the particles into a beam by aerodynamic lenses) into the desolvation chamber where the solvent is vaporized by temperature and low pressure. A fraction of the vaporized particle beam is ionized and diffuses into the mass spectrometer (Smith et al. 2011).

### Mass Spectrometer

The ions are separated by their mass-to-charge ratio and recorded with the aid of a detection system according to their mass and count-frequency (qualitative/quantitative). To realize the separation of the ions, static or dynamic electric and magnetic field are used as well as differences in their time of flight. Sector field mass spectrometers and, more commonly, quadrupole mass spectrometer (see Fig. 9) are widely used (Gross 2011).

LC-MS systems are widely used as in the analysis of pesticides, mycotoxins, in the field of clinical chemistry and in forensic analysis (Gergov 2008; Maurer Hans 2010; Botitsi et al. 2011; Roux et al. 2011; Shephard et al. 2011).

### LC-MS/MS

LC-MS/MS, also often called tandem MS, is a LC technique with two or more mass spectrometers which are coupled together. This combination increases efficient separation, sensitivity, and selectivity. This kind of mass spectrometry is often used for the analysis of biomolecules (proteins or peptides) and drugs as well as

**Fig. 9 Scheme of a quadrupole used in quadrupole mass spectrometer.** The quadrupole electromagnetic field is adjusted so that only a special mass-to-charge ratio of the total ion beam can pass through the quadrupole (stable ion path; green arrow) and enter the detector system. Ions with another mass-to-charge ratio cannot pass the detector (unstable ion path; red arrow). The potential on the quadrupole, and in consequence the electromagnetic field, is not static. It will change many times per second. Therefore other mass-to-charge ratios reach a stable ion path and can traverse the quadrupole and thus reach the detector system

the study of metabolic pathways (El-Najjar et al. 2017; Adaway et al. 2015; Brandsma et al. 2017; Dong et al. 2018). A widespread variant of the tandem MS is the triple quadrupole MS. This technique is closely related to the chemists R. Yost (1953), C. Enke (1933), and J. Morrison (1924–2013). Their investigations began in the 1970s, and this technique has been widely used since the mid-1980s. Three quadrupoles are used for this MS construction. Usually, the first quadrupole (see section “LC-MS (Thermospray, Fast Atom Bombardment, Particle Beam)” and Fig. 9) is set so that only ions with a certain mass-to-charge ratio can pass through (selection step/selection of the ions). These ions are fragmented in the second quadrupole using a collision gas and transferred to the third quadrupole, where the fragments are separated and, after leaving the quadrupole, detected (see Fig. 10) (Niessen and Falck 2015). By prior separation of the substance mixture (first quadrupole) and subsequent defined fragmentation (second quadrupole), specific fragments (daughter ions) can be measured with the third quadrupole. In other words, specific daughter ions are formed from a mother ion (parent ion). The observation of the masses of the mother and daughter ions is called mass transition. This transition is characteristic for many substances during a certain fragmentation, which increases the analytical sensitivity. The higher sensitivity is of particular interest in drug analytics (e.g., determination of antibiotics from serum, misuse of illegal substances) or the detection of smaller molecules in the ng/l range.

In addition, it is also possible to make smaller molecules out of larger molecules such as proteins by further fragmentation, which can then be detected. It is also possible to add further MS to this cascade.

### GC: Including Coupled Techniques

The chemists E. Cremer and F. Prior are among the most important pioneers in gas chromatography (quantitative adsorption-GC with mixtures of gases) (Bobleter 1990). They conceived this technique in 1944. A. Martin and A. James invented

**Fig. 10 Schematic diagram of a triple quadrupole mass spectrometer.** The ionization of the substances is carried out using techniques such as electrospray ionization (ESI) or atmospheric pressure chemical ionization (APCI). The first selection takes place in the first quadrupole. Only molecules with a certain mass-to-charge ratio pass through the first quadrupole. These molecules are also called mother/parent ions. They are fragmented in the collision chamber in the second quadrupole. Gases such as argon or nitrogen can be used for fragmentation (symbolized by a star). The fragment ions, which are also called daughter ions, are separated in the third quadrupole according to their mass to charge ratio. Subsequently, the detection takes place, e.g., by means of an electron multiplier

the GC detector in 1952. GC is suitable for chromatography involving the separation of gases or other substances that are vaporizable. The mobile phase is a gas. The stationary phase can be liquid (gas-liquid chromatography, GLC) or solid (gas-solid or adsorption chromatography, GSC). For GLC thin films of a liquid are deposited on a solid particle. Together, this combination builds the stationary phase. It is important to use nonvolatile liquid substances like silicone oil, liquid paraffin, waxes, and polymeric esters. Materials for particles are glass, PTFE powder, diatomaceous earth, or alumina. In adsorption chromatography, the molecules from the sample interact with the solid adsorbent. Typical materials used as adsorbent are aluminum oxide, silica gel, zeolites, or polyamide.

In analytical chemistry, capillary GC, sometimes also called high resolution (HR)-GC, is often used. The capillary columns consist of amorphous sintered quartz (fused silica, FS-columns) stabilized with a thin layer of polyimide. Two different types of capillary columns or Golay columns (named after the inventor) are used: the wall-coated open-tubular column (WCOT-column) and the support-coated open-tubular column (SCOT-column). A WCOT-column can have a length from 5 to 200 m, an inner diameter of 0.1–0.5 mm, and a thin film of separation fluid (stationary phase) at the inner wall of 0.1–0.3  $\mu\text{m}$ . SCOT-columns have an impregnated support material instead of a thin film of fluid as the stationary phase. Special forms of SCOT-columns are the porous-layer open-tubular columns (PLOT-columns). In this case, the stationary phase consists of adsorption material such as aluminum oxide, silica gel, or a molecular sieve. For practical use, the column dimensions (length, diameter, film thickness), as well as the phase composition (such as 10% phenyl polysiloxane) are of interest.

Only compounds with vapor pressures exceeding about  $10^{-10}$  torr can be analyzed by GC. Many compounds with lower pressures can be analyzed if they are chemically derivatized. Derivatization, in this context, is the process of chemically modifying a compound to produce another compound that has properties suitable for

analysis using GC. In most cases the volatility or the stability of the analytes as well as their chromatographic behavior requires improvement. In chemical terms: Derivatization can eliminate polar groups such as OH, NH, COOH,  $\text{PO}_4^{3-}$ , or SH and therefore increase the volatility and thermal stability of the compound. With steroids and cholesterol, the detectability is increased. GC derivatization methods can be classified into four groups according to the reagents used and the reaction achieved: silylation, acylation, alkylation, and esterification (see section “GC-MS”).

### Headspace GC

Headspace GC analysis is a special technique for the detection of volatile analytes in the space over fluid or solid samples (see Fig. 11). The sample is put in a gas-tight vial with a septum and heated within the headspace apparatus to a certain temperature. After establishing equilibrium between the sample and the space over the sample, an aliquot from the headspace is analyzed. In routine analytical use, the headspace technique has been applied to the detection of chlorinated hydrocarbon and other (organic) solvents in drinking water, oxbow lake, and wastewater. Moreover the amount of unpolymerized monomers from acrylate, isocyanate, or styrene-based materials can be detected.

This technique has some parallels to the SPME technique (see section “Solid-Phase Microextraction”). But in contrast to that technique, no adsorption material is used. For headspace GC, it is necessary to have an aliquot from a sample to put inside the apparatus. The SPME technique, however, can be used outside the laboratory for onsite measurements.

**Fig. 11** Scheme of a headspace sampler. A solid or liquid sample is applied to a heating unit (e.g., a water bath). After heating (and waiting), an equilibrium is formed between the analyte(s) in the sample and the analyte(s) in the vapor space (headspace). Aliquots from the headspace are transferred with a carrier gas to a gas chromatography instrument

## GC-MS

The great advantage of this combination is that GC can separate volatile and semi-volatile compounds with high resolution, although it cannot identify them. MS can provide detailed structural information on most analytes such that they can be exactly identified, but it cannot readily separate them. After the separation of the analytes by the chromatography column, a mass scan can be obtained. The mass spectrogram of each component is a characteristic fingerprint. To identify a substance, the fingerprints can be compared with mass spectrograms from a database. To quantify the analyte(s), a special mode (selected ion monitoring, SIM) can be used. In this case, the mass spectrometer measures not all masses but only a few analyte typical masses. In this case the sensitivity is increased up to the pg or ng range (Song and Marriott 2012; Watson and Sparkman 2008).

GC-MS systems are used for the identification and quantization of volatile and semi-volatile (organic) compounds and for structural determination (in combination with other techniques) of unknown substances. Common applications are the quantization of pollutants in drinking and wastewater as well as quantization of drugs and their metabolites in blood and urine for pharmacological and forensic reasons. Moreover GC-MS is used for the identification of unknown substances in waste dumps, for the identification of reaction products in synthetic steps, and in quality management for the analysis of industrial products. For a suitable and effective derivatization reaction, some criteria should be considered before choosing the derivatizing reagent:

- High degree of derivatization achievable (90–100%).
- The derivative is stable with respect to time.
- The derivative does not react/destroy the GC column.
- During the derivatization reaction, no rearrangements or structural alterations should occur.
- The derivatization reagent should not induce a loss of analytes during the reaction.

Typical chemical derivatization reagents are:

- (a) For silylation, e.g., allyltrimethylsilane, *N,O*-bis(trimethylsilyl)trifluoroacetamide (both introduce a trimethylsilyl (TMS) group: which is the most popular and versatile silyl group).
- (b) For acylation, e.g., trifluoroacetic anhydride, 1-(pentafluoropropionyl)imidazole.
- (c) For alkylation, e.g., *N,N*-dimethylformamide dimethyl acetal, trimethyloxonium tetrafluoroborate
- (d) For esterification, e.g., boron trifluoride, methanol-HCl (Halket and Zaikin 2006; Rosenfeld 2010; Soederholm et al. 2010)

## Thin-Layer Chromatography (TLC)

The physical principle of thin-layer chromatography (TLC) is the movement by capillary forces of a liquid phase, usually an organic solvent, through a thin, uniform

layer of solid phase, usually silica gel ( $\text{SiO}_2$ ). The solid phase is held on a rigid or semi-rigid support, normally a glass, aluminum, or plastic sheet or plate. The analytes of the sample are separated by the interaction between the mobile and stationary phases (Spangenberg et al. 2011). Advantages of TLC, especially in the field of forensic analytics, are (Bele and Khale 2011):

- Reliable, rapid, and easy procedure (normal case)
- Relatively inexpensive
- Relatively simple in use
- Possibility of detecting upward of 700 different types of drugs, medications, and metabolites
- Validated as a diagnostic tool that holds up under the scrutiny of legal challenges, inside and outside the courtroom
- Combined with sample pretreatment (e.g., solvent extraction) TLC can be a powerful qualitative technique

It should be mentioned that the interpretation of TLC results is sometimes very difficult, especially when a number of drugs, medications, and metabolites are present.

TLC can detect, accurately, a large number of medically significant substances, such as anticonvulsants/antispasmodics (e.g., phenytoin, carbamazepine), antidepressants (e.g., amitriptyline, nortriptyline, sertraline), antihistamines (e.g., chlorpheniramine, diphenhydramine), anti-inflammatories (e.g., naproxen, ketoprofen, ibuprofen), anesthetics (e.g., lidocaine, procaine), decongestants/broncodilators (e.g., ephedrine, theophylline), muscle relaxants (e.g., carisoprodol, meprobamate), narcotic analgesics (e.g., methadone, tramadol), sedatives (e.g., ketamine, imipramine), stimulants (e.g., methylphenidate, methylenedioxy-methamphetamine (MDMA)), and miscellaneous (e.g., strychnine, verapamil, haloperidol) (Parmar et al. 2011; Shewiyo et al. 2012; Tuzimski 2011).

### **Ion Exchange Chromatography (IEC/IEX)**

IEC is a distinctive kind of adsorption chromatography, which allows separation of ions. It has a special significance in the analysis of organic and inorganic ions such as phosphate ( $\text{PO}_4^{3-}$ ) or sulfate ( $\text{SO}_4^{2-}$ ). Ion separation is based on the charge and the size of each analyte ion itself as well as the counter-ions, the pH, and the ionic strength in the mobile phase and the type of exchange resin. The stationary phase is an ion-exchange resin. Ion-exchange resins are categorized as cation and anion exchangers. In both classes, strong and weak ion exchange resins exist (see Table 3). Liquid-phase analyte ions are attracted via Coulombic forces to ions in the exchange resins (stationary phase). Elution of the analyte ions occurs by an exchange with an ion from the eluent (Inamuddin and Luqman 2012a, b).

IEC is used in many fields where small molecules/ions must be detected; for some molecules/ions, it is the preferred method. Here are some examples: In the field of environmental analytics, it can be used for the detection of inorganic anions such as nitrate, nitrite, bromide, fluoride, chloride, or inorganic cations like  $\text{Cr(VI)}$ ,  $\text{Ni}^{2+}$ ,

**Table 3** Classification of ion exchange resins and their chemical functional groups

Ion exchange resin	Functional group	
<b>Cationic exchanger</b>		
Strong acid	Sulfonic acid	-SO <sub>3</sub> H
	Phosphoric acid	-PO(OH) <sub>2</sub>
Weak acid	Hydroxyl group	-OH
	Carboxyl group	-COOH
<b>Anionic exchanger</b>		
Strong alkaline	Quarternary amine	-N <sup>+</sup> (CH <sub>3</sub> ) <sub>3</sub>
	Diethylaminoethyl-(DEAE)	-(CH <sub>2</sub> ) <sub>2</sub> -N <sup>+</sup> H (C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub>
Weak alkaline	Primary amine	-NH <sub>2</sub>
	Secondary amine	-NH-
	Tertiary amine	-N- 
	Chelating resins (aminophosphonic acid, iminodiacetic acid, thiols)	NH <sub>2</sub> CH <sub>2</sub> PO (OH) <sub>2</sub> NH (CH <sub>2</sub> COOH) <sub>2</sub> -SH

Cu<sup>2+</sup>, or metals in complexes such as Au(CN)<sup>2-</sup> and Au(CN)<sup>4-</sup> from complex matrices. In the field of food analytics, organic molecules such as pyruvate, lactate, citrate, or amino acids can be measured (Inamuddin and Luqman 2012a, b; Karlsson and Hirsh 2011).

## Electrophoresis

The electrokinetic phenomenon was observed in 1807 by the German scientist F. Reuss at Moscow University (Reuss 1809). Electrophoresis, as known today, was first described in 1937 by the Swedish chemist A. Tiselius. The term derives from the Greek words “ηλεκτρον, electron” “electron” and “φορεσις, phoresis” “carrying” meaning “electric carried.” The physical principles of electrophoresis are based on the motion of analytes (cells/particles/proteins/substances) relative to a fluid under the influence of a spatially uniform electric field (see Fig. 12). The migration speed and in consequence the retention time of the analytes depend on their charge, mass, and size as well as the electrophoresis media and the strength of the electric field. The results are singular bands visualized on a gel, a foil, or an electropherogram (e.g., presentation of DNA sequencing). Modifications of electrophoresis are, for example, slab-gel electrophoresis and capillary electrophoresis (CE). CE (also known as capillary zone electrophoresis, CZE) uses – besides the normal electrophoresis conditions (conductive liquid medium under the influence of an electric field) –

**Fig. 12 Principle of electrophoresis.** The sample with the macromolecules is applied on a film/gel, e.g., a cellulose acetate gel. Then an electric field is applied. The charged molecules migrate toward the positive or negative pole according to their (opposite) charge (in the Figure, the positive macromolecules migrate to the cathode). By passing through the film, the macromolecules are separated by their size, charge, and conformation. After a certain time, the electrophoresis is stopped and the macromolecules are stained (discontinuous working system). The gel is only for single use. In contrast to electrophoresis, capillary electrophoresis is a continuous working system. The separated macromolecules are detected by a UV-detector, or a similar device

electroosmosis, as a further separation principle. If ions are in the solution medium, then an electroosmotic flow will be generated with the negatively charged analytes and the negatively charged ions moving to the anode. The positive ions in the medium as well as the analytes (independent of the charge) flow to the cathode. A short overview of the application fields and possibilities are given in (Pascali et al. 2012; Harrington et al. 2010; Simpson et al. 2008).

## Atomic Spectroscopy

Atomic spectroscopy embraces a set of spectro-analytical techniques for the qualitative and quantitative determination of chemical elements (Hywel Evans et al. 2012). J. Marci von Kronland described in 1648 the diffraction and the scattering of light in waterdrops. The first spectroscope, consisting of a lens, a prism, and a screen, to define a light beam, was developed by I. Newton in 1666. He showed that the white light from the sun could be dispersed into a continuous series of colors (a light spectrum). In 1752, T. Melville discovered that putting different substances/salts in flames, and passing the light through a prism, leads to different spectra. He

found that table salt generated a “bright yellow.” In 1815, J. Fraunhofer discovered in the optical spectrum of the Sun dark features (absorption lines). In 1853, A. Angstrom analyzed the spectrum of hydrogen and obtained the first insight into atomic structure. In the years from 1855 to 1863, R. Bunsen and G. Kirchhoff systematically investigated thousands of spectral lines (Burns 1975; Thomsen 2006). The first element discovered by spectral lines was helium. The first hint of the existence of helium was seen in 1868 by the astronomer J. Janssen. He saw a bright yellow line with a wavelength of 587.49 nm in the spectrum of the chromospheres of the Sun (Tayler 1995). The principles of quantum theory, interrelating atomic structure with electromagnetic radiation, were initiated by M. Planck, about 1900.

The principle of all atomic spectroscopy techniques is based on the characteristic behavior of atoms/elements (but not chemical compounds) that under certain physical circumstances an *element-specific* electromagnetic emission or absorption takes place (Bings et al. 2010). This interaction corresponds to a change of the energy state of the outer electrons of each atom. For this reason, the analyte elements in the sample have to be released from their compounds. Free atoms can be generated by atomization in a flame or plasma. Widely used atomic spectroscopy techniques are:

- Atomic absorption spectroscopy (AAS)
- Atomic emission spectroscopy (AES)
- Atomic fluorescence spectroscopy (AFS)
- Optical emission spectroscopy (OES)
- Inductively coupled plasma mass spectrometry (ICP-MS)
- X-ray fluorescence spectroscopy (XRF spectroscopy)

The interaction between the outer electrons of the atom and electromagnetic radiation can involve atomic absorption, atomic emission, and atomic fluorescence. Atomic absorption occurs when they absorb ultraviolet (UV) and/or visible light (VIS) radiation. The unabsorbed radiation is measured. The atoms reach an excited state (higher orbital) from the ground state. In the case of atomic emission, the excited electrons (e.g., after thermal or electronic excitation) revert to the ground state by emission of electromagnetic radiation. With fluorescence spectra, the atoms are excited with light or laser, and then light of a longer wavelength range is emitted and measured.

In *qualitative* atomic spectroscopy, the characteristic lines (wavelengths) for each element are measured. In *quantitative* atomic spectroscopy, the intensity of the lines from each element is determined, and the amount of this element is calculated with the aid of a calibration line. The quantification relies on the Beer-Lambert law. With different atomic spectroscopy techniques, the following (most relevant) elements that can be measured are Ag, Al, As, Au, B, Ba, Be, Bi, Ca, Cd, Ce, Co, Cr, Cs, Cu, Dy, Er, Eu, Fe, Ga, Gd, Ge, Hf, Hg, Ho, In, Ir, K, La, Li, Lu, Mg, Mn, Mo, Na, Nb, Nd, Ni, Os, P, Pb, Pd, Pr, Pt, Rb, Re, Rh, Ru, S, Sb, Sc, Se, Si, Sm, Sn, Sr, Ta, Tb, Te, Th, Ti, Tl, Tm, U, V, W, X, Y, Yb, Zn, and Zr (Welz et al. 2005; Skoog et al. 2018).

## Atomic Absorption Spectroscopy (AAS)

This technique is based on the absorption of optical radiation by free atoms in the gaseous state. AAS can be used to determine over 70 different elements in solution or in solid samples. AAS was developed in the 1950s by the team led by A. Walsh. The first stage of AAS requires atomization of the sample analytes in the atomizer. Then the atoms are irradiated by optical radiation. To obtain an exact element-specific wavelength for each element, the radiation has to pass a monochromator. The element-specific radiation is measured and the signal amplified within the detection system (see Fig. 13) (Welz and Sperling 2007).

Within the general technique of atomization, different atomizers are available: Flame atomic absorption spectroscopy (FAAS), electrothermal atomic absorption spectroscopy (ETAAS), graphite furnace atomic absorption spectroscopy (GFAAS), and cold-vapor atomic absorption spectroscopy (CVAAS). In the case of FAAS, a combination of a burning gas and an oxidation gas is used. The combination depends on the analyte elements (poorly vaporable elements like Mg, Ca, W needs higher temperatures). Usual combinations include acetylene (burning gas) and nitrous oxide ( $N_2O$ ; oxidation gas), which reaches temperatures of about 3,200 K, or acetylene and oxygen, reaching temperatures of about 3,000 K. In the case of GFAAS, the liquid, solid, or gaseous sample can be analyzed directly. The sample is put in the graphite tube, and a temperature program is started leading to drying, pyrolysis, and atomization of the sample. As a final step, the graphite tube is cleaned at high temperature.

Different lamps are used as radiation sources. First, it is necessary to distinguish between two types of lamps: line source (LS) and continuum source (CS) lamps. LS lamps emit a single line spectrum. CS lamps emit continuous spectra. In classical AAS, CS lamps like deuterium hollow cathode lamps (HCL) were used for

**Fig. 13** Schematic description of atomic absorption spectroscopy (AAS). The elements in the sample are atomized. The elements are activated by a radiation source. The emitted spectra from the elements are, after passing a monochromator, detected, multiplied, and evaluated

background compensation. Newer developments, such as high-resolution continuum source atomic absorption spectroscopy (HR-CS AAS), use CS lamps like xenon compact-source arc discharge lamps. These provide a high radiation density and cover the complete spectral range from the near vacuum-UV to the near infrared.

For LS AAS, normally HCL are used. HCL consist of a glass tube containing a cathode, an anode, and a buffer gas (usually a noble gas). The cathode is made from the element to be analyzed. The high voltage between the anode and cathode ionizes the buffer gas (a plasma is created). The gas ions are accelerated towards the cathode, sputtering off atoms from the cathode. The sputtered atoms from the cathode will be excited by collision with other particles in the plasma. By decaying to lower energy states, these excited atoms emit photons, which are used for identifying the element in the sample (Karabegov 2011; Kumar et al. 2009; Ataman 2008).

## Inductively Coupled Plasma Mass Spectrometry (ICP-MS)

In the early 1980s, the commercialization of ICP-MS started. Today, many different ICP-MS instruments are commercially available, each with their own strengths and limitations. They all share similar components such as the nebulizer, spray chamber, plasma torch, interface, and detector but can differ significantly in the design of the mass spectrometer and in particular the mass-separation device (Nelms 2005).

ICP-MS is based on the ionization of sample elements in a plasma at about 5,000 to 10,000 K. Normally the plasma is produced by the interaction of an intense magnetic field (produced by radiofrequency radiation passing through a copper coil) on a tangential flow of gas (normally argon), flowing through a concentric quartz tube (torch) at about 15 L/min. This setup ionizes the gas and, when seeded with a source of electrons from a high-voltage spark, forms a very high temperature plasma discharge (~10,000 K) at the open end of the tube.

The sample, typically in liquid form, is pumped into the sample introduction system, which is made up of a spray chamber and nebulizer. It emerges as an aerosol and eventually passes – by way of a sample injector – into the base of the plasma. As it travels through the different heating zones of the plasma torch, it is dried, vaporized, atomized, and ionized. During this time, the sample is transformed from a liquid aerosol to solid particles, then into a gas. When it finally arrives at the analytical zone of the plasma, at approximately 6,000 to 7,000 K, it exists as excited atoms and ions, representing the elemental composition of the sample.

In the next step, the ions are directed into the mass spectrometer via the interface region. The role of the interface is to transport the ions (and only the ions) from the plasma, which is at atmospheric pressure (760 torr) to the mass spectrometer analyzer region at approximately  $10^{-5}$  torr. Moreover the interface has to reduce or eliminate the secondary discharge, which arises by capacitive coupling between the radiofrequency coil and the plasma. After the interface the ion optic (a series of electrostatic lenses) focuses the ion beam toward the mass separation device, and it

stops photons (that would otherwise increase the signal noise), particulates, and neutral species from reaching the detection system. The most common types of mass separation devices are based on quadrupole, magnetic sector, time of flight, collision/reaction cells, and dynamic reaction cell technology. The basic principle of these different types of mass separation devices is to allow only analyte ions of a particular mass-to-charge ratio ( $m/z$ ) to pass the device and to fly to the detection system. Other particles such as matrix ions have to be filtered out. At last, the ion detector converts the ion beam into an electrical signal. Widely used are dynode detector systems, containing a series of metal dynodes along the length of the detector. In this case the ion beam impinges upon the first dynode and creates an electron beam, which attracts the next dynode. The process of electron multiplication starts.

One great advantage of this technique is its ability to carry out rapid multi-element determinations at low detection limits (ultra-trace level), especially enhancing the speed of analysis and the isotopic capabilities (Aggarwal 2010; Butler et al. 2010).

---

## Selective Analytical Chemistry

### Sensor Techniques

The term sensor techniques subsume different molecule measuring techniques. Biosensors are widely used with their special form of ion-selective electrodes (ISE), for detecting supramolecular interactions on interfaces. According to the International Union of Pure and Applied Chemistry (IUPAC), a biosensor is defined as “a self-contained integrated device that is capable of providing specific quantitative or semi-quantitative analytical information using a biological recognition element (biochemical receptor) which is in direct spatial contact with a transduction element” (Turdean 2011). Biosensor techniques are based on direct measurement of a (biological) component with the aid of a biorecognition phases, such as enzymes, antibodies (immunosensors), single-stranded DNA, or microorganisms (whole-cell based biosensors). The analyte interacts with the biorecognition phase and produces a signal, e.g., a change in proton concentration; a release or uptake of gases like oxygen; a release or uptake of electrons; a light emission, absorption, or reflectance; a heat emission; or a mass change. For example, an antigen can be detected by coupling with an antibody. The antibody is directly coupled with a transducer, transforming the chemical signal into a measurement signal/measurable response. This type of system is quite general. Transducers can be electrodes based on an optical fiber, a piezoelectric crystal, electrochemical methods (potentiometric or amperometric systems), sonic methods, or a calorimetric system (thermistor). The signal from the transducer is electronically processed, and the measurement value is displayed (see Fig. 14) (Farré and Barceló 2009).

One classification of biosensors is based on the detection system of the transducer. Biosensors are used in ecotoxicology (formaldehyde detection) and

**Fig. 14 Principal construction of a biosensor.** An analyte-specific detection system is used, which is coupled with a transducer. The transducer converts the chemical signal from the detection system into an electronic signal that is amplified, and the value obtained is reported

environmental monitoring (pesticides, nitrites) as well as for breath tests, in food control measurements (“artificial nose” to determine freshness, aroma, odor) and for military use, e.g., detection of nerve gas and chemical or biological weapons.

ISE is a form of potentiometry. That means a special form of electrochemical-based biosensors that determine the equilibrium cell voltage of galvanic cells. ISE measure the activity of a special analyte ion in a solution of different ions. This produces a potential that is proportional to the concentration of the analyte ion. ISE are used for measuring in brass, bronze, copper, lead, and cadmium baths as well as for the determination of ethylenediaminetetracetate (EDTA) and citrate. Dependent on the ion-selective membrane, solid-state and liquid membranes are distinguished. Solid-state membranes can be based on glass membranes, single crystal membranes, or precipitation membranes. Liquid membranes can be based on ion carrier membranes or ion exchange membranes (Gruendler 2007).

## Immunoassays

Immunoassays (IAs) are widely used laboratory methods for clinical and (forensic) toxicology diagnostics. IAs are useful for blood or serum therapeutic drug monitoring. They are also useful for serum and urine determinations of ethanol, medicines, drugs of abuse (amphetamines, barbiturates, benzodiazepines, cannabinoids, cocaine, ecstasy, methadone, opiates, phencyclidine, tricyclic antidepressants), and other toxins. The basic principle of the IAs is the detection of the analyte (in this case “the antigen”) in a liquid phase by bonding with an antibody (antigen-antibody reaction, see Fig. 15). Normally, IAs are based on a competitive and cooperative interaction between the analyte (a hormone, a protein, a drug or a hapten) to be determined and a labeled ligand, which is thus measurable, and an unlabeled ligand, both of which occupy the same binding site on the analyte. The labeling can be achieved with a fluorescent dye, a luminogen, a fluorophor (FIA), an enzyme (EIA), or a radioactive (RIA) substance. IAs are fast, sensitive, and accurate and permit

**Fig. 15 Principles of an enzyme-linked immunosorbent assay (ELISA).** (1) Analyte-specific antigens are bound to the wall of a reaction vessel. (2) After adding the sample, the analyte binds to the analyte-specific antibody. (3) After washing, a second biotin-labeled antibody binds to the analyte. (4) After washing, a streptavidin-enzyme conjugate binds to the biotin-labeled antibody. (5) The streptavidin-enzyme conjugate catalyzes the formation of a chromogen from a colorless substance that is added

determination of analytes in different kinds of (biological) fluids or suspensions (Durner 2010; Moody 2006; Chan et al. 2008). One problem is cross-reactivity with additional matrix components, such as metabolites or structurally related substances.

IAs can be classified by different criteria. Widely used is the classification depending on their realization. In this case, homogeneous IA can be distinguished from heterogeneous. In contrast to homogeneous IAs, the unbound reactants are separated prior to measurement in heterogeneous IAs. In the case of heterogeneous IAs, two further types can be distinguished, a competitive IA and an immunometric IA, also known as “two-site” or sandwich IA. A very common form of sandwich IA is the enzyme-linked immunosorbent assay (ELISA). In ELISA test systems, the antigen in the liquid sample is captured by immobilized antibodies (e.g., on the wall of cavities in 96-well plates or on polystyrene globes). After washing steps, a second, enzyme-labeled antibody (e.g., with horse radish peroxidase, alkaline phosphatase, b-galactosidase) against the antigen is added. Then a substrate is added which is converted to a chromogenic reaction product if the enzyme from the antibody (and therefore the analyte) is present in the reaction vessel. The concentration of the analyte can then be determined through absorption spectroscopy according to the Lambert-Beer law.

In general, homogeneous IAs are more amenable to full automation and thereby quicker throughput. Heterogeneous IAs are less susceptible to matrix interference and thereby more versatile with non-urine matrices.

Other common IAs are cassette or strip rapid tests like lateral flow immunoassays (LFA) (Christopher et al. 2005; Posthuma-Trumpie et al. 2009). Such tests are used

in environmental analytics (water testing, pesticides, dust mite testing), food testing (genetically modified (gm) food, *Escherichia coli*, *Salmonella* strains), military analytic (germ warfare, explosives chemical warfare), veterinary analytics (feline cancer, BSE, canine heart worm), disease diagnostics (malaria, hepatitis B, tuberculosis), testing of sexual transmitted diseases (STDs; *Chlamydia*, syphilis, HIV), fertility diagnostic (pregnancy, luteinizing hormone), or drug abuse (cocaine, cannabis, ecstasy).

---

## Special Types of Mass Spectrometers

The very widely used quadrupole mass spectrometers were discussed in the chapter on separation techniques, as they are often combined with a GC or HPLC/LC and are used for routine investigations (see section “[LC-MS \(Thermospray, Fast Atom Bombardment, Particle Beam\)](#)”). At this point, a special type of mass spectroscopy will be discussed, which is mainly used in research.

### (LC)-MALDI-TOF

MALDI-TOF-MS is one of the newer methods in the field of analytical chemistry. The technique was developed in the 1980s by M. Karas and F. Hillenkamp and also K. Tanaka et al. (Karas and Hillenkamp 1988; Tanaka et al. 1988). It is a discontinuous method that produces ions after exposure to a laser beam. Ion generation, acceleration, and mass analysis can be repeated in short time intervals. It is a suitable method for protein, peptide, oligonucleotide, synthetic polymer, and organic macromolecule measurements as well as for bacterial identification in clinical microbiology (Seng et al. 2010; Kafka et al. 2011; Li et al. 2010; Oeth et al. 2009; Vestal 2009). The sample is mixed with a matrix. This consists of low-molecular mass organic substances such as all-*trans*-retinoic acid, 2,5-dihydroxybenzoic acid, 5-hydroxysalicylic acid, or 9-nitroanthracene which have an absorption maximum at a laser wavelength of 337 nm. This mixture is presented on a sample plate. Then the solvent is evaporated, the plate inserted within the sample chamber of the MS and bombarded with the laser beam (discontinuous in the range of ns). Then an acceleration voltage is applied to accelerate the ions to the detector. The kinetic energy from each ion is equal. Their velocity depends on their mass-to-charge ratio. After detection, the mass of the ions can be determined by their time of flight. In some MALDI-TOF, mass spectrometers reflectors are inserted. A reflector generates a multilevel electric field. The ions are reflected from their trajectory and registered by a second detector. Using this technique, it is possible to compensate for smaller kinetic energy differences from ions equal in mass (see Fig. 16). Faster ions plunge deeper into the electric field of the reflector and stay there longer (Mamyrin 1994). By using this “trampoline effect,” it is possible to reduce the mass resolution limit many times over.

**Fig. 16 MALDI-TOF MS schematic.** A laser beam ionizes the analyte(s) from the sample plate which are accelerated in the electric field. In the linear mode, the analyte ions are separated by their mass-to-charge ratio ( $m/z$ ) in the time of flight tube. The higher the molecular mass the lower the velocity in the tube. During the flight, the analyte ions can be decomposed (post source decay; PSD). In the linear mode it is not possible to separate these PSD ions. By using the reflection mode, uncharged molecules pass the reflector, whereas charged ions will be deflected to a "V"-like path by different potentials in the reflector. Thereby a further separation of ions takes place

## Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR-MS)

Cyclotrons are circular particle accelerators in which ions are accelerated within a magnetic field into a spiral-shaped path to trigger, for example, nuclear reactions. A prominent application is the production of isotopes for medical diagnostics such as positron emission tomography (PET). The principle of this ion acceleration is also used in FT-ICT-MS. To arrive at this high-resolution spectroscopy method, basic work on particle accelerators had to be completed first. In the 1920s, there were numerous considerations about building a cyclotron, but these were not implemented. Inspired by a publication on particle acceleration, E. Lawrence (1901–1958) realized that a linear accelerator would require too large dimensions, especially length, for the generation of ions with high kinetic energy. He proposed to develop a more compact design by using circular acceleration. In 1930, he built a cyclotron and produced ions with high kinetic energy (Lawrence and Edlefsen 1930; Lawrence and Livingston 1932). The next milestone was the introduction of the

Omegatron by Sommer in 1950 (Sommer et al. 1950). The Omeatron was based on the principles of the cyclotron. However, it was much more compact (approximately the size of a cigarette packet). The advantage of this invention was that the electron/proton mass ratio could be determined physically (and not electrochemically, as before) and with high accuracy for the first time. Also it became possible for the first time to determine the masses of gases and vapors with high resolution (National Bureau of Standards 1950). The now common Fourier transform technique was introduced in 1974 by Marshall and Comisarow and is based on a pulsed measuring method (Comisarow and Marshall 1974).

In this overview, only the basic function and design of FT-ICR-MS can be described. There may be major differences between the various manufacturers. Central components are a strong magnet (up to 21 Tesla) and an ICR trap. This is a modified, advanced Penning trap: that is an ion trap that can hold ions by means of a strong magnetic field. Depending on the geometric shape, there are cubic or cylindrical ICR traps (Fig. 17).

The traps consist of six pairs of electrodes/plates, two axial and four radial. The axial plates are used to trap the ions, similar to creating an electrostatic field in a quadrupole mass spectrometer. The two pairs of radial plates serve on the one hand to excite the ions (excitation plates) and on the other hand to detect the current induced by the ions (detection plates).

By modification by the electrostatic field created by the trapping plates in combination with the static magnetic field, the ions are trapped. To a first approximation, in accordance with the Lorentz force, the ions move in the ICR trap within the magnetic field on a circular path with the so-called cyclotron frequency. The radius of this resting movement of the ions depends on their thermal energy as well as on the strength of the magnetic field (the stronger the magnetic field, the smaller the radius). By emitting radiofrequencies (RF) through the excitation plates (RF generator), the ions can be excited when their cyclotron frequency is in resonance

**Fig. 17 Cylindrical ICR trap.** The two trapping plates are attached axially (dotted area with an inlet for the ions in the middle). Both the excitation plates (light grey) and the detection plates (dark grey) are mounted radially. The ICR cell is located in a strong magnetic field  $B$  that points in the axial direction

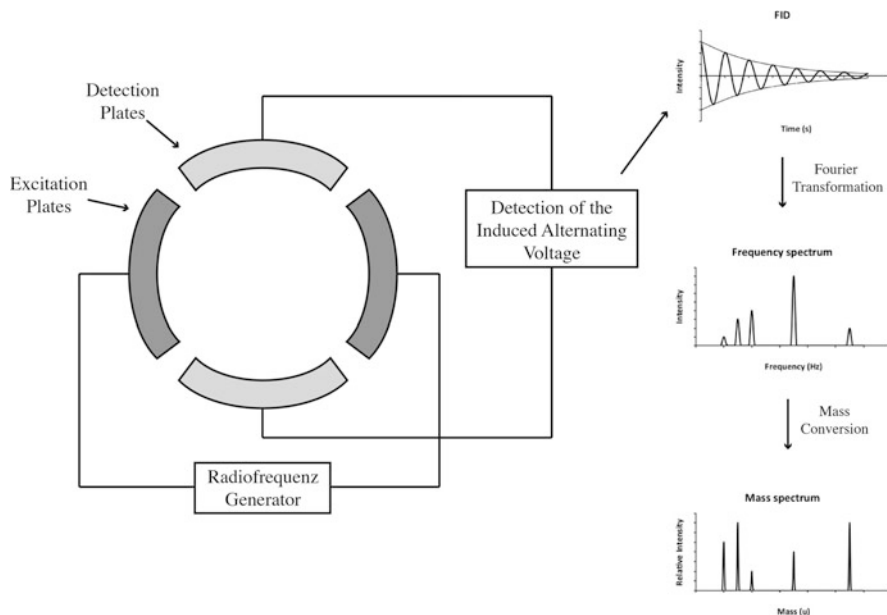

**Fig. 18 FT-ICR-MS principle.** (a) Ions move within a magnetic field on a circular path because they are affected by the Lorentz force. The direction of movement is perpendicular to the magnetic field. The orbital frequency is called the cyclotron frequency. (b) Ions can be excited in resonance by irradiation with an alternating radio frequency. (c) The excited ions move close to the detection plates and thus induce a measurable voltage

with the corresponding wavelength of the RF (Gross 2017). Their orbital radius becomes increasingly greater. If the radius becomes so large that they are close to the detection plates, it induces a detectable voltage (see Fig. 18). The strength of the induced voltage depends on the number of ions and the distance to the detector plates (orbit radius) and is independent of the mass of the ions. The detected signal is converted into a frequency spectrum via a Fourier transform. From this the mass spectrum is calculated (see Fig. 19), for which a prior external calibration with known masses is required (Marshall and Chen 2015; Pico 2015). One advantage of FT-ICR-MS is that it delivers the greatest resolution and mass accuracy. With classical mass spectrometry, masses in the range between 100 and 1,000 u (u = unified atomic mass unit; it is defined as 1/12 of the mass of a neutral atom of carbon isotope  $^{12}\text{C}$ : unbound, in the electronic ground state, at rest) can be resolved very well. With the FT-ICR-MS, measurements over 1,000,000 u can be resolved. One reason for this is that frequencies can currently be determined with higher accuracy than any other physical parameter. However, the FT-ICR-MS devices are large, heavy, and expensive.

The FT-ICR-MS has a wide range of applications. The main focus is for petroleum analytics and the “omic” sciences (such as proteomics, metabolomics) (Zhao et al. 2016; Cho et al. 2015; Ghaste et al. 2016). This technology is increasingly finding its way into pharmacology and toxicology. Pharmaceutical companies often buy the active ingredients for their preparations on the international market. In addition to the active ingredient, the product may also contain adulterants (unethical manufacturers are unfortunately also among the producers of the active ingredients). Due to the increasing demand for phosphodiesterase type 5 (PDE-5), enzyme inhibitors like sildenafil for the treatment of erectile dysfunction in men, counterfeits are available.

**Fig. 19 FT-ICR-MS detection.** The voltage induced at the detection plates is measured and converted into a frequency spectrum via Fourier transformation. The mass spectrum is obtained from this after conversion and calibration with standards

More than 50 unauthorized analogues of PDE-5 inhibitors have been described in the literature (Patel et al. 2014). The counterfeiters of the active ingredients constantly synthesize new, cheaper analogues, in the expectation that they will be unnoticed by the normal analytical controls of the buyers. By using new and different analytical techniques, these contaminated and stretched active ingredients can be identified (Patel et al. 2014). In geochemistry, this technique is used to investigate dissolved organic matter (DOM). DOM are dissolved organic substances in the soil with a particle diameter  $<0.45 \mu\text{m}$ , which are important for the nutrient cycle and biogeochemical processes in both aquatic and terrestrial environments. It is said that DOM is one of the most mobile and actively cycling organic matter fractions (Bolan et al. 2011). Anthropogenic pollutants can accumulate and be made bioavailable. It has been shown that the release of nano-titanium dioxide (Nano-TiO<sub>2</sub>) into the aquatic environment increases the consumption of DOM and reduces its molecular diversity (Lv et al. 2017). Other research groups study the composition of DOM under different conditions and locations. It has been shown that the pH of forest soil has a greater influence on DOM than its temperature (Roth et al. 2015). Other fields of application include the investigation of posttranslational modifications such as methylation of histones to control chromatin function (Starkova et al. 2017) and the influence of chronic alcohol abuse on posttranslational acetylation of histones and cytokine release. In comparison to controls, alcohol abuse causes a significant increase in acetylation of histone H4 at lysine 12

(H4K12ac), which in turn intervenes in the inflammation cascade (Parira et al. 2017). In neuroscience, the hormones of habenular nuclei (a pair of small symmetrical structures in the epithalamus) have been investigated. At the medial core, 27 prohormones were identified; and at the lateral core 20, which in turn were split into 262 and 177 neuropeptides (Yang et al. 2018). FT-ICR-MS can also be used to search for pharmacological active substances in various plant sources. In one algae species, substances have been found that inhibit the reverse transcriptase of HIV-1. Using FT-ICR-MS and database analysis, a structural analysis of these substances has been carried out (Kremb et al. 2017).

## Abstract

Within the last decade the documentation of uncertainty has become mandatory as a necessary part of any exposure and risk assessment. A key document that is used as a framework in many regulatory approaches is the guidance document published by the WHO (IPCS) in 2008. The structure of this chapter follows the guiding principles described there, adding information from various regulatory documents. The process of an exposure assessment is structured by the definition

of the scope of analysis, the selection of appropriate exposure scenarios for the population under concern, and the choice of conceptual and mathematical models with appropriate parameters. The evaluation of the resulting exposure calculation should support conclusions about the likelihood of exceeding health-based guidance values. The choice of parameters must cover the existing variation of all influence factors. The process should start with simplified approaches and repeated iteratively until the level of residual uncertainty can be tolerated with respect to the purpose. Each uncertainty may be analyzed at one of three tiers: qualitative, deterministic, or variance based. The identification and evaluation of the different kinds and sources of inherent uncertainty is part of the overall analysis and documentation. By this, uncertainty analysis strongly supports informed decision-making and risk communication under uncertainty.

**Introduction**

Communicating the results of an exposure assessment that is based on model assumptions and numerical estimates is demanding, communicating the inherent uncertainties at the same time makes the task complex. Any exposure analysis relies on information on the concentrations of a pollutant in an exposure media, on the circumstances and the human behavior and the activities that result in contact and exposure, as well as on the transfer rates from the exposure media to the individual. Exposure increases the internal dose when the agent is transferred into and taken up by the body. Any exposure assessment includes knowledge and assumptions with respect to appropriate exposure scenarios, in relation to the models that should reflect the selected exposure scenarios and with regard to the type and quality of available data that characterizes the exposure conditions described for a population or a subgroup of concern. Risks cannot be reliably estimated if exposures are not properly characterized and, if necessary, sufficiently quantified (IPCS-WHO 2008). Any risk quantification relies on good measurement or appropriate estimates of influential variables. Since valid exposure assessment is a core element in quantitative risk assessment, any inherent uncertainty will influence the quality of results.

Risk assessment results are predictions of the frequency and severity of effects on the ground of exposure estimates. The quality of any risk assessment, and in consequence risk management and risk communication (NRC 1994), are directly dependent on the quality of the exposure assessment process. Risk reduction is often achieved through regulation, enhancement of existing rules and laws that should result in exposure mitigation. For all regulatory purposes, sufficient knowledge about exposure conditions is a basic prerequisite for characterizing subsequent risk

management strategies. For all situations which might contribute to an exposure, the possible active sources, the relevant pathways, and the behavior patterns that contribute to exposure must be identified. The role of exposure assessment is to provide information about the distribution of expected total magnitude of exposure, about the nature of the source, about the routes of exposure, and about the individuals who are exposed. Uncertainty in risk assessment is defined by IPCS (2004) as “imperfect knowledge concerning the present or future state of an organism, system, or (sub)population under consideration.” The evaluation of uncertainty has in consequence both qualitative, quantitative descriptive, and prognostic aspects.

Describing the variability, e.g., over individuals (esp. age and sex groups), over exposure situations, over time, over regions, as well as over groups with different behavior and susceptibility should reflect existing differences. These differences might reflect varying contact to hazards, different substance intake or the body burden. Variability and heterogeneity refer to the natural variations (IOM 2013) in the environment, exposure paths, and susceptibility of subpopulations. They should be seen as inherent characteristics, which cannot be controlled by the exposure assessor or the decision makers. Variability and heterogeneity cannot be reduced by collecting more information, only by a stepwise selection of more homogeneous subgroups (stratification of analysis) within the evaluation process.

Uncertainty in exposure assessment refers to any lack of knowledge regarding the true value of quantities describing the real or the expected exposure. Any uncertain information used in the exposure estimation process will lower the confidence into the validity of exposure assessment results. The National Research Council (NRC 1994) stated: “Uncertainty forces decision makers to judge how probable it is that risks will be overestimated or underestimated for every member of the exposed population, whereas variability forces them to cope with the certainty that different individuals will be subjected to risks both above and below any reference point one chooses” (NRC 1994, p. 237).

---

## Development of a Regulatory Status of Uncertainty Analysis

Within the last decade, the documentation of uncertainty as a necessary part of any exposure and risk assessment has become mandatory for accepted chemical safety dossiers in the United States of America and Europe (U.S. EPA 2001, 2019; EU 2003; ESFA 2006; ECHA 2008, 2012a, b). Other countries have adopted the approaches (e.g., MEP 2012).

A key document that is used as a framework in all regulatory approaches is the IPCS-WHO (2008) guidance document. The structure of this overview follows the outline and the guiding principles described there. The terminology is mainly in accordance to IPCS/WHO (2004, 2008), specific terms in the context of REACH are described in ECHA (2008). A glossary of terms in the field of food safety is published by EFSA (2012).

Uncertainty analysis plays a central role in risk communication. It might clarify the question which confidence should be given to the risk assessment results in total

and how the reported results might be evaluated in relation to the residual uncertainties. Since the objective of any exposure assessment in a regulatory context is contributing reliable information to the process of decision-making, all sources and all consequences of existing variability, heterogeneity, and uncertainty should be identified (e.g., Morgan and Henrion 1990; Özkaynak et al. 2008). Uncertainty analysis increases the transparency about the state of knowledge, about inherent assumptions, and about the data quality that influences the results of an assessment. The IPCS-WHO (2008) document includes ten recommendations, which summarize methods and some experience with uncertainty analysis.

**(IPCS/WHO 1) Uncertainty analysis should be an integral part of exposure assessment.**

The recommendation proposes that all steps from the definition of the scope of assessment, the selection of the target variables up to the summary report of the assessment should be evaluated and at least the main results of an uncertainty analysis must be part of the documentation.

Uncertainty analysis should display which information might be assumed to be sufficient reliable and which should be used with caution. Furthermore, an uncertainty analysis might clarify which steps and actions might be taken to reduce the level of uncertainty. A sensitivity analysis as part of uncertainty analysis might additionally contribute important information for the risk management process:

It will clarify which model variables (influence factors) have a high impact on the overall exposure. A comparative evaluation of the costs, the time and the necessary efforts for an increase in quality on one side and the expected information gain for the risk management process on the other side might be an additional result of such an evaluation.

An exposure and risk assessment should be organized as a stepwise process (tiered approach) that starts with a simplified approach, e.g., with simplified scenarios, simple models, and/or with defaults for reasonable upper-bound estimates for all model variables. Such screening approaches should mostly overestimate the real population exposure since it is based on conservative assumptions in terms of influence. However, the approach has the advantage of simplicity, not requiring detailed information about each variable. Using appropriate parameter values the calculation might result in an estimate with high coverage of possible exposure and risk. If no risk is identified with such a screening methodology, it is not necessary to use more sophisticated calculation tools (EFSA 2007). If the documentation of inherent uncertainties does not indicate to restrictions with respect to an interpretation of results, even such a simplified analysis might be useful for the management decision. But such simplified approaches should generate valid upper-bound-estimates of possible exposure for the population under consideration, with a low degree of inherent residual uncertainty.

**(IPCS/WHO 2) The level of detail of the uncertainty analysis should be based on a tiered approach and consistent with the overall scope and purpose of the exposure and risk assessment**

If the quality assessment points to relevant limitations or if the results indicate to uncertain, but relevant results, an iterative refinement of the scenarios, of the models, and of the data basis will be necessary. Under these circumstances, a refinement would be required to achieve a sufficient quality of the results.

A simplified upper-bound exposure assessment together with an uncertainty analysis might have a high value in risk communication: The management might use the preliminary results as a first and timely, but uncertain, estimate. The risk management might furthermore describe the ongoing and planned steps to clarify the exposure situation, requiring iteration. And, the exposure assessors will have a justification for a time- and resource-binding refinement of the exposure assessment on a higher tier.

**(IPCS/WHO 10) Communication of the results of exposure assessment uncertainties to the different stakeholders should reflect the different needs of the audiences in a transparent and understandable manner.**

Communicating uncertain information in parallel with a description of the inherent problems, joined by a statement about necessary or ongoing steps to reduce uncertainty, might have a higher degree of perceived accuracy and credibility than waiting for complete information. Giving no or restricted information to the public is communication too. If necessary, even decisions for controlling existing risks might be made on a provisional basis, subject to verification or revision. It is the responsibility of the exposure (and risk) assessment experts to explain the inherent uncertainties. Since the audiences of risk communication may differ with respect to knowledge in the field, interests, and demands, the task of explaining exposure assessment results together with an uncertainty analysis will always be difficult. A detailed analysis of uncertainties will support the risk communication process with respect to the demands, to arising individual questions, and to the general requirements.

## **Rationale for Characterizing Uncertainty in Exposure Assessment**

The evaluation of human health risks requires information about the pollutant (e.g., emission rates, physical and chemical characterization of the substances, rates of degradation, and transformation), environmental concentrations, sources and pathways of exposure, and exposure/dose-response data. Information about each of these assessment elements might be limited. The identification of critical gaps in knowledge (scenarios and models) and data quality will be supported by a stepwise evaluation of uncertainties.

**(IPCS/WHO 3) Sources of uncertainty and variability should be systematically identified and evaluated in the exposure assessment**

## Definition of Assessment Objectives

The assessment objectives should be clearly defined. “Which information is of most interest?” This question has to be decided together with the risk management by the risk assessor prior to any exposure analysis. Within the first phase of an assessment, the reduction of language-based uncertainty should be seen as a communication target. Precision of language is often overlooked as a source of uncertainty in this phase of the assessment (Carey and Burgman 2008), it can result in misunderstanding, lost efforts, and delay. In general, exposure assessment should provide information about the nature of the source(s) and route(s) of exposure as well as information about the individuals who are exposed (Cullen and Frey 1999). Two different purposes for exposure assessment might be distinguished, (a) to assess the safety of legal limits (e.g., preregulatory dietary exposure assessment), or (b) to assess the actual exposure situation of a population or a specific subgroup (post-regulatory exposure assessment).

For regulatory purposes a mayor question that should be answered is “Do the results indicate to exposure higher than a predefined critical limit?” This requires in general a comparison to TDI, ADI, PTWI, or DNEL values. The unit of evaluation, in general expressed as [mg substance per kg body weight for a given time scale (maximal daily, average daily of long-term exposure)] should be defined in advance. If the results of an exposure assessment indicate, even in parts, a “higher/near the evaluation level” answer, (a) those ranges of the input variables that generate high exposure or risk, (b) those subgroups which show high exposure, and/or (c) those specific sources and pathways contributing to this situation should be identified (IPCS/WHO 1994, 2005). This requires qualitative evaluation, quantitative ranking of relevant inputs variables, and a discrimination of the importance among the influence factors. By this, input variables (and their inherent variance) that do not contribute to critical results could be separated from those influence factors (variables) that contribute mostly to high exposure conditions. It is the task of the exposure assessor to clarify the influence structure together with the identification of possible error sources and uncertainties.

Typical questions of the management and the public which call for an uncertainty analysis (Saltelli et al. 2004) are: (a) How confident are you in the results? (b) How much will the results change if the basic (input) data is slightly wrong or will change over time, over regions, over subgroups? (c) Which impact any change of input data and assumptions will have? (d) Which of the uncertain input factors is most important in determining the output? (e) If we could invest in elimination of uncertainty in one of the input factors, which factor should we start with to reduce the uncertainty of results?

Once the objectives are defined, the assessment must be designed to address them. An emerging challenge is how to quantify variability and uncertainty in integrated assessments over the source to exposure to uptake continuum. Since in general many scientific fields are tangled, any exposure assessment process should be seen as an interdisciplinary approach.

## Sources of Uncertainty in Exposure Assessment

The IPCS-WHO (2008) harmonization document calls for an analysis and full description for characterizing uncertainty using qualitative as well as quantitative approaches. Although inconsistencies in the application and methodology of uncertainty analysis might be seen, comparing the recommendations of different organizations, some common elements should be highlighted – these include qualitative and quantitative approaches.

**(IPCS/WHO 7) Uncertainty analyses for exposure assessment should be documented fully and systematically in a transparent manner, including both qualitative and quantitative aspects pertaining to data, methods, scenarios, inputs, models, outputs, sensitivity analysis and interpretation of results.**

The level of uncertainty that is contributed by the selection of scenarios, the conceptual and mathematical model applied and the choice of parameters should be documented. A qualitative evaluation should include the appraisal of the current scientific knowledge base. Controversial sources of uncertainty should be referred to and a (qualitative) evaluation of inherent subjectivity of choices for each of the controversial sources should be presented.

**(IPCS/WHO 5) Data, expert judgement, or both should be used to inform the specification of uncertainties for scenarios, models and model parameters.**

If different scientific approaches are available, then evidence and plausibility, the scientific support and the consistency of methods and data should be considered. The robustness of results using different assumptions and models (choice space) should be checked. By this, a full uncertainty analysis might offer a framework to facilitate and promote a qualitative consideration of the impact that uncertainties might have on the exposure assessment's results.

## Scenario Uncertainty

The scenarios should describe how people may be exposed to substances by emission, by ambient air pollutants, during manufacture, during industrial, professional, and consumer use of products as well as during the service life of articles and products. In principle, all scenarios do not reflect one specific local situation, but have the objective to be representative of either mean, typical, or most sensitive situations in a region for a defined population (EC 2000). Scenario uncertainty includes possible descriptive errors (e.g., wrong or incomplete information about the facts), aggregation errors (e.g., approximations for population subgroups, time scale, season, and regional differences), errors of assessment (e.g., choice of provisional model, extrapolation from other exposure situations), and errors of incomplete analysis (e.g., overlooking/ ignoring important exposure pathways and sources).

For exposure to chemical substances, ECHA (2008) proposed some rules for considering exposure scenarios: If the intended use of a chemical is known, as it is assumed in ECHA regulations, then a detailed description of all resulting exposure scenarios is required. The type and the number of exposure scenarios depend on how the substance is used in a predictable manner. Attributes that trigger the description of exposure scenarios are the sectors of use (SU), the product category (PC), the article category (AC) together with the environmental release category (ERC). For exposure in occupational settings the process category (PROC) should characterize production- and application-related characteristics. For consumer exposure, the product categories are defined in ECHA's Guidance R.12 (2008), describing the scope of exposure scenarios.

Uncertainties might arise, (a) if the identified uses are not consistent with other sources of information, if (b) identified uses are not covered by exposure scenarios or, (c) if operational conditions do not seem to be sufficiently realistic. Within a REACH chemical safety report (CSR) the description of all exposure scenarios should ensure the safe use of the substance. The necessary control measures must be described by the manufacturer or the importer. All determinants that reflect the conditions of use and the risk management measures should be reported within the exposure scenario description. Model assumptions should be reported in the exposure tables included in the chemical safety reports (CSR).

The variability in consumer behavior and the recognition of possible multiple exposures to the same substances from different products have to be taken into account in the consumer exposure setting. Additional information about the scenario description and the assessment methods are available in the ECHA (2010, 2011, 2012b) guidance documents which includes several practical examples.

A concise description of exposure scenarios might be used as a starting point for a conceptual description how exposure might occur. Relevant exposure events might differ over age (e.g., due to behavior, consumption, sources), sex/gender (e.g., with respect to behavior like using cosmetics, product usage), and region (e.g., by nutritional habits and environmental conditions).

A valid and reliable estimation of exposure requires appropriate description of scenarios, scientific concepts to translate this knowledge in to appropriate models and adequate formulas within a mathematical model to represent the exposure scenario.

## **Model Uncertainty**

Any mathematical model corresponding to an exposure scenario should reflect the dependencies of the degree of exposure in relation to all influential factors. The identification and description of all relevant exposure scenarios is an important prerequisite. An exposure assessment should provide full information about the origin of the model together with a detailed description and its validation status. This includes all formula(s) and a brief description of all variables. The set of involved variables needs a definition with respect to the content and the units

used. A list of all parameter values or distributions that represent the exposure factors within the population under concern should be part of the documentation. Any uncertainty that is related to the exposure scenarios will propagate to the exposure model and will influence the uncertainty of results. A general structure of exposure models includes information for each route/pathway (oral, dermal, inhalation) as well as for all exposure sources: the contact or intake frequency, the amount of transfer per contact/intake/uptake, as well as information about the concentration of the substance per item unit (e.g., mg Me Hg/kg Fish fresh weight,  $\mu\text{g NO}_2/\text{m}^3$  air). The total exposure is calculated as the sum over all pathways each including a sum over all contributing sources. The specific time intervals for all these intake-related variables should be defined in a homogeneous way.

$$\frac{\text{Intake}}{\text{Time}} = \sum_{i=1}^{\text{Path}} \left( \sum_{j=1}^{\text{Sources}} \frac{\text{ContactFrequency}_{\text{Sources}}}{\text{Time}} * \text{Intake}_{\text{Event/Time}} * \text{Concentration}_{\text{Sources}} \right) * \text{Transfer}_{\text{Path}}$$

Although the structure of the model is simple, the collection of information for an exposure model with many sources for exposure and different contributing pathways is demanding. For each pathway, at least one variable for a transfer factor is necessary. If the concentration of the substance of interest is changing in preparation (e.g., peeling or cooking/frying) or if concentration data is only available for whole food concentration then a transfer factor should describe the corresponding rate of change in concentration. If the internal (ingested/absorbed) dose is the target variable, assessing the dose within the body after the agent enters the body via ingestion, inhalation, or dermal absorption requires a transfer factor including sufficient information about the rate of absorption. The intake by each pathway (oral, dermal, inhalation) is a sum over all contact items (sources). All sources of exposure (e.g., food items, contact material, product application, indoor and outdoor immission) must be considered, as long as not at least one of the multiplication terms of the exposure equation equals (near) zero.

It should be noted that variance, measurement errors, and uncertainty of each element in the calculation propagate in a factorial manner (multiplication). The uncertainty of each source-related exposure is dependent on the quality of information of all elements in the part of model equation. The errors  $\varepsilon_i$  of each source-related intake estimate, describing the total of uncertainty for this item (e.g., the average methylmercury intake MeHg per day by tuna consumption) will increase the total error in a multiplicative manner.

The measured (or estimated) value of each parameter might be described as a composite of the true value  $x_i$  and an error  $\varepsilon_i$ , the latter dependent on the uncertainty of each variable (e.g., for the estimate of methylmercury intake by tuna the frequency of consumption, the amount eaten per meal, the MeHg concentration in fresh tuna,

and transfer factor for preparation factor and absorption rate). The type of error linkage might be additive ( $V_i = x_i + \varepsilon_i$ ) or multiplicative ( $V_i = x_i * \varepsilon_i$ ), depending on the variable.

**Total Error of intake estimate**  $\text{Item } i = \varepsilon_i \sim \varepsilon_{\text{frequency}} * \varepsilon_{\text{amount}} * \varepsilon_{\text{concentration}} * \varepsilon_{\text{transfer}}$

The error of the intake estimates of each source is the multiplicative combination of all errors. Any systematic shift or error in exposure frequency, of the amount consumed, or in substance concentration will result in an error of the exposure estimate. The sum of substance intake over all items (e.g., methylmercury exposure sources) per pathway might include many partial calculations (e.g., with varying consumption of different fish/food species with varying substance concentrations). Each might have a different quality. An exposure assessment integrates all the information about the sources and the relevant pathways into one exposure estimate. In consequence, the uncertainty analysis gains complexity. At least a basic evaluation of possible error sources is necessary to avoid wrong or distorted estimates.

The lack of quality might be a result of the model selection too. Describing an average exposure (per day, per week, per month) will require statistical information about average contacts, average frequencies, and average amounts of use, consumption, ingestion, or inhalation together with information about the substance concentration over time. A model that is describing exposure in an event-based manner requires much more information (e.g., the number of hand-to-mouth-contacts for toddlers per time unit, the contamination distribution of the contact environment over a certain period, the substance transfer by hand-to-surface-contact and by hand-to-mouth-transfer). In consequence, the time scale of the model variables and the information about the variables should be in accordance with the time scale of the target variable of the assessment.

Exposure models might describe different periods of time: The temporal scale for estimating exposure (and dose) depends on the scope of assessment. These might be peak doses (aRfD: acute reference dose), exposures occurring over a very short period of time (e.g., minutes), time-weighted averages, or exposure per day (e.g., for ADI, TDI, RfD comparison) or doses per week (e.g., for PTWI comparison). Exposure models should express the total intake for a specific time interval as the sum over all relevant pathways: e.g., dietary and nondietary intake (oral), skin contact (dermal), and inhalation.

$$\text{Intake}_{\text{total exposure}} = \text{Intake}_{\text{oral}} + \text{Intake}_{\text{dermal}} + \text{Intake}_{\text{inhalation}}$$

The errors and uncertainties of the path related intake estimates  $\varepsilon_{\text{total exposure}}$  will add up over all pathways. In general, the contribution of each path to the total exposure should be documented. An evaluation of inherent uncertainty per pathway is recommended.

$$\text{Error of estimate}_{\text{total exposure}} = \varepsilon_{\text{total exposure}} = \varepsilon_{\text{oral}} + \varepsilon_{\text{dermal}} + \varepsilon_{\text{inhalation}}$$

The magnitude of exposure is in general reported as an approximation of a risk-related numerical value, the total exposure divided by the body weight (as a proxy for the distribution volume). By this, the exposure estimate and the regulatory values, e.g., for the TDI, ADI, PTWI are reported in unified units [e.g., mg substance/kg body weight per time unit]. The step of dividing exposure by body weight introduces some additional uncertainty: (a) body weights show variation, (b) the intake (e.g., water, and food consumption) might be correlated to the body weight, (c) the relation between intake (e.g., breathing volume) and age might show non-linearities and (d) the relationship between nominator (exposure) and denominator (body weight and time scale used) might be moderated by other influential factors (e.g., level of activity, cultural and nutrition habits). All these relations might result in a lack of independence of the parameters. If these influences might result in systematic over- or underestimation, correlation and dependency between variables of the model must be included into the assessment.

**(IPCS/WHO 4) The presence or absence of moderate to strong dependencies between model inputs is to be discussed and appropriately accounted for in the analysis.**

Good modelling approaches use sensitivity analysis as a companion tool to identify possible errors (e.g., by evaluation of predictions of the model results against known data as a model calibration). Sensitivity analysis might demonstrate the possible impact of dependencies (e.g., described by correlation between the input variables).

## Parameter Uncertainty

As a starting point for a (deterministic) exposure assessment in general, default values (single-value-estimates) are used. These defaults should correspond to a description of the central tendency (mean, median of the parameter distribution representing the target population) or should stand for an upper-bound-estimate (e.g., reasonable-most-exposed (RME) in general described by 95%-distribution coverage of the particular variable. If the assessors intended as a screening step to produce conservative estimates of exposure (Hart et al. 2002), a combination of RME values for variables in the nominator (e.g., consumption per day, concentration) and lower-bound-estimates (e.g., 5%-quantiles) of the denominator (e.g., body weight) should be used for calculation. It has to be provided that the choice of a model and RME default parameters include appropriate conservative assumptions to take account for uncertainty. The Scientific Committee of the EFSA (2006, 2007) recommends that each scientific panel should review whether this requirement is satisfied by the assumptions and default values that they used previously. Treating the most significant uncertainties at each refinement step (higher tiers) progressively should refine the characterization of uncertainty about the likelihood of exceeding health-based guidance values. This should be done stepwise by evaluating the variability and the uncertainty in an integrated assessment. The numerical

description of uncertainty in parameters might be given as (a) symmetric confidence intervals (e.g., defined by standard deviations), (b) defined quantile ranges and error bands, or (c) as asymmetric confidence bands [ $CI_{\text{lower bound}}$ ,  $CI_{\text{upper bound}}$ ] for skewed distributions. A short justification for each selection should be given.

### **Uncertainty in Measurement**

Ideally, any measurement informing an exposure assessment would be free of random error and should not be influenced by systematic error. The higher the quality of a measurement instrument with respect to accuracy (bias) and precision, the lower the uncertainty will be. Random error is associated with the fact that repeated measurement in general will provide different measured values although the attributes of the object are assumed to be constant over time. The term “random error” describes the unpredictability of the deviances in a series of measures. Random error of a model parameter restricts the reliability. If a numerical estimate of the random error is available (e.g., by repeated measurement → reliability), the quantitative impact of random errors on the exposure results might be evaluated directly.

Systematic errors generate shifts on the measurement scale of model parameters. They might depend on external influence factors (e.g., differences over measurement instruments, over observers, over laboratory standards, and in relation to conditions of measurement and sampling). The degree of confidence about the absence of systematic error is described in general in a qualitative manner. If the direction of a systematic error is known, but not its magnitude, then the impact on the results might be estimated only in a qualitative manner. If a systematic error might be described by numerical boundaries, then the range of a possible quantitative impact on the results might be estimated too.

The resulting one-dimensional uncertainty interval of the results might describe the range of “true” value(s) of the outcome. For a detailed description and discussion of dealing with uncertainty in measurement, we refer to references for standards of measurement (e.g., ISO 1993; ASME 2005; JCGM 2008; NIST 2011).

Exposure assessment involves the specification of numerical values for all variables which are included in the exposure model. Selecting appropriate parameters for the model’s variables is a crucial factor for the model validity. But, with few exceptions the data available for an assessment will not be closely related to the exposure scenario (e.g., specific subgroups of consumers, regions) that has given rise to the request from the risk managers. In consequence, there will be always uncertainties, most of which cannot be quantified (EC 2000, p. 38) but discussed in a qualitative manner.

### **Data Sources for Model Parameters (Exposure Factors)**

Numerical default values for exposure parameters are obtained using various approaches (e.g., expert judgement, statistical analysis) and different sources (e.g., survey data, consumer panels, market observation). Within the last years, several countries have reported National Exposure Factor handbooks. Those

collections with a longer tradition back to the 90th are U.S. EPA's Exposure Factors Handbook (for adults: U.S. EPA 2011, for children: 2008, 2009), the European Union's (EU) Technical Guidance Document (EU 2003), the German XProb project (AUH 1995; Mekel et al. 2007, UBA 2011), and the European KTL's ExpoFacts (Vuori et al. 2006; JRC 2010) and the ConsExpo Fact sheets (RIVM 2012a, b).

Adjacent to reporting default values (e.g., median, mean, upper quantiles), these documents include information about the parameters: (a) descriptive statistics including variability, (b) the cumulative distribution and in parts (c), the type of underlying distribution (EPA 1999). In general, a stratification for age and sex, and if necessary due to population heterogeneity, stratification by ethnic groups is included. "Variability and heterogeneity refer to the natural variations in the environment, exposure paths, and susceptibility of subpopulations. They are inherent characteristics of a system under study, cannot be controlled by decision makers, and cannot be reduced by collecting more information." (IOM 2013, p. 3). Statistical uncertainty of estimates resulting from restricted sample size, are in parts reported for single-value-estimates (defaults). By this, conducting statistical uncertainty analysis using default values and confidence intervals is possible (see, e.g., Filipsson et al. 2011). Uncertainty due to sampling strategies (e.g., selection of study participants, response rates, regional differentiation) require a qualitative evaluation. Using the exposure factors (and variability indicators) published on a national level will result in general in an accepted state-of-the-art exposure assessment.

Uncertainties inherent in parameter values for exposure factors can be classified as sampling and non-sampling errors. Sampling errors arise from limited sample sizes in relation to the population size under consideration. The magnitude of this error is a function of (a) the variability of the measured attribute and (b) the sample size. In practice, we have to deal with the situation, that we have very low sample sizes, mostly for contamination measurement (esp. for food items, environmental measures). In these cases, the confidence intervals of the mean, the median and much more those for the upper quantiles show wide ranges. The selection of a type of distribution, in these situations, is based merely on scientific experience, not on data. If we only have data from selected subpopulations, we must assess the degree of representativeness for the target population and the expected effects of deviation. For selected scenarios and for statistical uncertainty calculation examples see e.g., Hammonds et al. (1994), IAEA (1989), RIVM (2009), U.S.EPA (2008, 2011).

More general problems might occur if exposure magnitude should be estimated for specific periods of the life span (child development, pregnancy, occupation). The age stratification of exposure factor handbooks is restricted. Especially for developmental studies, any changes in the exposure media, with respect to the sources and the pathways over the life stage should be considered. Each developmental stage requires the selection of specific scenarios, models, and appropriate age-related parameters – and a specific uncertainty evaluation (U.S. EPA 2006a).

## Evaluating the Total Impact of Uncertainty

The objective of a full characterization of uncertainty of an exposure assessment includes transparency, the identification of key sources of uncertainty and an evaluation of the consequences of limited information in the decision making. A systematic qualitative characterization of the sources of uncertainty is encouraged, as it provides the appropriate degree of confidence in outcome and associated recommendations. Short overviews of concepts of and methods that might be useful for reading assessments and for the evaluation in parallel to preparing an exposure assessment are given in IPCS-WHO (2008), EFSA (2006), ECHA (2006), and BfR 2015.

A simple documentation scheme for identified uncertainties (Table 1) is proposed by IPCS-WHO (2008). The rows reflect the steps of exposure assessment, the column headers might be used as a guide for the identification of the mayor sources of uncertainty: Each element of the matrix contains many aspects that might contribute to the overall uncertainty of exposure assessment results. For each element a classification of the uncertainty should be assigned. IPCS-WHO (2008) recommends the terms (No, Medium, High or NA = “not applicable”) for the quality and uncertainty assignments; EFSA (2006) proposed a ranking using two “+” and “-” signs indicating the direction and the magnitude of uncertainty for each subject of consideration. Short verbal descriptions of relevant uncertainty aspects for each cell of the table will support the transparency of the documentation.

## Model Evaluation

The promise given by an exposure assessment is, that the estimated results would approximately reflect the real exposure situation for a defined population. According to the classification of exposure assessment methods, data and model-based exposure assessment belongs to the class of indirect measurement. They utilize existing

**Table 1** Modified version of the EFSA (2006) and IPCS-WHO (2008) evaluation scheme

Sources of uncertainty	Characteristics of uncertainty

<b>Result(s)</b>			

(secondary) data on chemical concentration, frequency, strength, and duration of contact, without doing any specific measurement of the outcome variable.

In contrast, a point-of-contact approach involves measurements of chemical concentrations at the point where exposure occurs to assess the outcome variable. These quantify concentration close to the interface between the person and the environment (e.g., by personal samplers, by personal protocols, or duplicates of dietary intake). If the time interval of contact is recorded, the average exposure per time unit might be calculated. This type of exposure estimate requires data from environmental samplers (e.g., measuring pollutants in indoor or outdoor), information of the individual's characteristics (e.g., breathing rates), time-budget in different environmental media like indoors, outdoors, in cars. An example from Payne-Sturges et al. (2004) shows, for instance, that personal sampler-based exposures measures show higher values than exposure calculations for indoor volatile organic compounds (VOC) exposure based on standard exposure factors. Personal monitoring might reflect the variance of exposure conditions better than exposure estimation.

Since the target variables of an exposure assessment should reflect the uptake of a substance in relation to the distribution volume (indicator: body weight), the most appropriate information for comparison exposure estimates stems from biomonitoring studies. For example, Xue et al. (2010) studied the intake of inorganic arsenic in the general US population with the objective to compare exposure model predictions with observed biomonitoring data (see also NHANES 2020). The goal was to quantify the distribution of total dietary arsenic exposure. Comparing model predictions with observed data, the evaluation was conducted via comparing exposure and dose-modeling predictions against duplicate diet data and biomarker measurements, respectively, for the same individuals. The distribution of the modeled exposure (biomonitoring with pharmacokinetic dose estimation) and the distribution of estimates of exposure matched well with the distribution of the Duplicate Diet estimates. Kurzius-Spencer et al. (2013) show that Total Diet Studies (TDS) might underestimate the dietary intake in comparison (a) to modeled dietary arsenic exposure based on 24-h duplicate diet samples intake, (b) exposure estimation using distributions as well as compared (c) to backward estimation of arsenic intake from 24-h urine measurement.

The use of biomarkers of exposure may provide a more detailed and less biased estimate of substance uptake and distribution than any indirect methods. But this requires full information about the distribution in the body and metabolism of the substance. The linkage of biomonitoring data to specific sources requires again exposure models (U.S. EPA 2006b). Burns et al. (2014) describe the sources of uncertainty associated with the results of most epidemiologic studies together with techniques that exist that can be applied to improve weight-of-evidence evaluations and risk characterization efforts. Only few evaluation studies have analyzed the predictive quality of exposure assessment for Human Biomonitoring data in detail. In consequence, the usage of exposure assessment should be directed to a comparison of prognostic results to regulatory recommendations for substance intake (like ADI, TDI, RfD, DNEL).

## Sensitivity Analysis

Cullen and Frey (1999) define sensitivity analysis as the assessment of the impact of changes in input values on model outputs. Sensitivity analysis is used to determine how different values of an input, the independent variables, will impact a particular output, the dependent variables, under a given set of assumptions. Sensitivity analysis studies the relationships between information flowing in and out of the model (Saltelli et al. 2004). Frey and Patil (2002) underline the use of sensitivity analysis in exposure assessment for an identification and comparison of sources of uncertainty that influence the target variables and the assessment conclusions. Furthermore, a sensitivity analysis is useful for providing insight regarding model verification and the robustness of models (Cullen and Frey 1999).

**WHO/IPCS 6) Sensitivity analysis should be an integral component of the uncertainty analysis in order to identify key sources of variability, uncertainty or both and to aid in iterative refinement of the exposure model.**

If risk managers like to consider the impacts of alternative regulatory or risk management choices than sensitivity analysis is inevitable. Any maximizing of benefits will depend on a comparison of results based on scenarios, models, and parameter alternatives. Incorporating variability and uncertainty into such comparative assessment is state-of-the art. Ignoring variability would mean neglecting existing differences in exposure conditions (e.g., over persons, over exposing situations, application/usage/contact of hazards). Ignoring uncertainty would mean providing results as reliable, even if they are questionable.

The identification of model variables which are not controllable by the risk management (e.g., breathing rates, body surface area, body weight) will inform about the limiting conditions that might not be changed by regulation, control or advice.

Uncertainty concerning causal analyses must be characterized qualitatively. A qualitative judgment of the overall uncertainty should be accompanied by a list of major sources of uncertainty and a quantification of the expected influence of variation of the parameters on the results. Variables that might not be modified can have a high impact on the outcome (e.g., breathing rates, water consumption). Using for instance physiologically based pharmacokinetic (PBPK) models to predict the dose of a chemical substance or metabolite will result in a strong dependency of many model parameters to organ weights or body weight (see, e.g., Farrar et al. 1989; Krewski et al. 1995; Clewell et al. 2000; U.S. EPA 2006b; Bois et al. 2010). The identification of all variables that have a high influence on the target variable requires quantitative analysis.

Building a ranked list that describes the influence of the input variables on the target variables requires statistical analysis. The goal is to quantify the degree of influence of the input variables variance on the variance of the target variable. An analysis of all possible outcomes for all ranges of the input variables (variability), together with a consideration of inherent quantitative (and numerical expressed

qualitative) uncertainties, is a scientific task that will call for an involvement of mathematical, statistical and exposure science expertise. This has to be considered if the models include many pathways and sources. If the global exposure model contains several submodels for influence factors, uncertainty evaluation should be conducted by scientists from different faculties.

### **Quantitative Sensitivity Analysis: Identification of Key Sources of Exposure, Uncertainty, and Variability**

Since the efforts for a statistical sensitivity analysis should be balanced with respect to cost and time versus the expected gain of information, any uncertainty analysis should start with a screening step, which uses defaults for all parameters, evaluating the change of the outcome by stepwise changing these values. The identification of those input variables that have a strong influence on the variance of the target variables will indicate to variables with a high potential for possible exposure control (Frey et al. 2004).

The impact of variability might be controlled by a parameter-wise alternation of central tendency default to an upper-bound-estimate (e.g., the 95%- or 5%-quantiles). This procedure gives an overview about the 95% ranges of an influential variable, keeping all other influence variables on the mean or median (default for central tendency). In a similar manner, the impact of statistical uncertainty might be controlled by a parameter-wise alternation of the central tendency and/or the upper-bound-estimates using the confidence intervals (a fixed percentage) of these values, this describes the degree of uncertainty due to statistical reasons about the stability of estimates. These “One-At-A-Time” (OAT) methods (Murphy et al. 2004), changing always only one input parameter while keeping all other values constant, are strongly recommended at the screening level. A “tornado diagram,” ranking the variables by the outcome change, might illustrate the relative importance of each input variable. This approach corresponds to the economic evaluation term “elasticity” that describes sensitivity as the ratio of the percentage change in one outcome variable to the percentage change in an input variable; it is in general calculated as the ratio of changes in natural logarithmic units:  $E_{x,y} = \ln(\text{change in output } y) / \ln(\text{change in input } x)$  which corresponds approximately to (% output change in y)/(% input change in x). For an overview of graphical methods for presenting quantitative uncertainty, see, e.g., Ibrek and Morgan (1987) and Edwards et al. (2012).

The main advantage of these One-At-A-time approaches is the fact, that the resulting changes in the model outcome are directly related to the change of input. These methods are simplified approaches for gaining information about the slope of change (mathematically the local partial derivate) at a given point in a multidimensional problem. An evaluation of results based on a One-At-A-Time approach is in general understandable for risk managers and the public. But it describes only the effects of variability or uncertainty for selected values, possible interactions between variables and nonlinearity are ignored. The behavior of the model might deviate if all variables show variation (and uncertainty) in a multivariate setting with dependencies and interaction (Cacuci 2003; Murphy et al. 2004).

Taking into account the combined effects of many input variables requires data sampling plans similar to experiments (e.g., Morris 1991) or simulation analysis. Looking at the variance impact is mostly done by Monte Carlo (MC) simulation. If the uncertainty of the parameters might only be described by ranges (numerical intervals), then these values might be used too (e.g., in a uniform distribution). If relevant association exists between the input variables, information about the correlation (covariance) structure should be used in the simulation model. Technically a Monte Carlo simulation (see, e.g., Fishman 1996) consists of random combinations of random variates following the distribution of each input variable. Repeating these random choices many times, the distribution of the exposure variable will represent the set of all possible combination of input variables, constraint by the distribution of input. Technically, these approaches are called probabilistic. If uncertainty is included into the simulation, the analysis changes from a one-dimensional variance propagation model into a two-dimensional analysis. WHO-tools that combine the output from the probabilistic hazard characterization with the probabilistic exposure to rapidly characterize risk and its uncertainty are described by Bokkers et al. (2017).

Using Monte Carlo simulations, the dependency of the output values on the input variability might be evaluated by a variance-based approaches. Typical methods are: (a) drawing scattergrams for visual inspection of dependency, (b) calculation of rank correlation calculation describing the ordinal degree of the “the more/less of input, the more/less of exposure). Ranking the correlation coefficients of the variables by the degree of association gives information that illustrates the positive and negative impact of the input variance and the degree uncertainty on the calculated exposure variance. (c) Calculation of a regression models with the input variables as independent and the exposure estimate as the dependent variable allows an integrative view. Using the standardized regression coefficients, allows a direct comparison (Cacuci 2003).

Introducing quantitative estimates of uncertainty into a variation-based model results in a calculation that consists of a (in general additive) mixture of variation and uncertainty. Uncertainty and variance compounds need to be represented by different variables within the model. They should be used as different terms in the (rank) correlation and regression calculations too. The combined effect might be evaluated. But this approach presumes a lot of information about the set of variables. In practice, a full sensitivity analysis including variability and uncertainty components is rarely done. If necessary due to model complexity or safety requirements, even more elaborated mathematical methods (e.g., Saltelli et al. 2004) might be appropriate.

If raw data sets from representative samples of the population (e.g., collected as national surveys) are available, then the original data set might be used as a calculation basis for exposure estimation. Using the individual consumption frequencies, the individual amounts eaten/used together with the individual anthropometric data (e.g., body weights), only the substance concentration distribution needs to be simulated according to the information about the type of distribution. The calculation results in a population-based estimate of exposure. This approach avoids the problems of data dependency, correlation, and interaction and reduces data and

model uncertainty. The techniques for a sensitivity analysis are the same as described above.

An approach of stratifying for homogeneous subgroups (e.g., age, sex, region, nutritional habits) will reduce the variability within each stratum (subgroup) but will keep the variation over the groups. Stratification rules should be guided by attributes that are reasonable linked to exposure. Differences in behavior (e.g., typical activities, consumption habits, product usage) might provide an indication for such a classification. This might be done by an exclusion of the exposure sources. Alternatively, the scope of the assessment might be changed, e.g., developing a model tailored for the “exposed fish-eater group” (see, e.g., EFSA 2012b).

If a sensitivity analysis identifies uncertainties in relation to knowledge about important data, this should be seen as a prioritizing argument for additional data collection or research. By this, it justifies a higher tier analysis and further iteration (Recommendation 2 of the IPCS-WHO 2008).

---

## Interpretation of Uncertainty Characterization Results

Exposure assessment is based on scenarios, models, as well as sufficient data about all influential exposure factors. The result of an exposure assessment is a prognosis about the expected level of exposure or the resulting body burden. Instead, direct methods of exposure assessment, such as personal sampling, duplicate studies, and human biomonitoring provide information on a measurement level. In consequence, exposure assessors and risk managers should balance the reasons for using prognostic techniques instead of direct exposure measurement methods. The main advantage of using exposure models over direct measurement is cost and time – in general at the price of a higher degree of uncertainty.

A prerequisite for exposure analysis is that the state of knowledge about all the different influence factors is sufficient and that existing knowledge might be translated into an exposure model. The assessor should keep in mind, why an assessment was required, which problems and which questions have triggered the request. Zehr (1999) pointed to the problem that “. . . unknowns, indeterminacy and ignorance, that exist in science are often transformed into uncertainty when reported to the public in order to make issues more manageable.” A full and concise uncertainty assessment avoids this, it describes what is known and certain and what might be known doing additional research. Critical questions about the validity of the exposure assessment (accuracy, precision of prediction, validity, and objectivity) that should be expected in the course of risk communication can be anticipated and answered within an uncertainty analysis.

**(IPCS/WHO 8) The uncertainty analysis should be subject to an evaluation process that may include peer review, model comparison, quality assurance or comparison with relevant data or independent observations.**

The guiding principle eight of the IPCS-WHO document (2008) is related mainly to the questions if the exposure assessment is valid in the sense of scientific sound

quality and if it provides answers that are resistant to critical questions. Identification of uncertainty does not restrict the quality of the assessment. Although it might restrict the utility of an exposure assessment for regulatory or prevention-directed purposes, an uncertainty analysis increases the quality of information. A documentation of information about what is known, what is reasonable to expect, and what needs further clarification might have a high impact on the risk management process.

**(IPCS/WHO 9) Where appropriate to an assessment objective, exposure assessments should be iteratively refined over time to incorporate new data, information and methods to better characterize uncertainty and variability.**

Where the level of uncertainty is too high, only doing additional research, collecting more information, and/or obtaining better exposure measurements will change the situation.

## Abstract

Grouping approaches like read-across (RAX) are one of the most widely used methods to fill data gaps in human risk assessment. In a RAX approach, in vivo animal data from one to several source substances are extrapolated to a target substance that has not been tested. Here, we describe the currently accepted read-across workflow, which begins with the problem formulation that defines the level of the acceptable uncertainty. The evaluation progresses iteratively from an initial list of structurally similar substances to source compounds with similar toxicodynamic and toxicokinetic properties. Finally, the data gap is closed with a worst-case or a regression analysis, and the uncertainty of the prediction is identified. New approach methodologies, such as in vitro assays and in silico models, have great potential to strengthen read-across assessments by providing mechanistic data and estimates of bioavailability of the grouped compounds.

## Introduction

**Chemical risk assessment** aims at compound-specific threshold values, like acceptable daily intake values, below which an exposure to a compound is considered to be safe for the human population. Within this approach, the hazard assessment provides information on the substance-inherent toxicological properties. This means in a qualitative manner the identification of the type of toxicity caused by the compound of concern and classifying it, e.g., as potentially genotoxic, or reprotoxic, or harmful after chronic lifetime exposure. This information is traditionally derived from *in vivo* animal studies. In addition, for a quantitative evaluation, a dose level is identified, below which the animals did not show any adverse effect. This dose level is called a No Observed Adverse Effect Level (NOAEL). The NOAEL is thereafter extrapolated to a human threshold value by using appropriate assessment factors that account, i.e., for inter and intraspecies differences (ECETOC 2003).

The absence of appropriate and relevant *in vivo* animal data is a frequently occurring problem in human risk assessment specially, i.e., in case of an unintended release of compounds to environmental compartments like drinking water or air or in the case of impurities occurring within a production process. This is also of particular importance for the assessment of cosmetics, for which *de novo* animal testing has been prohibited in EUROPE since 2013 (EU Regulation 1223/2009). Nonetheless, safe levels for human exposure need to be defined. To date, three **alternative non-testing models** can be applied, namely, QSAR models, grouping approaches, and the Threshold of Toxicological Concern (TTC) concept.

Already starting with the OECD HPV program (OECD 2004), grouping approaches have been developed and applied over the last decades as important risk assessment tools. In EUROPE, this development was supported by the REACH (Registration, Evaluation, Authorization, and Restriction of Chemicals) legislation, which requires the use of alternative approaches before animal testing is carried out as a last resort. Also, other international agencies like the US EPA and Health Canada apply grouping approaches like read-across for regulatory purposes (Rovida et al. 2020; Patlewicz et al. 2019; US EPA 2010).

Under REACH, grouping approaches like **read-across** (RAx) are the most often applied alternative methods for higher tier endpoints like repeated dose or reprotoxicity (ECHA 2014). A read-across assessment is using the technique of predicting toxicity data for one compound, named as target compound (TC), by using data for the same endpoint from one to several source compounds. The analogue approach uses one, the category approach several source substances for extrapolation (Fig. 1). A read-across assessment is used for hazard assessment and

**Fig. 1** Illustration of the concept of a read-across evaluation. The toxicity of the target compound “2-ethylbutyric acid” is predicted from the toxicity data of similar source compounds (in this case other branched carboxylic acids), for which appropriate *in vivo* data are available. A many-to-one (N to 1) prediction is termed category approach, a one-to-one prediction analogue approach (Escher et al. 2021)

can derive qualitative properties, like “is genotoxic,” or quantitative estimates, like a NOAEL value.

The authorization procedures under REACH have shown that many of the submitted read-across approaches were not acceptable to ECHA (Ball et al. 2016). The reasons for rejections within the compliance check were manifold, such as (i) lack of sufficient *in vivo* information from source compounds, (ii) insufficient scientific plausibility, (iii) identity of the target compound not clearly defined like UVCBs (unknown or variable composition, complex reaction products, or biological materials), etc. The low level of acceptance led to the development of the read-across assessment framework (RAAF), in which ECHA outlines in a systematic way the read-across assessment elements (ECHA 2017). A read-across (RAX) case according to ECHA always includes structural similarity. The RAAF distinguishes six different scenarios, which are defined based on the number of source compounds (analogue/category approach) and the so-called RAX hypothesis. This hypothesis must be based on a relationship between structural similarity and the predicted properties and needs to be supported by read-across justification. The RAX hypothesis has to outline whether the toxic effect to be read across is caused by (i) one common toxicant, i.e., formed through metabolism from both the target and source chemicals, or (ii) structurally slightly different source and target chemicals, which cause similar toxicological effects. The latter is also acceptable, if these similar effects follow a trend within the grouped compounds. The RAAF intends to increase the transparency of the assessments and to provide guidance to the applicant on which

assessment elements have to be included in the read-across assessment to be accepted by ECHA. The RAAF, however, doesn't reflect the iterative process required to build a category/analogue approach.

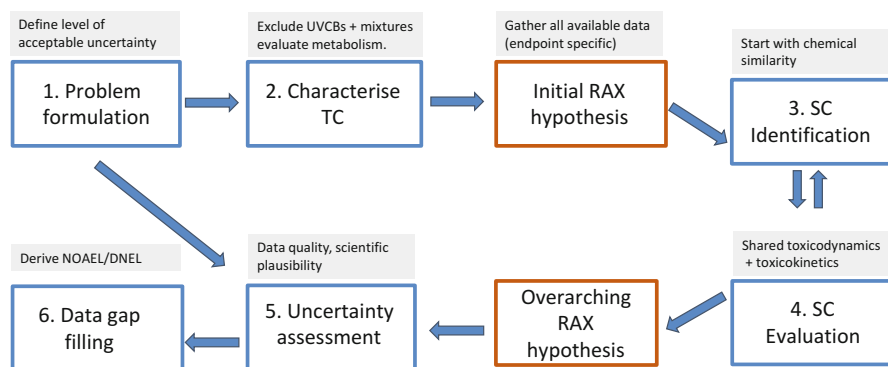

## Read-Across: Step-by-Step

The workflow of the read-across assessment comprises six main steps (Helman et al. 2019; Escher et al. 2019, Fig. 2).

### From Problem Formulation to the Initial Read-Across Hypothesis

The problem formulation (**step 1**) defines the objective of the read-across and thus the degree of acceptable uncertainty for the obtained extrapolation. For example, if the RAx analysis aims to fill a data gap for a regulatory study, a lower uncertainty is acceptable compared to a prioritization approach.

The target compound usually has no data for the endpoint for which a read-across conclusion is made. Often, it is characterized only by its chemical structure and its physicochemical properties. To date, it is not possible to perform the analogy concept without structural information. For compounds of indeterminate compositions such as multi-constituent substances and substances of unknown or variable composition, the RAAF can in principle also be applied but need additional

**Fig. 2** Schematic overview on the six main assessment steps within a read-across approach (adopted from Escher et al. 2019, with kind permission from Springer Nature). The problem formulation and the characterization of the target compound (TC) lead to an initial read-across hypothesis, which then guides the selection of relevant source compounds (SCs). SCs are often defined based on structural and physicochemical similarity compared to the TC. Step 4 evaluates the toxicokinetic and dynamic properties of the SCs that leads to an overarching read-across hypothesis. The read-across hypothesis, e.g., defines which toxicological effect has to be read across the compounds. In case of property cliffs, the initial RAx hypothesis is modified; some SCs might be excluded to include new SCs. Steps 5 and 6 include the data gap filling process and the assessment of the remaining uncertainty

assessment steps (ECHA 2017). This chapter will illustrate RAx concepts for mono-constituent compounds, with a defined chemical structure. As a **second step** for the read-across assessment, all available data that might be useful to characterize the target compound have to be gathered. Which data to consider is endpoint dependent, i.e., it might be reasonable to include data on chemical and biological reactivity to address genotoxicity/sensitization, e.g., derived from experimental or QSAR models. For other endpoints like reprotoxicity, this information might be considered to be less relevant.

Let's assume that we like to do a read-across to assess toxicity after repeated exposure for the substance diethylamine (CAS 109-89-7). Diethylamine is a basic, water-soluble, colorless liquid with an ammonia-like odor. Its high vapor pressure of 25.9 kPa<sup>1</sup> indicates that humans will be mainly exposed via inhalation. Application of the pure substance results in corrosiveness to the eyes and skin and potentially also to the respiratory tract. A special concern for genotoxic activity is not predicted using the rule-based QSAR models of the OECD QSAR toolbox<sup>2</sup>. The initial read-across hypothesis could therefore be that structurally similar compounds, e.g., other volatile alkylamines, will be good candidates for source compounds. Here the structural similarity but also the physicochemical properties support the read-across hypothesis.

---

## Identify Source Compound(s) Starting with Structure Similarity

Taking this initial hypothesis into account, similar source compounds are identified (**step 3**). Several tools can be applied to search for structurally similar compounds, e.g., noncommercial applications like the OECD QSAR toolbox, AMBIT<sup>3</sup>, ToxRead<sup>4</sup>, and GenRa (Helman et al. 2019). Typically, the 2-D structure of the TC is entered in a computer-readable format (e.g., as Smiles or INCHI code), and a molecular fingerprint is generated (e.g., Morgan fingerprint; Toxprints, MACCS fingerprint, etc.).

For a structural definition of the source compounds, the molecular fingerprint describes the presence or absence of structural features, as binary string. Several algorithms can be used to calculate a degree of similarity between a pair of molecular fingerprints, like the Tanimoto or Dice coefficients (Bajusz et al. 2015; Murgia and Villasenor 2003). These algorithms have in common that the number of unique molecular features of molecule (a) and (b) is set in relation to the number of shared molecular features in both (c) (Fig. 3). In the present hypothetical example, diethylamine is compared to dimethylamine. The Tanimoto coefficient results in a similarity score of 78% and Sorensen-Dice in a similarity score of 88%. This example illustrates that the similarity score is a relative measure, dependent on the applied fingerprints and algorithm.

A structural similarity search might result in a list comprising many different analogues. In case of diethylamine, high similarity scores are obtained for analogues that differ with regard to the nature of the alkyl substituents, the number of alkyl substituents, or the salt. They might all be good candidate source compounds, or a subset (A to C) might be most appropriate (Fig. 4).

**Fig. 3** Calculation of similarity coefficients between dimethyl and diethylamine based on a hypothetical molecular fingerprint (*blue* present, *white* not present); (**a**) number of unique structural features in diethylamine; (**b**) number of unique structural features in dimethylamine; (**c**) number of shared structural features

**Fig. 4** Initial list of structural analogues for the target compound diethylamine (top structure). (**a**) secondary amines with different alkyl-side chains (C1 to C4); (**b**) different number of substituents ranging from mono- to triethylamines; (**c**) diethylamines with different counter anions

The analogues will have to have high-quality endpoint data for which the read-across is performed. Recently, Pawar et al. reviewed existing databases that are intended to be used in *in silico* chemical or drug safety assessment (Pawar et al. 2019). Some of the abovementioned tools like the OECD QSAR toolbox or GenRa<sup>5</sup> allow the user to search for toxicological data. Read-across is most often performed for higher tier endpoints like toxicity after repeated exposure. High-quality databases

with subacute, subchronic, and chronic studies are RepDose (Bitsch et al. 2006), ToxRef (Martin et al. 2009), and Hess (Abe et al. 2012), as well as eTox (Sanz et al. 2017) and CPDB (Gold et al. 1999, focus on chronic and cancer studies).

---

## Source Compound Evaluation

The initial list of analogues is the starting point of **step 4** “source compound evaluation.” **Step 4** aims to identify from the list of structurally similar substances those source compounds that exhibit similar toxicokinetic and toxicodynamic properties compared to the target compound.

The objective of the toxicokinetic assessment is to identify potential differences in compound bioavailability in the human/animal organism. Since the bioavailable concentrations will interact with tissues/cellular targets and cause systemic toxicity, toxicokinetic studies on absorption and excretion are needed to compare toxicological potencies within the grouped sources and to extrapolate to the target compound. Differences in tissue distribution might help to explain the presence/absence of effects in target organs between grouped compounds. Furthermore, the impact of metabolism needs to be identified. Metabolism plays an important role, as biotransformation might lead to more toxic (e.g., phase 1 metabolism) or less toxic (e.g., conjugation reactions in phase 2) metabolites. In the rare cases where the source compounds cause their effects by the formation of a common "toxic" metabolite, metabolite formation is at the heart of the RAx hypothesis, and its kinetics will be the basis for extrapolation. However, *in vivo* ADME (absorption, metabolism, distribution, and excretion) data do not belong to the standard regulatory test requirements, e.g., under REACH, and are, therefore, rarely available for chemicals. Surrogate parameters (e.g., water solubility, octanol-water partition coefficient (logPow)) may be used for an initial assessment of potential risk factors, such as bioaccumulation in humans.

The toxicodynamic assessment aims to show that the target compound causes similar toxicological effects as the source compounds. Ideally, source and target compounds share the same mode of action, e.g., as illustrated by an adverse outcome pathway (AOP).

Adverse outcome pathways (AOPs) describe in a linear, transparent, and quality-controlled linkage of key events within a biological process leading to an adverse effect in the organism. After chemical perturbation, the AOP links a molecular initiating event (MIE) to key events on the cellular and organ level, which then progress to the adverse outcome (AO, Leist et al. 2017). Although the concept of AOPs was only introduced in 2010, over 300 AOPs have already been established or are under development (AOP wiki<sup>6</sup>).

A well-known example are acetylcholinesterase (AChE) inhibitors, in particular carbamates and organo(thio)phosphates (OPs), which are characterized by their common  $\text{PO}_{4-x}\text{S}_x\text{R}_3$  motif. Carbamates are classical pseudo-irreversible AChE inhibitors, which bind to the AChE catalytic site covalently via carbamylating a conserved serine residue. Inhibition of AChE prevents the degradation of the

neurotransmitter acetylcholine, leading to overstimulation. Chronic toxicity resulting from OP exposure ranges from cholinesterase inhibition in plasma, erythrocytes, and brain tissue to the appearance of clinical signs of long-term damage to the central nervous system (CNS) as well as peripheral nervous system (Ecobichon et al. 1990). This is an ideal situation, where the read-across can be based on the MIE (AChE inhibition) and draw a link to the observed adverse in vivo outcome (AO, damage to central nervous system). Often the in vivo studies, like subchronic studies in rodents, only provide the information about the adverse effect. The different molecular interactions (MIE or KEs) leading to the observed effects are often not known. The situation is in addition complicated by the fact that in vivo animal data of the source compounds not always follow the same study design. Data variance may be caused by the use of different species, strains, and exposure regimes, e.g., in terms of dose selection and dose intervals.

The evaluation of source compounds might lead to the conclusion that some structural analogues are dissimilar with regard to their toxicokinetic and dynamic properties. In this case, the initial RAX hypothesis failed. These analogues have to be excluded, and, as an iterative loop, potentially new criteria have to be defined to identify more suitable analogues.

In case that the analogues show similarity, this leads to the overarching RAX hypothesis, based on the observed effect data. Examples are as follows: all source compounds are liver toxicants in vivo that induce cholestasis, or all analogues cause pulmonary irritation progressing to inflammation, etc.

---

## Data Gap Filling and Uncertainty Assessment

The next assessment steps comprise the uncertainty assessment (**step 5**) and the data gap filling (**step 6**). As a read-across is a method of prediction, ideally based on an interpolation, the derived result always inherits an uncertainty, which has to be addressed. One main source of uncertainty is the number of analogues with endpoint data. With a decreasing number of source compounds, the similarity assessment with respect to toxicological properties becomes more and more difficult, in particular within the one-to-one extrapolation (analogue approach). Another aspect that contributes to the uncertainty of the assessment is the quality, relevance, and accuracy of the in vivo endpoint data. Several publications have proposed schemes to address the uncertainty of each step of the read-across assessment, e.g., in a semiquantitative way (Blackburn and Stuard 2014; Schultz et al. 2015; EFSA 2018). In addition to uncertainty analysis of each individual assessment element, finally, the impact of the combined aspects has to be weighted and an overall uncertainty estimate has to be given.

The data gap filling (**step 6**) is done for the endpoint that is read across. In case of qualitative predictions, e.g., is the target genotoxic allows only the conclusion it is or it is not. The weighting of conflicting in vitro and in vivo evidence will require a weight of evidence approach, and approaches already well described for the

assessment of compound-specific experimental data can be applied (Benfenati et al. 2019; EFSA 2017).

In case of a quantitative read-across, e.g., derivation of a no-observed-adverse-effect level (NOAEL), the user has to decide on the most appropriate approach. Three options are available:

- (a) A worst-case estimate: The lowest value of all available analogues is chosen and read across to the target compound. This option is often preferred as it follows the precautionary principle of human risk assessment.
- (b) A regression analysis: The endpoint values of the grouped analogues follow a consistent trend, and the values of the target compound can be derived from the regression.
- (c) Local similarity or nearest neighbor approach: One of the analogues is closest to the target compounds with regard to its toxicological properties, and its values are used for read-across.

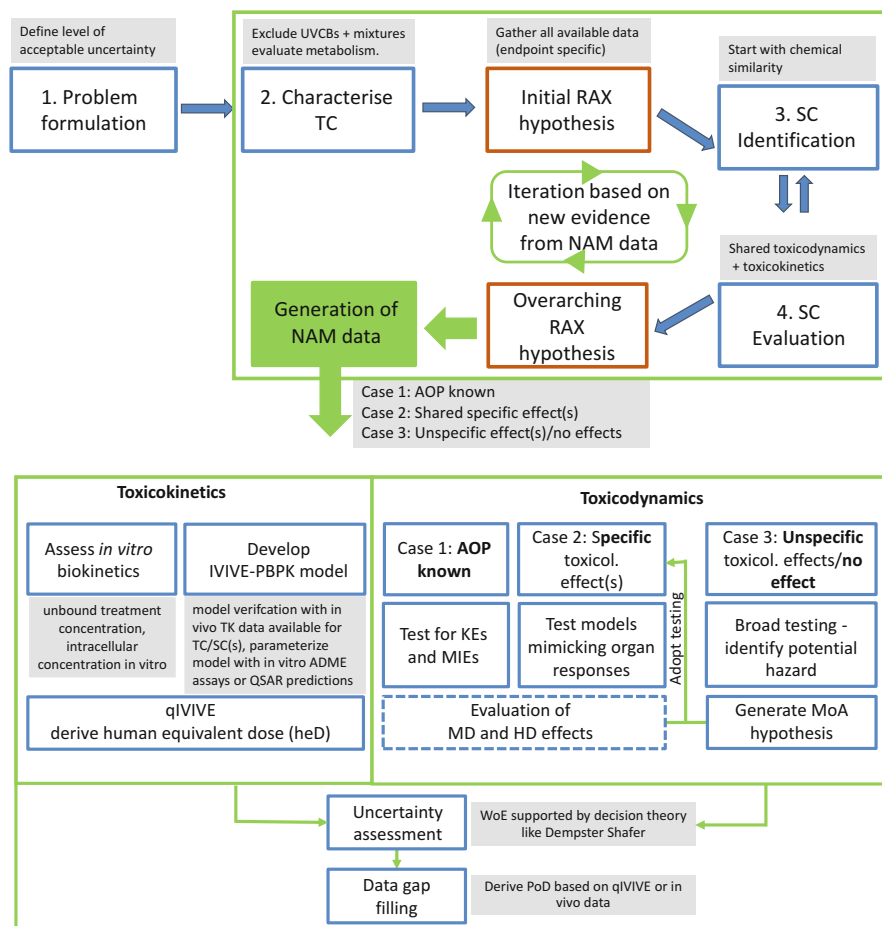

---

## Moving Toward Mechanistic Risk Assessment Using In Vitro and In Silico Models

In the previous sections, we have seen that read-across is dependent on the availability of source compounds with relevant in vivo endpoint data. The main challenge within the assessment is to provide convincing evidence on the shared toxicodynamic and kinetic properties within the grouped compounds (Schultz and Cronin 2017). To further enhance the quality of read-across cases and to reduce its uncertainty, it can be useful to support the read-across hypothesis by mechanistic and kinetic evidence from new approach methodologies (NAMs, Zhu et al. 2016). NAMs in this context stand for human in vitro and in silico models. The application of in vitro assays in the context of an integrated approach to testing and assessment (IATA) goes along with new challenges. These challenges include, e.g.:

- Assay-specific aspects like the robustness, reproducibility, and applicability domain of the individual assays (Krebs et al. 2019, 2020)
- The scope of NAM testing needed to address the endpoint under evaluation
- The relevance of different assays/the IATA for the endpoint of concern
- Characterization of the uncertainties associated with the in vitro to the in vivo extrapolation
- Many more

Recently, the EUTOXRISK project developed a concept of an IATA with the aim to integrate NAMs into a RAx assessment for the endpoint repeated dose toxicity (Escher et al. 2019, Fig. 5). As before, the read-across hypothesis is built on the lead effect being observed within the available in vivo data from the source compounds. In this context, lead effect is defined as adverse effects that are observed at the lowest-observed-adverse-effect level (LOAEL). The source compounds are then

**Fig. 5** The EUTOXRISK project scheme on the integration of NAMs into a RAX assessment. Steps in which NAM data can be involved are indicated in green. (Adopted from Escher et al. 2019, with kind permission from Springer Nature). Driven by the overarching read-across hypothesis, NAMs are generated in a systematic way to better characterize the mode of action (MoA, toxicodynamics) and the differences in bioavailability (toxicokinetics) within the grouped compounds. The quantitative *in vitro* to *in vivo* extrapolation (qIVIVE) uses an IVIVE-PBPK model and the unbound free intracellular concentration from the *in vitro* assays to model a human equivalent dose (heD). The uncertainty assessment has to address each individual step of the testing strategy, and decision theories like Dempster-Shafer might be useful to support the integration of data from different *in vitro* assays. Data gap filling is possible based on the available *in vivo* endpoint data of the source compounds that are based on the derived heD from the qIVIVE approaches

tested in a systematic way according to this hypothesis to better characterize their hazard with selected *in vitro* and *in silico* models. The concept distinguishes three cases.

**Case 1:** The source compounds share lead effects for which AOPs are known. The well-characterized AOPs are then used to identify relevant *in vitro* assays to test for the shared mechanisms of action within the grouped compounds and get qualitative as well as quantitative information.

**Case 2:** The source compounds share specific lead effects, but AOPs are not yet known. Relevant *in vitro* assays will be selected that cover as far as possible the target organ physiology also with the aim to demonstrate that the grouped compounds share the same mechanism of actions.

**Case 3:** All the source compounds show low toxic and/or not specific toxicological. In this case, it is recommended to use a broader *in vitro* testing battery to detect potential dissimilarities between the grouped compounds that may alert for a specific toxicological concern for the target compound.

The screening of the hazard of the grouped compounds with NAMs reduces time and costs compared to *in vivo* testing, so that more analogues can be tested and the impact of minor structural changes can be investigated. The selection of source compounds can thus be expanded to analogues without *in vivo* endpoint data.

As stated above, most chemicals don't have *in vivo* ADME data (Wetmore et al. 2015). NAM-based approaches allow to address the toxicokinetic properties within the grouped compounds by using *in vitro* to *in vivo* extrapolation linked to physiologically based kinetic (IVIVE-PBPK) modeling (Arora et al. 2020). PBPK models use physiological (systems) data to estimate the distribution of the compounds within the human/animal organism and indicate the resulting bioavailable concentration, e.g., in certain target organs or plasma. IVIVE is used as indication that *in silico* and *in vitro* parameters are used to parameterize these PBPK models, namely, binding to plasma proteins, the blood/plasma ratio, and the intrinsic clearance in primary human hepatocytes. IVIVE-PBPK models are open source models like the htk model developed by US EPA (Pearce et al. 2017a, b), TK-plate developed by EFSA (Wiecek et al. 2019), or commercial models like the SIMCYP<sup>TM</sup> PBPK Simulator (Certara<sup>7</sup>).

The evidence from the NAM data is used to establish a strong link to the overarching RAX hypothesis. Ideally, concordance between the assays is observed allowing to conclude on a shared mode of action (MoA). For some endpoints, several KEs and MIEs might have been tested, so that data integration and interpretation might get difficult. Decision tools like the Dempster-Shafer theory (DST) are suggested for data integration. The DST is a rigorous decision-theory approach that can be used to combine multiple sources of evidence to obtain a weight-of-evidence prediction by quantitatively accounting for the reliability of each of the sources being combined. In addition, the DST provides a quantitative estimate of the associated uncertainty.

Although the IATAs and NAM models work with a lot of assumptions, it has been shown in first case studies that they are useful to estimate (dis)similarities and trends within a read-across assessment (OECD 2020a). The experiences of these case studies also contributed to a reporting template (OECD 2020b).

In conclusion, RAX is a very useful method/tool to close data gaps in human risk assessment (also for regulatory purposes), and integration of NAM data has shown to enhance the quality of the assessment by providing data on shared mechanistic and kinetic properties.

## Abstract

The increasing environmental pollution, industrial accidents and chemical-induced exposures, and resulting disease led to the concept of a green chemistry in 1998. It proposes to design chemicals in a way that no hazardous reagents, products, or exposures would occur. The concept is of outstanding importance,

when considering, that all aspects of human civilization including clean water, global nutrition, agriculture, housing, household goods, and medication all depend on functioning chemical designs, industrial production, and on recycling/regeneration efforts. The UN-Sustainable Development Goals (SDG), adopted in 2015, will have to rely on green and sustainable chemistry tools. International and national organizations adopt green and sustainable chemistry into their regulations.

**Introduction**

Regulations for the protection of health and to reduce specific risks have been established since long. But when new types of environmental health problems were noticed, such as the London smog episode of 1952 (Bell et al. 2004), techniques to analyze the causes in detail or to avoid hazardous exposures where not yet available.

The widespread pollution of outdoor air, aquatic systems, and soils (brownfields) became evident in the 1960s, and with it the causal relationship between chemical exposures and occupational/environmental disease was investigated in more detail. State agencies, industry, and the public were in alert. Main stream politics showed little interest initially, being preoccupied with other problems such as the arms race. Nevertheless, environmental protection became a topic and concerned people joined green movements with the aim to prevent pollution and reduce environmental disease. At the same time, technical solutions to limit emission became available or affordable.

Before the 1970s, chemistry students were proud to work in a laboratory that smelled of solvents. But that changed. The green chemistry concept of the 1990s (Anastas and Warner 1998) was a valuable contribution to find ways for future-oriented chemical design and sustainable products. In 2015, the UN-Agenda 30 with its 17 sustainable development goals (UN 2015) provided an internationally accepted roadmap. Basically, green chemistry and sustainable chemistry have the same goal and their concepts support sound regulations for the protection of health and of the environment (Kummerer 2017; Anastas and Zimmerman 2018; OECD 2020, Umweltbundesamt 2020).

The present contribution describes the cumulating problems, and the developments, that led to the green chemistry concept, depicts areas where green chemistry can support a sustainable development, and suggests the idea of integrating toxicology into this concept.

## **Developments Before the Area of Green Chemistry**

### **Early Industrial Chemistry**

Since the beginnings of industrial chemistry, more than 200 years ago, synthesis processes were stepwise improved to increase output, product variety, and profit. Rare and valuable chemicals were recovered, when possible. Rules were developed to fight accidents in chemical plants. But other areas were initially neglected, such as workers health, waste production, emissions, and environmental pollution.

### **Pollution and Accidents (1965–1990)**

The period from about 1965 to 1990 was characterized by major chemical accidents and increasing awareness of pollution and the need for more chemical safety.

### **Pollution of Environmental Media**

#### **Outdoor Air**

Emissions from incineration processes were found to cause health risks through fine particles, acids, and many other combustion- and photochemical reaction products further polluting the clean air.

#### **Ozone Hole**

Chlorofluorocarbons were found to deplete stratospheric ozone and its filter function against harmful solar ultraviolet light.

#### **Surface Water**

Domestic and industrial wastewater often went unfiltered into rivers, carrying pollutants into river beds, lakes, and oceans.

#### **Ground Water**

Chemicals from landfill waste and agricultural applications were found to leak into the ground and to contaminate ground water, the important source for drinking water.

#### **Dumping Sites and Soil**

Some areas, formerly used as dumping sites for toxic substances were converted to residential areas (e.g., Love Canal in the USA). Moreover, benzo(a)pyrene and toxic metals, emitted during combustion processes into ambient air, were found to contaminate the soil of (former) industrial neighborhoods.

### **Indoor Air**

Urea formaldehyde foams, widely introduced to improve the thermal insulation of homes, were found to release formaldehyde, causing intolerable indoor concentrations. Solvents of paints and adhesives as well as volatile wood preservatives (e.g., pentachlorophenol), sealing joint material (polychlorinated biphenyls), insecticides (e.g., DDT), and asbestos caused partly high indoor air concentrations.

### **Consumer Goods**

Just to give one example: Carcinogenic nitrosamines were found as side products in rubber-based soothers.

## **Pollutants of Major Concern (1965–1990)**

### **Persistent Organic Pollutants (POP)**

A whole range of cyclic and aromatic chlorinated hydrocarbons were used as pesticides (e.g., DDT) or technical applications (e.g., PCBs). Even more, the polychlorinated dibenzodioxins (PCDDs) which had no technical application were identified as side products of some synthesis processes and of waste-incineration reactions. Such substances are today labeled as POP, because of their very long persistence, widespread distribution around the globe, and accumulation in the food-chain.

### **Toxic Metals**

In the 1950s, toxic metals had still applications as pharmaceuticals, paints, plumbing, cosmetics, and antimicrobial agents. For example, tetraethyl lead was the common antiknock additive of gasoline until the 1980s. Phosphate fertilizers and sewage sludge were found to be contaminated with cadmium, a toxic metal that is taken up by agricultural plants. Mercury from industrial processes entered a bay in Minamata and the mercury was converted by microorganisms to neurotoxic methylmercury that gradually accumulated in fish. The substance poisoned the fish-eating population. Reduction of global mercury usage was later regulated in the Minamata Convention.

### **Polycyclic Aromatic Hydrocarbons**

Benzo[a]pyrene is the lead toxic substance of polycyclic aromatic hydrocarbons. It is formed during coal combustion processes, and found as contaminant that persists very long in soil around industrial areas, fire places, and brownfields.

### **Endocrine Disruptors**

A number of environmental chemicals (e.g., phthalates, polychlorinated biphenyls) used, e.g., as additives to plastic materials were found to exhibit hormonal effects. They may disrupt reproductive physiology of aquatic organism. The role for humans is not entirely clear.

## Chlorinated Volatile Solvents

This group of solvents has the practical advantage of evaporating very quickly. They were used in paints, glue, and cleaning liquids by occupational users and non-professionals, often indoor. They were found to induce a range of substance-specific chronic-toxic disorders. Being volatile, they also disturb atmospheric chemistry.

## Industrial Accidents (Examples)

### Seveso

Due to accidental overheating of a chemical reaction in a pentachlorophenol-producing plant in northern Italy in 1976 the minor side-product 2,3,7,8-tetrachlorodibenzodioxine was generated at high levels. It was released into the environment, causing widespread pollution.

### Bhopal

An accident in a pesticide-producing unit in Bhopal (India) in 1984 released large amounts of a mixture of irritating and toxic agents that caused a disaster with thousands of fatalities in the nearby living population.

### Chernobyl

A nuclear power plant went out of control in the Ukraine in 1986 and emitted radioactive products. Beyond the tragedy of the massive regional radioactive contamination, some radioisotopes such iodine-131 and cesium-137 were carried with the atmospheric stream thousands of kilometers. They washed out with the rain and caused long-lasting soil-contaminations in distant regions of Middle-Europe.

## Chemical-Induced Disease

In conclusion, chemical exposures were identified to constitute a health risk for workers in the chemical industry, for professional users, and also in the general population. Some of these associations became visible between the 1950s and evident with the publication by the epidemiologists Doll and Peto (Doll and Peto 1981; see also Blot and Tarone 2015). Each toxic chemical tends to have a specific fingerprint with regard to its adverse chronic effects, as exemplified in Fig. 1.

## Drug Scandals

Two major incidents with pharmaceuticals concerned exposed pregnant women: Thalidomide, sold in the late 1950s as sedative and anti-nausea medication, caused limb abnormalities in the developing child. The synthetic estrogen diethylstilbestrol-

**Fig. 1** Examples for causal relationships between occupational exposures or population exposures, and disease

<b>Chemical Exposures and Disease (Examples)</b>	
<u>Workplace exposure</u>	<u>Chronic Disease</u>
Asbestos	Tumors of the lung (Mesothelioma)
Tetrachloromethane	Liver cirrhosis
Chloroethane	Liver tumors
Benzene	Bone marrow cancer
Isocyanate	Airway allergy, asthma
Beryllium	Immunological lung disease
Aniline dyes	Bladder cancer
<u>Population exposure</u>	<u>Acute and Chronic Effects</u>
Smoking	Artherosclerosis, Cancer
Outdoor pollutants	Airway- and eye irritation
Indoor pollutants	Sick building syndrome
Barbeque	Exposure to carcinogens
Fish-based nutrition	Elevated PCDD levels in mother milk.

induced vaginal tumors in daughters. This contributed to profound reconsideration of drugs- and chemicals safety in general.

## Advances in Chemical Safety

Improved quantification techniques for environmental chemicals and the advances in toxicology made it possible to identify pollution problems, and whistleblowers helped to make these problems known; this later resulted in the “Green Chemistry” concept.

## Analytical Chemistry and Clinical Chemistry

Steadily improving analytical separation procedures (often GC, HPLC) together with the advances in instrumental detection methods, like atom absorption technology to detect toxic metals, made it possible to reliably detect and quantify increasingly more anthropogenic chemicals in environmental media and body fluids. The availability of enzyme-linked immunoassays further expanded the detection possibilities.

## Toxicological Advances

Due to progresses in biochemistry, analytical chemistry, and molecular cell biology, it was possible to identify mechanisms of acute toxic cell damage and tissue damage as well as chronic organ disorders. The role of reactive intermediates, that are formed during enzymatic biotransformation of some substrates, was recognized and became the key for an understanding of carcinogenic mechanisms of substances like aflatoxin, benzo[a]pyrene, or nitrosamines. Novel in vitro test systems allowed to better study such mechanisms. The roles of gene-regulation, death receptors, and apoptosis

on the one side and of cellular DNA-repair and tissue regeneration on the other side are still today in the focus of research.

### **Whistle Blowers**

Whistle blowers are often annoying and troublesome, and sometimes they are wrong. But whistle blowers were extremely important to promote discussions that resulted in more awareness of the long-time risks of chemicals in the environment and risks associated with exploitation of the global resources. Here some examples:

*Rachel Carson*, a marine biologist, described in her book “Silent Spring” (Carson 1962), the phenomenon of bioaccumulation of persistent environmental pollutants (e.g., DDT) in the food chain and its negative consequences for wildlife.

*Greenpeace*: Canadian activists went on a boat trip in the Pacific to demonstrate against nuclear testing in 1971, when the nuclear arms race was in full swing. This peaceful action initiated the Greenpeace organization.

*Club of Rome*: This highly respected institution published the book “Limits to Growth” in 1972. Based on mathematic models, it convincingly argued that further economic growth and population expansion will deplete the resources on earth.

*Ashford and Miller*: The book “Chemical exposures, low levels and high stakes” (Ashford and Miller 1991) collected evidence for chemical-associated sensitivities in the population that had been previously described by Cullen as “Multiple Chemical Sensitivity” (Cullen 1987).

### **Information Systems**

Until the early 1970s, scientist informed themselves from books, conferences, and scientific journals. This changed. The World Health Organization started editing information on toxic substances in 1976. The Hazardous Substances Databank (HSDB) of the US-National Library of Medicine became available for users in 1978, and Medline started to offer access to its databank in the 1980s. Many other high-quality toxicology databanks followed and started to get accessible via the Internet. The fast access to original publications and to condensed secondary information about chemicals and their hazards provided an invaluable basis for evidence-based regulations.

### **Harmonization of Regulations**

As a consequence of the awareness of the pollution problem scientific committees, national agencies, and international organizations were founded. Prevention started to become important. Major pollution problems, as described above, were increasingly regulated by banning, restricting, or limiting the use and/or release of hazardous substances.

Initially, it took a long time until harmonization of test systems and respective test guidelines were developed. With the years, the guidelines of OECD for chemicals and ICH for therapeutic drugs have developed to be backbones for hazard and risk assessment.

## Green- and Sustainable Chemistry

### Green Movements

*Green* movements initially emerged from protests against environmental pollution. “Greenpeace” may have played a pioneer role. Regional green movements started in the mid-1970s; some converted to political parties, others are active as NGOs.

### “Green Chemistry” Beginning and Mission, Expansion

Outsiders often assume, that “green chemistry” simply refers to the use of biomass as energy source and organic raw material or refers to the application of bioengineering methodology; others may assume that it refers to “Organic Movement,” the proponents of which tend to avoid synthetic chemicals. But green chemistry is much more.

In “The Slow Birth of Green Chemistry” (Amato 1993), the author described the ongoing pollution and the necessity for an environmentally responsible chemistry. Not much later (1996) came the EPA Green Chemistry Award that has successfully continued until today (EPA 2020a). The early cooperations were described by Goehl in 1997 (Goehl 1997). Then appeared the book “Principles of Green Chemistry” by Anastas and Warner in 1998 (Anastas and Warner 1998). The authors defined 12 principles of green chemistry and provided discussions and outlooks for each of them. Table 1 lists the 12 principles in their original form (Anastas and Warner 1998) and in a nice short version that is found on a green chemistry website of the American Chemical Society (ACS 2020a).

In essence, the 12 principles express, that chemical synthesis processes should be designed in a way, that avoids waste, minimizes energy input and avoids products that are toxic to humans or the environment.

Anastas and his group continue to intensely promote the green chemistry concept. The 12 principles developed to a paradigm of green chemistry (Anastas 2018). Thus, the “green” idea transformed into a constructive practical guidance for chemistry. The US-EPA has been involved from the beginning and still plays a lead role (EPA 2020b). The American Chemical Society (ACS) promotes the concept among scientists in academia, industry, and regulation (ACS 2020b). Large companies of the chemical industry tend to cooperate as a contribution for the future.

### Sustainability Movements

*Sustainability* can be considered as a conservative concept that has routes in forestry. Tree saplings were planted to regenerate deforested areas, with the idea to provide next generations with grown trees. Sustainability has long been neglected in the twentieth century. So it was a milestone, when the United Nations (UNCED) “Rio Declaration on Environment and Development” (1992) used “sustainability” as its key plan to protect

**Table 1** The left columns shows the 12 principles of green chemistry, as published by Anastas and Warner in the booklet “Green chemistry- theory and practice” (Anastas and Warner 1998). The right panel shows a short version, according to the American Chemical Society (ACS 2020b)

No	Principles, Original Version (Anastas and Warner 1998)	Short Version (ACS 2020b)
1	It is better to prevent waste than to treat or clean up waste after it has been created	Waste Prevention
2	Synthetic methods should be designed to maximize incorporation of all materials used in the process into the final product	Atom Economy
3	Wherever practicable, synthetic methods should be designed to use and generate substances that possess little or no toxicity to human health and the environment	Less Hazardous Synthesis
4	Chemical products should be designed to preserve efficacy of function while reducing toxicity	Design Benign Chemicals
5	The use of auxiliary substances (e.g., solvents, separation agents, etc.) should be made unnecessary wherever possible and, innocuous when used	Benign Solvents & Auxillaries
6	Energy requirements should be recognized for their environmental and economic impacts and should be minimized. Synthetic methods should be conducted at ambient temperature and pressure	Design for Energy Efficiency
7	A raw material or feedstock should be renewable rather than depleting whenever technically and economically practicable	Use of Renewable Feedstock
8	Unnecessary derivatization (use of blocking groups, protection/deprotection, temporary modification of physical/chemical processes) should be minimized or avoided if possible, because such steps require additional reagents and can generate waste	Reduce Derivatives
9	Catalytic reagents (as selective as possible) are superior to stoichiometric reagents	Catalysis (vs. Stoichiometric)
10	Chemical products should be designed so that at the end of their function they break down into innocuous degradation products and do not persist in the environment	Design for Degradation
11	Analytical methodologies need to be further developed to allow for real-time, in-process monitoring, and control prior to the formation of hazardous substances	Real Time Analysis for Pollution Prevention
12	Substances and the form of a substance used in a chemical process should be chosen to minimize the potential for chemical accidents, including releases, explosions, and fires	Inherently Benign Chemistry for Accident Prevention

the earth and its resources. It can be mentioned, that the Rio declaration had given the mandate for safer use of toxic chemicals, thus establishing the Globally Harmonized System of Classification and Labelling of Chemicals (GHS) in the Agenda 21, para. 19.27: “A globally harmonized hazard classification and compatible labelling system, including material safety data sheets and easily understandable symbols, should be available, if feasible, by the year 2000” (UN 1992).

## The United Nations Sustainable Development Agenda 30

In the year 2015, the 17 United Nations Sustainable Development Goals (SDGs) were launched as core part of the Agenda for Sustainable Development 2030, the Agenda 30 (UN 2015). The SDGs are based on the Agenda 21 of the Conference on Environment and Development (Rio de Janeiro, 1992). They address the most urgent topics for a global sustainable development (Fig. 2, left panel). They constitute the consensual results of intensive consultations of stakeholders from governments, NGOs, and other groups. The UN expects that the goals will stimulate actions that will be of critical importance for the future of humanity and the planet (UN 2015).

### “Sustainable Chemistry”

The 17 UN goals for sustainable development have a wide coverage. The term “sustainable chemistry,” stands for more than the term “green chemistry” that has its focus on chemical production/synthesis processes. “Sustainable chemistry” includes synthesis, but has a second focus on processes, not directly related to synthesis and including innovations that allow to reach the UN sustainability goals.

The term “sustainable chemistry” may have the additional advantage of not being associated with a political movement/party (“the greens”), so may receive a wider acceptance. But in principle, both have the aim of a “chemistry for a sustainable world.”

### UN Sustainable Development Goals (SDG) and Chemistry

UN-Goals (2015)	Sustainable Chemistry Approaches (examples)
1: No Poverty	1. Local solar panels, sanitation products.
2: Zero Hunger	2. Water desalination, adapted agrochemicals.
3: Good Health and Well-being	3. Drug design, healthcare products.
4: Quality Education	4. Courses in environmental sciences.
5: Gender Equality	5. Equal gender chances in the profession.
6: Clean Water and Sanitation	6. Water regeneration and purification items.
7: Affordable and Clean Energy	7. Improved energy yield and energy storage.
8: Decent Work and Economic Growth	8. Chemical design for a circular economy.
9: Industry, Innovation and Infrastructure	9. Novel materials for each purpose.
10: Reduced Inequalities	10. International science networks and exchange.
11: Sustainable Cities and Communities	11. Community hygiene products, clean water.
12: Responsible Consumption and Production	12. Common sense for stable flow equilibria.
13: Climate Action	13. Innovative energy systems.
14: Life Below Water	14. Respect for nature and its preservation.
15: Life on Land	15. Sustainable use of raw materials.
16: Peace, Justice and Strong Institutions	16. Prohibition of chemical weapons.
17: Partnerships for the Goals	17. Cooperation with UN, OECD etc.

**Fig. 2** Chemistry and the Sustainable Development Goals of the United Nations. The figure lists on the left panel the 17 UN global sustainable development goals (SDG) of the Agenda 30 (UN 2015), and on the right panel some examples for possible/necessary contributions of chemistry to achieve the goals. After IUPAC (2017), modified

It is evident that chemistry must play a key role in actions for the future: To minimize pollution and harmful exposures by chemical intermediates and products, as well as providing tools to achieve the goals of clean energy, clean air, clean water, and a clean environment. Chemistry will be of special importance for research, design, production, and the safe disposal of existing and novel chemicals. Figure 2 (right panel) depicts some of the fields, in which chemistry will be needed to actively support the SDGs.

Basically chemists may appear not to have specific responsibility for the sustainable development of the world. But they do. Only chemists have the knowledge about synthesis processes and the properties of their products, on which the non-experts will rely.

The huge complexity of the human activities affecting atmospheric chemistry, water quality, ocean life, climate, soil pollution, and depletion of essential natural resources makes very clear that sustainable chemistry is a global task.

Many regulating agencies and scientific organizations soon adopted the “Green chemistry” concepts in their programs in 1995–2000. The International Union of Pure and Applied Chemistry (IUPAC) that represents the chemical societies of many countries, developed a working group on green chemistry which culminated in a Special Issue of the Journal Pure and Applied Chemistry in the year 2000 with an introductory contribution by Tundo et al. (Tundo et al. 2000). IUPAC’s Interdivisional Committee on Green and Sustainable Chemistry is very active to promote green chemistry concepts worldwide (IUPAC 2020).

The Organization “Strategic Approach to International Chemicals Management” (SAICM), adopted in 2006 is a policy framework to promote chemical safety around the world.

Chemical industry provides signals that it goes in line with SDG (Axon and James 2018).

OECD, that is the lead organization for toxicological guidelines, also discusses and promotes green and sustainable chemistry (OECD 2020).

The UN-Organization for the Prohibition of Chemical Weapons (OPCW) is assigned to achieve chemical disarmament, including destruction of stored chemical weapons and the banning of production or use of chemical weapons. It also has to control potential precursors of known chemical weapons (a sustainability goal in itself), and supports cooperation in sustainable chemistry to strengthen peace and security (OPCW 2018).

Regulatory Systems like the European REACH have goals in sustainable chemistry (Umweltbundesamt 2020). Many national agencies with responsibility for chemical safety have programs to support green and sustainable chemistry.

## Green Chemistry Methods

“Metrics” provides an instrument to analyze with suitable parameters all steps of the production process with regard to energy-use, atom economy, and adversity of reactants and products as an objective bases with the aim to further optimize chemical reaction processes (Tabone et al. 2010; Sheldon 2018). Green chemistry metrics have been used to improve the efficiency in reaction design (Sheldon 2012).

Chemistry's traditional commitment to "quality" also promotes improvements, as described by Murphy for the pharmaceutical drug ibuprofen (Murphy 2018). Ideally, metrics would include toxicity/tolerability data, an analysis of the life-cycle, benefit/cost of recycling and environmental cost of dumping in landfills.

*Catalysts* have a central role in green synthesis. The potential for optimization can be seen, by comparing the historic total chemical synthesis of cholesterol in 1951/52 by Woodward (Woodward et al. 1952) with the biochemical pathway in cells. The Woodward synthesis involved 40 reaction steps, including laborious stereoselective reactions, harsh conditions such as heat, acids, and various metal catalysts. Animal cells assemble the cholesterol molecule from acetyl-CoA units in about 40 enzymatic steps at 37 degrees Celsius and neutral pH, using enzymes as catalysts and coenzymes/cofactors as supporting agents in a compartmented, regulated cellular environment. It can be expected that biocatalysts, biosimilar synthetic catalysts and biomimetic techniques may become more important for chemical synthesis in the future (Sheldon and Woodley 2018).

*Education* is of central importance, in order to train students in systems thinking (Mahaffy et al. 2019) and to support creation of truly sustainable technologies (Cannon and Warner 2011). Courses on green chemistry are regularly offered on national and international levels. IUPAC has taken a lead role in organizing courses in different continents thus generating an incentive for scientific and technical advances. Prizes for green science and for green industrial performance are awarded by various institutions and organizations, such as the US-EPA (EPA 2020b) and IUPAC.

## The Complexity of Sustainable Decisions

The global problems of toxic exposures and pollution have recently shifted from chemical-industry production sites and products, to new types of problems such as side effects of energy production (CO<sub>2</sub>, depletion of fossil reserves), animal farming (depletion of soil nutrients, pesticides and resistance to pesticides, release of methane into the atmosphere), combined with poor waste management, insufficient waste chemistry, and continuing exploitation of natural resources.

New types of pollution become visible, such as microplastic in the environment and aquatic media, and airborne engineered nanoparticulate materials of different composition (Gubala et al. 2018). The exploitation of novel types of raw materials (manganese nodules, methane clathrate) will be associated with new risks for aquatic systems and climate.

The sustainability goals of the Agenda 30 are interconnected. Decisions that support one goal may be of disadvantage for other goals. Thus, the idea of using renewable feedstock and raw material has been widely considered as a breakthrough of the sustainability-goal that would help to reduce worldwide carbon dioxide emissions. Subsidies are provided to use forests and grown soy as raw material sources. But this aggravates the worldwide deforestation, the loss of farmland, and the depletion of sweet water reserves.

Similarly, increasing the lifetime of chemical products may appear to be a requirement for sustainable chemistry. However some long-living chemicals and composite materials have the disadvantage of being difficult to recycle and/or being resistant to decomposition when carried into the environment, where they may cause long-lasting pollution of unknown consequences.

Therefore, integration of system-thinking with anticipation of the long-term consequences will be increasingly important in general, and also for a green and sustainable chemistry.

## Toxicology for Sustainable Development

Fruitful interdisciplinary cooperation will be required to reach the goals and visions of the UN-Agenda 30. Teaching green chemistry encourages chemists in systems-thinking and in understanding toxicology; this will facilitate communication between chemists and toxicologists (Zimmerman et al. 2014).

A green toxicology should include reduced animal testing, reduced testing time, and saving of resources and of test materials. This goes hand in hand with the trend to replace traditional tests by quality-validated *in vitro* techniques, such as proteomics, metabolomics, genomics, cell cultures, organoids, and target-oriented high throughput test systems like ToxCast (Dix et al. 2007; Watt and Judson 2018). QSAR and bioinformatics will continue to play a great role. One day it may become possible to define the quantum mechanics features of the ligand-binding pocket of macromolecular receptors and predict its binding characteristics for small molecules, thus providing toxicology-relevant information in the absence of any biological test. However, one can anticipate that a lot of questions will remain unsolved by any *in vitro* or *in silico* test and can only be answered by studies in the intact organism, such as the calibration of *in vitro* assays, aspects of chronic organ toxicity, two generation assays, or detailed toxicokinetic analysis.

The impacts of green chemistry on a green toxicology have been discussed recently (Hartung 2009; Crawford et al. 2017; Rusyn and Greene 2018). It is evident, that the combined expertise of chemists and toxicologist will be required in all aspects of green and sustainable development, whether it concerns innovative chemical products and applications or the reduction of existing and upcoming global pollution problems in a sustainable manner.

## Abstract

With sound understanding of biological concepts, the notion of threshold effect levels has grown in acceptance especially for electrophile-induced mutations. However, mutagenesis is only one part of the exposure-to-tumor process in chemical carcinogenesis. Another important part is carcinogen-induced cell death and senescence that eliminates or immobilizes heavily damaged and

mutated cells, respectively. In the following chapter, we postulate diverse protective mechanisms that may contribute to no-effect thresholds in chemical carcinogenesis. Key mechanisms contributing to threshold doses are carcinogen detoxification, including reactive oxygen species (ROS) scavenging and error-free deoxyribonucleic acid (DNA) repair. Elimination of cells harboring pre-mutagenic DNA lesions by apoptosis and other cell death pathways, reduced proliferation rates within tissues, and the induction of senescence may minimize mutation rates and, therefore, also contribute to threshold dose effects for carcinogenesis.

**Introduction**

One of the most significant questions in the field of regulatory toxicology pertains to the concept of threshold dose: do genotoxic carcinogens have a no-effect threshold? The practical ramifications of this question are immense. If there is no evidence of a threshold dose, then limiting exposure to any dose of such chemicals is essential. Conversely, if effect pertains to be threshold, then exposure limitation far below such a threshold becomes an unnecessary burden. The current paradigm assumes that genotoxic carcinogens do not have a threshold dose, whereas tumor promoters and non-genotoxic carcinogens do. Recent evidence for direct genotoxicants has challenged this assumption. There is considerable need for sound understanding of cellular defense mechanisms to substantiate the no-effect levels observed for potent genotoxicants, which is necessary for their acceptance of nonlinearity in risk assessment. In order for accurate conclusions as to the biological relevance of exposure, one has to consider the fate of treated cells. With recent work, we are uncovering the multifaceted cellular responses to genotoxicants, which depend on dose and time and determine cellular fate, i.e., if a cell survives and retains proliferative capacity with or without mutations; dies via apoptosis, necroptosis, or mitotic catastrophe; or remains viable but enters a senescent state. The fate of cells following treatment is not as simple a relationship as the mutation/repair paradigm as a biological basis for thresholds. However, considerations must be made, and our understanding of the signaling mechanisms following treatment must improve because cellular fate, following genotoxic treatment, will have significant bearing on cancer risk. Therefore, the impact of determining cell fate and the signaling mechanisms involved on cancer risk assessment are challenging tasks. Whether different cell fates are elicited at different doses is to be determined. We also have to consider the possibility that at each dose, there will be differing proportions of cells experiencing all possible cell fates, but how this situation contributes to thresholds in carcinogenesis remains to be established.

The question of whether absolute thresholds exist for genotoxic carcinogens cannot be experimentally determined because potential low-dose effects are masked by inherent biological variation. Additionally, due to the complexity of the multi-target model of carcinogenesis, the theoretical deduction of a no-effect threshold is difficult. Thus, *practical* thresholds are *inferred* through experimentally determined dose-response relationships for each endpoint of the carcinogenic process. Therefore, the terms no-*observed* effect level (NOEL), no-observed *adverse* effect level (NOAEL), and no-observed *genotoxic* effect level (NOGEL) are used. With data sets of sufficient statistical power, the parameters point of departure (PoD) and benchmark dose (BMD) are calculated in this respect. Increasing evidence reports nonlinear and even exponential curves for long-term carcinogenicity bioassays in rodents (Waddel et al. 2006). Increased cell proliferation through regenerative hyperplasia at higher doses may potentiate the mutagenicity and carcinogenicity of adducts that remain “dormant” at lower doses, where cell proliferation is comparatively slow (Schulte-Herman et al. 1980). Needless to say, the question of a *true* null effect at low dose will require extensive work.

---

## Tumor Promoters

It is generally assumed that the non-genotoxic mode of carcinogenicity of tumor promoters comes from their ability to modulate signaling pathways, which can lead to stimulation of cellular proliferation or inhibition of apoptotic cell death (Blumberg and Boutwell 1980). Incidentally, there are suggestions that proliferation is stimulated by tumor promoters specifically in cells that were initiated by a genotoxic carcinogen. An example is provided by c-Ha-ras-mutated skin keratinocytes in the two-stage mouse skin cancer model (Parkinson 1985). It is conceivable that genotoxic effects arise indirectly from the promoters’ mode of action. For example, the tumor promoter phorbol-12-myristate-13-acetate (TPA) is non-DNA reactive. The promoting effect of TPA is the consequence of interaction with protein kinase C (PKC) and the resulting alteration of signaling pathways under its control. However, TPA indirectly induces DNA damage, sister-chromatid exchanges, and chromosomal aberrations (Dzarlieva and Fusenig 1982) by releasing intracellular DNA-reactive oxygen species (ROS). This DNA damage mode of action (promotion I) may have a mutagenesis threshold, dependent upon the level of ROS production and the concentration of intracellular radical scavengers (Seager et al. 2012). Additionally, the observations of Lutz et al. (1996) indicate that tumor promoters may well be characterized by a threshold dose. Thresholds are dependent upon the mode of action, and whether this threshold is due primarily to protection against ROS-induced damage or through lack of mitogenesis at low doses is unclear. Other tumor promoters stimulate cell division through binding to and activating cell surface receptors. According to the pharmacological receptor concepts, a specific amount of ligand and activated receptor is required to activate a signal pathway to elicit a biological effect. For example, a certain amount of epithelial growth factor

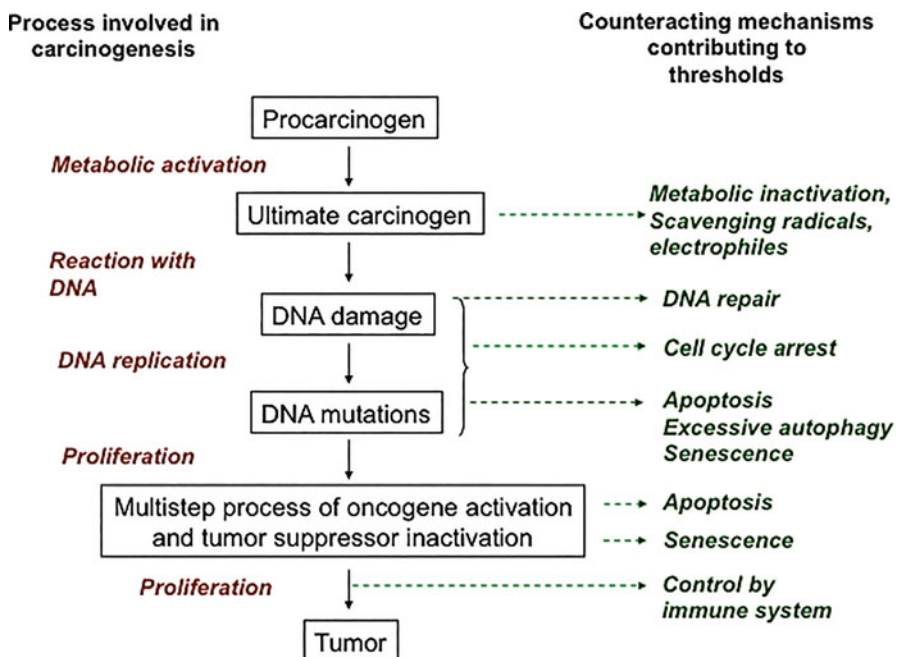

(EGF) is required to activate sufficient receptors to have an impact on cell proliferation and promotion of initiated cells. Therefore, to postulate in this process the existence of a NOEL seems reasonable.

## Factors Modifying Carcinogenesis

The hypothesized cytoprotective mechanisms that can theoretically result in a no-effect threshold are summarized in Fig. 1.

The following passages report on the arguments concerning the involvement of each mechanism in no-effect thresholds through the carcinogenic process.

**Carcinogen Activation.** An important part of the genotoxic effect of many carcinogens is their metabolic activation through enzymes such as cytochrome P450 monooxygenases. The importance of activating enzymes, for provoking a carcinogenic threshold, is observed in the cynomolgus ape. Due to a deficiency in cytochrome P4501A2, cynomolgus apes are resistant to the carcinogenic effects of particular heterocyclic aromatic amines. However, assuming first-order kinetics, it seems likely that even at the lowest dose, each molecule of (pro-) carcinogen could be activated into a carcinogenic metabolite. Saturation of such pathways has only been observed at high dose, thus rendering a low-dose threshold unlikely.

**Fig. 1** Multistep process of carcinogenesis and factors that possibly determine thresholds

**Fig. 2** Expression of recombinant microsomal epoxide hydrolase (*mEH*) protects V79 cells from styrene-7,8-oxide-induced DNA damage. *mEH* induced a “practical threshold” up to concentrations of 100  $\mu\text{M}$ . (Modified from Herrero et al. 1997)

**Carcinogen Detoxification.** A typical example is the impact of the microsomal epoxide hydrolase (*mEH*) on styroloxide-imparted genotoxicity (Fig. 2). Chinese hamster fibroblasts (V79) constitutively express low *mEH* activity and are, therefore, not able to detoxify styroloxide efficiently. Consequently, a threshold following styroloxide exposure was not observed in this cell line (Herrero et al. 1997). Following transfection and expression of human *mEH*, V79 cells are able to inactivate styroloxide by cleaving a reactive epoxide group in the molecule, and, therefore, they display a threshold (Fig. 2; in a linear plot a hockey stick curve). In human cells, the involvement of a radical scavenger, glutathione, has been implicated in a no-effect threshold upon treatment with hydrogen peroxide (Seager et al. 2012). On the other hand, theoretical examinations render a model unlikely in which detoxifying enzymes work “perfectly.” In fact, it is likely that some molecules of a carcinogen escape detoxification and thus induce DNA damage at low doses. Thus, we assume that detoxifying enzymes can cause a “practical” but not a genuine no-effect threshold.

**DNA Repair.** DNA repair mechanisms are potentially the main causes of no-effect thresholds. In this context, we assume that DNA repair of premutagenic adducts prior to replication is free from errors. Of note is the protection offered by the suicide repair protein  $\text{O}^6$ -methylguanine-DNA methyltransferase (MGMT) in the repair of the critical premutagenic adducts  $\text{O}^6$ -methylguanine ( $\text{O}^6\text{MeG}$ ) and  $\text{O}^4$ -methylthymine ( $\text{O}^4\text{MeT}$ ) and, thus, in the prevention of point mutations. MGMT is also very efficient in protecting against MNU and chloroethylnitrosourea-induced skin cancer formation by blocking the tumor initiation, but not the tumor promotion step (Becker et al. 2003). It is important to note that overexpression of MGMT significantly protected, but not completely nullified, the effect of MNU in tumor initiation (Becker et al. 2014). We should consider the possibility of mispairing mutations at replication forks, which may occur in replicating cells before the lesion is removed. In contrast to overexpression, lack of MGMT renders mice highly susceptible to colon cancer formation induced by azoxymethane (AOM), an  $\text{O}^6$ -methylating colonotropic agent (Ochiai et al. 2001; Wirtz et al. 2010). Comparing colon cancer formation (using the elegant technique of mini-colonoscopy) upon

AOM initiation and sodium dextran sulfate mediated promotion in MGMT and alkyladenine -DNA glycosylase (AAG)-deficient mice, which are base excision repair (BER) defective, it turned out that MGMT, but not AAG, causes a threshold (Fahrer et al. 2015). This finding can be explained by the minor role of N-methylpurines in the induction of point mutations.

Even more complicated is the situation if we consider the susceptibility of PARP-1 knockout mice. PARP-1 (poly(ADP-ribose) polymerase-1) participates in several DNA repair pathways, including BER. PARP-1 knockouts (ko) showed a lower tumor incidence than wild-type mice, whereas MGMT/PARP-1 double ko developed more but smaller tumors than MGMT ko animals. The findings revealed PARP-1 as a double-edged sword in colorectal carcinogenesis: it suppresses tumor initiation following DNA alkylation in a MGMT-dependent manner, but promotes inflammation-driven tumor progression (Dorsam et al. 2018). This unexpected observation shows how difficult it is to arrive at conclusions regarding thresholds just from theoretical considerations. Nevertheless, there is a bulk of data supporting the notion that MGMT is at the forefront in setting up thresholds in organs that are targeted by O<sup>6</sup>-methylating carcinogens (i.e., agents inducing O<sup>6</sup>methylguanine). Data has also shown the importance of MGMT-mediated repair of O<sup>6</sup>MeG in the no-effect level of MNU-induced point mutations in lymphoma cells (Johnson et al. 2012; Thomas et al. 2013). Once this protection has been removed, the threshold dose is reduced (Zair et al. 2011).

We wish to stress the point that upregulation of DNA repair genes or repair activity following genotoxic stress would allow the cell to tolerate a higher dose of chemical and should potentiate a no-effect threshold. This was first shown in *E. coli*, in which MNNG treatment induces the expression of the *ada* gene, thereby equipping the cell with significantly more Ada protein (alkyltransferases) as part of the “adaptive response.” Upon future exposures, adapted cells tolerated a higher exposure without an increase in mutation frequency (Lindahl et al. 1988). While the *MGMT* gene has been shown to be inducible in rodent hepatocytes, it was not found to be upregulated in human fibroblasts (Fritz et al. 1991). A recent comparative study with human cancer cells revealed that MGMT is not really subject to upregulation by ionizing radiation and DNA alkylation through temozolomide, but there was to some extent significant increase in the MGMT level following glucocorticoid treatment (Aasland et al. 2018). Therefore, hormone and growth factor regulation should also be taken into account if thresholds are discussed.

In human cells, the nucleotide excision repair (NER) genes *XPC* and *DDB2* are upregulated in response to p53 stabilization following genotoxic stress, whereas the *XPF* and *XPG* NER genes are upregulated via the transcription factor AP-1 (Christmann et al. 2006) following exposure to ultraviolet light (UV). This induction protected the cells against a second, “challenging” dose of UV and, thus, provides an example of a genuine adaptive response in mammalian cells (Tomicic et al. 2011). Similar upregulation was also observed for apurinic endonuclease as part of the adaptive response to oxidative stress (Ramana et al. 1998). On the contrary, there are indications that increased repair activity does not necessarily confer greater resistance to cell death and mutation. DNA mismatch repair (MMR), base excision repair

(BER), and NER are complex pathways involving the coordinated activity of sequentially working enzymes. Overexpression of only one enzyme in the pathway can lead to unbalanced DNA repair, conferring a hypermutable phenotype, which was shown for cells overexpressing *N*-methylpurine- DNA glycosylase (MPG), a primary glycosylase in the BER pathway that removes *N*-alkylpurines from DNA (Coquerelle et al. 1995).

Additionally, some DNA polymerases involved in translesion synthesis (TLS) are known to be error-prone and induce mutations as they bypass bulky lesions to prevent replication fork stalling. One of these is DNA polymerase eta (POLH), which is upregulated on gene level following exposure of cells to benzo(a)pyrene diol epoxide (BPDE) and other genotoxicants that activate p53. As a consequence, BPDE exposure gives rise to genotoxic tolerance in the sense that survival of cells is enhanced at the expense of mutations (Christmann et al. 2016). Whether this has impact on cancer initiation and progression remains an open question. Theoretically, genotoxic tolerance (i.e., tolerance of replication-blocking lesions) could be reduced by a lower expression of these “error-prone” polymerases, or the adduct is removed from DNA before it interferes with replication by error-free NER.

It could be said that post-replicative DNA repair of base mispairs could contribute to a no-effect threshold level. However, in the example of post-replicative MMR processing of O<sup>6</sup>MeG-thymine mispairs, the outcome can be unpredictable. In this case, although thymine is removed, it is reintroduced due to the miscoding potential of O<sup>6</sup>MeG. An ensuing futile cycle eventually leads to DNA strand breaks that are toxic to the cell. This mechanism is thought to remove cells from the cell pool, which harbor mutagenic O<sup>6</sup>MeG adducts, which has in fact been suggested to occur in colon carcinogenesis induced by azoxymethane (Wirtz et al. 2010). O<sup>6</sup>MeG is a highly mutagenic, clastogenic, and recombinogenic lesion (Kaina et al. 1993). Therefore, MMR-driven cell killing may be considered a causal factor for causing a no-effect threshold for gene mutations, clastogenicity, and cancer formation.

**DNA Damage Response.** The repair of adducts by such excision repair processes has been the sole focus of mechanistic studies into the threshold-dose responses observed. However, many different types of adducts can result in clastogenic DNA double-strand breaks (DSBs) and become substrates for the DNA damage response (DDR). The influence of the DDR in a cancer threshold may be twofold. Firstly, at the DNA level, DDR contributes to the cellular tolerance to the possible damage from adducts via its role in the orchestrated repair of DSBs following cell cycle arrest and homologous recombination (HR) or non-homologous end-joining (NHEJ), assuming faithful repair. One would imagine this would be a similar situation to adduct repair, which has already been substantiated in thresholds. Secondly, at the cellular level, the DDR plays an important role in determining different cell fates, following treatment (Roos et al. 2016). In this regard, the DDR removes or immobilizes damaged cells via apoptosis and senescence, respectively. Indeed many cancers display mutations in key DDR enzymes, and, furthermore, many cancer predisposition syndromes stem from inherited defects in DDR components such as ATM, ATR, and p53. Therefore, its role as a defense mechanism in carcinogenesis is

**Fig. 3** Dose response of LN-229 glioblastoma cells treated with temozolomide. (a)  $\gamma$ H2AX foci and (b) apoptosis were measured 48 and 96 h after treatment with TMZ, respectively. (Modified from He and Kaina 2019)

realized. It is hypothesized, and textbook knowledge, that at low doses, the DDR arrests cells in the cell cycle, giving time for repair of the damage, while at high doses, senescence or apoptosis (which may have its own threshold of damage) is induced. However, this classical concept has been challenged by the observation that the dose- response of phosphorylated H2AX ( $\gamma$ -H2AX) is a linear function of dose (Fig. 3a) and activation of HIPK2, the kinase responsible for activating the death pathway (He et al. 2019), increases with a similar linear function at the posttreatment time of analysis (He and Kaina 2019). Although the data were obtained on cancer cells treated with the alkylating drug temozolomide, there are indications that  $\gamma$ -H2AX is a linear function of dose/concentration in other cell systems as well (B. Kaina, unpublished data). Nevertheless, it can be concluded that DDR plays a pivotal role in protecting against cancer and reducing the risk of exposure, which has been discussed extensively especially for simple alkylating agents (Thomas 2020).

**Apoptosis.** The process of programmed cell death (apoptosis) is generally seen as a process to remove mutated cells. It is reasonable to posit that elimination of cells harboring critical mutagenic adducts or, at a later stage, cells in which these adducts have caused mutations in critical genes, counteracts tumor initiation and tumor progression. The existence of “sensor mechanisms” is postulated to trigger the apoptotic pathway in response to DNA damage. The critical lesion  $O^6$ MeG provides us with a useful example: it is highly mutagenic, pre-carcinogenic, and a potent trigger of apoptosis. Signaling studies have shown that the MMR proteins MSH2 and MSH6 initiate apoptosis through a variety of pathways upon recognition of  $O^6$ MeG-thymine mispairs (Quiros et al. 2010).

It is often speculated that only severely damaged cells are removed from the population through cytotoxicity occurring at high doses. At low doses, however, with comparatively low levels of DNA damage, the trigger for apoptosis may be

insufficient, and therefore, apoptosis may not play a role in low-dose thresholds. In this “classical” model of cell death through apoptosis, p53 plays a key role as switch maker between survival and death. In more detail, the model claims that critical DNA lesions that block replication, or DSB themselves, activate the DNA damage-responsive kinases ATM and ATR, which in turn phosphorylate SIAH1, an inhibitor of the kinase HIPK2. This results in activation of HIPK2, which phosphorylates p53 at serine 46 (p-p53ser46) (He et al. 2019). This p53 modification causes p53 to act as a tetrameric transcription factor for pro-apoptotic genes, such as *BAX* and the death receptor *Fas*. In this model, p-p53ser46 serves as stimulator of pro-apoptotic genes, while another modification of p53, p-p53ser15, triggers upregulation of anti-apoptotic genes, including DNA repair genes such as *DDB2* and *XPC* (Christmann and Kaina 2013). According to this model, it is anticipated that only high doses of genotoxic agents trigger upregulation of the ATM/ATR-HIPK2-p53ser46 axis, but surprisingly (as outlined above) recent experiments revealed a linear, threshold-lacking dose response at the posttreatment time of analysis. Thus, the induction of HIPK2 triggered by *O*<sup>6</sup>MeG was a linear function of dose, and apoptosis did not display a threshold in p53 wild-type cancer cells that are MGMT deficient (Fig. 3b) (He and Kaina 2019). Given that damaged cells become eliminated at low- and high-dose levels, apoptosis is even a more powerful mechanism of removal of precancerous cells than hitherto thought.

We should stress the point that the presence of a no-effect threshold depends on the genotoxic agent and the repair capacity of the cell to be considered. Thus, agents inducing *O*6-alkylguanine display a clear threshold if cells are MGMT proficient, due to fast and error-free repair of the killing (and mutagenic) lesion, while in MGMT-deficient cell types, a threshold may be lacking (as outlined above). Genotoxicants that induce bulky lesions or induce DNA breaks via inhibition of topoisomerases may show a threshold due to activation of HIPK2 death pathway, which was shown to occur in this case only at high-dose levels (Winter et al. 2008).

Apoptosis is a critical eventuality of response following exposure, but there are many other outcomes for a cell (senescence, autophagy, mitotic catastrophe, necroptosis, ferroptosis, and others), and the importance of dose in determining cell fate is yet to be fully elucidated. Nevertheless, the fate of a cell, following genotoxic exposure, may play a crucial role in likelihood of cancer. Understanding what determines cell fate is of critical importance for its extrapolation into cancer risk.

---

## Dose, Time, and Cell Fate Heterogeneity

While genotoxicity assessment, in terms of mutagenicity and clastogenicity, provides the mainstay of assessing DNA damage tolerance, the ultimate fate of a cell, following treatment, underpins pragmatic dose-response assessment. Cell fates can be broadly classified into distinct phenotypes including cell survival with or without mutations, cell death, cell cycle arrest, and senescence. It is important to note that these outcomes may not all be mutually exclusive but rather successive states that

may culminate in the same cell fate. In this context, the rapid or delayed initiation of a particular cell fate, or the presence or absence thereof at specific times following genotoxic insult, may indicate inherent thresholds, but whether these are dosage thresholds is uncertain, but may be dependent on time. The elucidation of the factors involved in determining cell fate will play a very important role in determining biological risk.

It was shown that human bone osteosarcoma cells, treated with the platinum DNA strand cross-linker, cisplatin (0.07 and 0.14  $\mu\text{M}$ ), had nearly indistinguishable growth curves (measured every 30 min until 5 days after treatment) compared to untreated controls (Granada et al. 2020). Moreover, the authors demonstrated distinct cell fates in response to variable cisplatin doses (7, 10, and 13  $\mu\text{M}$ ). Of note here is that the reported “medium” dose (10  $\mu\text{M}$ ) is not much less than the “high” dose (13  $\mu\text{M}$ ), yet these doses elicited distinct cell fates. However, cell fate was also tied to the proliferative index of individual cells preceding treatment. Specifically, 7 and 10  $\mu\text{M}$  doses preferentially caused cell cycle arrest in cells with a high proliferative index (HPI). Surprisingly, cells of low proliferative index (LPI) preferentially died. One would imagine that LPI cells would have fewer mutations than those in the same culture with HPI. However, mutation induction was not measured in cells of either status. Nevertheless, the study highlights that cell fate, even within a population exposed to the same insult, is heterogeneous and dependent upon biological factors other than dose. The impact of dose on cell fate is, therefore, difficult to predict. However, when examining the relationship in reverse, i.e., the impact of cell fate on eliciting a genotoxic threshold, the death of cells with low proliferative index may be a contributing factor.

Exploring this a little further, it is not unreasonable to assume that certain cell populations may respond heterogeneously to DNA damage, as a result of having different transcriptomes. This could differ between cell types and, as the previously mentioned study suggested, even across individual cells within an experimental system both *in vitro* and *in vivo* over time, to facilitate specific functions, i.e., cell division as previously eluded to. It is possible that the transcriptomes of some cells are geared toward a lower genotoxic threshold of apoptosis and perhaps a higher threshold level for cancer. For example, mouse epiblasts are more susceptible to undergo apoptosis following low-dose irradiation than surrounding tissue (Laurent and Blasi 2015). The authors demonstrated pronounced 53BP1 accumulation at DSB sites within 10 min of 0.5 Gy X-ray irradiation in epiblasts, but not visceral endoderm (VE) or extra-embryonic ectoderm (ExE) cells. Similarly, p-p53ser18 phosphorylation was readily observed within the same time and dose in epiblasts but only after 1 h in ExE cells. The authors alluded to epiblasts being primed for apoptosis as evidenced by inherently elevated levels of pro-apoptotic Bim, Bak, and Noxa and decreased levels of anti-apoptotic Bcl-xL, as compared to extra-embryonic tissues. These findings underpin the ability of certain tissues to have an inherently lower apoptosis threshold to prevent mutation propagation. On the other hand, Paek et al. (2016) demonstrated the apoptotic threshold to increase with time following cisplatin treatment, owing to increased abundance of inhibitors of apoptosis. Therefore, it seems reasonable to infer that in a particular cell, the DNA damage threshold to elicit cell apoptosis is dynamic and may be shifted by intrinsic or extrinsic mechanisms.

In line with this notion, non-coding RNAs may function as intrinsic modulators of the DNA damage threshold. Specifically, small non-coding RNAs such as microRNAs (miRNAs) are promising candidates as they are known to regulate several DNA repair genes (reviewed by Wang and Taniguchi 2013). Consequently, as DNA repair mechanisms are potentially key determinants of no-effect thresholds (reviewed by Jenkins et al. 2010) and cell fate, the importance of miRNAs is evident. For example, miR-192 hinders NER in liver carcinoma cells. miR-192 directly targets ERCC3/4, components of NER (Xie et al. 2011). Moreover, poly (ADP-ribose) polymerase (PARP1) is a proposed target of miR-7-5p (Luo et al. 2018; Lai et al. 2019). Importantly, PARP1 functions in several DNA repair pathways including NER (Robu et al. 2013) and base excision repair (BER) (Reynolds et al. 2015) and modulates homologous recombination repair (HRR) (Lai et al. 2019). Lai et al. (2019) demonstrated endogenous miR-7-5p expression to be significantly reduced in doxorubicin (dox)-resistant small-cell lung cancer cells (SCLC), compared to dox-responsive SCLC cells. Moreover, miR-7-5p transfection significantly reduced the dox  $IC_{50}$  in dox-resistant SCLCs. Luo et al. (2018) demonstrated that lymphoblastoid cell transfection with miR-7-5p, followed by hydroquinone treatment, resulted in a significant increase in apoptosis and, hence, a lower damage threshold. Likewise, miR-7-5p transfection also prominently increased the proportion of apoptotic cells both with and without hydroquinone treatment. This suggests miR-7-5p-mediated PARP1 inhibition is sufficient to drive the DNA damage threshold below endogenous DNA damage levels. As PARP1 was implicated as a target for suppression by miR-7-5p in both the study by Luo et al. (2018) and Lai et al. (2019), PARP1 inhibition appears to be the principle pro-apoptotic and anti-survival mechanism of miR-7-5p. By extension, this also implies a mechanism for reduced DNA damage tolerance, especially considering the consequences of PARP1 inhibition likely stem from its impaired role in multiple DNA repair mechanisms. These examples exemplify the potential for miRNAs to shift DNA damage thresholds and, at least partially, promote a pro-apoptotic cell fate. Whether they contribute to a cancer threshold is only postulated, but warrants further investigation.

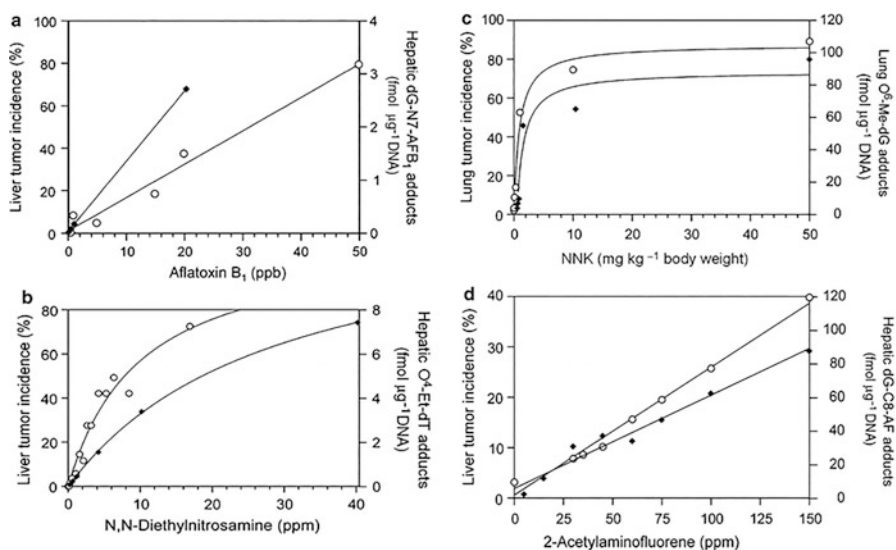

**Immune System.** The immune system is equipped with cells to recognize and eliminate tumor cells. The system involves dendritic cells that may represent tumor cell antigens, cytotoxic T cells, neutrophils, and macrophages that respond upon activation with a cytotoxic ROS burst. The question remains if tumor cells are targeted following initiation, but prior to phenotypic transformation. It can only be speculated that a no-effect threshold would be dependent upon a perfectly functioning immune system, which becomes saturated due to an increased demand for removal of tumor cells at higher concentrations, where more cells are initiated. The role of immunity against genotoxicant-initiated cancer cells in thresholds has not yet been addressed experimentally. But there is growing evidence that the immune system can become activated to eradicate cancer cells. Impressive examples are checkpoint inhibitors (Chapman et al. 2011) and immunomodulators (Hogan et al. 2018), which abrogate the inhibitory activity of CTLA-4 cytotoxic T-cell receptor and tumor T-cell ligand interactions through PD-1 inhibition, respectively,

thus activating cytotoxic T cells to target and destroy tumor cells. Whether the CTLA-4 and PD-1 pathways are subject of genotoxicant mediated regulation is an open and highly challenging question.

## Further Examples of Genotoxic Carcinogens

The following examples outline the heterogeneity of the dose-response relationship among direct acting genotoxicants. For most genotoxic carcinogens, the linear assumption holds true. These include aflatoxin (B1), diethylnitrosamine (DEN), and the tobacco-specific carcinogen 4-(*N*-methyl- *N*-nitrosamino)-1-(3-pyridyl)-1-butanone (NNK). Figure 4a-c shows their dose-response relationship for tumorigenesis and the amount of adducts involved. The largest tumorigenesis research was performed with 2-aminoacetylfluorene (2-AAF). In a large study (24,000 mice), researchers were unable to prove a threshold for the induction of liver tumors (Littlefield et al. 1980) (Fig. 4d).

Despite these definitive examples, we should not assume the generalizability of the linear model for all genotoxicants given recent and ever-increasing support for nonlinearity. For example, tumor induction by vinyl acetate has a no-effect level of <100 mg/kg/day (Fig. 5). The underlying mechanism has been exhaustively discussed (Hengstler et al. 2003).

**Fig. 4** Induction of tumors (o) and DNA adducts (◆) induced by different carcinogens as a function of dose. (a) Incidence of liver tumors and aflatoxin B1 adducts in rat livers. (b) Induction of liver tumors in rats by DEN. Incidence of liver tumors (o) and the DNA adduct O<sup>4</sup>-ethylthymine (◆) is shown as a function of dose. (c) Incidence of lung tumors (o) and levels of O<sup>6</sup>-methylguanine (◆) in rats after administration of NNK. (d) Incidence of liver tumors (o) and DNA adducts (◆) after administration of 2-acetylaminofluorene to BALB/c mice. (Data are from publications compiled in Hengstler et al. 2003)

**Fig. 5** Incidence of squamous cell carcinoma as a function of vinyl acetate dose in rodents. (From Hengstler et al. 2003)

exposure considered acceptable. The risk levels considered acceptable (e.g.,  $\leq 1:100,000$ ) (ICH 2017) are so low that experimental proof in life time animal carcinogenicity experiments is simply not possible as this would require millions of animals for one experiment. Therefore, the risk levels are referred to as a “theoretical cancer risk.”

In our daily life, we are exposed not only to one genotoxic compound or one tumor promoter, but many. Cooked or fried food, combustion exhausts, cured meat, active and passive smoking, or natural plant products contain a considerable number of mutagenic carcinogens, tumor promoters, and compounds interfering with carcinogen activation and detoxification. Determination of a threshold for a certain DNA-reactive chemical would need deciphering all the key steps it takes to cause cancer from transport into the cell, reacting with DNA, forming adducts, steps needed for transformation into mutation, hitting all necessary genes needed for cellular transformation, and bypassing apoptotic mechanisms and immune defense. For all steps, a threshold dose needs to be determined and finally an overall threshold by modeling the whole process for this chemical. Different people have different exposure to other chemicals interfering with the activation, detoxification, and defense mechanisms. Individuals also differ by their individual capacity for each step due to, e.g., genetic variations in key enzymes. The threshold must therefore be transferred into a limit by applying adjustment factors to be protective for a heterogeneous population. To protect a population, it can be argued that the threshold for the first critical step, the reaction with DNA, will provide a protective threshold. This however requires to measure this threshold reliably in experiments, which is difficult and may only be possible in cases where DNA adducts can be reliably distinguished from the background of endogenous adducts. Actually, there are examples showing that this can be achieved. Thus, the difference in the dose response of MGMT lacking and MGMT expressing cells is dramatic if  $O^6$ MeG following treatment with an alkylating agent is measured (Kraus et al. 2019). This also leaves out all defense processes of cells and organisms and may lead to a very low threshold with questionable biological relevance. Standard studies to detect gene mutations in mammalian cells and animals are used for regulatory purposes to verify or deny the hazard of increased mutation formation. The data are not used to quantitatively analyze the dose-response relationship and derive PoDs used for extrapolations and risk assessment to determine regulatory limits. One major problem for determining a threshold in these assays is the impossibility to distinguish the mutations caused by the chemical from the background mutations. The formation of mutations is one key step in the development of cancer by genotoxic chemicals. It is considered plausible that dose levels not increasing mutation frequency also will not lead to an increase in cancer. It may therefore be possible to use dose-response modeling to determine a PoD in mutation assays which can be used to extrapolate protective limits. Major investigations are ongoing, and an example how this may be done is described for benzo[a]pyrene by Long et al. (2018).

The relationship between dose responses in adduct formation, mutation frequency, and increase in pre-carcinogenic and carcinogenic lesions in organs is described in MacGregor et al. (2015) for the mutagenic carcinogen

2-amino-3,8-dimethylimidazol[4,5-f]quinoxaline (MeIQx), one of the still very rare examples such data are available for. In this example, the BMD for 10% increase over background (BMD<sub>10</sub>) is used for comparison. BMD<sub>10</sub> and BMDL<sub>10</sub>, the lower end of its 90% confidence interval, are the most frequently used in comparison of results in rodent carcinogenicity studies. The BMD<sub>10</sub> is increasing from adduct formation to cancer in rat by four to five orders of magnitude. Such data suggest that below a certain dose level where the risk for genetic damage is small, the subsequent risk for developing cancer is negligible. This comparison supports the hypothesis that a threshold for MeIQx may eventually exist, although it cannot be determined yet. As outlined above, a threshold for O<sup>6</sup>MeG resulting from its repair by MGMT (Kraus et al. 2019) and mutations and cancer resulting from this damage has been demonstrated unequivocally (see above). Whether these findings can be translated to humans expressing different amounts of repair enzymes is an open question.

In contrast to O<sup>6</sup>-methylating genotoxicants and MeIQx, the data above shown for DEN, NNK, AFB1, and 2-AAF do not seem to support the hypothesis that no-effect thresholds for carcinogens are the rule. Of note, O<sup>6</sup>-ethylguanine is removed from DNA less efficiently than O<sup>6</sup>MeG, which may cause a difference in responses and possibly also thresholds elicited by DEN versus DMNA. There are presumably more exceptions, and the examples given here demonstrate that the potencies of mutagenic carcinogens vary widely. For the highly potent carcinogens (except the O<sup>6</sup>-methylating agents), a threshold may be extremely low and in a dose range simply impossible to measure in any assay. At least the biological mechanisms behind chemical carcinogenesis are the same.

The bottleneck is still the experimental proof of a no-effect threshold or even a practical threshold with no biologically relevant effect for mutagenic carcinogens. Extensive scientific investigations are ongoing. Until there is experimental evidence for the existence of “genuine” thresholds, the need of regulatory toxicology for setting acceptable limits for mutagenic carcinogens has to be covered by the established methods at hand.

---

## Conclusions

A practical no observed effect level could occur with genotoxic carcinogens. Effective detoxification, scavenging mechanisms, and lack of activation could prevent DNA interaction. Critical DNA adducts are subject to error-free repair, which might be considered a major mechanism provoking a no-effect threshold. Furthermore, elimination of damaged cells by apoptosis and premalignant cells by the immune system may further reduce the level of risk. The concept of a threshold is theoretically plausible at each requisite step involved in chemical carcinogenesis. Manipulating the intracellular levels of metabolizing enzymes and upregulation of MGMT and other repair enzymes in a balanced fashion, as well as increase in their activity following genotoxic stress through post-translational mechanisms, may potentiate the existence of a threshold. Conversely, due to the complexity of the DNA repair and damage response pathways, altering expression of effector proteins may

unbalance the repair process and abrogate a threshold by promoting genomic instability and mutagenesis. The processes discussed here have been implicated as the casual event in nonlinear dose-response relationships. Whether the observed thresholds are a true null effect remains to be seen. Mechanistic investigations are ongoing to discover the biological relevance of low-dose exposures. Such studies are mandatory in the acceptance of no-effect thresholds.

## Abstract

Effective protection against harmful effects of toxic substance mixtures requires the ability to assess the combined risk potential of the various constituents. The biological impact of chemical mixtures may arise from independent, additive, synergistic, or antagonistic effects of single constituents. Mathematical models may be used to characterize corresponding toxic effects. In most cases, models act

on the assumption of independent effects or unknown mechanisms of action. However, a mechanistic understanding of interaction/s among mixture constituents, if available, is the best basis for quantitative predictions of the consequences of co-exposure to different stressors. In the following chapter, the possible modes of interaction of substance mixtures and the general mechanisms of interactions are described. Furthermore, formulae to quantify the combined risk of co-exposure to multiple substances are depicted.

Risk potential · Agonist · Antagonist · Agent-to-agent interaction · Mixture toxicology · Hazard quotient · Hazard index

---

**Introduction**

It has long been known that co-exposure to different substances may trigger effects other than the simple summation of the effects caused by the individual constituents. The supra-multiplicative increase in the risk of esophageal cancer by co-exposure to tobacco smoke and ethanol is a well-known example. Nevertheless, most risk assessments performed by regulatory boards like the US Environmental Protection Agency (EPA), the US Food and Drug Administration (FDA), the European Chemicals Agency (ECHA), or the European Food Safety Authority (EFSA) have focused on single substances.

In the following review, the modes of interaction between individual contaminants, including cases of synergism and antagonism, are described. In addition, important concepts for assessing the risks of a combined exposure, such as formulae allowing to quantify the combined risk of co-exposure to multiple substances, are introduced.

---

**Basic Considerations**

Multiple substances, acting simultaneously on the human or animal organism, in general result in two fundamental possibilities concerning their toxic effects:

1. The individual substances affect each other neither directly nor indirectly and exert completely independent effects on the exposed organism (independent effects, no interference). Thus, the constituents of the mixture act as if each one was the sole substance in the body.
2. The toxic substances influence each other either via substance-substance interactions (e.g., substance “a” binds and “neutralizes” substance “b”) or via identical toxicological endpoints (e.g., substance “a” and substance “b” target the same organ).

**Fig. 1** Combination effects of three single compounds with identical toxicity endpoints. The left columns show the relative toxicity of compound b and c in comparison to the exposure of substance a. Each compound is given as individual substance (*single treatment*). The right group of columns illustrates examples where a simultaneous exposure of two or even all three compounds elicits either additive (a + b), synergistic (a + c), antagonistic (b + c) or not predictable toxic effects (a + b + c) (*combination treatment*). The numbers above the bars in both groups quantitate the relative toxic effect in comparison to substance a. (Modified from Bolt 2004)

In scenario (1), the risk assessment of the substance mixture relies on the analysis of the single compounds.

In scenario (2), a mechanistic understanding of the interaction is desirable for risk evaluation although this is often not available. In such a complex situation, three possibilities are conceivable regarding the resulting combination effects (see also Fig. 1).

- The effects of a substance mixture correspond to the sum of the effects of the single constituents, thus leading to dose additivity.
- The effect of a substance can be increased by another substance. This process results in more-than-additive effects and is known as synergy.
- The effect of a substance is attenuated by the presence of a second substance (antagonism). One utilizes this phenomenon in the therapy of intoxications. The mechanisms behind antagonistic effects are physical, chemical, or biological processes.

In principle, three types of interactions can lead to antagonistic, additive, or synergistic effects of combined substances.

- The single compounds of the mixture can react with each other (agent-to-agent interaction) prior to incorporation or after ingestion in the body. An example of a

reaction occurring outside the body is the formation of ozone and peroxyacyl nitrates as so-called secondary pollutants in the air, following the interaction of hydrocarbons with nitrogen oxides (NO<sub>x</sub>) in the presence of ultraviolet light. Agent-to-agent interactions occurring within the body have rarely been identified in mixture toxicology. However, this phenomenon is commonly used to neutralize drugs or toxic substances. One example is the binding of excessive muscle relaxants of the aminosteroid type by modified  $\gamma$ -cyclodextrin (sugammadex) or the neutralization of digoxin by application of digoxin-specific antibody fragments.

- A much more common mechanism in mixture toxicology occurs when constituents of the mixture display toxicokinetic interactions. These may lead to altered concentrations of substances in target organs by effects on the elimination or distribution. An illustrative example of a toxicokinetic interaction is the consumption of ayahuasca, a hallucinogenic mixture of *Banisteriopsis caapi* vine and *Psychotria viridis* shrubs. The latter ingredient contains serotonergic dimethyltryptamine, and the former contains a monoamine oxidase inhibitor preventing the inactivation of dimethyltryptamine.
- Another very important mechanism of altered toxicity of substance combinations relies on toxicodynamic interactions. This means that the effect of a substance on a target structure is altered by another substance that in turn modifies the susceptibility of the target structure. Many well-established examples for toxicodynamic interactions are related to the field of carcinogenesis. For instance, the methylation of DNA by many DNA-methylating carcinogens like methyl nitrosourea or dimethyl nitrosamines can be repaired by O<sup>6</sup>-methylguanine DNA methyltransferase (MGMT). Thus, co-exposure to inhibitors of MGMT substantially increases the DNA damaging and carcinogenic effects of these methylating agents.

---

## Basic Aspects of the Scientific Evaluation and Regulatory Specifications of Safety Values for Combined Substance Exposures

The regulatory recommendations for risk assessment of substance mixtures suggest the use of empirical toxicity data, if available. Unfortunately, the experimental investigation of substance interactions using a full factorial design (every combination is tested) is limited by the high number of permutations to be tested. Thus, to test the interaction of two substances using three different concentrations of each compound leads to  $3^2 = 9$  combinations, whereas the testing of five substances leads already to  $3^5 = 243$  combinations. However, most toxicologically relevant mixtures contain far more constituents. For example, cigarette smoke contains over 7.000 gaseous and particulate compounds among them more than 70 identified carcinogens.

In the case that no toxicity data for the substance mixture are available (which is the normal situation), the regulatory recommendations suggest combining the

toxicity data of single constituents in an additive manner. As a rule of thumb, additive effects are most likely in mixtures of compounds with similar modes of action (especially with identical molecular target structures), whereas independent, antagonistic, or synergistic effects may appear if the substances have different modes of action.

To quantify additive effects of substance mixtures, the calculation of the Hazard Index is an appropriate approach. The Hazard Index results from the concentration (C) of the individual substance in the mixture and the reference dose (RfD, for ingestion or transdermal uptake) or the reference concentration (RfC, for inhaled exposures) (see formula below). The RfD (or RfC) value is defined as the highest dose or concentration of an individual constituent that, as an independent exposure, does not produce harmful effects. Another important factor for a single compound is the Hazard Quotient (HQ), which calculates the ratio of the potential exposure to a substance and the level at which no adverse effects are expected.

$$\text{Hazard Index} : \frac{C1}{RfD1} + \frac{C2}{RfD2} + \dots + \frac{Cn}{RfDn} = \sum_{i=1}^n HQ_i$$

**Hazard Index: A value < 1 indicates that exposure is unlikely to be harmful**  
**HQ<sub>i</sub> = Hazard Quotient of each individual substance**

Since the Hazard Index is based on the assumption of an additive mode of action, its application leads to an overestimation of the real risk of the substance mixture if antagonistic effects occur. Vice versa, the Hazard Index will underestimate the risk of a mixture if synergistic effects play a role. An established application of the Hazard Index is evaluating the risk from exposure to hazardous air pollutants.

## Abstract

For many life science professionals, biological products represent the cutting edge of medical research and are the smartest means to target and treat a variety of disease and conditions for which the current treatments are still unsatisfactory. In contrast to small molecule drugs, including new chemical entities (NCEs), biomolecules (also

called biologics, biologicals, biopharmaceuticals, or biotechnology-derived pharmaceuticals) are complex macromolecules, sometimes occurring as mixtures that are not easily identified or fully characterized. Nevertheless, due to the rapid development of biotechnology in the last three decades, the number of approved biomolecules is increasing at a faster rate than it is the case for new chemical entities. Biologicals are usually highly specific for a target, are more heat sensitive and susceptible to microbial contamination, and are likely antigenic. Thus, the quality and security testing of biologicals is becoming increasingly important. This updated chapter compares the evolving regulatory environment relevant for biomolecules, with a typical “case-by-case” development program versus NCEs, which are generally developed according to a more standard “classical” manner.

**Introduction**

Biotechnology-derived pharmaceuticals (biopharmaceuticals, biologicals, or more simply biologics) are defined as products derived from characterized cells through the use of various expression systems including bacteria, yeast, insect, plant, and mammalian cells. The active substances include proteins and peptides, their derivatives, and products of which they are components; they could be derived from cell cultures or produced using recombinant DNA technology including production by transgenic plants and animals.

Conversely, a NCE (new chemical entity) can be defined as a novel drug substance obtained by chemical change or synthesis and not yet approved for the prevention or treatment of human diseases.

In the EU, all human medicines derived from biotechnology and other high-tech processes are evaluated by the European Medicines Agency (EMA) via the centralized procedure (Notice to Applicants 2016, Vol. 2A).

In the USA, the regulatory evaluations are made either by the Center for Biologics Evaluation and Research (CBER) or by the Center for Drug Evaluation and Research (CDER). The mission of the CBER at the Food and Drug Administration (FDA) is to ensure the safety, purity, potency, and effectiveness of biological products including vaccines, allergenics, blood and blood products, and cells, tissues, and gene therapies for the prevention, diagnosis, and treatment of human diseases, conditions, or injury. As part of the FDA, the Center for Drug Evaluation and Research (CDER) regulates over-the-counter (OTC) and prescription drugs, including biological therapeutics and generic drugs.

In order to reduce regional discrepancies, the International Conference of Harmonization (ICH) has contributed to a significant global standardization of test conditions and regulatory approval of drugs for quality (ICH Q guidelines), safety

(ICH S guidelines), efficacy (ICH E guidelines), and multidisciplinary (ICH M guidelines). ICH guidelines consider current practices from participating countries and provide a unified view, intended to facilitate mutual acceptance of data and clarify key issues. However, they are typically not statutory by definition and hence not usually legally binding or directly enforceable. The aim of this updated review is to clarify the nonclinical and toxicological regulatory differences encountered when developing NCEs or biologics, not only taking into account ICH perspectives but also considering regional differences between the EU and US regulations.

---

## **Biomolecules Versus Smaller Chemicals in Toxicology**

### **ICH Guidelines**

The major ICH guidelines and related Questions and Answers (Q&As) applicable for nonclinical development (ICH S and some ICH M guidelines) are listed in Table 1.

All ICH guidelines listed in this document and their corresponding associated files can be freely downloaded on the <https://www.ich.org/> website.

In contrast with the development of NCEs, the list comprises a unique guideline, ICH S6(R1), to address the regulatory environment for the nonclinical development of all biologics (see also Baumann 2009 for a “fundamental review” on nonclinical development of biologics). It is crucial to follow the recommendations of ICH S6(R1) to achieve the three main goals of nonclinical safety evaluation which are to identify (1) an initial safe dose and subsequent dose escalation schemes in humans, (2) potential target organs for toxicity and for the study of whether such toxicity is reversible, and (3) safety parameters for clinical monitoring. Complying with the recommendations of ICH S6(R1) may, however, still be insufficient to fully predict life-threatening adverse events in man, as discussed below.

It is also important to mention that sometimes assessments may vary between authorities. As an example based on our experience, despite the clear mention in ICH S6(R1) that this guidance may also apply to oligonucleotide drugs, oligonucleotides are usually considered as biotechnology-derived pharmaceuticals by the EMA (following ICH S6(R1), while in the US oligonucleotides are rather evaluated as small molecules by the FDA (following ICH M3(R2)). Therefore, the recommendation for oligonucleotides would be to prepare a nonclinical package that would comply to both guidelines for a worldwide drug development and to request a scientific advice meeting with a regulatory agency to discuss the relevance of the nonclinical development program.

### **The Regulatory Environment to Initiate First-in-Human Studies**

Despite the conduct of a nonclinical development plan in line with the ICH regulations, two dramatic clinical cases necessitated the revision of the regulatory environment for First-in-Human trials in the EU.

**Table 1** List of ICH guidelines to assess the safety of NCEs and biotechnology-derived pharmaceuticals

ICH Guideline	Topic (date of coming into force)
M3(R2)	Nonclinical Safety Studies for the Conduct of Human Clinical Trials for Pharmaceuticals (re-amended in 2009). Q&As to ICH M3(R2)
M7(R1)	Assessment and control of DNA reactive (mutagenic) impurities in pharmaceuticals to limit potential carcinogenic risk (amended in 2017). ICH M7(R2) is in preparation
S1A	The Need for Long-term Rodent Carcinogenicity Studies of Pharmaceuticals (1995). ICH S1 as a whole is under revision. The goal is to define when 2-year rat carcinogenicity studies are mandatory
S1B	Testing for Carcinogenicity of Pharmaceuticals (1997)
S1C(R2)	Dose Selection for Carcinogenicity Studies of Pharmaceuticals (amended in 2008)
S2(R1)	Genotoxicity Testing and Data Interpretation for Pharmaceuticals Intended for Human Use (amended in 2012)
S3A	Toxicokinetics: The Assessment of Systemic Exposure in Toxicity Studies (1994). Q&As to ICH S3A: Note for Guidance on Toxicokinetics: The Assessment of Systemic Exposure in Toxicity Studies. Focus on Microsampling (2017)
S3B	Pharmacokinetics: Guidance for Repeated Dose Tissue Distribution Studies (1994)
S4A	Duration of Chronic Toxicity Testing in Animals: Rodent and Non-rodent Toxicity Testing (1998)
S5(R2)	Detection of Toxicity to Reproduction for Medicinal Products & Toxicity to Male Fertility (re-amended in 2000, a new version, R3, is in preparation)
S6(R1)	Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals (amended in 2011)
S7A	Safety Pharmacology Studies for Human Pharmaceuticals (2000)
S7B	Nonclinical Evaluation of the Potential for Delayed Ventricular Repolarization (QT Interval Prolongation) by Human Pharmaceuticals (2005). Q&As Clinical and Nonclinical Evaluation of QT/QTc Interval Prolongation and Proarrhythmic Potential (in preparation 2018)
S8	Immunotoxicity Studies for Human Pharmaceuticals (2005)
S9	Nonclinical Evaluation for Anticancer Pharmaceuticals (2009). Q&As: Nonclinical Evaluation for Anticancer Pharmaceuticals (2018)
S10	Photosafety Evaluation of Pharmaceuticals (2013)
S11	Nonclinical Safety Testing in Support of Development of Paediatric Medicines (2018, step 2b)

1. In 2006, the press (Suntharalingam 2006) reported that failure to select a safe starting dose in humans at the early clinical stage with the CD28 super-agonist monoclonal antibody TGN1412 led to serious toxicity including multi-organ failure in six healthy volunteers. EMA subsequently issued recommendations and a guideline for the safe and rational conduct of clinical trials (EMEA/CHMP/SWP/294648/2007).

Therefore, since 2007, both the NOAEL dose (No-Observed Adverse Effect Level, which is related to the “toxicological” effects of a drug) and MABEL dose (Minimum Anticipated Biological Effect Level, which reflects rather the “pharmacological” effect of the drug) should be determined by the Sponsor. The lower of these two

doses should be considered for selecting the starting dose in humans. Even if the European guideline was implemented for both NCEs and biologics, the acquired experience demonstrates that the MABEL dose should be especially considered, and receptor occupancy at this dose calculated, when the drug under development is a biological super-agonist molecule and when its mechanism of action suggests it can lead to uncontrolled enzymatic or cytokine cascade reactions.

2. In 2016, a Phase 1 trial of BIA 10-2474, a fatty acid amide hydrolase inhibitor, led to one death and caused serious neurological damage in few other healthy volunteers (Singh 2018).

As a consequence, in 2017 the EMA updated the 2007 clinical guideline to further assist stakeholders in the transition from nonclinical to early clinical development and to identify factors influencing risk for new investigational medicinal products (EMA/CHMP/SWP/28367/07 Rev. 1, 2017). This new version focused on the maximum exposure of healthy volunteers that should be within the estimated human pharmacodynamics dose range. This guideline, applicable to all new chemicals and biologics, somehow supersedes in the EU the previous US 2005 Guidance for Industry “Estimating the Maximum Safe Starting Dose in Initial Clinical Trials for Therapeutics in Adult Healthy Volunteers.” The new 2017 version of the European clinical guideline mentions the PAD (Pharmacologically Active Dose) and/or ATD (Anticipated Therapeutic Dose) range that must be estimated in humans. In addition, the calculation of the MABEL, PAD, and/or ATD should consider target binding and receptor occupancy studies *in vitro* in target cells from human and the relevant animal species. Whenever possible, all relevant data should be integrated in a suitable modeling approach for the determination of the MABEL, PAD, and/or ATD.

The bottom line is that the test program to be performed when developing such biologics should be adapted (“case by case”) to the properties of the product in development and may be fundamentally different from the toxicological and more “conventional” or “classical” program designed to develop small molecules (see Table 2).

## Comparison Between the Nonclinical Assessments of Biologics and New Chemical Entities

Table 2 compares the main nonclinical activities (pharmacology, pharmacokinetics, toxicology) to be performed with biologics and new chemical entities.

### Pharmacology

#### Pharmacodynamics

For both NCEs and biologics, the intended pharmacological target is a main factor for deciding which test systems should be selected for the nonclinical development of the drug under investigation. The Sponsor should justify the relevance of the

**Table 2** Nonclinical activities to be conducted for biologics vs. NCEs

Nonclinical activities (guidelines)	Biologics (ICH S6 applies)	New chemical entities
<b>Pharmacology</b>		
Primary pharmacodynamics (ICH M3(R2))	Yes, in vitro and in vivo, in at least a relevant species/model (case by case: humanized model if necessary)	Yes, in appropriate in vitro and in vivo models
Secondary Pharmacodynamics (ICH M3 (R2))	If relevant, in appropriate in vitro and in vivo models	If relevant, in appropriate in vitro and in vivo models
Safety pharmacology (ICH M3(R2), ICH 7A & B)	Yes (CNS, cardiovascular and respiratory systems, other systems if necessary)	Yes (CNS, cardiovascular and respiratory systems, other systems if necessary)
<b>Pharmacokinetics and Toxicokinetics</b>		
Analytical methods and Validation reports (EMA/CHMP/EWP/192217/2009 Rev.1 Corr. 2)	Yes	Yes
Absorption (ICH S3A & B)	Yes	Yes
Distribution (ICH S3A & B)	Yes	Yes
Metabolism (ICH S3A & B) CDER guidance: safety testing of drug metabolites	No (degradations in small peptides and single amino acids)	Yes. If metabolite represents >10% of parent compound
Excretion (ICH S3A & B)	Yes	Yes
<b>Toxicology</b>		
Single-dose toxicity (ICH M3(R2))	Can be helpful to select the doses for repeated-dose toxicity	Can be helpful to select the doses for repeated-dose toxicity, however no need to reach LD <sub>50</sub> levels anymore
Repeated-dose toxicity (ICH M3(R2), ICH S4A)	Yes (only in relevant species)	Yes (two species, rodent and non-rodent)
Genotoxicity (ICH S2(R1))	No	Yes (in vitro and in vivo)
Carcinogenicity (ICH S1A, B, and C)	Generally, not necessary	Yes (except for anticancer agents (ICH S9))
Reproductive and developmental toxicity (ICH S5(R2))	Yes, the program could be done in a single species	Yes (two species, rodent and rabbit)
Local tolerance (ICH M3 (R2), CPMP/SWP/2145/00)	Yes, stand-alone study usually not necessary	Yes, stand-alone study usually not necessary
Immunotoxicology (ICH S8)	ICH S8 does not apply, immunogenicity and anti-drug antibodies (ADA) assessments are needed	Yes, immunotoxicity assessment
Phototoxicity (ICH S10)	No	Yes, if light absorption, generation of UV reactive species, and skin/eye distribution is achieved

animal species to humans taking into account the target, its structural homology, its distribution, the signal transduction pathways, and the nature of pharmacological effects. The demonstrated pharmacodynamics (PD) characteristics of a drug under development in relevant animal model(s) will be considered as the nonclinical proof of concept for NCEs as well as biologics. In contrast to the key toxicological activities (including toxicokinetics evaluation), it is acknowledged that PD studies do not need to be Good Laboratory Practice (GLP)-compliant.

### **Safety Pharmacology**

Safety pharmacology studies should be GLP-compliant (ICH S7A&B) and need to include assessment of effects on vital functions (cardiovascular system, central nervous system (CNS), and respiratory systems) to investigate undesirable effects of a substance and its metabolites on physiological functions based on exposure at low, medium, and high doses. For some products, the evaluation of safety pharmacology endpoints can be conducted as part of toxicology and/or pharmacodynamics studies. Cardiotoxicity is a major reason why NCEs fail to reach the market. In November 2018, the establishment of Q&As for the ICH E14 and ICH S7B guidelines was endorsed. ICH S7B and ICH E14 describe nonclinical and clinical risk assessment strategies concerning the pro-arrhythmic potential of non-antiarrhythmic test substances and contribute to the design of clinical investigations. These guidelines will inform on best practices for the design, conduct, analysis, interpretation and reporting of *in vitro*, *in silico*, and *in vivo* nonclinical assays (as the Comprehensive *in vitro* Pro-arrhythmia Assessment (C<sub>i</sub>PA) initiative), in order for these assays to influence nonclinical and clinical evaluations.

### **Pharmacokinetics and Toxicokinetics**

Guidelines ICH S3A and B require a comprehensive knowledge of the absorption, distribution, metabolism, and excretion (ADME) in view of the interpretation of pharmacology and toxicology studies. Measurement of drug concentrations (PK determinations) in biological matrices is an important aspect of medicinal product development for both NCEs and biologics. Tissue distribution studies are essential, especially in relation to potential sites of action. For NCEs, the nonclinical characterization of human metabolites is only warranted when these metabolites are observed at exposures greater than 10% of total drug-related exposure at steady-state and at significantly greater levels in humans than the maximum exposure seen in the toxicity studies (FDA Guidance 2016, Rev 1, Safety Testing of Drug Metabolites). Such studies should be conducted to support phase 3 clinical trials. In contrast, the expected consequence of metabolism of biologics is the degradation to small peptides and individual amino acids. Therefore, the metabolic pathways are generally understood, and thus classical biotransformation studies as performed for pharmaceuticals are usually not needed.

In 2017, ICH issued a Q&A document to ICH S3A (Note for Guidance on Toxicokinetics: The Assessment of Systemic Exposure in Toxicity Studies: Focus

on Microsampling). This document focuses on points to consider before incorporating the microsampling method in toxicokinetics (TK) studies and acknowledges its benefits and some limitations for assessment of TK in main study animals and its overall important contribution to the 3R benefits (Replacement, Reduction, and Refinement) by reducing or eliminating the need for TK satellite animals. This recommendation is now widely in place for any pivotal studies performed.

## **Toxicology**

As a general rule, safety evaluation programs should only include the use of relevant species. Toxicity studies in non-relevant species may be misleading and are discouraged by the regulatory authorities. A relevant species is any animal model in which the test material is pharmacologically active, and thus knowledge of receptor/epitope distribution provides a general understanding of potential *in vivo* toxicity of biologics. A respective “case-by-case” cross-reactivity evaluation, *in vitro* and/or *in vivo*, by immunochemical, analytical, or functional tests between species and organs/ tissues/cells should be performed to help in the selection of the relevant test system. This would optimize the evaluation of toxicity arising from the binding to the receptor/epitope and any unintentional tissue cross-reactivity. An animal species which does not express the desired receptor/epitope may still be of some relevance for assessing toxicity if comparable unintentional tissue cross-reactivity to humans is demonstrated.

## **Repeated-Dose Toxicity**

For NCEs, repeated-dose toxicity studies in two species are normally required. The studies should be designed to reflect the intended clinical use (duration and frequency of administration, clinical route of administration) and take into account the therapeutic indication. Frequency of administration is based on PD, PK, and toxicological profile. Dose levels often include a low (pharmacological), an intermediate, and a high (potentially toxic) dose. Of note, the regulation recommends multiple approaches for the highest dose of general, *i.e.*, repeated-dose toxicity studies). When possible, this includes a maximum dose 50-fold the therapeutic target. A control group should also always be included.

For biologics, however, it is not rare to note that the pivotal toxicity program can be performed in a single species only (*i.e.*, cynomolgus monkey). In case no relevant species can be determined, the use of transgenic animals expressing the human receptor or the use of homologous proteins should be considered. The information gained from the use of a transgenic animal model expressing the human receptor is optimized when the interaction of the product and the humanized receptor has similar physiological consequences to those expected in humans.

ICH M3(R2) requires treatment durations in non-rodents (9 months) and rodents (6 months) to enable long-term administration to humans (>6 months). It is noteworthy that for non-rodent animals, a treatment for 6 months may usually be

sufficient in the EU, yet to ensure a global approval, it is nevertheless preferable to treat non-rodents animals for 9 months.

For both NCEs and biologics, the evaluation of local tolerance (ICH M3(R2)) by the intended clinical route of administration is performed as part of the general toxicity studies. Stand-alone studies are generally not recommended.

### **Genotoxicity and Carcinogenicity**

Genotoxicity tests can be defined as *in vitro* and *in vivo* tests designed to detect compounds that induce genetic damage by various mechanisms, such as gene mutations, chromosomal damage, or recombination. Extensive reviews have shown that many NCEs that are mutagenic in the bacterial reverse mutation (i.e., AMES) test are rodent carcinogens. To increase the sensitivity for detection of carcinogens, a battery approach has been implemented because no single test is capable of detecting all genotoxic mechanisms relevant in tumorigenesis. Thus, ICH S2(R1) states that if an assay for gene mutation is sufficient to support single-dose clinical trials with NCEs, a complete battery of genotoxicity tests, such as an AMES test, a cytogenetic test for chromosomal damage, and *in vivo* test for genotoxicity, should be completed before initiation of phase 2 trials, as well as to later on support the marketing of a product. Of note, genotoxicity studies are not considered essential to support clinical trials for therapeutics intended to treat patients with late stage or advanced cancer.

ICH S6(R1) states that biopharmaceuticals do not need to be tested for genotoxicity, as standard proteins and peptides are not supposed to induce damages at the DNA/chromosomal level.

Moreover, ICH M7(R1) has been introduced to define the maximal levels of daily mutagenic impurities which can be authorized within a NCE formulation. Importantly, genotoxicity studies are not applicable to biologics and therefore are presently not required (see ICH S6(R1)).

Conditions relevant for the carcinogenicity testing of NCEs are discussed in ICH S1A. In general, carcinogenicity studies should be conducted to support the marketing application and thus logically launched during phase 3. However, for pharmaceuticals developed to treat certain serious diseases, in order to speed up the development process, it is possible to discuss the timing with the agencies and conduct carcinogenicity studies post-approval. The basic scheme is one long-term rodent carcinogenicity study and one other study both supported with TK data (e.g., *in vivo* tests). A change to the current S1 guideline is foreseen and expected to introduce a more comprehensive and integrated approach to address the risk for human carcinogenicity. Ideally, this analytical approach will yield sufficiently instructive criteria for when a work-of-evidence option would be preferable to a 2-year bioassay in a development program, thereby improving assessment of human carcinogenic risk of pharmaceuticals and minimizing regulatory discordance across regions. As mentioned in ICH S6(R1), standard carcinogenicity bioassays are generally inappropriate for biologics. However, product-specific assessment of carcinogenic potential may still be needed depending upon the duration of clinical

dosing, patient population, and/or biological activity of the product (e.g., growth factors, immunosuppressive agents).

### **Reprotoxicity and Juvenile Animal Studies**

As a consequence of the thalidomide disaster in the early 1960s (Vargesson 2015), reproduction toxicity studies should be conducted as appropriate for the population to be exposed (ICH S5(R2)). The goal is to reveal any adverse effect of the product on mammalian reproduction. The combination of studies (fertility, embryo-fetal, and peri-/postnatal assessment) selected should cover all stages of development from conception to sexual maturity. For NCEs, two species should be tested (rats and rabbits) to assess the potential of a NCE on the embryo/fetal development, as the thalidomide disaster revealed that mice are less sensitive to thalidomide than other species such as rabbits (Vargesson 2015). Observation should be performed from conception in one generation through conception in the following generation (complete life cycle).

For biologics, reproductive toxicity studies should also be conducted in accordance with the principles outlined in ICH S5(R2). However, one species only can be sufficient to address effects on embryo-fetal development. This guideline is currently under revision since 2015 (ICH S5(R3) EWG Revision of S5 Guideline on Detection of Toxicity to Reproduction for Human Pharmaceuticals). Interestingly, this draft version mentions the notion of Weight of Evidence (WoE). This is based on the fact that toxicity studies in pregnant animals are not always necessary for assessing the human risk of developmental toxicity of biopharmaceuticals. Therefore, the accumulated knowledge on target biology and molecule-specific pharmacokinetics should allow to accurately anticipate the effects of target activation by biopharmaceuticals using a WoE approach (Rocca et al. 2018). Such a WoE-based assessment should include all available data including target biology, pharmacokinetics, class effects, genetically modified animals, human mutations, and an exhaustive literature review. Such an evaluation may be sufficient to inform risk for specific clinical indications and patient populations, even though this approach is currently only applicable for oncology drugs and biologics. Noteworthy as well is that ICH S9 states to support the treatment of patients with late-stage or advanced cancer, generally neither warrants a fertility study nor any peri- and postnatal toxicology study. These are clear examples for modernizing testing paradigms to enhance human risk assessment while also potentially reducing animal use, notwithstanding that there are further areas where the guideline could be revised or amended for greater clarity, as well as to align more fully with other more recent ICH guidelines such as ICH M3(R2), ICH S6 (R1) as well as ICH S9.

As regards juvenile animal studies (JAS), a draft 2 guideline (ICH S11) was issued in 2018 to ultimately harmonize regional guidelines from various agencies to reach an agreement on the need for, timing of, and design of JAS and thus allow a common development program of medicines for the pediatric population. This is particularly relevant in the EU, where filing for a marketing authorization, even for an indication intended for adults only, will be systematically refused by the EMA in the absence of a Pediatric Investigation Plan (PIP) previously accepted by the Pediatric Committee of the agency.

## **Immunogenicity and Immunotoxicity**

In contrast to the majority of NCEs, many biologics intended for human are immunogenic in animals. The immunogenicity of biologics can cause hypersensitivity responses, anaphylaxis, and infusion reactions (Rosenberg 2003). Anti-drug antibody (ADA) responses could affect the efficacy and/or safety of protein therapeutics and/or complicate interpretation of the toxicity, pharmacokinetic, and pharmacodynamic data. It is also known that particular glycosylation patterns might be immunogenic and some protein aggregates might trigger immunogenicity. Animal models are increasingly used to study immunogenicity of therapeutic proteins. They are employed as predictive tools to assess immunogenicity during drug development and have become vital in studying the mechanisms underlying immunogenicity of therapeutic proteins. However, the use of animal models needs critical evaluation (Brinks 2011). Because of species differences, the predictive value of these animal models is limited.

It is widely acknowledged that biologics often reveal their real immunotoxicity potential for humans only during clinical studies. The predictive value of animal studies and traditional *in vitro* screens is thus questionable. Despite these limitations, antibody levels associated with administration of biologics should be measured during repeated-dose toxicity studies. Antibody responses should be characterized (titer, number of responding animals, neutralizing or non-neutralizing), and their appearance should be correlated with any pharmacological and/or toxicological changes. Specifically, the effects of antibody formation on PK/PD parameters, incidence and/or severity of adverse effects, complement activation, or the emergence of new toxic effects should be considered when interpreting the data. Possible pathological changes related to immune complex formation and deposition should be evaluated.

In line with the above comments, both the FDA and the EMA recently issued guidelines on these topics. The FDA released a guidance on the development of biologics and biosimilars (FDA Guidance for Industry 2019). The FDA recommends a multi-tiered testing approach, and the document spells out the development and validation of screening, confirmatory, titration, as well as neutralization assays. In the EU, the guideline on the immunogenicity assessment of therapeutic proteins (EMA/CHMP/BMWP/14327/2006 Rev 1) states clearly that the current predictive value of animal studies for evaluation of immunogenicity of a biological medicinal product in humans is low due to differences between human and animal immune systems and to immunogenicity of human proteins in animals. The development of adequate screening and confirmatory ADA assays to measure immune responses against a therapeutic protein is the basis of the evaluation of immunogenicity.

As regards NCEs, dedicated immunotoxicity studies are mandatory only when a cause for concern is identified in the repeated-dose toxicity studies (ICH S8). In this case, additional immunotoxicity studies should be performed to verify the immunotoxic potential of the compound, completed before exposure of a large population (before phase 3).

## **The Standard for Exchange of Nonclinical Data (SEND) Format**

As regards the submission of toxicology and safety reports to regulatory agencies, the SEND initiative has been recently implemented by the FDA (Demollari 2019; Carfagna et al. 2020) in order to submit nonclinical data in a structured manner. The format was created by the Clinical Data Interchange Standards Consortium (CDISC). The governing document of the SEND standard is the Standard for Exchange of Nonclinical Data Implementation Guide (SENDIG). It describes the rules for providing standardized data according to the study data tabulation model (SDTM) for nonclinical studies.

The FDA requests that all nonclinical data from safety studies started on or after December 17, 2016, should be presented according to SEND. This applies to New Drug Applications (NDAs), Biologic License Applications (BLAs), and Abbreviated New Drug Applications (ANDAs), and for Investigational New Drugs (INDs) after December 17, 2017. Our strong advice to Sponsors is to ensure that all single/repeated-dose toxicity, carcinogenicity, and safety pharmacology (on cardiovascular and respiratory evaluation) data are provided in adequate format. The modalities should be discussed and aligned in-house or with the selected Contract Research Organization where the study will be performed.

## **Impact of Manufacturing and Formulation Changes on the Development Process**

The performance of safety bridging strategies within batches of the same biological produced at different scales is a key element to master in order to obtain clinical trial and marketing authorization. The use of cells of human, animal, or even plant origin for the production of biologics is subject to potential contamination. A change in manufacturing process and/or of formulation of the product represents a potential risk for patients (such as immune-suppression, immuno-stimulation, hypersensitivity, and autoimmunity). Particular attention must be paid to the characterization, purity, and stability of the starting materials, as well as the presence of aggregates. Products should be tested for viral safety (ICH Q5A(R1) Quality of Biotechnological Products: Viral Safety Evaluation of Biotechnology Products Derived from Cell Lines of Human or Animal Origin) and genetic stability (ICH Q5B Quality of Biotechnological Products: Analysis of the Expression Construct in Cell Lines Used for Production of r-DNA Derived Protein Products). A European guideline on the requirements for quality documentation concerning biological investigational medicinal products in clinical trials was adopted in 2008 and revised in 2018 (EMA/CHMP/BWP/534898/2008 rev.1 corrigendum).

The production process must provide relatively large amounts of test material. The degree of comparability of the test material from batch to batch in the development program requires an early validation of the production and testing methods as well as the precise definition of the product specifications (EMA/ CHMP/BMWP/101695/2006). An early well-designed bridging strategy in terms of upscale process is preferable to a subsequent full test program.

## Alternative Methods Including In Silico Evaluation

Animal models are widely used for a long time for toxicity testing. However, *in vivo* animal tests are constrained by time, ethical considerations, and financial burden. ICH M3(R2) states that “consideration should be given to use of new *in vitro* alternative methods for safety evaluation. These methods, if validated and accepted by all ICH regulatory authorities, can be used to replace current standard methods.” Therefore, not surprisingly, this last decade has seen the emergence of a paradigm shift: in line with the 3Rs principle (reduce/refine/replace), regulatory agencies now appear more open to alternative approaches to decrease the number of animals during the nonclinical development of NCEs and biologicals. This change is particularly apparent in the draft guidance ICH S5(R3), which once adopted may take into consideration data from, e.g., qualified alternative *in vitro* and non-mammalian assays, in combination with one or more *in vivo* mammalian embryo-fetal development studies. For tolerance assessment, alternative methods on 3D reconstructed human epithelium (ocular or cutaneous) can already replace the previous eye and skin irritation studies in rabbit.

*In silico* toxicology is one type of toxicity assessment that uses computational methods to analyze, simulate, visualize, or predict the toxicity of chemicals. *In silico* toxicology aims to complement existing toxicity tests to predict toxicity, prioritize chemicals, guide toxicity tests, and minimize late-stage failures in drug design (Raies and Bajic 2016). *In silico* toxicology methods involve a wide variety of computational tools: databases for storing data about chemicals, their toxicity, and chemical properties; software for generating molecular descriptors; simulation tools for systems biology and molecular dynamics; modeling methods for toxicity prediction; modeling tools such as statistical packages and software for generating prediction models; expert systems that include pre-built models in web servers or standalone applications for predicting toxicity; and visualization tools. A plethora of databases (almost 1000) exist online for *in silico* drug safety assessment. A recent review (Pawar et al. 2019) provides a comprehensive listing of the key *in silico* data resources such as chemical identity and properties, mechanism of action, toxicology, exposure, ADME properties, clinical trials, pharmacovigilance, patent-related databases, protein-protein interactions, and, finally, databases related to animal alternatives in support of 3Rs policies.

Finally, based on our own experience, the FDA seems more advanced than the EMA as regards modeling and simulation (M&S), having already identified M&S tools as one of the priorities to improve in the FDA’s 2011 Strategic Plan for Advancing Regulatory Science. This plan included the need for developing also clinical trial simulation models that can reveal interactions between drug or device effects, patient characteristics, and disease variables influencing outcomes, as well as development of data management tools to inform computer model development, clinical risk prediction, and regulatory decision-making (Rousseau et al. 2019).

## Environmental Risk Assessment (ERA)

An Environmental Risk Assessment is required by EMA since 2006 for all new marketing authorization applications (MAA) for a medicinal product through a centralized, mutual recognition and decentralized and national procedure regardless of its legal basis. This affects all new products (with some exceptions like vitamins, amino acids, peptides, electrolytes, and herbal products), including already marketed drugs, if, e.g., a new indication results in significant increase in their extent of use (EMA/CHMP/SWP/4447/00 corr 2, 2006). A revised draft guideline is in preparation with a consultation period closed in June 2019 (EMA/CHMP/SWP/4447/00 Rev 1, 2018). These guidelines follow a risk-based approach based on environmental release of the pharmaceutical, with testing dictated by partitioning; solubility; persistent, bioaccumulative, and toxic (PBT) characteristics; and endocrine activity.

Even if the ERA requirements in the USA may appear less stringent than in the EU, the FDA stipulates also that a risk assessment or categorical exclusion claim should accompany every IND, NDA, or BLA (FDA/CDER/CBER/1998). In 2016, FDA supplemented this guidance (FDA/CDER/2016) by addressing specific considerations for drugs that have potential estrogenic, androgenic, or thyroid hormone pathway activity in the environment.

---

## Conclusion and Recommendations

Biologicals can provide more innovative, effective, and targeted therapies for numerous diseases than NCEs. In order to detect any potential toxicity of these promising products, the determination of the safe dosage at the start of clinical studies and the establishment of dose–response relationships, a rationale “case-by-case” nonclinical testing strategy, should be put in place taking into account not only ICH S6(R1) (Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals) but also all other guidelines listed in this chapter. Biologicals differ in many aspects from the more conventional NCE drugs, because of their species- and tissue-specific characteristics and their immunogenicity potential due to their particular nature and complex mode of production.

With biologicals, the required safety testing may appear more science-driven and designed around the product and the predicted safety issues resulting from the biology (mechanism of action), rather than being a standard list of tests. This is because toxicity with biologicals is, in the vast majority of cases, secondary to the pharmacology, whereas NCEs can have off-target effects unrelated to the biology or pharmacology.

It is also our view that, in the next decade(s), the importance of alternative methods (in vitro and in silico) to assess the toxicity of our future medicines will considerably expand. Such a (r)evolution is already initiated and may not only impact animal research. Indeed, the FDA initiated a pilot program known as the model-informed drug development (MIDD) in which the agency meets with drug developers to discuss and agree on which key program decisions can be supported

by mathematical models and simulations. The FDA may even accept in the near future some selected clinical trials performed with virtual patients.

Finally, in order to avoid critical issues at the time of marketing authorization application, we strongly advise any drug developer to request a timely scientific advice meeting with a regulatory agency to discuss and find an agreement on the relevance of the nonclinical development program they intend to perform.

## Abstract

The sensitivity of human beings to toxic insults or pharmaceuticals varies considerably. This fact has a series of reasons, e.g., health status, age, body weight, as well as genetic background. An above average sensitivity against a noxious substance can have severe or even lethal consequences. Sensitivity varies not only between individuals but also between populations as a whole. Therefore, it is compulsory for toxicologists to take these differences into account when establishing limits for toxic compounds.

## Introduction

The genetic background of human beings from all over the globe varies quite a lot. In addition, different environmental conditions and cultural habits can influence the susceptibility against a substance either of natural origin or manmade. On the first glimpse, these differences are not a problem, but from a toxicological and/or pharmacological point of view matters are different. Besides accidents and (attempted) suicides, there is usually no toxicological data based on human exposure to high doses of xenobiotics. We thus have to rely on animal testing. A group of animals used for testing is usually well defined, regarding genetic background, age, and body weight. The problems which may arise when the data acquired are transferred to humans are based on the fact that humans are considered a good deal more genetically diverse than animals which are used for toxicity testing. Defining an “average person” is already impossible in a small population, let alone on a worldwide scale. Therefore, safety margins big enough to include those rare people with a very high sensitivity against a certain compound have to be set.

This chapter deals with the different reasons for diverging susceptibility in humans. Probably the most important cause is genetic polymorphisms, followed by parameters like age, health status, and body weight. Toxicological implications are discussed, followed by a special focus on children.

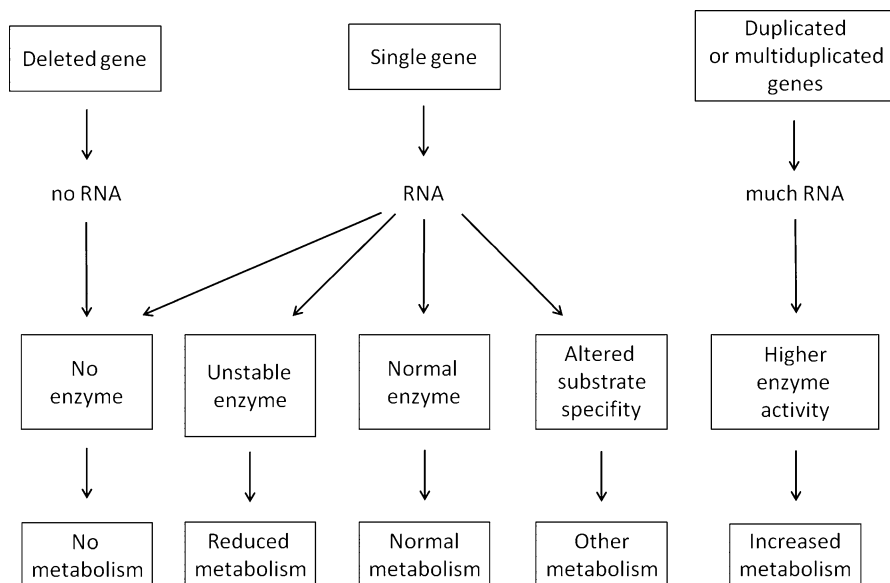

---

## Genetic Polymorphism

The effects of genetic polymorphisms vary greatly depending on the enzyme concerned. It is common knowledge that many adult Asians (~80%) have developed lactose intolerance. This might be undesirable for the respective person, but it's usually not life threatening. Things are getting more complicated when we look at cytochromes for example. This big class of enzymes encompasses at least 18 families (<http://drnelson.uthsc.edu/human.P450.table.html>), which in turn can be divided into two major groups: cytochromes that are responsible for synthesizing endogenous substances like steroids and fatty acids as well as enzymes dealing with xenobiotics (Lin and Lu 2001). Among those xenobiotics are toxicants like aryl hydrocarbons from tobacco smoke as well as pharmaceuticals. Pharmaceuticals are mainly metabolized by three cytochrome families: CYP1, CYP2, and CYP3, with the latter two accounting for about 50% of a person's hepatic cytochrome make-up. Only two of almost 60 known isoforms seem to be well preserved: CYP1A1 and CYP2E1. The reason might be that the former is part of the cell cycle, whereas the latter is part of gluconeogenesis.

Similar variability is seen in other important molecule classes, from glutathione S-transferases (GSTs), to CC chemokine receptor (CCR) and nicotinic acetylcholine receptors (Dasari et al. 2018; Qidwai 2016; Wei et al. 2015).

Genetic variations can account for differences in drug uptake, metabolism, and drug-receptor interaction. Each of these differences can lead to adverse drug effects. The estimate that more than 10% of the admissions to internal medicine departments

**Fig. 1** Possible causes for differences in cytochrome P450 activity in different subjects, (Ingelman-Sundberg 2001, redrawn)

in Swedish hospitals are due to adverse drug effects, gives an idea about the importance of the knowledge of polymorphisms (Mjörndal et al. 1999). Even more alarming is the US assessment that about 100,000 deaths annually are caused by adverse drug effects (Ingelman-Sundberg 2001). An overview of possible effects of gene mutations in cytochromes can be seen in Fig. 1.

One prominent example for genetic polymorphisms is CYP2D6, which metabolizes a variety of pharmaceuticals like anti-depressants, anti-hypertensive drugs, and anti-arrhythmic agents. Altogether it is estimated that CYP2D6 metabolizes about 25% of all pharmaceuticals on the market (Byeon et al. 2018). The field of CYP2D6 is rapidly expanding. When Byeon et al. wrote their paper, 113 allelic variants of this cytochrome were known (Byeon et al. 2018). The linked webpage (<http://www.pharmvar.org/gene/CYP2D6>), in June 2020, indicated almost 140 allelic variants. Of these, nine alleles are most important and they show different levels of activity: \*1 and \*2 are fully functional alleles, \*3, \*4, \*5, and \*6 are nonfunctional alleles and \*10, \*17, and \*41 are reduced functional alleles (Byeon et al. 2018). Variant CYP2D6\*17 has a frequency of about one third in people of African origin whereas it is almost nonexistent in Caucasians (Ingelman-Sundberg 2001). Since this variation results in reduced substrate affinity, severe adverse drug effects have to be considered before prescription. One of the pharmaceuticals affected is the neuroleptic perphenazine, with variations of about tenfold in patient's serum, when comparing standard to poor metabolizers. CYP2D6 is also known for being a cytochrome encoded by multiple, i.e., up to 13, gene copies. Consequently, the individual concerned can be a very rapid metabolizer, which would result in only limited

**Fig. 2** Effects of different metabolic rates on the plasma level of a compound: normal metabolizer (a), rapid metabolizer (b), or slow metabolizer (c)

effects of conventional drug dosing regimens. Different plasma concentrations of a drug given at four intervals as expected by standard-, rapid-, or slow metabolizers are shown in Fig. 2. The differences in CYP-regulated metabolism between two individuals can amount up to 100-fold for a single drug. A meta-analysis on global distribution of CYP450 alleles can be found in Zhou et al. (2017).

There are also polymorphisms of the steroidogenic cytochromes. But due to their severely debilitating or even fatal effects, they are generally regarded as genetic defects (Guengerich 2002).

---

## Additional Parameters

Variations in the plasma level of the same pharmaceutical of up to 1000-fold between two persons with identical body weight, have not only genetic reasons (Ingelman-Sundberg 2001). In addition, age, (patho) physiological, nutritional, and environmental effects have to be taken into account. One class of xenobiotics that is known to increase cytochrome activity is polyaromatic hydrocarbons (PAHs). The induction observed can have different reasons, depending on the source of the PAHs, which can be rather diverse: it could be the 8 oz. steak from the barbeque, the cigarette or the chemical plant in the neighborhood. All this results in an uptake of PAHs, which in turn induce CYP1A activity. Contrary to lab animals used in pharmaceutical testing, the diet of humans is very diverse, as are possible effects induced by food. Therefore, finding the reason for variations in two persons is very complicated and sometimes a virtually impossible task.

---

## Toxicological Implications

The main task of CYPs in dealing with xenobiotics is the detoxification of these compounds. Thereby hydrophilic groups such as hydroxyl-groups are added to the original substance to increase its water solubility. Thus, renal clearance can be facilitated. Alas, this strategy has a drawback: adding one or more hydroxyl-groups

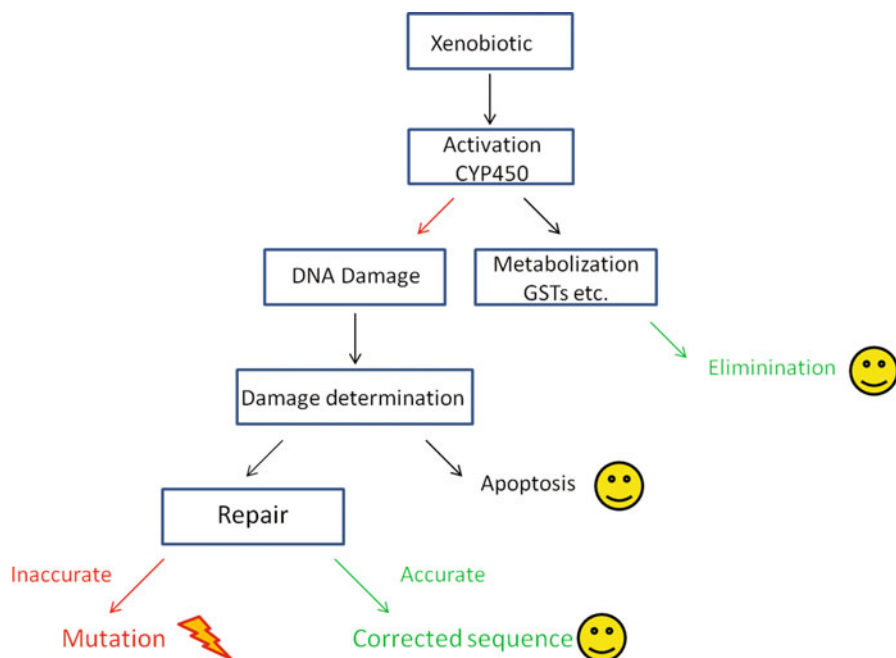

**Fig. 3** Activation of benzo[a]pyrene by adding 4 hydroxyl-groups and formation of DNA adduct ([http://www.chemgapedia.de/vsengine/media/width/713/height/190/vsc/de/ch/4/cm/funktgruppen/bilder/benzpyren\\_dna.svg.jpg](http://www.chemgapedia.de/vsengine/media/width/713/height/190/vsc/de/ch/4/cm/funktgruppen/bilder/benzpyren_dna.svg.jpg))

to a substance can also result in an increased reactivity. Due to its lipophilic properties, benzo[a]pyrene has to be subjected to several activation steps by CYPs. Since benzo[a]pyrene can be metabolized by several cytochromes as well as epoxide hydrolase, several different metabolites are formed. One of the metabolites formed is 7,8-dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzo[a]pyrene (Fig. 3). The epoxy-group is very reactive and can easily bind to amino groups of proteins or, more dangerous, DNA. Although the epoxide can be eliminated via glutathione transferases (GSTs), increased amounts of DNA- adducts can be formed, e.g., when sufficient amounts of GSTs are not available.

Depending on the activity of the enzymes involved in this reaction, the amount of DNA adducts formed can vary widely. With more adducts formed, the risks of unrepaired or inaccurately repaired DNA damage increases. Once the damage is done, there are three alternatives on the cellular level: apoptosis, correct repair, or inaccurate repair, resulting in mutation and possibly cancer (Fig. 4). Although deadly for a single cell, apoptosis is very useful for the organism as a whole, since the damage will not be inherited to daughter cells, thereby eliminating the risk of cancer.

Polymorphisms in cytochromes can result in severe consequences, when pharmaceuticals are not metabolized as expected by the physician. This can result in very different plasma levels as shown in Fig. 2. Antibiotics, like erythromycin, are metabolized by CYP3A4. In a worst-case scenario, too much CYP3A4 can lead to septic shock, because the plasma level of the antibiotic is insufficient. A second problem arising from rapid metabolism can be an indirect effect. Acetaminophen also called paracetamol, for example is metabolized by CYP2E1. It is known that the inter-individual concentration of CYP2E1 can vary by a factor of 12. High levels of CYP2E1 can lead to an accumulation of N-acetylbenzoquinoneimine, a major product in the metabolism of paracetamol. This can result in irreversible hepatic necrosis, when the liver cannot provide enough glutathione for the detoxicating conjugation of N-acetylbenzoquinoneimine. Table 1 gives an overview of cytochromes, their variability, substrates, inducers, and inhibitors.

**Fig. 4** Possible pathway after activation of a xenobiotic by CYP

**Table 1** Inter individual variability of cytochrome activity. (Data from Lin and Lu 2001; Pelkonen et al. 2008)

P450-enzyme	Variability	Substrate	Inhibitor	Inducer
CYP1A2	20-fold	caffeine	ciprofloxazine	smoking
CYP2A6	>50-fold	nicotine	pilocarpine	phenobarbital
CYP2B6	>50-fold	nicotine	17- $\alpha$ -ethinyl estradiol	phenobarbital
CYP2D6	>50-fold	codein	fluoxetine	?
CYP2E1	12-fold	ethanol, acetaminophen	pyridines	ethanol(!)
CYP3A4	8-fold	testosterone	grapefruit juice	phenobarbital

Since cytochromes are in contrast to many other enzymes inducible, the interplay between enzyme and its substrate(s) becomes even more complex. Inhibition or induction can be triggered by pharmaceuticals like fluoxetine, phenobarbital or 17- $\alpha$ -ethinyl estradiol. But not only medications can cause additional variations in CYP activity but also dietary products are known to influence cytochrome activity. A very effective inhibitor of several cytochromes is grapefruit juice. The inhibition of CYP3A4, CYP1A2, CYP2C9 and CYP2D6 was observed after treating liver microsomes with grapefruit juice. Due to the fact that at least four different CYPs are

inhibited by the juice, a broad spectrum of pharmaceuticals is affected: Calcium channel blockers, immunosuppressive drugs, sedatives and others. Cytochrome inhibition can increase the bioavailability of these pharmaceuticals up to fivefold, e.g., for the calcium antagonist felodipine (Bailey et al. 1991). Although oranges are closely related to grapefruits, these effects are not seen after consumption of orange juice (Tassaneeyakul et al. 2000). Grapefruit ingredients like naringin cause the interactions.

---

## Susceptibility in Children

### Physiological Differences

It is well justified to assume that there are biological reasons why children, and especially newborns, can be more sensitive towards a comparable toxicological stress than adults. Compared to adults, their consumption of food, water and oxygen is increased in relation to their body weight. Moreover, children are on average physically much more active. Consequently, their exposure to environmental stress is also elevated. What makes matter worse is the fact that especially in the first 6 months the ability to metabolize xenobiotics may not be fully developed.

### Increased Susceptibility in Fetuses, Babies, and Children

It is common knowledge that exposure during pregnancy to certain substances results in damage selectively in children. Examples are smoking, alcohol consumption, or uptake of pharmaceuticals which lead to neurotoxic or teratogenic effects or developmental retardation.

Less is known about intoxication of children with chemicals, like pesticides or food additives that are used only in restricted applications. Children are more susceptible against high acute doses of the pesticide chlorpyrifos, but on the other hand, less or as sensitive as adults against repeated low dose exposure. Although many persistent organic compounds have been banned, and their prevalence is reduced, neurotoxins, like methylmercury, that damage the developing brain of children, are still on the agenda in regulation. Lead is of special concern in children for two reasons. Firstly, the adsorption in a child's gastrointestinal tract is higher than in an adult and, secondly, the central nervous system of children is four times more susceptible than that of an adult (ATSDR 2019). Therefore, the main focus is on neurotoxic effects in children, when it comes to discussing tolerable lead concentrations. Consequently, the new EU drinking water directive to be published in 2020 will lower the maximum allowable lead concentration to 5 µg/L instead of 10 µg/L and therefore be stricter than WHO Guidelines. The rationale behind this is the developmental toxicity of lead putting fetuses and children at particular risk.

There is only limited evidence from literature, that low doses of easily metabolized and excreted substances are more toxic to children than to adults. Damage

through alcohol or cyanoses induced by nitrate/nitrite from private wells are known examples.

According to current knowledge about ontogenic development of human metabolism, children up to the age of 6 months are generally more susceptible against toxic insults than adults. This is caused by the fact that biotransformation and elimination is slower, which in turn results in higher plasma levels of many chemicals and pharmaceuticals. An example for this is an enzyme called NADH cyb5r reductase which converts nonfunctional methemoglobin to functional hemoglobin. Infants under the age of 6 months have much lower level of this enzyme than adults, rendering them susceptible to the toxic effects of nitrate/nitrite (Fossen Johnson 2019). In addition, fetal hemoglobin is more rapidly converted to methemoglobin than its adult counterpart. Therefore, infants have a double disadvantage when they have to deal with nitrate uptake.

The metabolic capacity for dealing with many xenobiotics is already established prior to or at the time of birth, but the capacity is smaller and the enzyme patterns can be different. At the age of 6 months, the metabolism of children is developed well enough, that there are usually no important variations in the toxic susceptibility compared to adults. Nevertheless, the susceptibility of organs like brain, bones and hormonal system can remain different until sexual maturity. Children can also be less susceptible to chemicals or pharmaceuticals, when certain receptors or final metabolic capacities are not yet fully developed.

Due to age specific behavior, oral exposure to chemicals is increased in children. Since especially small children are trying to put almost everything, they can grab a hold on into their mouth, households, and public playgrounds have to be taken into account as additional sources of exposure. The risk is dependent on a child's susceptibility and the exposure conditions. Provided that the chemical exposure remains below the threshold above which detoxification mechanisms of the organism are overstrained and toxic effects are triggered, the hazard is the same as for an adult. During the first half-year, when the human organism is generally most vulnerable, the exposure to chemicals is, also because of limited mobility, rather low. Therefore, exposure to environmental risks can be considered lower than in older children.

## Regulatory Considerations

Children of all ages are still in the process of maturation. This has to be taken into account, when assessing the risk of substances that impair the development of organs when children could be exposed against them. Based on this, the US-EPA considers the implementation of an extra safety factor of 10, when the data on a compound does not provide reliable information about a toxicological threshold in children.

Moreover, there are additional regulations for the special protection of children, e.g., in regulations concerning food and toys (Diätverordnung, Spielzeugverordnung in Germany). In accordance with the WHO "Guidelines for Drinking-Water Quality" (WHO 2017), some parameters of the German drinking water directive

(Trinkwasserverordnung), like the concentration of nitrate and copper, were set to meet the requirements of children.

## Abstract

Only rarely is sufficient toxicological knowledge available on a risk of interest. In cases where toxicological data are incomplete for a specific quantitative risk assessment, the assessment may also draw on general scientific knowledge gained from experience with other chemical substances. However, this approach of extrapolation, using default factors based on empirical evidence, is not without controversy.

## Introduction

Suitable human data for the relevant risk group is frequently absent when performing quantitative risk assessment. Risk assessment is therefore often based on test animal data which need to be evaluated with regard to the risk group in question. Such an assessment and estimation was first performed in the USA as early as 1954 based on defined principles. Also since the 1950s, bodies of the World Health Organization (WHO), the Joint FAO/WHO Expert Committee on Food Additives (JECFA), and the Joint FAO/WHO Meeting on Pesticide Reviews (JMPR) have set ADI values (► Chaps. 44, “Health-Based Threshold Values Versus MOS in Toxicology,” and ► 99, “Limit Values and Guideline Values in Regulatory Toxicology”) for food additives and pesticide residues in food as at least 1/100 of the NOAEL (► Chap. 22, “Dose-Response Analysis: Identification of Threshold Levels for Chemicals”) in experimental animals.

This factor-based assessment with the help of conventions has been the subject of discussions again and again since then. On the one hand, it is rejected as unscientific, while on the other hand attempts have been made at the same time to justify the factor physiologically or empirically. For this purpose, the overall factor was subdivided into individual factors. For example, the WHO typically defines, in purely formal terms, the traditional intraspecies factor of 10 as a quantity made up of 3.2 for toxicokinetic variability times 3.2 for toxicodynamic variability (= 10), without further justifying the size of the factor. The WHO applied a similar approach in the case of the interspecies factor (4.0 for toxicokinetics times 2.5 for toxicodynamics, see Table 3).

Depending on the regulatory context (e.g., occupational safety and health or public health), different factors must be chosen with regard to the relevant population at risk which the risk assessment proposes to protect (healthy workers or the general population). However, it is generally acknowledged that substance-specific information should be used to replace default factors whenever possible (Bhat et al. 2017). WHO developed guidance on how to derive so-called chemical-specific adjustment factors (WHO 2005).

The following focuses on public health aspects. But also for deriving occupational exposure levels (OELs), empirically derived factors are increasingly used (Maier et al. 2015; Schenk and Johanson, 2018; ECHA 2019).

---

## Nomenclature

In general, a distinction can be drawn between two types of assessment steps: physiologically/empirically based assessment steps and assessment steps that cannot be scientifically or empirically validated (Kalberlah and Schneider 1998):

1. Physiologically/empirically based assessments use toxicological data and extrapolations to an expected level on the basis of those data (e.g., lowering of the

**Table 1** Subdivisions of extrapolations and qualitative aspects in quantitative risk assessment

Physiologically/empirically based extrapolations	Qualitative aspects
Duration extrapolation	Data quality/completeness of database
LOAEL/NAEL extrapolation	Type/severity of effects
Interspecies extrapolation	Grounds for suspicion
Intraspecies extrapolation

NOAEL to extend the test period to lifelong exposure). This quantitative assessment should include a comprehensive interpretation of empirical data.

- Additional, qualitative aspects, not based on the same data, are considered in order to safeguard against uncertainties (e.g., consideration of an incomplete data base to safeguard against potential, untested effects).

Table 1 provides an overview of how extrapolations and qualitative aspects are subdivided.

According to its “Guidance document for use of data in dose/concentration-response assessment,” the WHO distinguishes between the terms “adjustment factor” for chemical-specific factors and “uncertainty factor” for default factors. The WHO applies these factors to account for both uncertainties and variabilities. The US Environmental Protection Agency (US EPA) also uses the term “uncertainty factors” for its assessments but also applies “empirically derived scaling factors” as addressed in Table 2. A possible reason for replacing the previously common term “safety factor” with “uncertainty factor” may have been to avoid conveying the (wrong) impression of absolute safety. The European Chemicals Agency (ECHA) uses the term “assessment factor” for factor-based “extrapolations.”

## Extrapolations

The following extrapolations may have to be performed in quantitative assessment:

- Duration extrapolation (e.g., from subchronic to chronic exposure)
- Extrapolation from an available LOAEL (lowest observed adverse effect level) to a NAEL (no adverse effect level) as the desired level of protection (► [Chap. 22, “Dose-Response Analysis: Identification of Threshold Levels for Chemicals”](#))
- Interspecies extrapolation (from experimental animal to human)
- Intraspecies extrapolation (from groups with average susceptibility to groups with increased susceptibility)

Such extrapolations are a component of most assessment concepts. Standard or default values of up to 10 are usually invoked for these extrapolation steps (see [Table 3](#)), which are described in more detail below; these default values should, however, be adjusted to reflect substance-specific knowledge as far as possible. The following rationales for applying these assessment steps, and the following empirically derived quantifications, based on the analysis of relevant data on a large number of substances, have been under discussion:

**Table 3** Comparison of default factors used by different organizations in quantitative risk assessment (systemic effects)

Factor for	US EPA <sup>a</sup>	WHO <sup>b</sup>	ECHA <sup>c</sup>

## Duration Extrapolation

Duration extrapolation will be necessary if, in a risk assessment designed to cover lifelong exposure (70 years), toxicological data are only available for short-term exposure, and it cannot be ruled out that the effect increases over time. An analysis of toxicological studies resulted in the following relations as compared to the traditional, commonly used default factor of 10 mentioned above.

For extrapolation *from subchronic to chronic*, a factor of 10 presumably covers a high percentile of the examined cases (substances) (with geometric means observed in empirical investigations in a range of 2 to 3). This means that for a large number of substances, this factor is sufficient to cover possible increases in effect over time. In terms of the geometric mean, a factor of about 2 or 3 results.

For extrapolation *from short-term ("subacute") to chronic*, a duration extrapolation factor of 4 to 6 appears to be justified, based on the geometric mean.

The factor resulting from such an analysis does not directly represent a measure of the actual dose-time relationship but only describes the commonly observed dose-time relationship, since the design of the respective studies has a strong influence on the outcome (► [Chap. 9, "Examination of Acute and Repeated-Dose Toxicity"](#)).

## Extrapolation from LOAEL to NAEL

This extrapolation is applied sometimes in cases where a no observed adverse effect concentration is the desired level of protection and no dose without an effect was obtained in experimental studies.

The data on LOAEL-NOAEL relations reported in the literature reflect the study-design-dependent spacing between doses more than the actual steepness of the dose-response curve. Results will vary depending on the conventions on which the underlying data are based. Therefore, as a better alternative to this extrapolation, benchmark procedures (benchmark dose approach, BMD) are recommended (► [Chap. 26, "Benchmark Dose Approach in Regulatory Toxicology"](#)).

## Interspecies Extrapolation

The toxicity of a substance is determined not only by its dose but also by anatomical features and physiological parameters. The relationship between these parameters and body weight, which is used as dose reference, has been observed to follow certain laws (allometric scaling) which deviate from a simple linear correlation. Thus, the basal caloric demand of species of different sizes correlates with the results of toxicokinetic and toxicity (including toxicodynamics) studies in different species. Basal caloric demand correlates with body weight to the power of 0.75.

Consequently, the analysis of relevant available data leads to factors which are bodyweight-dependent and therefore species-specific (scaling factors) for equipotent

extrapolation of data from animal experiments to humans (dose extrapolation based on basal caloric demand (or metabolic rate) scaling). The factors and underlying assumptions are shown in Table 2.

Assuming the allometric relation with basal caloric demand is valid, identical inhalation exposure concentrations must be considered to be equipotent in different species. Hence, no extrapolation factor is applied for this route, or the factor is 1 for all species comparisons.

Of course, individual substances may deviate from this “average situation,” leading to higher or lower susceptibility of humans, compared to that predicted by caloric demand scaling. So, if the variability of substance data is to be accounted for, this needs to be considered by an extra factor.

### **Intraspecies Extrapolation**

Sensitivity differences between individuals may be influenced by age, health status, gender, genetic factors (enzyme polymorphisms), or their specific constitution and situation (weight, body mass index, gravity).

The analysis of available data shows that the commonly used default factor of 10 is probably sufficient to protect a large part of a group of healthy adults, including with regard to potential toxicokinetics-related differences. However, there is considerable uncertainty when it comes to assessing the significance of genetic polymorphisms of xenobiotic-metabolizing enzymes. Data analyses suggest that, in fact, such polymorphisms may lead to large individual differences in internal exposure. When higher internal exposure due to polymorphisms occurs in subgroups with higher susceptibility, such as children, the sick and the elderly, a factor of 10 may not adequately account for these differences, but this variability cannot yet be quantified.

A more in-depth analysis for the group “children” reveals a higher sensitivity, above that of the average healthy adult, of infants, and of new-born babies due to their still-incomplete capacity to excrete xenobiotics. The aforementioned default factor covers this deviation for the most part. In contrast, older children are not considered more sensitive compared to adults with respect to toxicokinetic differences. Phases during which sensitivity is particularly elevated occur in particular during the period of organ development (perinatal exposure) and rapid organ growth.

---

### **Consideration of Qualitative Aspects**

A distinction must be drawn between the extrapolations addressed above and the consideration of qualitative aspects. The need for this is often justified by qualitative risk assessment aspects. Their quantification requires subjective assessment steps which cannot be scientifically or empirically validated.

Such safety factors are derived to account for, e.g.,

- Data quality (additional factor due to a poor database)
- The quality/severity of the observed effects (additional factor for particularly critical toxicological endpoints; ► [Chap. 43, “Adverse Effects Versus Non-adverse Effects in Toxicology”](#))
- Grounds for suspicion (additional factor for hitherto unquantifiable potential properties of a substance, e.g., suspected carcinogenicity).

Conventions on this have been defined by, e.g., the WHO and the US EPA (Table 3). The WHO applies a factor of up to 10 to account for suspected carcinogenicity, and the EPA gives a “modifying factor” of up to 10 in case of a poor database. Typically, these factors cannot be validated by data analysis.

---

## Application Framework

The assessment steps discussed here always constitute the attempt to incorporate into the assessment fundamental findings and standards on which no substance-specific knowledge exists. An overview of factors applied by different organizations, and their sizes, is provided in Table 3.

In the case of extrapolations, knowledge drawn from experience can provide justification both for each factor itself and for its quantification. The range this allows to be delimited, or default factors, should be refined as better knowledge becomes available. When in doubt, the decision should generally be in favor of the risk group to be protected. The consideration of better knowledge also means consideration of better, alternative procedures. The replacement of LOAEL/NAEL extrapolation by benchmark procedures is a case in point. For interspecies extrapolation, for example, this means, in the first instance, use of a validated PBPK model (► [Chap. 29, “Toxicokinetic Models”](#)); in the second instance, use of substance-specific data for species comparison; and in the third instance, an extrapolation based on metabolic rate scaling which also takes data variability into account. Similarly, in risk assessment, valid human data should always be preferred over data from animal experiments, which require additional extrapolation steps (e.g., for differences in susceptibility between species). Most of the existing extrapolation concepts combine the various subfactors by multiplication. However, this is only statistically correct if the individual factors are independent of each other. This is not necessarily the case. For example, when data from a large lifetime animal study are transferred to humans, the age component of sensitive groups of persons may already be covered, at least partially, by the study design. It seems appropriate to limit the size of overall factors obtained by multiplication, for when above a certain level, they express a data uncertainty which makes the performance of a quantitative risk assessment difficult to justify (Table 3). Here too, the use of better alternative procedures, such as probabilistic methods, should be considered where possible (► [Chap. 24, “Probabilistic Methods in Toxicology”](#)). Recently, a probabilistic framework for hazard assessment was proposed by WHO (WHO 2017; Chiu and Slob 2015).

Regulatory toxicology is concerned essentially with predicting health effects and making decisions on the basis of limited data. In that sense, risks assessment outcomes contain uncertainties, due also to the use of extrapolations and factors, which are problems intrinsic to this field. These uncertainties must be described clearly in order to characterize the reliability of a risk assessment, especially since that reliability is an important information item for risk management.

## Abstract

Human biomonitoring means the analytical measurement of xenobiotics, their metabolites, and their reaction products (internal exposure monitoring), but also detection of specific effects in human biological molecules and materials (effect monitoring). Its purpose is the evaluation of the exposure, but also of the health risk associated with exposure, by referring to appropriate assessment values. The weight of human biomonitoring parameters is different from case to case, and depends on the linkage of the parameter with the toxic effect, e.g., xenobiotics adducts at proteins and deoxyribonucleic acid (DNA) may be linked more strongly with the carcinogenic risk compared to urinary excreted metabolites. Human biomonitoring is also able to reveal a background exposure of individuals

without any identified specific exposure, which may result from various environmental sources but in some cases also endogenously from physiological processes. Independent of the source, a quantified internal exposure needs an evaluation, preferably by referring to health-based assessment values. In the case of nonderivability of such values, the comparison of human biomonitoring results with so-called reference values or risk-related assessment values may serve an adequate option.

---

**Introduction**

Human biomonitoring (HBM) is used since many decades for the assessment of occupational exposure to hazardous chemicals. A joint statement of the Commission of the European Union and the US occupational safety agencies NIOSH and OSHA defined human biomonitoring as the measurement and assessment of working agents or their metabolites either in tissues, secreta, excreta, expired air, or any combination of these to evaluate exposure and health risk compared to an appropriate reference (Berlin et al. 1982). However, human biomonitoring is not anymore restricted to workplace control, but increasingly includes suspected environmental exposures in individuals of the general population (Boogaard et al. 2011).

Moreover, many human biomonitoring parameters may show already background levels, if they are detected in populations without known specific exposure to the chemical. These may be the result of various environmental sources and exposures and can in some cases also be generated endogenously from physiological processes. This means that background exposure might be composed of avoidable and non-avoidable sources. Food and lifestyle predominantly contribute to background levels. Nevertheless, an additional specific exposure in the proximate environment can affect the internal exposure of the inhabitants too. Every biomonitoring result has to be assessed keeping in mind a possible background and the determinants, which modulate the background (Göen et al. 2012). The additional burden of a suspected compound should therefore be treated as an increment to background (Sugimura et al. 2000).

Human biomonitoring data do not only distinguish between background and additional exposure, but, where reliable associated data on substance-related adverse effects are available, also need a toxicological evaluation. The so-called “human biomonitoring” (HBM) assessment values provide limits, above which health effects cannot be excluded or are probable. Such values are presently generated in many countries around and by international and national researchers, committees, and governmental agencies. The eminent scientific committees for the evaluation and definition of biological assessment values include the Biological Exposure Indices (BEI) committee of the American Conference of Governmental Industrial Hygienists (ACGIH), the

Permanent Senate Commission of the Deutsche Forschungsgemeinschaft for the Investigation of Health Hazards of Chemical Compounds in the Work Area (MAK Commission), the Human Biomonitoring Commission of the German Federal Environment Agency (HBM Commission), and the former Scientific Committee on Occupational Exposure Limits (SCOEL) of the European Commission. Governmental agencies provide additional assessment values, particularly for questions, which cannot be cleared on scientific basis, e.g., setting of socially accepted risk limits.

---

## Special Issues of HBM Data Assessment for Carcinogens

A special challenge is the evaluation of human biomonitoring data of carcinogenic substances. First of all, it should be considered that substances with carcinogenic potential may differ with respect to their carcinogenic evidence, mode of action, and potency. In this context, the MAK Commission extended the classification of carcinogenic chemicals to five categories (DFG 2020; Neumann et al. 1997). Carcinogens were classified basically according to the strength of evidence: (category 1) sufficient evidence of carcinogenicity in humans, (category 2) evidence of carcinogenicity only in experimental animals, and (category 3) the evidence is inadequate in humans and inadequate or limited in experimental animals, but suspicious data exist. This approach decided essentially about the evidence of the carcinogenic potential, but not about the potency. With two additional categories, the mode of action and the carcinogenic potency were introduced into the classification system. A carcinogenic chemical may either be nongenotoxic (category 4) or genotoxic (category 5), and members of both categories are characterized by having low or manageable carcinogenic potency. The novel perspective indicated by category 5 is that the limit, i.e., a tolerable risk, is not expressed as an absolute value, but based on the contribution to total risk by the active agent (including background exposure and/or physiological background). Low risk means the tolerable exposure does not contribute appreciably to cancer risk.

The distinction between different carcinogens by mode of action and non-appreciable effectivity enables a differentiated assessment of human biomonitoring results. Whereas carcinogens of categories 1 and 2 do not exhibit any clear threshold for avoiding any carcinogenic effect, health-based assessment values, containing prevention against carcinogenic effects, can be derived and applied for substances of categories 4 and 5 (DFG 2020).

---

## Health-Based Assessment Values

The most effective health assessment values are gained by dose–response relationships between internal concentration or dose and the associated adverse effects (No Observed Adverse Effect Level (NOAEL), Lowest Observed Adverse Effect Level (LOAEL)). Those health-based values may be derived from studies, in which both human biomonitoring data and health effects were assessed concurrently. However,

data of human studies are rare and therefore health-based assessment values are often derived from animal toxicological studies. Here, the inequality of the species as well as of the exposure scenarios has to be considered. This is performed by the application of specific as well as generic uncertainty factors. The risk observed with the high doses and the limited exposure periods used in animal experiments must be extrapolated down to low doses and long exposure periods, relevant in the human situation, assuming that the same mode of action works in both cases. Moreover, both the species specificity and individual susceptibility have to be accounted for. The use of default values, like 10 for dose uncertainty, 10 for species differences, and 10 for individual variability, is very common, but may not always meet the real substance- and species-specific conditions.

Moreover, it should be considered that a single substance can provide several health assessment values, each representing a different endpoint. In the field of occupational health, assessment values usually refer to the average “healthy” worker of working age. In this field, uncertainty factors that would protect sensitive persons are usually not applied. Deviating from that, the DNELs (derived no effect levels) under the European “REACH” regulations and the biological assessment values for the general population uses a number of uncertainty factors, to take into account inter-individual variabilities in the average population, with the aim to protect sensitive individuals. Another part of the difference is attributed to the fact that in the field of occupational health, assessment values are based upon chronic exposure over the working life (assuming a total of 40 years and 40 working hours a week), whereas assessment values for the general population in the context of environmental health assumes exposures throughout an entire lifetime (24 h a day, 365 days a year, 70 years). Health-based assessment values in the occupational field, released by the MAK Commission, include the biological tolerance values (BAT) and biological guidance values (BLW). Moreover, there are the biological limit values (BLV) set by the EU Scientific Committee on Occupational Exposure Limits (SCOEL) as well as the biological exposure indices (BEI) published by the American Conference of Governmental Industrial Hygienists (ACGIH).

For environmental health purposes, the HBM Commission establishes the so-called “Human Biomonitoring Values I and II” (HBM I, HBM II). The HBM I value marks the concentration of a chemical in a body medium below which no harm is expected. If the concentration exceeds the HBM I value, further controls are necessary. The HBM II value indicates the limit above which an individual may suffer health effects. In this case, environmental follow-up is recommended and if possible measures should be initiated to reduce the exposure. The HBM I value is considered a check and control value, the HBM II value an interference or interaction point. HBM I/II values are derived either based on human data (approach 1) or a defined tolerable intake (approach 2) or a point of departure for critical effects seen in animal studies (approach 3) (Apel et al. 2017). In the second approach HBM I values are derived on the basis of a daily intake reference value, e.g., acceptable daily intake (ADI), tolerable daily intake (TDI), and reference dose (RfD), which is toxicologically evaluated by scientific commissions, e.g., WHO, US EPA, and EFSA, and already includes the uncertainty factors (see above) (Barnes and Dourson 1988;

Herrman and Yones 1999). Hence, a prerequisite for this approach is the availability of reliable information on the toxicokinetics in humans, which is needed for transferring the daily intake into a level of a human biomonitoring parameter.

---

## Risk-Based Assessment Values

As described, no safe threshold concentration or dose can be specified for genotoxic carcinogens. For these substances an evaluation of HBM results is possibly based on risk-related assessment values, which target the limitation of carcinogenic effects. For these effects, stochastic relationships between the exposure level and the cancer risk can usually be established. Frequently, the supplemental cancer risk is expressed as one additional tumor in an exposed population of specific size, e.g., 1:10<sup>5</sup> or 1:10<sup>6</sup>. The weight of evidence of human carcinogenicity and quantitative estimates of inhalative and oral exposures can also be characterized by the unit risk and cancer slope factor, respectively. A unit risk is the upper bound of excess lifetime cancer risk estimated to result from continuous exposure to an agent at a concentration of 1 µg/m<sup>3</sup> in air. A cancer slope factor is the upper bound, approximating a 95% confidence limit, of the increased cancer risk from lifetime dietary exposure to an agent; it is usually expressed as a proportion of a population size affected per milligram per kilogram bodyweight per day (US-EPA 2020).

The question which risk should be considered a tolerable risk cannot be answered with scientific arguments. However, using scientifically derived exposure scenarios together with risk comparison tools, the current sociopolitically tolerated or accepted risk levels can serve as a basis for the derivation of critical exposure values, beyond which a risk would be unacceptable. In Germany, the Committee for Hazardous Substances (AGS) of the Federal Ministry of Labor and Social Affairs has developed such a concept for the determination of occupational exposure to carcinogens. For the concentration of some carcinogenic substances in the workplace air, “acceptance values” and “tolerance values” were defined in the AGS document TRGS 910. The values correspond to an “acceptance risk” defined as an additional cancer risk of 4:10,000 until the year 2018 and 4:100,000 after 2018. An exceedance of a “tolerable risk” of 4:1000 is evaluated as intolerable (AGS 2019). When the quantitative relationships between air exposure and resulting internal exposure is known, the acceptance and tolerance values can apply to results of human biomonitoring, on the basis of exposure equivalents for carcinogenic workplace substances (EKA), compiled since more than 30 years by the MAK Commission for those chemicals at the workplace that have proved to be carcinogenic either in animal or human studies (DFG 2020). The EKA tables deliver the correlation between the workplace air concentration and the resulting internal exposure, when absorption takes place exclusively by inhalation. These correlations allow to derive from the air limit values the internal exposure concentrations, as measured by biomonitoring, that correspond to the acceptance and tolerance risks (see also Göen 2018).

It should be noted that cancer risk values are extremely uncertain. Consequently, no estimate value should be given without the associated uncertainty.

The US National Research Council suggested already in 1974 (National Research Council 1974) that for any single-point estimate, the sources for the calculation and the extent of uncertainty should be stated and the upper bound given. Since this requirement can mostly not be fulfilled, the announcement of point estimates for additional cancer risks is discussed very controversially. A fundamental objection against the unit-risk concept is that the result cannot be tested; it cannot be falsified. With a background cancer rate of 20–25% in the human population, it is impossible to prove an increment of  $1:10^5$ – $1:10^6$ . The use of default asset values, particularly more than one combined, is quite unsatisfying. It follows that the calculation of an absolute risk leads to uncertain and unrealistic results.

---

## Reference Values and Other Descriptive Assessment Values

There exist other types of descriptive values, which are gained from epidemiological studies in the form of frequency distribution or correlations. A frequency distribution shows how often each obtained measurement value occurs in the studied population. Such frequency distributions often reveal that many substances are detectable in the body of persons, even if there is no specific evidence for any exposure. In such cases, there exists a background internal exposure in the population. The “reference value” reflects the extent of the background exposure. The reference value for a chemical substance in human biological material is a value that is derived from a series of measuring results according to a specified statistical method (Apel et al. 2017; Göen et al. 2012). Samples to be used for this purpose have to be collected from a defined group of the general population (e.g., adults, children, and non-smokers) or the whole population in a randomized way. Data from national environment surveys, for instance, can be considered a suitable base and have been used in several countries to quantify background exposures. To establish a reference value, it is necessary to characterize the reference population and to take care for possible confounding factors as precise as possible. The values are statistically derived from exposure biomonitoring results and are without relevance for health or disease issues. The reference values of a general population are derived from the 95<sup>th</sup> percentile of a group of persons who are not occupationally or otherwise specifically exposed to the substance. It is often reasonable to define reference values for subgroups, such as smokers and nonsmokers. The 95<sup>th</sup> percentile value also means that some 5% of the specified group exceed the reference values, which may sometimes lead to discussions. The availability of solid reference values is of great importance as a baseline for the validation of routine- and incidence-related biomonitoring results, both in occupational and environmental context. Reference values may vary between countries, depending on the exposure situations, habits, and hygiene. For Germany, the Human Biomonitoring (HBM) Commission collects and publishes reference values for an increasing number of chemicals, partly

differentiated according to age and gender (Apel et al. 2017). Likewise, the MAK Commission with its mandate to define maximal workplace concentrations evaluates and publishes biological reference values (BAR) (Göen et al. 2012; DFG 2020). Moreover, SCOEL published biological assessment values derived from the background levels in the general population recently too. The latter reference values are of relevance primarily for preventive occupational health care. The results of biomonitoring measurements in the respective class of workers are compared with reference values to find out, if the internal exposure of workers to a substance remains within the background level. Since external exposures to traditional toxicants tended to decrease in the past decades, but those of new substances increased, and confounding habits like smoking changed, reference values need to be reevaluated from time to time (Göen et al. 2012).

As mentioned, there is also a need to correlate external exposures (e.g., inhalation exposure at the workplace) with internal exposure, represented by biomonitoring (HBM) parameters. The exposure equivalents for carcinogenic workplace substances (EKA), for example, describe the relationships between the employee's external exposure (air exposure at the workplace) and the concentration of a HBM parameter (Göen 2018; DFG 2020).

---

## Parameters of Biological and Biochemical Effects

Several biochemical end points exist which correlate with cancer risk and can be used as powerful HBM parameters. This approach basically permits via quantification of reaction products of mutagenic and genotoxic substances, which are covalently bonded as adducts to macromolecules such as proteins (e.g., albumin or hemoglobin) and DNA to estimate risk levels. The experience with biochemical effect monitoring indicates that a contribution to risk could be called non-appreciable if an external exposure leads to an internal exposure and corresponding biochemical effects which are within the variability of the background of a reference population which is not knowingly exposed. If the level of a relevant biomarker lies within the range of the background level, a contribution to risk cannot be established.

Human biomonitoring is not only limited to exposure monitoring but also includes the assessment of effect parameters, which is called biological effect monitoring. However, in this context effect parameters should be of high specificity for the substance or substance group. Biological effect monitoring is closer to the end point of disease than biomonitoring of exposure. Biological effect monitoring provides information about the biologically active dose and the individual susceptibility. The difference to the generally used risk assessment is that the end point of the assessment is not the population-based disease but the use of analytical data from an individual. The data represent the immediate situation of an individual human, without any defaults for the environmental situation or species differences or susceptibility.

## Can Thresholds Be Certain?

A threshold is usually understood to separate an effective from an ineffective dose, although one may find in most dose–response relationships an exposure for a biological end point for which no strain can be seen (NOAEL). Even with ineffective exposures to compounds producing reversible effects, the search for the “ineffective threshold” is not anymore adequate. Now it appears more appropriate to look for deviations of physiological balances, which are detectable below the NOAEL, and to assess how well the system adapts against strain and which degree of imbalance should be considered adverse.

The cell adapts to stress at the mitochondrial respiratory chain, for instance, with an increased synthesis of respiratory chain components. If that stress increases beyond a critical point, the cell is eliminated by apoptosis and substituted by a new one. Several signaling pathways are involved and may control a common end point, such as apoptosis (Bolt and Degen 2004). With this perspective, it is not reasonable to search for a concentration threshold of ineffectiveness. It is important to find out how much a certain stress affects the cellular energy balance, in other words, leads to proliferation. A threshold between effect and no effect cannot be defined for a chemical which affects the respiratory chain. Effects on processes taking place below the NOAEL should be considered as stress, which under favorable circumstances can be compared with a reference value. DNA lesions produced by genotoxic compounds have been shown experimentally to be linear down to extremely low doses without threshold. This does not support the threshold concept on the molecular level (Neumann 2009).

## Abstract

The term “adverse” is used with the meaning “disadvantageous” or “harmful.” An effect should be avoided if it is adverse but could theoretically be tolerated when non-adverse. Generally it is more or less clear what is meant by “adverse,” but in a real situation, it may be difficult to position the line separating adverse from non-adverse.

## The Meaning of the Term *Adverse*

The term “adverse” is an adjective which is often used to describe negative effects on health. We take the term “adverse” to imply some degree of harm or the likelihood of unfavorable consequences for the individual or population concerned. The term “undesired” seems, to us, less appropriate as a synonym for “adverse”: not all effects that might reasonably be described as undesirable need necessarily be adverse.

The term “adverse” is commonly used without reference to a clear definition. Using imprecisely defined terms in assessments of effects, or possible effects, on health is not at all uncommon. For example, Article 3 of the Charter of Fundamental Rights of the European Union says: “Everyone has the right to respect for his or her physical and mental integrity.”

---

## Definition of Adverse Effects

The IPCS/WHO definition of adverse effects, published in 1994 (IPCS/WHO 1994), is often quoted, but the second and very important sentence of the definition (our italicizing below) is frequently omitted:

“Adverse effect: change in morphology, physiology, growth, development or life span of an organism which results in impairment of functional capacity or impairment of capacity to compensate for additional stress or increase in susceptibility to the harmful effects of other environmental influences. *Decisions on whether or not any effect is adverse require expert judgement.*”

In 1985 and 1999, the American Thoracic Society (ATS) tried to define adversity in context of air pollution. Supplementing their 1985 statement, in 1999 the ATS referred to health-related quality of life. However, the ATS emphasized that this statement does not offer strict rules or numerical criteria, but rather proposes principles which may be used in weighing the evidence and setting boundaries between adverse and non-adverse health effects, and the placement or positioning of dividing lines should be a societal judgment (ATS 1985, 1999). An update of these statements discusses a wider range of effects and biomarkers as a “set of considerations” for judgments on the adversity of effects (Thurston et al. 2017). Any increase in deaths from cardiovascular or respiratory disease is classified as obviously adverse. For some effects or biomarkers the extent of change that the authors consider to be adverse is discussed, and other effects or biomarkers are discussed only under semi-quantitative or qualitative aspects.

In including quality of life and well-being, ATS is supported by the 1948 WHO definition of health ([www.who.int/about/definition/en/print.html](http://www.who.int/about/definition/en/print.html)): “Health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.”

## Dimensions of Adversity

The ATS statements and other summarizing reviews indicate and define several dimensions or characteristics of adversity, in part referring to an individual concerned, in part, in addition or exclusively to a population, and also referring to qualitative or general aspects.

Dimensions of adversity:

- Severity of an effect
- Detectability of an effect
- Reversibility of an effect when exposure stops
- Probability of an effect
- Particularly concerned subgroups (“environmental justice”) and effect on current or next generation
- Causal relationship between exposure and effect

## Severity of an Effect

According to ATS, death or an increased risk of death and any consequence on life expectancy as well as clinically significant effects should be classified as adverse effects.

For respiratory symptoms and changes in indices of physiological function, the ATS sees the line between non-adverse and adverse being crossed if quality of life is impaired. In this context, health-related quality of life refers to factors including capacity to look after oneself, mental health, pain, and generally feeling well. Decrease in health-related quality of life is classified as adverse, e.g., shown by clinically significant findings when diagnostic tools, including questionnaires, are used to assess health status.

Keeping in mind that there is a considerable lack of knowledge of the meaning of changes in biomarkers, ATS does not generally classify changes in biomarkers as being adverse. The 2017 statement offers advice for assessing adversity of changes in biomarkers.

## Detectability

Concerning detectability of effects, statistical significance is usually demanded. Tests of statistical significance are used to distinguish, with a conventionally acceptable but arbitrary level of confidence, between effects that might be taken to imply some actual relationship between a potential cause and an effect and those which might occur by chance. Thus, unless an association reaches “statistical significance,” it is likely to be ignored. The possibility of error should be noted. Large epidemiological studies have great statistical power and can detect very small effects. Thus, in the air pollution field, a change in the daily average

concentration of particles defined by  $PM_{10}$  has been shown to be associated with a less than 1% increase in the risk of death over a short period. This is a small effect but the coefficient that specifies the effect is statistically significant and is thus regarded as unlikely to have resulted from chance.

Statistical significance should not be taken as proof of a causal relationship: the possibility of confounding needs to be considered. Death is clearly an adverse effect on health, but is a small increase in the risk of death also, by definition, an adverse effect? It should be noted that when death is discussed, the long-term risk, for all, is absolute: we all die. What is usually meant is an increased likelihood of death in a specified period or a shortening of life expectancy. This opens up the question of what degree of shortening of life expectancy should be regarded as adverse. Many would say that any effect on life expectancy is an adverse effect. This leads to a rather philosophical point: the effect may be adverse but is it important? There is no scientific way of answering this question: the answer will vary from person to person.

In the 1985 statement, the ATS showed a pyramid or triangle to illustrate the relationship between severity of an effect and number of persons likely to be affected. At the top of the pyramid is death as the most severe effect, followed by disease, and finally respiratory symptoms. This pyramid, broadening from top to bottom, is thought to illustrate that with decreasing severity the frequency of an effect increases in a population. The hypothesis that influences on mortality are severe but rare effects, however, no longer corresponds to current knowledge at least with respect to particulate matter. It seems reasonable to think that less exposure to some toxic material is needed to produce a minor effect than a major effect, but work in the air pollution field has shown, especially with regard to particles, that at all ambient concentrations studied, effects on all outcomes (deaths, hospital admissions, symptoms, restriction of daily activity) occur. Thus, it is now felt that the idea of different thresholds separating exposures with effects on, for example, symptoms from exposures with effects on the likelihood of death is incorrect. Whether or not a very small decrease in life expectancy should really be seen among the most severe health effects may be debated, but we can no longer assume that effects on mortality generally concern only a very small part of the population exposed.

The traditional classification distinguishing between substances without effect threshold (carcinogenic substances) and those with effect threshold is not supported by recent findings. This makes the classification of toxicologically active materials by their effects more difficult. Without an effect threshold, a purely qualitative statement (effect/no effect) is no longer adequate. There will always be the quantitative aspect to be added (i.e., how large or how frequent an effect may be or should not be).

## **Subjective Perception**

At an individual level, the more an effect is perceived as imposing a limitation on physical or mental activity and as having negative emotional overtones, the more the effect is likely to be classified as adverse. Aspects including the assessment of the

possibility that action taken by individuals can influence effects or – in contrast – perceptions of helplessness can act as modifiers.

The subjectively perceived probability of an effect occurring at a certain exposure does not always correspond to “objective” reality, but it contributes to the subjective assessment of adversity. A feeling of threat and danger subjectively associated with environmental influences might also be an adverse effect – beyond the influence of environmental regulators.

## Reversibility

Reversibility of effects after the end of exposure is certainly very important as regards symptoms and functional changes. Complete or partial irreversibility would suggest adversity (the occurrence of adverse effects); complete reversibility might support non-adversity, especially in the case of very low severity of effects. However, an effect which is reversible for most of the persons exposed might be irreversible for susceptible individuals. With respect to functional physiological parameters, the ATS advises that minor transient deteriorations of lung function values should not to be automatically classified as adverse, but if connected with symptoms, they should. A detectable, permanent deterioration of lung function, however, is classified as always adverse.

## Probability and Number of Persons Concerned

In terms of clinical parameters, at a population level even a minor level of effects of air pollutants is generally declared unacceptable by the ATS. This may be an example of the fact that changes classified as being not adverse at an individual level may demand different consideration if they occur in a group or a population. Figure 1 schematically shows that a possible classification as adverse or non-adverse depends on the severity of the effect in an individual concerned as well as on the percentage of persons concerned in a population at a certain exposure.

Below the line through  $y$ , the severity of effect in an individual concerned is so low that the effect would not be classified as being adverse even if the whole population were to be affected. Left to the line through  $x$ , the number of individuals concerned is so low that a relationship to exposure is not verifiable due to statistical reasons. To the left of and below the dashed curved red line, an effect is not adverse because the severity of the effect is small even considering the number of persons concerned. To the right and above the dashed curved line, an effect is classified as adverse because considering the severity in an individual concerned as well as the number of persons concerned in the population exposed seems to be not tolerable. In this case, the large fraction of persons concerned suggests the classification of an effect as adverse even if it would be classified as non-adverse at an individual level.

However, the difficulties begin when one tries to fix the positions of the lines  $x$  and  $y$  on defined and scaled axes.

**Fig. 1** Pragmatic classification of an effect as adverse in relation to the number of persons concerned and to the severity of the effect in concerned individuals

## Groups Concerned

If effects are limited to certain subgroups of the population, this will need to be considered when assessing effects at both an individual and population level. Effects focused on certain subgroups may lead to different assessments on an individual level (“I am not concerned, so it is not so severe”) and at the level of effects on public health (“it is a particular injustice because some groups are at a much higher risk”). Moreover, the severity of an effect may be neglectable in more or less healthy people but important in frail or impaired persons.

Effects probably appearing for the first time in the next generation tend to be classified as “adverse,” although due to the potential manifestation in the future, the uncertainties are larger than in effects without large temporal latency.

## Causality

The question of causality is a matter of discussion in all epidemiological findings. The Bradford Hill features of causal associations may be helpful (Hill 1965), but whether or not an effect – be it directly measured or “only” calculated – is attributed to its real cause cannot always be clearly decided.

Whether or not a causal chain: *cause – change in a biomarker of exposure – change in a biomarker of effect – functional change – symptom – disease – death* could be demonstrated or only hypothesized and whether that chain describes a possible or an unavoidable course should be considered when assessing the adversity or non-adversity of the initial steps of such a known or hypothesized chain. And an additional aspect may be the possible “co-operation” of causes which are not powerful alone but effective in combination.

## Final Remarks

Generally, the IPCS/WHO definition of 1994 – extended by aspects of (subjectively perceived) quality of life – seems to be a reasonable basis for deciding on whether an effect should be regarded as “adverse.” For classifying an effect as adverse or non-adverse, it is not possible to give precise criteria which in any particular case result in an “objective” and transparent assessment. Expert judgment remains a necessity. This should not be seen as an unavoidable deficiency but rather as an opportunity for a discussion exactly adapted to each particular situation. Which persons are the appropriate experts who should be authorized to perform such a judgment is a question as difficult as that of the threshold between adverse and non-adverse. In a larger context, this is subject to societal agreement.

For regulators, expert advice on adversity of a health effect is a necessary and helpful basis for standard setting. Regulators have to consider aspects including feasibility, juridical implementation, and cost-benefit relations. In all, the ideal of setting standards which avoid any adverse effect on health is an aim which indicates the direction to follow even recognizing that it may never be entirely reached.

## Abstract

The derivation of health-based threshold values in various fields of regulatory toxicology is based on consented rules laid down in regulatory guidance papers (EFSA EFSA J 8:1325, 2010; ECHA, 2010) Guidance on information requirements and chemical safety assessment Chap. R.8: characterization of dose [concentration]-response for human health ECHA-2010-G-19-EN). The rules were developed according to the field of application and are improved when scientific evidence became available showing that elements of the framework have to be changed. No principle difference exists in the guidances from several European agencies.

The MOS concept applies the same principles; it is however more flexible as it allows to introduce scientific judgment.

## Introduction

In toxicology, risk assessment requires quantification of: (1) the hazard given by the inherent toxicological properties of a substance (resulting from experiments in animals or epidemiological data) and its dose-response characterization and (2) the exposure in quantified terms. Comparing the exposure with the outcome of the hazard assessment (a dose which is assumed not to exert adverse effects) gives the answer to the question “how dangerous for health is the exposure towards this substance?” This comparison is called risk assessment. Two approaches are used in regulatory risk assessment of chemicals. One approach is to set health-based guidance values, such as accepted daily intake (ADI) or tolerated daily intake (TDI), and to calculate the ratio between exposure and health based guidance value. If the value is below 1, that is, the exposure is smaller than the health based guidance value the outcome of the assessment is “no concerns.” The second (margin of safety, MOS) approach assesses the distance between the exposure and the dose without an appreciable effect. In general, it is assumed that the exposure is of no concern if the exposure is 100 fold lower than the dose without an appreciable effect. Depending on the data set available and the specificity of the substance, a higher factor than 100 may be deemed necessary.

---

## Health-Based Threshold Values

The basic concept of health-based threshold values, such as ADI values (acceptable daily intake), was introduced by JECFA (Joint Food and Agriculture Organization – World Health Organization Expert Committee on Food Additives) already in the 1950s. Applying the evaluation scheme, food additives are assessed by an international panel of experts. Later, the concept was adopted by the Joint Food and Agriculture Organization – World Health Organization Meetings on Pesticide Residues (JMPR). In the beginning, ADI values were developed only by the two scientific panels. Later, when the European Food Agency (EFSA) was established in 2002, ADI values were derived by scientific panels working for EFSA.

Other European regulatory bodies, in particular the European Chemicals Agency (ECHA), also used the concept to derive so-called derived no-effect levels (DNELs) whereby some differences exist between the two European agencies as EFSA derives a single ADI, whereas ECHA derives several DNELs depending on the route of exposure, even for specific end points separately, and separate DNELs for healthy workers and for the general population.

The principle of the concept is to define a dose, which, based on the scientific evidence, can be assumed to be safe, that is, without adverse health effects in humans even if the dose is taken up on a daily basis for a lifetime. In most of the cases, the point of departure (POD) to derive a safe dose is experimental data from toxicological studies in animals. The dose which did not produce an adverse effect in animals (no observed adverse effect level or NOAEL, lower benchmark dose level or BMDL) serves as the POD. The dose is adjusted to the human situation by

using a factor accounting for the interspecies difference and a second factor accounting for the variability in the human population to derive the dose which is assumed to be safe during a daily lifelong exposure by food (ADI), dermal contact, and inhalation (DNEL). Knowing this dose allows regulating exposure at a level which will not result in adverse health effects in the exposed population.

---

## **Dose Without (Adverse) Effect**

The dose without an (adverse) effect is the dose for which, in an experimental study, no effect has been observed compared to the control treatment. It should be taken into consideration that the dose critically depends on the experimental conditions such as number of animal tested, dose range and dose interval, and the range of end points tested (e.g., histopathology, clinical chemistry, and functional tests). It has not yet been decided whether the existence of an effect has to be demonstrated by a statistically significant difference compared to control or whether biological plausibility is sufficient.

The limitation of the procedure on how to derive a dose without effect is obvious. We must determine a dose with an adverse effect in order to be able to define the neighboring lower dose as the dose without an effect. Hence, the number of animals and the spacing of doses are crucial in this respect. If we do not see an effect, this is not proof for absence of an effect. Animal protection requires reducing the number of animals, whereas statistical power considerations would require a high number of animals. We should be aware that OECD guidelines are a compromise between the two principles which does not prevent us in overlooking effects because of the low statistical power of the study.

It has to be discussed whether the point of departure (POD) to derive health-based threshold values is a no-effect level (NEL) irrespective if the effect is adverse or adaptive or compensatory or just a biochemical change. In particular, in the era of genomics, studies at the level of genes do allow to observe changes which, however, cannot be attributed to be adverse. NAEL is used to describe a theoretical no-adverse-effect level, and NOAEL is the not-observed-adverse-effect level. An example for an adaptive effect is the induction of drug metabolizing enzymes in the endoplasmic reticulum in the liver, which will lead to an enhanced metabolic capacity and thus a reduced toxicity if the parent compound is the toxicant. An example for compensatory changes is the increased inhalation rate in metabolic acidosis. In the International Program on Chemical Safety (IPCS/WHO), definition of adverse effect is as follows: change in the morphology, physiology, growth, development, reproduction, or life span of an organism, system, or (sub)population that results in an impairment of functional capacity, an impairment of the capacity to compensate for additional stress, or an increase in susceptibility to other influences. Today, the NOAEL is taken as POD to derive health-based threshold values.

The duration of the study is also influencing the level of the NOAEL: this is partly due to the fact that in subacute and subchronic studies, the number of animals and also the number of parameters investigated are lower than in chronic studies which

**Table 1** Cumulation factors for substances with long half-lives: 28 day study versus 90 day study

Half-life (days)	% of steady state reached after 28 days	% of steady state reached after 90 days	Accumulation factor
7	93.75	100	1.07
14	75	100	1.3
28	50	90	1.8

may lead to higher NOAELs in subacute and subchronic studies as compared to chronic studies. Sometimes, adverse effects may only be developing after long-term exposure. One explanation can be the kinetics. Substances with long half-life will cumulate and reach the maximum level only after prolonged exposure as demonstrated in Table 1.

Toxic effects may develop only after prolonged exposure, for example, effects on the testes or thyroid as secondary effects with a primary effect on the liver. It is currently becoming clear that the whole database has to be taken into account including the studies for developmental toxicity and fertility. Those studies produce additional information not seen in repeated dose testing.

It is to be noted that using NOAEL as the POD does not use all available information on the dose–response relationship. International agencies (e.g., IPCS–WHO, EFSA) have therefore given advice to use all information by modeling the dose–response relationship and using the curve to derive a dose which corresponds to a low effect level. This is called the Benchmark dose approach. The Benchmark dose (BMD) is a dose level, derived from the estimated dose–response curve, associated with a predefined change in response, the Benchmark response (BMR) which size is to be determined based on the variability of the selected endpoint (Slob 2017). Several mathematical formulas exist for the modeling of the experimental data. In the most recent version of applying the Benchmark dose approach, it is recommended not to select a specific formula but to use a model averaging approach (EFSA Scientific Committee et al. 2017). For risk assessment purposes by convention, the lower confidence interval of the BMD, the BMDL, is used.

---

## Safety Factors/Uncertainty Factors/Assessment Factors

Point of departure (POD) for the derivation of a health-based threshold value is the NOAEL/the Benchmark dose from a chronic dose in animals, often in the rat. Adjustment factors are used to “adjust” the dose in the rat to the respective dose in man. It is assumed that in general the human organism is more susceptible when compared to the rat. To bridge the species difference between rat and man, a factor of 10 is used. The interspecies factor is subdivided into a factor accounting for the differences in toxicokinetics and a factor accounting for differences in toxicodynamics. The toxicodynamic factor is 2.5, a value which is not well supported by data. The toxicokinetic factor is dependent on the species and based on allometric considerations. For the rat, the factor is 4, rendering the total interspecies factor to 10. For mice the toxicokinetic factor is 7, rendering the total

interspecies factor to 17.5. For rabbit the toxicokinetic factor is 2, rendering the total interspecies factor to 5. The factors can be modified (so-called chemical-specific adjustment factors) if chemical-specific scientific data are available (WHO 2005).

An additional factor is used to account for the variability within the human population. The intraspecies factor is subdivided into a factor accounting for the toxicokinetic variability and a factor accounting for the toxicodynamic variability. The default value which is used is 10 whereby a factor of 3.14 accounts for toxicokinetics and a factor of 3.14 for toxicodynamics. Data from clinical studies showed when retrospectively analyzed that the factor of 10 is empirically supported. Only with chemicals/drugs metabolized by polymorphically expressed CYPs (such as CYP 2D6), the factor of 10 is not appropriate and a much larger factor is needed. If chemical-specific data are available, it is advised to use the data-derived factors instead of the default value (“chemical-specific factors”). International experience, increasing utility, and regulatory acceptance of chemical-specific factors have been described in a recent publication (Bhat et al. 2017).

---

## Margin of Safety (MOS)/Margin of Exposure (MOE)

There are situations where human exposure occurs, but no guideline level (such as ADI or TDI) is available that would help to assess the health risk of the chemical. In such circumstances, the value for the NOAEL in the available study is divided by the exposure level. The quotient is called the MOS or MOE (in cases of genotoxic carcinogens). The margin of safety is also used to assess the health impact in cases in which the exposure is higher than the ADI/TDI. The following aspects are to be taken into consideration when assessing the MOS/MOE: (1) scientific rigor of the database, (2) possible difference in the route of exposure between animal and man, (3) differences in the exposure scenario between animal experiment and human situation (duration, dosing, frequency of dosing: very often the total daily dose is given in one dosing, whereas in humans the dose might be divided in three meals), (4) steepness of dose–response relationship, (5) nature and severity of the effect, (6) differences between species, and (7) variability in the human population including possible sensitive subgroups. There is presently no regulatory document discussing cases explaining the derivation of an appropriate MOS.

---

## Exposure Assessment

It should be mentioned here that the assessment of exposure is as important as the hazard identification and dose–response assessment. The first step is the identification of the appropriate scenario, the second the parameterization of the scenario. Whereas for food intake databases have been collated and the content of chemicals in food is well known for most of the food items, the exposure situation is far from being known for other substances and other circumstances such as consumer products. In order to take a cautious approach, “worst case” assumptions are made which bear the potential to grossly overestimate the exposure.

---

## Risk Assessment

If the exposure is lower than the health-based threshold, it can be concluded that there is no health concern. Concerning the MOS/MOE a factor of 100–300 is sufficient for noncarcinogens and nongenotoxic carcinogens depending on the database. For genotoxic carcinogens, a MOE greater than 10,000 is interpreted in the way that no urgent measures have to be taken (EFSA 2012). In cases where the exposure is higher than the health-based threshold value, the MOS approach can be informative to assess the possible health impairment. For example, given the same effect (e.g., hepatotoxicity), a MOS of 10 is of higher urgency for measures as compared with a MOS of 90.

## Abstract

The pollution of water, soil, air, food, and everyday products with harmful chemicals is accompanied by risks for public health. The active defense or control of these risks can be effected using the principles of hazard prevention or precaution, respectively. Toxicological information is a basic contributor to preventing and controlling hazards together with data from other disciplines.

Protection of the health of consumers and their environment is dependent on scientific information and associated policy with preservation of public health through various measures. More specifically, consumers of food and everyday products are afforded protection by official regulations which concentrate on surveillance of the market and manufacturers and warnings against goods recognized as presenting actual or potential adverse effects for the public.

641

Environment-related health protection aims at safeguarding the public from toxic (carcinogenic, genome-altering, and other) effects that may come from contaminated water, soil, and air. Necessary tasks include the recognition and description of environmental influences adverse to health, the prevention or the removal of these influences where applicable, and the development and the transfer/mediation of findings such that harmful inputs from the environment may be avoided.

The administrative regulation of substance-related risks in this field is based on hazard prevention and/or precaution.

---

## Principle of Hazard Prevention

In general law, the term “danger” is described as a situation, which leads to damage of a protected legal good within a reasonable timeframe and with sufficient probability, if the expected course of events is not stopped. The basis is a safe prediction of the course of events. The requirements for the indication of danger are less demanding if the legal good in question is highly ranked (e.g., human life) and if serious damage is expected (e.g., health damage). The prevention of the development of such a situation is called hazard prevention.

To initiate official measures of hazard prevention concerning chemical substances, usually, a numerically fixed minimum triggering level, a threshold of danger or adverse effect is required. Because of the enormous legal consequences, in some cases, pure suggestion of hypothetical damage, 1 day is not sufficient to allow (legal) stipulation of the fixing of an absolute limit. Instead, the threshold must be based on scientific or otherwise obvious knowledge of a particular limit above which human health effects may occur.

The toxicologist may essentially contribute to the characterization of a threshold of danger by:

- Definition of the relevant route(s) of exposure
- Estimation of the extent of exposure
- Characterization of risk groups
- Determination of mechanism of action of a so-called adverse effect: an important health effect of not just a temporary nature out of a range of effects
- Assessment of a dose–response relationship
- Estimation of a NOAEL (no observed adverse effect level) or a NOAEC (no observed adverse effect concentration; for instance, in the context of air quality values) or otherwise derived thresholds of effect (for non-genotoxic substances, for instance, using the benchmark procedure)
- Determination of a limit dose by using assessment algorithm (e.g., unit risks) for genotoxic carcinogens based on “politically” agreed levels of acceptance or tolerance

Such characterization is based on appropriate animal studies (the quality of which is preferably categorized by the so-called Klimisch criteria (Klimisch et al. 1997), epidemiologic findings, and additional reliable data. In some cases, single observations in humans after accidents or disasters/catastrophes may also be of use in this endeavor.

---

## Suspected Threshold of Danger

During toxicological assessment, there are often imponderable aspects that arise due to the lack of useful epidemiological data and the ensuing need to extrapolate animal data (often at high doses) to long-term effects in humans linked to illness (mostly at lower doses relevant in the environment of the affected people). The resulting uncertainties need to be compensated by different (un)certainty and extrapolation factors, such as those proposed by the WHO, the ECHA (2010), or the German Committee on Hazardous Substances (AGS 2010). With respect to legal requirements, in some cases, this is also true for additional so-called danger-linked factors.

The quality of the basis of evaluation, the extent of the broadly agreed factors involved, the experience and the expertise of toxicologists, and finally political considerations influence the determination of the regulatory limit as shown as the area of danger marked in the risk plot, here better described as suspected threshold of danger (Fig. 1). Because of the mainly toxicologically based derivation, the principle of protection by hazard prevention is regarded as a toxicological principle.

---

## Principle of Precaution

The principle of precaution is based on the assumption of a risk continuum. It follows that the possibility of a health risk below the threshold may not necessarily be totally excluded, especially when investigating worst cases with respect to vulnerable groups of people. This is of particular relevance when considering

**Fig. 1** Assessment areas for harmful substances in the environment

genotoxic carcinogens. However, with the depletion of the concentration of the pollutant in the environmental milieu, the risk declines, and the initiation of health deterioration will become less probable (Fig. 1). The principle of precaution finally aims to reduce this risk to the greatest possible extent.

The application of the precautionary principle is thought to compensate for possible uncertainties (for instance, due to gaps of the toxicological data base) within the evaluation of substances/groups of substances (Mitteilung der Kommission 2000).

One special manifestation of the principle of precaution is the principle of minimization, as found in several legal acts. This means that, for instance, the concentration of chemical substances polluting the environmental source or adversely influencing its quality (e.g., drinking water) has to be kept as low as ultimately possible according to the state of the art while considering the circumstances of the particular case with reasonable expense/effort. In brief, it is referred to the ALATA (as low as technically achievable) or the ALARA principle (as low as reasonably achievable).

The principle of precaution also involves the predictive or forward-looking protection of people against adverse exposure by the development, by recommendations, and by the enforcement or implementation of measures on the basis of health quality goals. This is strongly linked to the term of sustainability, the future viability of quality goals, the results of which satisfy the needs of living people. At the same time, these results should not reduce the chances of future generations for a healthy existence.

The burden of exposure of human beings from environmental sources not only should be minimized but rather should be removed or eliminated wherever possible.

Overall, the principle of precaution therefore incorporates the general aspects of environmental health.

---

## Distinction of the Area of Precaution

In regulatory affairs, it is often necessary to complete such qualitative considerations by quantitative assessments/evaluations to enable administrative/official measures, if needed.

On the scale of a continuum between risk at the (suspected) threshold of danger and (unrealistic) zero risk, in principle, every value may be accepted for the entry into the area of precaution (precaution value). However, usually, the assumption is followed that a small deviation from the (suspected) threshold of danger is not enough to enter the precaution area. Instead, below the danger area, an area of concern is assumed in which individual hazards are not yet excluded. This area is tied to the area of precaution, in which a health hazard does not exist anymore or would be extremely unlikely (Fig. 1).

However, due to a lack of scientifically reliable data, the threshold to the area of precaution cannot be derived just by toxicological methods. Rather, it is oriented on technical, aesthetic, or general aspects of human well-being. Due to these considerations, the largest possible margin to the (derived) thresholds of effects (suspected

threshold of danger) is usually chosen. It is expected that this approach can allow for current imponderables and differences among individuals.

In this context, the toxicologist's expertise is needed with regard to, e.g., information about and weighting of the extent of, for instance, carcinogenic, immunotoxic, neurotoxic, and development blocking effects in the lower risk area, as well as guiding principles for further yet-to-be-fully-resolved exposures, vulnerabilities, and potentials of hazard.

This envisaged level of protection which is beyond the scope of protection against danger is regarded as mainly based on general aspects of environmental health.

This principle manifests itself in the development of (precaution) standards and quality goals with contributions of toxicologists in official working groups, committees, and commissions, for instance, to solve questions with respect to health impact assessment, land use planning, and so on. As for risk management, the implementation of such working results is usually modified to a high degree by the political weighting of various interests.

Along with administrative/regulatory measures, official recommendations and advice are addressed to users and consumers, such as aiming to avoid sources of pollution (behavioral prevention) (Fig. 1).

## Abstract

The hygienic approach aims at keeping the environment and the human body free of avoidable loads, which means to minimize – not necessarily exactly specified – environmental contamination and thus at the same time to prevent chemically induced illnesses. The toxicological approach assumes that an exposure level is definable – that does not lead to specific adverse health risk – and derives tolerable exposures from this starting point. Both approaches often seem to complement each other in regulatory considerations, as they possess different points of view and aims.

## Introduction

While toxicology derives tolerable or acceptable doses based on present knowledge (experimental or modelled data), hygiene aims at keeping the environmental media free of pollution/contaminants, which has the effect to reduce and avoid exposures (Fig. 1). The two concepts or disciplines have a right to exist in parallel in the regulations. They use quite different approaches that still reflect the ancient Greek terms “hygiene” (for health, salutary) and toxicon (poison). Today both approaches have a common purpose: protection of the human health, the population and the living nature. The differences are less in the type or content of applied methods, but rather in the way of thinking already from the beginning of a regulatory process.

*Schematic drawing showing a log dose versus effect plot. Hygienic precautions are made, even in the absence of any presently detectable risk. Toxicological approaches are interested in the doses, where a threshold is overrun or where danger must be assumed.*

## Toxicology

The assessment in toxicology is primarily based on the knowledge of effects caused by an individual substance (or a defined group of substances) and is evaluated according the principle defined by Paracelsus “dosis sola facit venenum.”

Absolute thresholds without detrimental effects are mostly derived from experiences with (high) toxic doses for a single substance or group of substances under strictly defined conditions (e.g., certain occupation-types or animal species). The definition of strict conditions aims at the reproducibility of results and the decreasing

### Hygienic- and toxicological views

**Fig. 1** Hygienic and toxicological view

the impact of confounding factors by minimizing variables. However, obtained results are sometimes difficult to translate to a complex exposure scenario as such of human beings. For example, up to now, most of the occupational exposure limit values (OEL) or also acceptable daily intake values (ADI) are generated in previous described way.

Environmental toxicology has the objective to assess health risks associated with substances of geogenic or anthropogenic nature and their distribution in the environment. The human being as well as the living nature is in its focus. Bioassays and studies with in vitro systems are used to determine or model the physical factors and the toxicity of substances that occur in the environment as intended active ingredients, residues, or resulting contaminants.

Limit values for pollutants in environmental media consider – in comparison with workplace regulations – the potentially longer persistence and exposure (24 h per day, each day of a year) and the higher diversity of influencing conditions, such as the potentially higher sensitivity of special population subgroups. It can be stated, however, that in most areas of regulation (work, environment, etc.), the idea of prevention and the hygienic approach to protection becomes increasingly important.

---

## Hygiene

Hygiene is more far-reaching, multifaceted, but at the same time, it is also more indistinct and less definable: Its scientific and educational approach aims at the prevention and control of illness as well as health preservation in particular through health protection and health promotion. The science of hygiene investigates all illness-causing factors in the natural, technical, occupational, chemical, microbotic, and social environment. Corresponding to that, the discipline develops counterstrategies and countermeasures to take the impact of these various influences appropriately into account.

Inherent to the vision of hygiene is the “precautionary principle or ALARA principle” to protect health against detrimental risks from a contaminated environment, e.g. contaminated with natural and anthropogenic pollutants. This is a guard or protective shield also against possible not yet sufficiently understood environmental-toxicological interactions, for the benefit of the current population and protection of the basis of life of future generations.

For regulatory purposes and risk management, hygiene also uses toxicological tools and methods in “risk assessment,” but more imponderability must be taken into account in the development of limit values. Environmental hygiene deals with water-, soil-, air-, and food-borne, potentially harmful influences on the living nature and human being. The environmental-hygienic evaluation has to pay attention to a much larger variation width of influencing factors than, for example, the traditional occupational toxicology. Broad variances of the life circumstances and considerable differences in the length of the exposure, the number of substances, and further factors (see Table 1) exist. Also, the prevention claim of the hygiene discipline is

**Table 1** Constraints and assumptions

	Toxicology/occupational health	Hygiene and environmental medicine
Exposure substances	Some few	Many
Exposure type	Mono-media (e.g., via air)	Polymedial (water, soil, air, food, toys, etc.)
Duration	8 h/day	24 h/day
	Working life (40–45 a)	Lifelong (70–90 a)
Substances (nature, number of)	Definable, known	Inconsistent knowledge, unknown
Philosophy	Exposure reduction when a limit value is reached	Preventive exposure avoidance, even when there is no current evidence for exceedance of specified limits
Use, handling	Handling by informed persons	Unpredictable handling by uninformed users possible
Health status	Healthy; under occupational medical control	Healthy and sick, old and young; no targeted control possible
Protection	Protective clothing, ventilation, air extraction	Not possible; substitution
Monitoring surveillance	Targeted occupational surveillance and investigation, targeted measurement (e.g., human biomonitoring)	Incidental findings (e.g., population-based human biomonitoring)
Substance combinations (combined effects)	Few	Many

more far-reaching and has recently been integrated in many regulation philosophies, including occupational medicine.

The derivation of toxicologically reasonable limit values, for example, OEL values, is always dependent on the state of scientific knowledge at the time point of implementation. Thus, it is also hardly disputable that in some cases in the past, limit values were subject to be corrected and judged more strictly a few years later, and some substances subsequently had to be classified as carcinogen. This may be considered as just barely tolerable for occupational (40 h/week) exposures and under consideration of the employers' liability insurance for economic compensation in case of damage. But the possible and nearly unavoidable impact of scientific uncertainty appears not acceptable when the population is exposed during the whole lifetime and when considering the cumulative effects for future generations (e.g., ground pollution, refuse dumps).

With this in mind, any complex weighted environmental-hygienic limit value usually provides a wider scope of protection compared to a similar value that is

derived using a toxicological approach. These additional weighing processes will be clarified further using the historical example of setting drinking water limit values for pesticides.

---

### **Example: Pesticide Regulation in the Drinking Water**

The different approaches are exemplifiable by comparing the previous regulations of pesticides in drinking water in Germany (predominately hygienic-environmental based) with that of the World Health Organization (predominately toxicological based). Although both aiming at apparently nearly the same objective of protection and conservation, the numerical values show that different approaches were applied: use of the chemical analytical detection limit in the German regulation but toxicologically derived values in the WHO drinking water guidelines (WHO 1993, 2017; Bundesregierung 2020).

---

### **The German Hygiene Philosophy**

The environmental impact of pesticides, e.g., due to (useful) agricultural activity, would reach an absolute upper limit, if such activities would inevitably lead to a (harmful) contamination of groundwater or drinking water. On the one hand, pesticides absolute lower limit is defined by the amount of active ingredients, which must reach the target organism (pest) in order to be effective. On the other hand, it should not contaminate the non-target-compartments of soil or groundwater. The compromise between harmfulness, usefulness, measurability, and preventability of pesticides leads therefore not to a value of “zero,” but to 0.1 µg/l per single active substance in ground- or drinking-water. This tolerance threshold corresponds to the state of the art and makes agricultural activity equally acceptable for positive and negatively concerned persons (Dieter 2010).

For most pesticides, this drinking water limit value corresponds to hardly 1% of the lifetime innocuous dose. Thereby, it is guaranteed that damages due to combination effects, barely investigated metabolites or disinfection by-products that may be formed during chlorination of drinking water (e.g., chloroform), can be excluded with practical certainty. This also means that a temporary minor limiting value violation would rarely result in an immediate health risk. Nevertheless, countermeasures should be applied immediately in any case, considering the sometimes decades long “contamination memory” of soil and groundwater.

---

### **The Philosophy of the WHO**

WHO has the task to evaluate, generate, and distribute scientifically derived health standard. The procedure is fundamentally different from that in the German regulation: departing from an health based guidance values for total exposure, e.g. ADI or

tolerable daily intake (TDI) value as a convention 10% is allocated to the drinking water path. For lipophilic pesticides such as aldrin, dichlorodiphenyltrichloroethane (DDT), lindane, and some others substances, for which it is assumable that the main transfer in humans occurs, e.g., via the food path, the allocation is only 1%. For substances which are probably carcinogenic for humans, concentration values were derived departing from a reference risk of  $10^{-5}$  using the usual exposure parameters for drinking water.

However, it is not expected by any means that the toxicologically derived limit values will be adopted directly into laws of the various countries. In the introduction to the "Guidelines for drinking-water quality," WHO states that for the derivation of national standards, it is necessary to consider the context of the local and national environment as well as the social, economic, and cultural conditions. In spite of references to necessary cost-benefit weighing, there is also a hint, that *"every effort should be done, to achieve a drinking water quality that is as high as possible. The best protection of the drinking water consists in avoiding the pollution of the raw water."* It is also stated: *"Although the guideline values describe a drinking water that meets the claim of lifelong health protection, their derivation must not be understood in a way, as if this approved a replenishment of a given drinking water quality up to the mentioned values. On the contrary, the protection of a drinking water quality that is as good as possible, demands and earns continuous effort"* (Dieter 1993).

WHO as supranational organization could hardly be clearer than in the quoted comments in expressing its support for a "Minimization principle or ALARA-principle" which exceeds the mere compliance with strictly toxicologically derived guideline values. This even more, because WHO must always keep in mind the specific conditions, in particular the economic situation of the less developed countries.

For the national adoption of the guidance values, WHO advises to take into account the specific ecological, geological, socioeconomic, and technical prerequisites. Therefore, the comparison of the WHO guideline values with the German legal limit values shows that the environmental-hygienic demands seem to be absolutely appropriate. In particular, they fulfill the claims for a sustainable protection of the environmental resources.

---

## Regulation of "Unknown" Substances

There are situations, such as incidents of raw-water contamination, where drinking water regulation can unexpectedly have to deal with formerly unregulated substances and a lack of toxicology data (e.g., per- and polyfluoroalkyl substances (PFAS) contamination in Germany in 2002). In such a situation, the public health authority has to check whether there is no hygienic concern present and whether the drinking water is still compliant with the requirements of the national drinking water regulation, despite the presence of the new contaminant. Such a specific approach was developed, e.g., by the German National Drinking Water Commission and published as a Recommendation of the German Federal Environmental Agency (FEA/UBA 2003).

## Abstract

The modern determination of standards (benchmarks, threshold values, etc.) is achieved in a multistep process, beginning with the definition of the subjects of protection as well as protection goals and levels of protection, respectively. The process is not strictly divided from step to step. The assessment of data from one step often requires a feedback to the primary subjects of protection and protection goals.

## Introduction

Subjects of general legal protection such as human being itself or the animated or inanimated environment are established in the constitutions of many countries worldwide.

Besides such general determinations of subjects of protection, it is equally important to define how far the protection should go. Protection goals describe the degree of intended protection and thereby the level of protection aimed at. If a protection goal is defined, this can be substantiated by quantitative risk assessment (QRA).

These general definitions will be explained in terms of toxicology in the following chapter.

## Subjects of Protection

Human being itself or the animated or inanimated environment can represent subjects of protection (Fig. 1). In this context, two objects of legal protection are of significant importance:

- “Physical integrity” (physical health)
- “Conservation of natural resources” (environment: ground, water, air, fauna, and flora)

In many countries, these objects of legal protection are firmly established in the constitution. Therefore, they have to be respected even if they are not explicitly

**Fig. 1** Determination of environmental standards

addressed in a relevant law. Additional constitutionally protected objects, which have to be considered in this context, are “**professional freedom**” and the “common freedom of action.” These basic rights are very relevant in the economic sector. They ensure the freedom to perform the profession of one’s own choice, the use of manpower against payment, the possibility for businessmen to compete, and the entrepreneurial freedom of action.

Against this background, for example, in Germany, the ad hoc commission “reorganization of proceedings and structures for risk assessment and standardization in environmental health protection” (risk commission) defined three subjects of protection:

- Human life
- Diversity of species and types
- Economic power

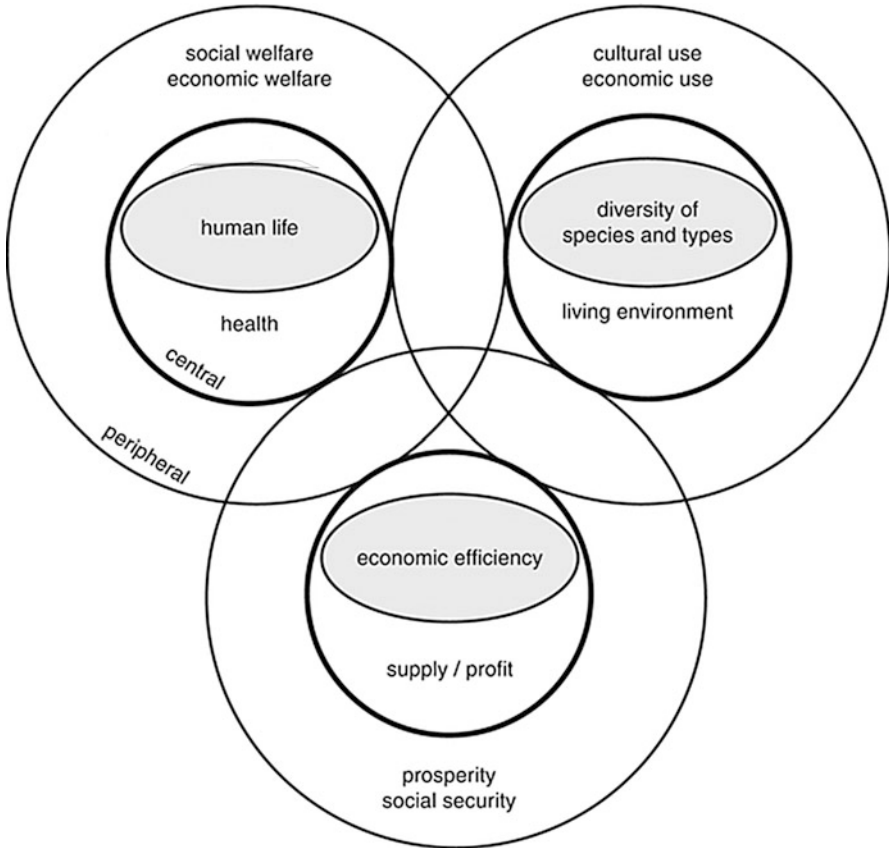

These three subjects of protection depend on each other. They are fundamental in context of the global action program for the twenty-first century “Agenda 21” and the resulting strategy of “Sustainable Development,” compiled in 1992 in Rio de Janeiro by the “Conference of the United Nations on Environment and Development,” that was a basis for the United Nations Sustainable Development Goals of 2015.

When concrete measures are planned or evaluated, these three subjects of protection can come into conflict with each other. In such cases, it is recommended to distinguish between **central and peripheral areas within the subjects of protection** (Fig. 2). For human beings, the protection of health and, for nature, the protection of the natural living environment represent the central area (anthropocentric versus ecocentric protection of the environment or nature). The peripheral areas cover especially socially, culturally, and economically associated subjects which influence and determine the central areas. These subordinated, peripheral areas overlap and often cannot be precisely assigned to a distinct subject of protection. If it comes to a conflict between the central areas of the different subjects of protection, one should seek a measure which shifts the conflict into the peripheral areas, in order to protect the central areas as much as possible. In the peripheral areas, activities that carry risks become comparable and calculable. Additionally, in a concrete situation, it has to be considered that upper-level objects of legal protection – normally, life and health of human beings – are favored compared to, e.g., economic objects. Compensatory measures should be considered for more affected subjects of protection. Moreover, risks depending on external influences should receive more weight than self-dependent risks.

---

## Protection Goals and Levels of Protection

Besides the definition of subjects of protection, it is also important to define how far the protection should go.

**Fig. 2** Areas and subjects of protection

**Protection goals** describe the degree of intended protection and thereby the **level of protection** aimed at. Their definition has significant impact on the quantification of standards and the following implications. Protection goals can be classified in two ways:

- Complete protection – partial protection
- Hazard control – prevention

### **Complete Protection: Partial Protection**

In this context, depending on the risks that are to be regulated and the subjects of protection, the following questions arise:

- Is complete protection of subjects of protection intended or are certain risks tolerable, because their complete exclusion is not possible, too expensive, or socially not accepted?

- Are entire systems (i.e., populations, ecosystems) to be protected or additionally each therein contained individual component, possibly including particularly sensitive components?

In the discussion of these questions, also constitutional criteria have to be considered, for example, suitability, requirement, and adequacy of a planned measure.

## Hazard Control: Prevention

In many countries, law differs between damage, danger, prevention, and remaining (residual) risk. **Damage** means that the probability of a negative event (adverse effect) amounts to one, i.e., a negative event occurs with certainty or has occurred already. **Danger** means that damage is expected with a (inacceptable) high probability. In context of law, dangers have to be defended. The borderline separating danger from the range of prevention is determined by the level of non-tolerable risk. The borderline separating the range of prevention from a remaining (residual) risk is defined as **tolerable risk** (**traffic light principle**, Fig. 3).

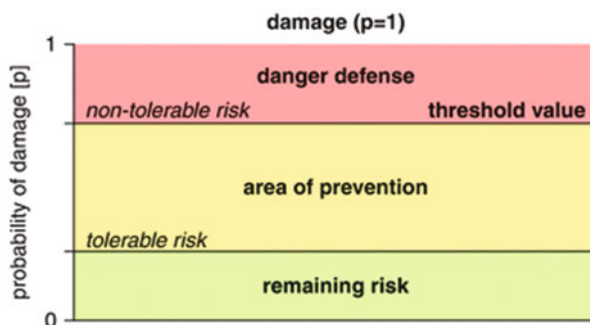

## Substantiation of Protection Goals: Deduction of Standards

If a protection goal is defined, this can – as far as possible and necessary – be substantiated for both protection levels, i.e., danger defense and area of prevention, respectively, by **quantitative risk assessment (QRA)**.

Generally, **danger defense** is implemented by definition of a normative **threshold value**. Threshold values generally separate the area of danger from the area of prevention. Exposures lower than the threshold values usually imply that affected objectives have no risk of damage. On the other hand, this does not imply that an exposure exceeding the threshold value automatically leads to damage.

An important source for the deduction of threshold values is toxicological data resulting from dose-effect or dose-probability estimations, respectively. In this

**Fig. 3** Traffic light principle

context, it is important to differ between agents with dose-effect curves revealing a level beneath which no effect is observable or expected from agents for which such a level is not apparent. The last applies particularly for genotoxic agents, e.g., benzene or benzo(a)pyrene.

For **agents with a threshold of effect**, regulatory values are generally defined using the ADI concept of the WHO. Point of origin in this context is the “no observed [adverse] effect level” (NO[A]EL) or alternatively the “lowest observed [adverse] effect level” (LO[A]EL). The threshold for human beings, at which lifelong no harm for health can be expected (convention, not toxicologically evidenced), is calculated by division by a safety (respectively uncertainty) factor (normally 100).

A method used for **agents without a no observed effect level** (e.g., genotoxic agents) is, for example, the **unit risk method** of the Environmental Protection Agency (EPA). The unit risk of an agent describes the estimated additional lifelong cancer risk posed on a person exposed for 70 years with 1 µg of the agent per m<sup>3</sup> air. An additional lifelong cancer risk between 1:10,000 and 1:1,000,000 is discussed as acceptable. The dose corresponding to a risk of 1:1,000,000 is called “virtually safe dose.”

The protection philosophy of threshold values based on quantitative risk assessment can be found, e.g., in the WHO “Air Quality Guidelines” and the “Guidelines for Drinking-Water Quality” for Europe or the “Maximum Residue Limits” of the WHO.

The **precautionary principle** implies that (environmental) exposure should be prevented or reduced far before the risk of danger occurs. This principle is particularly applied in case of a suspected risk of agents for which scientific data for (quantitative) assessment are not yet sufficient to define threshold values. This is, for instance, the case when causal correlation between an exposure and damage is likely but not (yet) proven. In these cases, the principle of exposure reduction as far as economically and socially justifiable (ALARA, “as low as reasonably achievable”) or as far as technically possible (ALATA, “as low as technically achievable”) can be applied. In these cases, the precautionary principle is often not related to measurable effects and refers to the principles of “sustainable development” and protection of environment for further generations.

The **protection level** aimed at the individual case (i.e., how safe is safe enough? definition of “tolerable” or “negligible” risks, respectively) and the subsequent options of action are generally defined in the course of a normative (political) process of decision-making. At best, science can contribute by describing scenarios using objective scientific data. Modern, socially accepted regulatory processes additionally require adequate information and participation of the public and transparent reproducible decision-making policies.

## Abstract

The conduction of clinical trials with medicinal products or medical devices is a mandatory requirement for the license of new, possibly more effective medicinal products/medical devices with a better risk/benefit profile.

Preclinical studies to determine pharmacokinetic parameters such as absorption, bioavailability, metabolism, half-life time, excretion mode, or toxicological properties of new medicinal products are necessary, but they are increasingly conducted on cell models in order to reduce animal experiments.

B. Henrikus (✉) · W. Eisenmenger  
Ethics Committee Ludwig-Maximilians-University Munich, Munich, Germany  
e-mail: [Beate.Henrikus@med.uni-muenchen.de](mailto:Beate.Henrikus@med.uni-muenchen.de); [Wolfgang.Eisenmenger@med.uni-muenchen.de](mailto:Wolfgang.Eisenmenger@med.uni-muenchen.de)

Both animal and human experiments are now subjects to strict and clear legal and ethical regulations. The first tentative approaches to ethical regulations can be observed at the beginning of the twentieth century, which have been amended and specified many times in the meantime. At the same time, towards the end of the twentieth century, there was an increasing demand to replace animal experiments by cell models as far as possible.

Nevertheless, before starting a first-in-human (FIH) study, experiments in two different animal species are usually necessary to estimate an initial dose using NOAEL or MABEL (minimum anticipated biological effect level). Such a study on healthy volunteers is an experiment under special ethical issues, because the medical ethics principle of “*nihil nocere*” is violated; the healthy participants have no chance of benefit, but the risk of a potentially serious adverse effect. This contribution describes the historical background and the current ethical issues of human studies and animal testing.

---

**Introduction**

Toxicological, pharmacological, and biomedical trials in humans or animals imply ethical issues. Due to legal requirements, these studies are subject to an ethical assessment in most countries. Although the ethical principles, the review criteria, and the legal basis have been well established and harmonized for many years, the formal ethical assessment procedure differs on several factors.

Investigators have multiple and comprehensible interests: the desire to conduct high-quality research, to complete the research quickly, to protect research participants, to obtain funding, and to advance their careers. The very nature of many ethical issues in research means that they cannot easily be defined as clearly right or wrong. The resolution of these issues relies upon the person’s values and beliefs, thus requiring an independent opinion. Independent review (frequently in the form of an ethics committee) provides public accountability and minimizes potential conflicts of interest.

Much has been written about the bureaucratic downside of formal ethics review systems. On the one hand, ethics review uses up precious time and can be seen as delaying the research. On the other hand, through the continuous dialogue between researcher and the review committee, a positive reflective process is embedded throughout the experiment’s life span.

In order to gain a deeper appreciation of ethical principles, it is helpful to consider the historical debate.

## Historical Development

In 1833, William Beaumont, a US Army surgeon, advocated for the right to perform human experiments. In 1865 Claude Bernard, a French physiologist, argued for animal experimentation as part of the standard scientific method. Both scientists only focused on the researchers' rights. About the same time, the scientific community in medicine became aware of ambivalence in medical studies. The discrepancy between an experimental therapy, aiming at scientific interests, and an individual treatment experiment, serving patient's welfare, was published by Charles Nicolle in his views on the moral responsibility of scientists. At the end of the nineteenth century, as the experimentation on human beings and animals increased, criticism and controversy began. The public began to demand that the welfare of the patient is respected as well as the interests of researchers.

In Prussia, research regulations were introduced in 1900, following the increased governmental awareness of the lack of standards in medical research. These regulations were among the earliest and clearest pronouncements on the importance of informed consent in medical research. The reason for these research regulations was based on vaccine trials, conducted on prostitutes and abandoned children without consent.

In 1931, a directive from the German Ministry of Interior demanded that innovative or experimental therapy could only be conducted on human subjects if the person concerned (or his legal representative) had unambiguously consented after being informed in advance about the nature of the procedures and their risks.

In 1947, the "Nuremberg Code" was published. This code was based on ethical principles developed by the Nuremberg Military Tribunals during the prosecution of physician researchers, accused of conducting horrible medical experiments on prisoners of war during the Second World War. Being the first international standard for the conduct of medical research, the code was designed to protect the rights and the well-being of human subjects in medical experiments and to establish voluntary consent in research.

In 1964, the World Medical Association issued new recommendations on "Ethical Principles for Medical Research involving Human Subjects," based on the principles of the Nuremberg Code. They are known as the "Declaration of Helsinki." The Declaration has been adapted and amended several times, most recently by the 59th World Medical Association in Seoul in 2008. The declaration modified the Nuremberg Code's first principle that the voluntary consent of the human subject is essential, with the recognition of the legitimacy of proxy consent for research involving children and persons with cognitive impairment. The Declaration of Helsinki states: "The research protocol must be submitted for consideration, comment, guidance and approval to a research ethics committee before the study begins. This committee must be independent of the researcher, the sponsor and any other undue influence. It must take into consideration the laws and regulations of the country or countries in which the research is to be performed as well as applicable

international norms and standards but these must not be allowed to reduce or eliminate any of the protections for research subjects set forth in this Declaration.”

In 1979, the Belmont Report was published. It summarizes the basic ethical principles developed by the United States Department of Health, Education, and Welfare, due to the problems arising from the Tuskegee Syphilis Study, an experiment in poor, rural black men. In this study the researchers knowingly failed to treat patients appropriately in order to study the natural progression of untreated syphilis.

In 1997 the International Conference on Harmonisation (ICH) published international ethical guidelines on Good Clinical Practice (GCP). These guidelines seek to harmonize clinical studies worldwide and to ensure that the data generated from studies are valid.

In 2004 the European Union implemented the principles of Good Clinical Practice. They have been laid down in the EU Directive 2001/20/EC. This Directive is currently law in all EU Member States but is to be replaced by EU Regulation 536/14 at end of 2021. The aim of the new regulation is to improve global harmonization and reduce bureaucracy. In the USA, they appear in FDA Federal Regulations Title 21, Subchapter A, Part 56.

In 2006, the disastrous results of the first application of the monoclonal CD 28 human antibody TGN1412 in healthy volunteers, a so-called first-in-human (FIH) study, raised many serious medical and ethical issues. The applied humanized monoclonal antibody acted in different fashion in humans as compared to the toxicological tests in laboratory animals. Nothing in the preclinical and toxicological tests predicted the overwhelming systemic reaction to the antibody; no previous animal tests demonstrated the toxicological response seen in humans. The severe adverse reactions occurred due to adverse immune-mediated drug reactions (such as cytokine storm, autoimmunity, and immunosuppression). As a consequence, a guidance for first-in-human studies was enacted by the European Medicines Agency (EMA) in 2007. Special care has to be paid to the novel mechanism of action (extent, amplification, duration, reversibility of the effect), the nature of the target, the relevance of animal species and models (questionable relevance implies an additional risk), the estimation of the first dose in human (when the methods of calculation (e.g., NOAEL, MABEL) give different estimations of the first dose in man, the lowest value should be used), the sequence and the interval between dosing of subjects within the same cohort, the dose escalation increments, the transition to next dosing cohort, the stopping rules, responsibilities for making decisions, monitoring, and communication of adverse events/reactions.

In 2017 the European Medicines Agency (EMA) has revised this guidance to further help researchers identify and mitigate risks for trial participants.

The differences in target affinity, mechanism of action, and immunogenicity between established toxicological models (i.e., NHP) and the human immune system, the functional potency of humanized monoclonal antibodies to modulate the target, and the new toxicology of these complex protein products (i.e., high target specificity, lack of metabolite toxicity) require the development and validation of new toxicological models.

Financial aspects must also be considered: the compensation of volunteers for the assumption of risk and the fair compensation of trial participants in case of injury.

---

## **Ethical Principles**

EU Directive, FDA Regulations, as well as the Declaration of Helsinki require an ethical review on a legal basis. Furthermore, they introduce legal obligations and specifications for the scope of the ethical assessment. Ethics committees have to guarantee that investigators act in compliance with fundamental ethical principles. These principles are as follows.

### **Respect and Protection**

A fundamental principle is respect and protection of the individual. This includes the well-being of research participants, their right for self-determination, protecting privacy by assuring confidentiality of personal information, and respecting anonymity. The privacy of research participants and the confidentiality of their personal information have to be protected to minimize the impact of the study on their social integrity.

### **Informed Consent and Transparency**

A further principle is the right of a participant to make informed decisions, regarding participation in medical studies, both initially and during the course of the medical study. Voluntary consent must be guaranteed. No competent individual may be enrolled in a clinical trial unless he or she freely agrees. A research participant also has the right to withdraw consent at any time for any reason, without affecting their subsequent care. The participant must also be informed of all potential trial risks and burdens and of any newly discovered risks or benefits during the course of a clinical trial. Participants shall be informed of the results of the medical study.

### **Favorable Risk-Benefit Ratio**

It is based on the principles of “non-maleficence” and “beneficence.” Every medical trial has some degree of potential risk and benefit; therefore, investigators have to insure that risks to study participants are minimized. Consequently, a careful assessment of the possible risks and benefits must be carried out for the trial participants. Medical studies involving human subjects may only be conducted if the importance of the objective outweighs the inherent risks and burdens to the study subjects. There has to be a reasonable likelihood of benefit to the population studied. Experimental studies should always be compared to the best methods, but under certain

circumstances, a placebo or no-treatment group may be utilized. Special attention has to be paid to patients involved in placebo arms. The subsequent treatment of the research subjects after the end of the study is part of the ethical assessment. This includes the assurance that they will have access to the best-proven medical procedures. Investigations that are contrary to morals and conventions are ethically not acceptable. An example for such an experiment is a trial in humans for detecting the threshold of injuring effects of pesticides or herbicides. Such studies provoke only harms but no benefit for the individual.

### **Fair Participant Selection**

This principle is based on the principle of justice. To be ethical, the selection of participants must be fair. Investigators need to ensure that:

On the one hand, stigmatized and vulnerable individuals are not targeted for risky medical experiments. Medical studies involving a vulnerable population are only justified if there is a reasonable likelihood that the population benefits from the result of the research. When a study participant is incompetent, physically or mentally incapable of giving consent, or is a minor, the investigator needs the consent of a legal representative or proxy acting in the subject's best interest. On the other hand, not only rich and socially powerful individuals should be favored for potentially beneficial research. This demand is especially relevant for nations from the so-called Third World or nations without public health insurance coverage.

### **Scientific Validity**

To be ethical, clinical research must be conducted in a methodologically rigorous manner and must be of scientific value. Bad science is bad ethics because it does not emerge better medical knowledge but may provoke additional risks and harms for study participants. Furthermore, bad science may generate incorrect and nonvalid data which may entail harmful, risky, or ineffective treatments. The allocation of safe and effective drugs is a mandatory ethical and legal requirement.

### **Ethical Review Criteria**

The primary task of an ethical assessment by ethics committees is the review of research proposals and their supporting documents. Therefore, special attention is paid to the informed consent process, documentation and the suitability and feasibility of the protocol. Ethical reviews need to take into account previous scientific reviews and the requirements of applicable laws and regulations. The ethical review is focused on – but not exclusively limited to – the following issues:

- Are the risks acceptable?
- Are there any precautionary measures to minimize the risks?
- What are the potential hazards and how they are handled? An example is the use of magnetic resonance tomography (MRT) as a diagnostic tool instead of a CT in order to eliminate radiation burden.
- What is the scientific validity of the proposal – will it achieve its stated objectives?
- Is the methodology appropriate to the study?
- Are the drug and its dose adequate? Is the dose used to examine the efficacy the same as used for the safety research?
- Is the sample size adequate?
- Is the use of placebo in the control arm justified? If there is a best care regime available as control that is well recognized and commonly applied, a placebo arm is ethically not justified.
- What are the criteria for withdrawing a research participant prematurely from the research or for suspending or terminating the research as a whole? Has the welfare of the participants been protected? This includes physical and emotional welfare, discomfort, and distress. The impact of the study on the participants must be anticipated.
- What are the characteristics of the population from which the research participants will be drawn? This includes gender, age, literacy, culture, economic status, and ethnicity.
- Are adequate provisions made for monitoring and auditing the conduct of the research, including the constitution of a data safety monitoring board (DSMB)?
- In which manner will the results of the research be reported and published?
- Are the conditions of insurance (insurance coverage) adequate?
- Are provisions for data protection according the corresponding law?
- Are the study sites suitable and the staffs adequately trained?
- Have human rights been respected? Was the consent obtained voluntarily? Any coercion invalidates the consent made. Is the informed consent form understandable to the potential participants, in particular, if vulnerable groups, such as children or partly incompetent patients, are involved? Is the research participant adequately informed about the nature, significance, risks, and implications of the medical study, as well as about his or her right to withdraw from the experiment at any time without affecting his or her subsequent care? A generally comprehensible information sheet is to be handed out to him. Furthermore, the person concerned is to be given the opportunity to have a counselling session with an investigator about the other conditions surrounding the conduct of the medical study. Is the right of privacy respected? The consent must refer particularly to the collection and processing of health-related data. The participant should know which data will be collected and who will have access to them.

---

## **Types of Experiments**

The spectrum of experiments with ethical implications is divided into different types. One of the main types is the clinical study on drugs or medical devices in humans. This type of study is well regulated and harmonized at the EU level and the USA, respectively. ICH Topic E 6 Guideline for Good Clinical Practice Note for Guidance presents detailed written instructions to achieve uniformity of the performance of specific drugs. The methodology must be clearly described, and copies of the patient's information and consent will be required.

Another main type is the epidemiological study. It seeks to detect the incidence or the prevalence of diseases (i.e., epidemiological studies led to the discoveries of the relationship between smoking and cancer and to the identification of heart disease risk factors). Population studies demonstrated the mechanism of the transmission of AIDS and other infectious diseases and also showed how these diseases can be prevented. It also includes studies of a new medical procedure in the context of diagnosis or radiotherapy, surgery, transplantation, psychotherapy, or studies in complementary or alternative medicine as well as research experiments performed to determine how health care is delivered or might be improved or to examine personal or social behavior, opinions, or attitudes. For this type of study, a set of recommendations is available, the so-called good epidemiologic praxis (GEP). These recommendations seek to standardize epidemiological studies and include ethical aspects, research questions, study protocol, biological sample banks, quality assurance, data management and documentation, analysis, data protection, contractual conditions/frameworks, interpretation, communication, and public health. In contrast to the GCP, the GEP are only recommendations without legal basis.

Another form of studies is the category "biomedical studies" which includes many subtypes. It includes studies on human materials (i.e., blood, tissue, urine) or on human data such as questionnaire-based projects. This form of study has not yet been standardized or been regulated at the EU level. A further main type is the animal study.

---

## **Animal Welfare**

In the middle of the nineteenth century, animal experiments were established as part of the standard scientific method. They include pure research such as genetics, developmental biology, behavioral studies, as well as applied research such as biomedical research, xenotransplantation, drug testing, and toxicology tests, including cosmetics testing.

One of the first opposition to the use of animals in medical research arose in the USA and resulted in the passing of the Animal Welfare Act (AWA) in 1966. In the meantime, the act has been amended several times (most recently in 2013). It regulates the treatment of animals in research. Other laws, policies, and guidelines

may include additional species coverage or specifications for animal care and use, but all refer to the AWA as the minimally acceptable standard for animal treatment and care.

Early objections to animal testing came from the belief that animals were so different to humans that results from animals could not be reliably applied to humans (i.e., *contergan*). There were also objections on an ethical basis, contending that the benefit to humans did not justify the harm to animals.

In 1985, a set of ethical principles known as the 3Rs, Replacement, Reduction, and Refinement, were outlined into 11 principles by the Council of International Organizations for Medical Sciences (CIOMS) and have become the international standard governing animal experimentation. In the European Union, the Directive 86/609/EEC on the protection of animals used for experimental and other scientific purposes was adopted in 1986. In November 2010, “Directive 2010/63/EU on the protection of animals used for scientific purposes,” which updates and replaces the 1986 Directive 86/609/EEC, was finalized and came into force. Full implementation of the new EU directive starts on January 1, 2013.

In the last decades, there was an enormous success in the replacement of animals. Meanwhile nonanimal test methods become more and more numerous and have been formally validated and accepted by most countries as replacements for an existing animal test. A variety of cell-based tests and tissue models can be used to assess the safety of drugs. Examples include models for tumor biology with a multifunctional microfluidic-based approach as well as sophisticated *in vitro*, genomic, and computer-modelling techniques of cell and tissue culture; healthy or cancerous or otherwise morbid human tissue (*in vitro*); and induced pluripotent stem cell lines, respectively, prevalent human diseases like diabetes, cancer, heart failure, or rare diseases like cystic fibrosis and muscular dystrophy. *In vitro* genetic research has isolated specific markers, genes, and proteins associated with Alzheimer’s disease, Parkinson’s disease, muscular dystrophy, schizophrenia, and other inherited diseases. A three-dimensional model of breast cancer has been developed that will allow investigators to study the earliest stages of breast cancer and test potential treatments. Rather than studying cancer in rodents, this model, which uses both healthy and cancerous human tissue, effectively allows the study of cancer as it develops in humans. An embryonic stem cell test, using mouse-derived cells to assess potential toxicity to developing embryos, has been validated as a partial replacement for birth-defect testing in rats and rabbits. The 3T3 Neutral Red Uptake Phototoxicity Test uses cells grown in culture to assess the potential for sunlight-induced (“photo”) irritation to the skin. Human skin model tests are in use, including the validated EpiDerm™ test, which has been accepted almost universally as a total replacement for skin corrosion studies in rabbits. The use of human skin leftover from surgical procedures or donated cadavers can be used to measure the rate at which a chemical is able to penetrate the skin. Furthermore there exist human lung cell model in order to test the health effects of inhaled drugs.

Another example for a well-regulated animal welfare is the system in the UK (Animals (Scientific Procedures) Act). It requires three levels of regulation:

- A project approval for the scientific substance of the project, which details the numbers and types of animals to be used, the experiments to be performed, and the purpose of them. The experiment can be performed on an animal if it can be successfully argued that it is scientifically justified and there are good reasons to cause an animal harm.
- An approval of the institution (it ensures that the institution has adequate facilities and staff).
- A personal approval for each scientist or technician who conducts any procedure. The clarification on responsibilities needs to be addressed for staff members who carry out research on animals as well as implementation of good animal welfare practices to ensure compatibility with scientific needs. In deciding whether to grant an approval, the regulatory agency has to refer to “the likely adverse effects on the animals concerned against the benefit likely to accrue as a result of the program to be specified in the license.” An approval should not be granted if there exists a “reasonably practicable method not entailing the use of protected animals.” The experiments must use “the minimum number of animals, involve animals with the lowest degree of neurophysiological sensitivity, cause the least pain, suffering, distress, or lasting harm and [be the] most likely to produce satisfactory results.” All three licenses must be obtained before starting the animal experiment. Animal experiments can be performed based on a review and approval of the institutional official.

All regulations contain provisions to ensure that animals used in research receive a certain standard of care and treatment. Animal care and use in research are largely controlled by Institutional Animal Care and Use Committees. Most governments aim to control the number of times individual animals may be used, the overall numbers used, and the degree of pain that may be inflicted. Furthermore, there exist numerous standard operating procedures (SOPs) for animal care. Animal care duties include – but are not exclusively limited to – housing (i.e., well-controlled airflow, room temperature), daily health checks (observation for sign of illness or injury, pathogen control, general medical surveillance procedures), body weight measurements, feed, and transport (a minimum acclimation period of 72 h, physical separation of animals accomplished by housing different species in separate rooms, the extent of the quarantine period).

Although the regulations that apply to animals in experiments vary across species (i.e., stronger rules for vertebrates) and around the world, the spirit of the regulations is always the same: animal welfare!

## Abstract

Chemical safety at work is the responsibility of every employer. He must ensure that every employee who works or has contact with hazardous chemicals is able to identify the risks posed by the chemical and is able to take measures that allow him to work safely. An important part of chemical safety is risk management. Furthermore, the correct identification, labeling, and handling of hazardous chemicals contribute to their safe use. It is imperative to teach chemical safety to every employee who works or comes in contact with hazardous chemicals and provide him with all the required information that ensures an appropriate and safe working environment.

**Introduction**

The use of chemicals by humans goes back several thousand years and today, almost everybody works with or has contact to chemicals. Thousands of novel chemicals emerge every year and are used for numerous applications, for example, pharmaceuticals, consumer goods, food products, and many others. To date, there are more than 100,000 chemicals listed in the EC inventory of the European Chemicals Agency (ECHA, EC Inventory 2020). This includes nontoxic chemicals such as sodium chloride, but also hazardous chemicals as sodium cyanide or mercury. The physicochemical properties among chemicals differ widely. It is the purpose of toxicology to determine the potential hazards of each chemical substance. In general, the safety of a chemical depends on its reactivity, concentration, the route of exposure, and use.

If chemicals are known to be harmful to humans, animals or the environment, they must be handled with care and precaution to reduce both the probability and consequences of accidents to a minimum. It is necessary that students, occupational workers, and household users who handle, store, transport, and dispose chemicals are aware of potential hazards and trained for the safe use of chemicals. The safety of chemicals depends on multiple factors: knowledge, judicious use, safe practices, appropriate methods of engineering controls, proper use of personal protective equipment, use of minimum quantities of materials, and substitution of a less hazardous chemical substance when possible.

---

**Chemical Safety at Work**

Millions of people around the globe have contact with chemicals at their workplace almost every day. This could be at a small research laboratory or an industrial manufacturer for chemicals. Typical hazards in laboratories and chemistry workplaces are

- Fire and explosion hazards resulting from flammable solids, liquids, and gases
- Risk of solids, liquids, or gases causing damage to health
- Risk of unknown, violent or reactions out of control
- Hazards affecting the eyes and skin because of caustic and irritant chemicals

It is a top priority to reduce dangers posed by hazardous chemicals to a minimum. To achieve this, general guidelines for chemical safety at work, regardless of the size

of the company, the kind and amount of chemicals used, can be followed. Simply speaking, three questions should be asked before working with any chemical or substance.

1. What can happen?
2. How likely will it happen?
3. What are the consequences if it happens?

The answers to those questions will help to minimize hazards by chemicals and are known as risk management. Doing this, we must identify hazards (e.g., a flammable liquid), their opportunity (chance of the formation of an inflammable atmosphere), and harm (explosion, fire). By weighing the evidence on the hazard, opportunity, and harm, we can choose appropriate safety measures (ventilation, absence of ignition sources) to protect us from the hazard.

## Risk Management

One part of risk management is risk assessment, which should be carried out before handling hazardous chemicals. The risk assessment includes the identification of hazardous chemicals in the workplace, the activities involving those chemicals, and the possible ways in which those chemicals could cause harm to humans. The purpose of a suitable and sufficient risk assessment is the determination of measures to eliminate or reduce the risks and exposure originating from these chemicals as much as it is reasonably practicable.

The risk assessment should consider the following parameters:

- The hazardous properties of the chemical (e.g., the information on the safety data sheet)
- The specific circumstances of the work with hazardous chemicals
- The amount of the chemicals involved
- The precautions for safe handling, storage, transport, and disposal of hazardous chemicals and any waste materials
- The likelihood and duration of an explosive atmosphere, the types of ignition sources, and their likelihood (including electrostatic discharges)
- The severity of anticipated effects of any fire or explosion

The purpose of a risk assessment is the determination of measures to eliminate or reduce the risks and exposure originating from these chemicals as much as it is reasonably practicable. Risk management typically includes strategies that avoid the risk and reduce the probability or the negative effect of the risk. One strategy could be the application of the so-called **STOP** principle (Table 1). **STOP** stands for **S**ubstitution, **T**echnical and **O**rganizational measures and **P**ersonal protective equipment. The **STOP** principles should be followed from top to bottom.

**Table 1** Risk management according to the **STOP** (Substitution, Technical and Organizational measures and Personal protective equipment) principle

Principle	Background	Example
Substitution	Can a hazardous chemical be substituted with less hazardous or harmless chemical?	Substitution of benzene with toluene
Technical measures	If a hazardous chemical cannot be substituted, which technical measures can reduce or eliminate the potential exposure or hazard?	Flammable liquids should be handled in the absence of ignition sources and in a well-vented area (e.g., fume hood)
Organizational measures	If technical measures cannot be applied, can the work be organized in a way that reduces or eliminates the potential exposure or hazard?	Reducing the amount of flammable liquids handled at the same time to prevent the formation of an explosive atmosphere
Personal protective equipment	How can the individual hazard risk be reduced to a minimum?	The use of appropriate protective gloves during the handling of hazardous chemicals

## Substance Information and Labeling

This section provides information for the identification of health risks posed by a chemical. It reviews how chemicals are classified and where helpful information can be found. In general, all laboratory containers with chemicals should be clearly labeled and identifiable.

### Globally Harmonized System of Classification, Labeling, and Packaging of Chemicals (GHS)

The United Nations' Globally Harmonized System of Classification, Labeling, and Packaging of Chemicals (GHS) is a globally uniform system for the classification of chemicals and their labeling on packaging and in safety data sheets (GHS Implementation 2020). The EU implemented the United Nations' GHS into EU law as the CLP (Classification, Labeling, and Packaging) Regulation, the US as the Occupational Safety and Health Administration (OSHA) standards. To date, most major countries adopted the GHS. The GHS ensures that a harmful chemical or product can be identified and is marked with a hazard pictogram, a signal word (e.g. danger) if necessary, hazard and precautionary statements, and information about the supplier.

### Hazard Pictograms

Unique hazard pictograms (Table 2) enable an intuitive and immediate recognition of dangers posed from a chemical. Specific pictograms warn of physical dangers (e.g., explosive, flammable), health hazards (e.g., toxic, health hazard), and environmental hazards. Additionally, there are specific pictograms for the transportation of hazardous chemicals.

**Table 2** GHS hazard pictograms used for rapid hazard identification

Symbol	Code	Hazard category
	GHS01	Instable explosive substances, mixtures, and products with explosives, self-reactive substances and mixtures, organic peroxides
	GHS02	Flammable, self-heating, self-reactive, pyrophoric, water-reactive, organic peroxides
	GHS03	Oxidizing
	GHS04	Gases under pressure, compressed, liquefied, frozen, dissolved gases
	GHS05	Corrosive to metals, corrosive to skin, severe eye damage
	GHS06	Acute toxicity
	GHS07	Caution (in combination with other hazard pictograms)
	GHS08	Multiple health hazards
	GHS09	Harmful to the environment

## **Hazard (H) and Precautionary (P) Statements**

Within the GHS, H/P statements replaced the former Risk and Safety statements (R/S statements). H statements describe the type and the severity of danger posed by a hazardous chemical or mixture. The P statements describe recommended measures to limit or avoid harmful effects due to exposure to a hazardous chemical or mixture during use or disposal.

H statements can be grouped into physical hazards (H200 to H290), health hazards (H300 to H373), and environmental hazards (H400 to 420). Additionally, there are country specific H statements for the EU (EUH001 to EUH401) and Australia (AUH001 to AUH071). Physical hazards can be explosions, fires, and corrosion of metals. Health hazards describe the health effect (harmful, toxic, fatal, sensitizing, and carcinogenic), target organ (eye, skin, and lung), and the route of exposure (ingestion, skin contact, and inhalation) of a chemical. Environmental hazards describe effects on aquatic life and public health.

P statements can be grouped into general precautionary statements (P101 to P103), prevention statements (P201 to P284), response precautionary statements (P301 to P391), storage precautionary statements (P401 to P422), and disposal precautionary statements (P501). General P statements request to have the container at hand if medical advice is needed, to keep chemicals away from children and to read the label before use. Prevention P statements serve as a guideline to prevent adverse effects, for example, by only using a chemical in a well-ventilated area or outdoors. Response P statements describe specific instructions after exposure or other chemical-related incidents such as a fire, for example, to rinse the skin after contact with hazardous chemical. Storage P statements include requirements for the proper storage of chemicals, for example, to store a chemical in a dry place or in a closed container.

In many cases, multiple H and P statements apply. For instance, the combination of H302 (Harmful if swallowed) and H332 (Harmful if inhaled) results in H302+332 (Harmful if swallowed or if inhaled), the combination P235 (Keep cool) and P410 (Protect from sunlight) results in P235+410 (Keep cool, protect from sunlight).

## **Safety Data Sheets (SDS) and Operating Instructions**

The SDS, sometimes also referred to as material safety data sheet (MSDS), or product safety data sheet (PSDS), lists information related to occupational safety and health. For every commercially available chemical or mixture, a SDS must be provided by the manufacturer. They assist professional users with important data and handling recommendations when dealing with chemicals and mixtures in order to be able to take necessary measures for health protection, occupational safety and environmental protection. It is mandatory to consult the SDS before handling a hazardous chemical or mixture. A SDS must be made available as long as the chemical is used or stored in the laboratory or workplace. Safety data sheets consist of multiple sections. Among other information, they inform about possible hazards and include hazard pictograms as well as H and P statements (section 2), describe first aid measures (section 4), and recommend actions for firefighting and after

unintended release (sections 5 and 6). Furthermore, they contain information about handling and storage (section 7), toxicological information (section 11 and 12) as well as statements about transportation of hazardous chemicals.

Based on the SDS, operating instructions are generated for any chemical or biological agent and their mixtures based on their specific use in laboratories or work places. In contrast to a manual, operating instructions solely indicate hazards and protective measures. They contain information about the specific use, hazards to humans and the environment, safety precautions, and measures. SDS as well as operating instructions must be provided to everyone working with hazardous chemicals.

## Handling

Before working with hazardous chemicals, it should be evaluated if and how a safe handling can be ensured. This includes technical protective measures at the workplace, appropriate personal protective equipment, and emergency procedures in case of accidents.

*Technical Protective Measures:* Hazards in laboratories and other chemical workplaces can be prevented significantly by an appropriately designed and equipped workplace. This includes structural measures, the building infrastructure, laboratory and safety equipment and the properties of devices, apparatus, and other appliances. An unsuitable workplace situation can increase the risk of accidents as well as if the accidental release of hazardous materials. Ideally, laboratories should have a documentation area where written work is physically separated from chemical work. The workplace must be equipped with an adequate number of escape routes, exits, and emergency showers that reflects the local conditions as well as the materials and work methods used. Floors, their coverings, and cable conduits must be watertight to prevent chemicals that have been spilled seeping away unnoticed before they can be removed. The same applies to workbenches. Additionally, they should be resistant to chemical and thermal stress.

Laboratories and workplaces must be equipped with technical capacities that ensure adequate ventilation at all times. Fume hoods should be preferably used when working with hazardous chemicals. They are typically enclosing five sides of a work area and commonly located at a standing work height. Fume hoods prevent that (a) gases, vapors, and dusts in hazardous concentrations or quantities enter the laboratory from inside the fume hood, (b) the formation of explosive atmospheres inside the fume hood, and (c) the splashing hazardous materials or flying broken glass. Fume hoods must be made of materials that withstand mechanical, chemical, and thermal stressors and be equipped with a sash that should be closed when the fume hood is not in use.

*Personal Protective Equipment:* The use of personal protective equipment (PPE) depends on the work procedures and chemicals used. The selection of PPE should be determined before starting to work with chemicals. The PPE can consist of sturdy footwear, a lab coat, and protective glasses. The lab coat should be made of a fire-

resistant material. The use of additional PPE, such as protective gloves, should be according to the properties of the used chemicals. For example, depending on the physicochemical properties of an organic solvent, protective gloves specified for the handling of the respective solvent should be used. Otherwise, the safe use cannot be guaranteed.

*Emergency Procedures* – Everyone working with hazardous chemicals should become familiar with the local emergency procedures. This includes emergency escape routes, the location of emergency showers, and fire extinguishers and related precautions. Escape and rescue plans with clear instructions should be placed at strategic, visible locations and followed in case of an emergency. The supervisors are responsible for ensuring that the number of people working is known and be consulted in the event of an emergency.

## Storage

All hazardous chemicals should be kept at appropriate storage locations with the correct labeling. A chemical inventory management system, which as a minimum includes an inventory list, helps to monitor chemicals on a regular basis. Safety Data Sheets (SDS) must be readily available for all hazardous chemicals stored, and these should be referred to for advice on storage, accidental release measures, and incompatibilities. Storage spaces for hazardous chemicals must be connected to an exhaust air. The interior of these storage spaces must be lined with material that does not burn easily. In the case of hazardous liquids, an adequately dimensioned collection pan must be located below the containers. Flammable liquids should be stored in solvent cabinets, compressed gases in gas cabinets. Hazardous chemicals used and stored outside of designated storage locations, for example, at a workbench, should be reduced to the amounts needed for the current work or experiment.

Incompatible chemicals should be segregated to avoid accidental adverse reactions that may occur due to container breakage in the storage areas. For the segregation of chemicals, all hazardous properties have to be identified (see above). Quantities of chemicals should be kept to a minimum and any bulk quantities of individual chemicals may be stored at external facilities (e.g., central chemical storage). The following table provides a general segregation scheme for the storage of selected chemical groups (Table 3).

## Disposal

The generation of hazardous waste should be avoided as much as possible. This should be considered when planning experiments and work with hazardous chemicals. All hazardous waste should be kept at appropriate waste storage locations. Storage spaces for hazardous waste must be connected to an exhaust air. The interior of these waste storage spaces must be lined with material that

**Table 3** Segregation scheme for the storage of selected chemical groups (green: compatible; red: incompatible, must be segregated).

	Flammable liquids	Oxidizers	Organic acids	Inorganic acids	Bases
Flammable liquids	Green	Red	Green	Red	Green
Oxidizers	Red	Green	Red	Green	Green
Organic acids	Green	Red	Green	Red	Red
Inorganic acids	Red	Green	Red	Green	Red
Bases	Green	Green	Red	Red	Green

does not burn easily. In the case of hazardous liquid waste, an adequately dimensioned collection pan must be located below the containers. Similarly, to the storage of chemicals, hazardous waste should be segregated in compatible groups and clearly labeled according to its content. The disposal of hazardous chemicals should be according to the guidelines of the company as well as federal regulations. Waste storage places should be checked for leakage or spills on a regular basis. The waste containers should be picked up or disposed by internal or external waste management personnel as soon as local storage locations reach their official capacities.

### Implementing Chemical Safety at Work

Country-specific laws and regulations require employers and employees to follow chemical safety rules. It is the employer's duty to determine whether the employees carry out activities with hazardous chemicals or whether hazardous chemicals can be released during workplace activities. If the employer does not have the necessary knowledge to carry out the risk assessment himself, he is obliged to seek expert advice. For this, the employer can appoint a knowledgeable person as a representative for hazardous substances. The central task of the hazardous substances officer is to advise the employer, but also employees, on all questions relating to the handling of hazardous substances and to carry out a risk

assessment. In order to be able to perform the tasks as a hazardous substances officer, he must have the appropriate knowledge. This includes:

- Regulations of chemicals (GHS)
- Safe handling of hazardous chemicals
- Storage and internal transport of hazardous chemicals
- Labeling of hazardous chemicals
- Operation instructions and safety data sheets
- Behavior and measures in the event of accidents

All employees should receive proper chemical safety training by the employer or the hazardous substances officer before working with hazardous chemicals. Chemical safety trainings should be repeated on a regular basis, for example, once a year, to refresh knowledge and provide updated information. It should include general information as described above but also workplace-specific information.

## Good Laboratory Practice

Good Laboratory Practice (GLP) is a formal framework by the Organization for Economic Co-operation and Development (OECD) for the nonclinical safety testing of chemicals, pharmaceuticals, pesticides, and food additives (OECD 2020). GLP is required by law in many countries if the results of the tests will be used to assess the possible dangers for humans and the environment in the course of an approval, permission, and registration or communication process. The implementation and regulation is carried out by national authorities. In contrast to safety measures, GLP ensures the uniformity, consistency, reliability, reproducibility, quality, and integrity of the tests. It determines the organizational processes and the conditions under which laboratory tests are planned, carried out, and monitored. It also includes guidelines for recording and reporting of results.

---

## Summary

This chapter provides basic information of how to identify risks by hazardous chemicals at the workplace. However, every process or experiment takes place under conditions that are specific for the individual workplace. Although there are general concepts for chemical safety, each potential risk posed by a hazardous chemical should be assessed by an individual risk assessment. Furthermore, each individual employer and employee should familiarize themselves with the risks associated with chemicals used in a specific process and should have access to relevant information about safe handling of chemicals. They also have to keep in mind that working with hazardous chemicals always involves some degree of risk and that a concerted effort is necessary to reduce potential exposure and dangers to human and environmental safety to a minimum.

## Abstract

Since people live together, they must try to answer the question whether what they do causes a risk to others. When people live in proximity to one another, society sets goals. These include avoidance of creating unnecessary risks to others, minimization of unavoidable risks, and seeking to make the residual risks as predictable as possible. However, what one person perceives as a necessary risk or an evil that should be tolerated may be considered by others as a threat. In regulatory toxicology, this phenomenon must be considered when determining courses of action.

**Introduction**

Many risks are associated with human activity. When the consequences of an activity are uncertain, this activity may be beneficial or it may be harmful (cause detriments). The concepts of risk and benefit characterize the consequences of any action. Risk involves a probability statement, the likelihood or frequency of the event occurring or the effect being observed, as well as a quantitative statement, identifying the extent and type of harm (detriment).

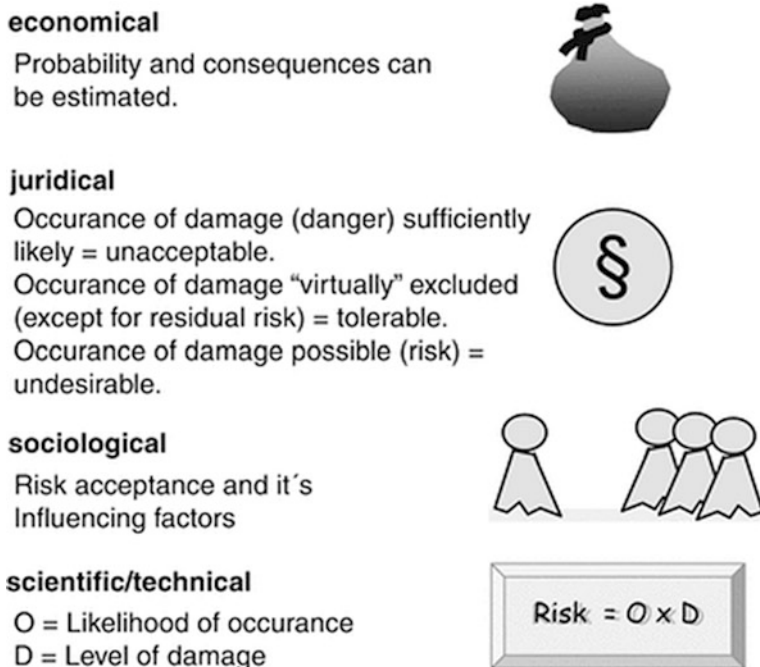

Damage (harm, detriment) has occurred when a physical or functional impairment is recognized to be the result of an activity. Damage can be determined only on a relative scale; for the toxicologist, this is the ill-health effects (including death), either on humans or on other species. In addition to acute damage and possible harmful effects visible only after prolonged or repeated dosing or in successive generations (e.g., cancer or detrimental effects on reproduction and development of offspring), reversibility of the damage must be included in an overall assessment. An internationally accepted standard methodology for quantifying damage is not yet available, although quantification is being attempted using methods based on direct monetary values and on values associated with particular effects in terms of quality of life for those harmed.

---

**History of the Risk Term**

The concept of risk has its origins in Italy and symbolizes semantically the process of venturesome circumnavigating a cliff. If you want to capture the historical dimension of the concept of risk, you will find the first hints of a deliberative decision-making in the ancient skeptics. In Pharisaic Judaism from 500 AD on, the text of the Bible and tradition were interpreted according to the requirements of the situation. Probability was considered but without the ability to undertake calculations of probability. In Europe until the late Middle Ages, the Christian personality was so dominated by religious forces that he or she was not able to make a free decision between alternatives that would be based on his own power and conviction.

The first systematic solution to a probability problem, that of playing dice, was recorded in the correspondence between Fermat and Pascal in 1654. At the beginning of the Enlightenment, Thomasius gave a hint that decision-making requires “courage and boldness.” In overcoming medieval thinking (or lack of thinking) concerning both the continuing craft skills and the explicability of natural phenomena, there was a need to see the development of technology as purposeful. Ground-breaking is the invention of the lightning rod in 1752, which put the people in a

**Fig. 1** Dimensions of risk

position to protect their property during a thunderstorm. The realization that the lightning strike is no longer solely an act of God but a manageable phenomenon led to the analysis of other events which were previously considered as uncontrollable. It certainly was of importance that Jesuitical casuistry was taken up as part of the general philosophy of science. Once this had happened, it was possible to develop the modern concept of risk, based on mathematical descriptions of phenomena and probability theory. Today, the term “risk” is used with varying meanings in economic, legal, sociological, and scientific/technical fields (Fig. 1).

## Dimensions of the Concept of Risk

**Economically** speaking, decisions can be made with uncertainty concerning the risk being taken: We call it uncertainty when all the possible consequences of an action are known, but the actual outcome is uncertain. If, in addition, the likelihood of occurrence is known, we call it “risk.”

The economic benefits of an activity can be optimized when one of several options for action is preferred, namely the one in which the desired sequence of actions occurs with the highest probability. The risk of being confronted with undesirable consequences of action may be low in this case but still exists. This

approach can be demonstrated using examples based on the successes (or otherwise) of different investment strategies.

**Legal perspectives** on the concept of risk will depend on the jurisdiction. From a German legal perspective, the concept of risk can be made clear, as it is distinct from the terms danger and residual risk. The term “danger” comes from the police law. There, the consequences of an action or activity must result with reasonable certainty in unacceptable damage. In our society, the state is obliged to avert such danger. This is the basis of laws that society has imposed on itself; the concept of danger is therefore defined by society. It also has important significance in safety and environmental legislation. When one speaks of a residual risk, absolute certainty is not given, and the non-excludable damage is accepted.

When there is a risk, a detrimental event cannot be excluded. Such a consequence is undesirable but still possible. If the damage is likely to be delayed, severe, and/or irrecoverable, the risk should be minimized by minimizing exposure (this is a statement of one form of the precautionary principle).

**Sociologists and psychologists** analyze how society and individuals deal with risk and with the insecurity and uncertainty of the consequence of an action. They are essentially concerned with the ways in which different groups within society perceive risks. The risk discussion is mainly concerned with risk acceptability. Often scientists are thought to deal in objective (or numerical) risk and the general public to consider risk in a subjective or judgmental manner. Depending on the perspective, the consequences of an action are considered by some sociological groups as manageable risk and by others as a threatening danger (others may feel unaffected by the risk); affected people articulate their concerns. Often, the residual risk is considered unacceptable by some or many of these groups of individuals, and they may then participate in public discussion of an issue in order to influence wider opinion.

The **scientific/technological** risk concept defines risk as the product of the extent of damage (disease/danger) and probability or frequency of the event occurring. From this simplified mathematical formula, a continuous description of all possible risk scenarios can be derived due to the variability of the factors. Here, risk is quantifiable. The Division of Toxicology of the IUPAC (International Union of Pure and Applied Chemistry) in its Glossary (IUPAC 2017) gives definition of risk: (1) the probability of adverse effects and (2) the expected severity of an adverse effect. In regulatory toxicology, the distinction between hazard (potential danger) and risk is of great practical importance.

The qualitative description of the harmful effects, imposed by a substance (inherent toxicity, hazard), is used to characterize and classify this material. As part of the IOMC (Inter-Organization Program for the Sound Management of Chemicals), the “United Nations Globally Harmonized System of the Classification and Labeling of Chemicals” (GHS) was adopted in 2002 after long discussion. GHS has the purpose to contribute to the worldwide harmonization of national communications systems on hazards posed by chemicals and thus protect people and the environment worldwide. This was based on the UN Recommendations on the

Transport of Dangerous Goods and the earlier classification and labeling systems in the EU, the USA, and Canada. Harmonized were criteria for the classification and definitions of risk potentials of substances and formulations and the elements of labeling. Most of the GHS has been formally enacted in the European Union through EU Regulation 1272/2008 (the Classification and Labeling Regulation).

To define the toxicological risk posed by the substance, its toxicity expressed as a dose–response assessment is combined with the likelihood of exposure. If an exposure is expected that would lead to an adverse effect on basis of the dose–response relationship, the risk can be quantified.

---

## Quantification of Probability

The risk is associated with the likelihood or frequency of exposure(s) of at least a certain duration and magnitude taking place. Such a concept of probability is difficult to describe objectively, although quantification is conducted, for example, using empirical statistics. This differentiates the term “probability” from the term “suspicion.” When trying to quantify, both the variability that is the actual scattering of quantifiable parameters and the uncertainty that is the uncertainty of the examiner must be considered.

**Variability** is the actual heterogeneity of the studied parameters; thus, it affects the accuracy of a statement. **Uncertainty**, however, can lead to false statements because it includes not only statements concerning the reliability and adequacy of a validating study at identifying and quantifying known effects but also includes allowance for possible inadequately quantified and nonidentified detrimental effects.

It is important for the further action of the toxicologists that different consequences result from variability and uncertainty. Often, uncertainties can be reduced by undertaking additional tests or involvement of additional expertise, although there is always the possibility of nonidentified effects being unknown effects appearing for the first time. Variability cannot be eliminated, however, and therefore prompts the regulatory toxicologists to adjust his protective measures, when a certain level of safety is to be maintained.

---

## Risk Comparison

Often it is not enough for regulatory toxicologists to describe the risk posed by a substance, but it is also necessary to compare the risk with that of potential “substitutes.” For this, detailed information about the **toxicological potency** of different substances is required.

In the derivation of parameters, one has to distinguish between those substances for which a threshold can be specified on the dose–response relationship and those substances for which such a threshold is considered inappropriate. One threshold measure is the acceptable daily intake (ADI). Originally, the ADI was for food

additives and then pesticides. It is the maximum level, according to present knowledge, considered to exclude a risk even when the consumer is exposed daily during his lifetime. The corresponding parameter for industrial chemicals is the “derived no effect level.” These are obtained by applying standardized factors to a parameter such as the “no observed adverse effect level” or the “benchmark dose.” For substances for which no threshold dose can be determined, there are several approaches. One, the unit risk and potency factor were originally introduced by the US EPA (1986). The dose descriptor T 25 can be applied to create a potency factor. T 25 is defined as the dose (in mg/kg body weight/day), which causes a tumor incidence of 25% in experimental animals after lifetime exposure. This value can be converted to the corresponding human HT 25 by being divided by an appropriate “scaling factor.” This metabolically and physiologically legitimated factor is derived from the comparison of metabolic rates. The third approach is to estimate a “derived minimal effect level” using, as the starting point for extrapolation, a dose at which no excess of tumors was experimentally detectable.

Just as the concept of risk can be understood in different ways, so the perception of risk is possibly different and subjective. The broad approach, which the sociological risk discourse opens, allows for the conclusion that a comparative risk assessment and evaluation is only effective if all the discourse participants have similar basic attitudes (e.g., social background, education, interests, similar life experiences, lifestyles, and desired goals in life).

A comparative examination of the risk posed by, for example, a defined household chemical with the risk posed by a substitute can be used meaningfully if effects and exposure scenarios are directly comparable. Whether different less serious and reversible toxic effects are equivalent may need discussing. Due to methodological problems (e.g., the classic “apples versus pears” scenario as in comparing, e.g., death from smoking cigarettes vs. prize in the lottery), there are limitations when undertaking these comparisons (but see ► [Chaps. 58, “Risk Comparison in Toxicology,”](#) and ► [59, “Risk-Benefit Considerations in Toxicology”](#)).

---

## Phantom Risk

The different perceptions of risk can lead to a phenomenon that is described by the term **phantom risk**. In general, this means that different assumptions about risky cause–effect relationships are made, which may remain unprovable. Such an approach may result in an assessment that unduly increases a potential risk (exaggerated fears). Similarly, new information that is made available often leads initially to an exaggerated perception, in which the risk appears greater than it actually turns out to be later. To what extent this behavior is phylogenetically useful to sustain human life during evolution, and thus is largely unalterable, remains to be established. However, the regulatory toxicologist has to take into account this phenomenon since it directly influences the general political decision on the classification of a risk, be it unacceptable or undesirable, although it cannot be proven on a rational basis.

---

## Dealing with the Concept of Risk

Both the definition of “risk” and the methodological processes that must be applied when dealing with questions of risk management are dependent on expert judgments. Thus, although the GHS system can provide a basis for common judgments concerning the hazard, one cannot assume that the same legal base for managing the risks will pertain internationally. In the event that no binding requirements/laws exist, all aspects of the decision finding must be presented as far as possible in a transparent way. New forms of chemistry-related global challenges will be identified. Examples are the control of atmospheric chemicals and of climate change, safe handling of toxic metals in novel electrical devices, new technologies to recycle plastic and garbage or the development of safe drugs/vaccines against newly identified infectious disease. Toxicologists (including environmental toxicologists) are accustomed to analyze and understand complex systems. Both now and in the future an understanding of risk assessment and risk management methodologies will be important when seeking sustainable development.

### Abstract

Physicochemical parameters are indicators for the identity and purity of a substance. Molecular size, surface charge, lipid and water solubility, vapor pressure, and other properties affect routes of human exposure and toxicokinetics. Volatility and resistance to environmental degradation are important causes of environmental distribution and persistence, and, combined with lipophilicity, they constitute a risk for bioaccumulation. This contribution describes basic physicochemical characteristics and provides examples of their relevance to toxicology.

---

## Introduction

Each chemical has a large number of characteristic physicochemical and physical features that define its identity as a unique substance. Such features include size, charge, solubility, and many more. Physicochemical properties codetermine the routes and extent of exposure, toxicokinetics in the human organism, and (adverse) interaction with biomolecules. Moreover, physicochemical parameters are important determinants for the fate of a substance in the environment, in essence distribution and persistence. Therefore, knowledge of physicochemical and physical parameters is important in all areas of pure and applied toxicology.

Guidelines concerning physicochemical requirements and testing are available for pharmaceuticals, for example, from the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH 2020), as well as national and supranational pharmacopoeias. Testing guidelines for physicochemical parameters of chemicals are part of the internationally harmonized guidelines of OECD (OECD 2020), and physicochemical features are integrated in the Hazard and Precautionary Statements of the Globally Harmonized System (GHS 2020) and in Safety Data Sheets. The appropriate interpretation of physicochemical properties, adapted to the situation or scenario, is an essential component of toxicological risk assessment and a basis of regulatory toxicology.

## State of Matter

Under environmental conditions, relevant to toxicology, one commonly differentiates among three states of matter: solid, liquid, and gaseous; the transition from one state to another is dependent on pressure and temperature. Molecules in a solid phase cannot move freely due to strong intermolecular interactions. The melting point is the temperature, above which molecules can leave their fixed position, though they are still held together by intermolecular bonding forces, resulting in a liquid.

Above boiling point, the kinetic energies of molecules in a liquid exceed the intermolecular bonding forces; the molecules evaporate into the gaseous space. Some molecules tend to possess sufficient kinetic energy to evaporate even below the boiling point. The vapor pressure of a substance is a parameter that quantifies this tendency.

Information about the state of matter of a substance in question and its transition temperatures is important in toxicology, since it affects the route of exposure. The airways will preferentially be exposed to gases and vapors or dust, skin to liquids, and the gastrointestinal tract to solids and liquids. It is also of consequence for ecological chemistry and ecotoxicology, such as atmospheric transport of volatile and particulate materials and their sedimentation or the migration of a chemical in soil. Here follow some examples:

### Solid Phase

Solid-phase materials may cause risks in different ways, e.g., by overdosing of pharmaceuticals or addictive drugs or ingesting toxins with contaminated food. Skin contact with solid allergenic metals such as chromium or nickel alloys may cause irritation and allergies. Solid implant materials are designed not to release substances (monomers, metals) after implantation, but minor risks remain. Inhalation of solid-phase particles like asbestos fibers, titanium oxide particles, or metal fume at the workplace is associated with lung disease. Solid plastic items may emit volatile ingredients, such as monomers or stabilizers.

### Liquid Phase

Liquid phases may consist of either a single, pure component, such as water, mercury, or an organic substance or a homogenous mixture of a liquid solvent and solutes. To estimate the toxicological hazard of a liquid, it is important to know all the components that it contains.

*Water* represents the most abundant and important hydrophilic liquid. Its bent molecular structure together with the polar bonds between hydrogen, which has a positive partial charge, and the oxygen with negative partial charge makes water a polar molecule with a high dipole moment (1,85 Debye). This is also the origin of the characteristically strong tendency for hydrogen bonding of water molecules. Water

hydrolyzes solid organic molecules like sugars and many solid salts (e.g., sodium chloride) via electrostatic interactions and dissociates the latter into dissolved anions and cations, characterized by the dissociation constant that determines the ratio of dissociated molecules under specified conditions.

*Organic liquids*, such as octane, propanol, or acetone, are liquids at ambient temperature and are suitable solvents for many solid and organic substances or diluents for other liquid organic compounds. Lipophilic organic molecules typically interact with neighboring molecules via weak Van der Waals forces.

## Gaseous Phase

Though the ambient air consists predominantly of the gaseous components dioxygen and dinitrogen, it also carries smaller amounts of other gaseous materials, volatile liquid molecules, liquid aerosols (fumes), and solid ultrafine particles (dust) of natural and anthropogenic origin. Synthesized toxic gases (e.g., ammonia, phosgene, chlorine, carbon monoxide) that may be released into the ambient air during a chemical reaction or from a defective gas container constitute a sometimes unnoticed risk.

---

## Structural Aspects

Molecular size or composition by itself is only poorly associated with toxicity. One finds very toxic agents among “small organic molecules” (e.g., carbon monoxide, benzene) or large molecules (e.g., botulinum toxin protein) as well as among multimolecular ultrafine particles (e.g., asbestos).

## Small Organic Molecules

The majority of industrial organic chemicals and therapeutic drugs are small organic molecules (< about 600 Dalton). Their molecular composition and positions of side chains and functional groups largely determine their individuality and their chemical name according to the rules of the International Union of Pure and Applied Chemistry (IUPAC 2020). Features such as chirality may decide about their interactions in a three-dimensional molecular surrounding, such as the binding pocket of a protein: one stereoisomer often exhibits much higher binding affinity than the other.

In the organism, most small xenobiotic molecules do not simply move according to physicochemical rules (see below). In the blood, they tend to bind to plasma proteins, notably albumin. They can be carried across cell membranes via organic cation transporters (OCT), organic anion transporters (OAT), or ABC transporters. Most small molecules are metabolized by biotransformation enzymes, which results in a change or loss of biological activity and altered physicochemical features of the products. Sometimes biotransformation involves reactive intermediates that are

genotoxic and cell toxic. Small molecules with a diameter of less than 6–8 nm fit through the renal glomerular filtration apparatus often followed by either reabsorption or secretion in the primary urine. Another elimination route, used by many conjugated metabolites, is via active transporters on the canalicular membrane from the liver cell into bile.

## Organic Macromolecules

Organic polymers, whether engineered or of biological origin, are composed of repeating molecular units (monomers), arranged as linear or branched chains. The chains self-associate also via non-covalent bonds and entanglement.

Most synthetic polymers are nondigestible in the intestinal tract. Nevertheless, they pose a health concern, when residual monomers or stabilizers are released, for example, from indoor plastic materials into the surrounding air (e.g., in automobiles) or from drinking bottles into the drink or from infusion tubes into the fluids. Many plastic materials that are disposed of in the environment tend to be quite resistant to chemical decomposition and get physically torn into tiny pieces to "microplastic," which constitutes a huge environmental problem and a threat to sea life. Incineration of polyvinylchloride, or other plastic material in combination with chlorine, is associated with formation of polychlorinated dibenzodioxins (PCDD).

## Biopolymers

Biopolymers are of utmost importance in toxicology, firstly, as targets of many toxic actions and, secondly, as biopharmaceuticals that must be toxicologically characterized before getting to the market. The major groups of polymeric biomolecules are proteins, deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and carbohydrates.

Proteins are large molecules, based on a set of 20 different amino acids connected linearly in a genetically determined sequence (primary structure). When they are synthesized, chaperons support the normal folding of the polypeptide chains, which results in secondary structure like beta-sheet, folded tertiary structure, and spatial motives like the beta barrel. In addition, many proteins get modified with phosphate, lipid, or carbohydrate groups. These additional modifications are required to (in) activate them or direct them to a particular location within the cell. Proteins have binding sites to interact with other biomolecules.

Dietary proteins get degraded by gastrointestinal proteases, however not always completely. Some proteins are protected from digestive proteases, as in the case of botulinum neurotoxin, or of wheat gluten, the latter causing immunological intestinal disease (celiac disease) in predisposed persons. Proteins (of pollen, house mites, animal hair) may have epitopes that make them allergenic. Cyclic peptides occur in mold, some are known for toxicity (amanitin, phalloidin), and others are used as therapeutics to suppress immune reactions (cyclosporine). The bacterial AB toxins (e.g., botulinum toxin) typically consist of two proteins, one anchoring to surface

components on the target cell and inducing endocytosis into the cell where the other component then exhibits destructive enzymatic activity.

Double-stranded deoxyribonucleic acid (DNA) in the cell nucleus consists of two corresponding DNA strands each composed of a set of four DNA-specific nucleotides; the two chains are stabilized by weak chemical forces between the corresponding base pairs. The very long DNA strand is organized in nucleosomes, where DNA is wound around histone proteins. DNA is the target of genotoxicity. When DNA is ingested as a normal nutritional component, the strands are split into nucleotides that may be absorbed, and it has no role as toxic agent (except in the form of DNA viruses).

Human ribonucleic acids (RNAs) are single-stranded ribonucleotide polymers, each characterized by the sequence of its nucleotides, length, and types of folding. RNAs occur as carriers (m-RNA) and decoders (t-RNA) of genetic information from DNA to protein, as structural component of ribosomes, and as regulators of protein synthesis (mi-RNA). The development of RNA-based therapies and vaccines will afford a toxicological characterization of the RNA *in vitro* and *in vivo*, an emerging new field for toxicology.

Carbohydrate polymers occur in plant-derived nutrients as digestible starch, partly digestible oligosaccharides, and nondigestible cellulose. Glycogen is a branched biopolymer consisting of glucose units, predominantly stored in liver and muscle cells as rapidly available glucose (energy) source.

## Particles and Nanoparticles

Fine particles in the air appear as dust. In an occupational situation, dust may be composed primarily of a single material, such as asbestos or silicon dioxide. But in the broader environment, fine particles originate from many different sources, such as volcanic activity, incineration processes, mining, ground erosion, plant pollen, and textiles. In cities, emissions from vehicles, industrial processes, heating systems, and tire abrasions tend to be primary sources, and on New Year's Eve, the hazy air is due to metal-loaded particles released by fireworks. Taken together, atmospheric particles are a mixture of fine particle species of varying composition and sizes that may get inhaled with the air.

Atoms on the surface of a solid material miss a cohesion partner. This deficiency is aggravated in nanoparticles by the curved particle shape that produces a radial tension on surface atoms, which rises surface energy. This augments the tendency to interact with reaction partners. In addition, the total surface also increases with smaller size (Fig. 1).

When inhaled, larger dust particles tend to be held back in the upper pulmonary airways and thereafter transported by ciliated epithelium back up to the pharynx and then swallowed. Smaller particles will reach the bronchioles, and nanoparticles with a size below 100 nm tend to behave like a gas and reach the sensitive alveoli (Tsuda et al. 2013), where extremely thin alveolar cells and adjacent endothelial cells enable gas exchange. Alveolar macrophages that move between the alveolar airway surface

**Fig. 1** Sizes and shapes of fine particles (schematic). The upper panel shows the relationship between particle size, particle number, and particle surface area. The lower panel shows some shapes of engineered nanoparticles

and the interstitial tissue phagocytize particles (Fig. 2a). The macrophages may be able to bring the particle components in solution or to store and finally deposit the particles in the lung tissue, with chronic disease risks for the lung. The overall adverse effect will depend on particle shape, number, solubility, and toxicity of its components (Wittmaack 2007; Graham et al. 2017).

Lung diseases such as metal fume-induced fever, hypersensitivity, silicosis, asbestos-related cancer, and smoking-associated pulmonary disease are well-known toxic outcomes of particle inhalation. There is also evidence for reduced life expectancy in association with high ambient particle concentration.

In order to minimize potential lung toxicity, it is important to analytically monitor particle number, size, and composition in the ambient air. Identification with particle counters, electron microscopy, and chemical analysis must be combined, in order to characterize a specific particle type and, ultimately, to avoid emissions of such particles. It is very difficult to distinguish between particles of different origin and composition in the ambient air, in water, and especially in biological fluids and tissues.

Today, engineered nanoparticles constitute a rising problem. They tend to have a well-defined composition and shape (Fig. 1, lower panel), with known scaffold and surface materials, providing technical advantages. But it remains challenging to predict the long-term toxicity of the various particle types.

**Fig. 2** Physicochemical aspects of inhalation toxicology. (a) Particle transport and deposition in the airways. The route of inhaled particles and their contact site with airway walls is shown in red. Their return transport by mucociliary activity in green. The sites of contact with the airway wall depend on particle size (particulate matter PM, given in micrometers). Larger particles hit the inner surface of the bronchial system by impaction and may then be removed by mucociliary clearance. Particles of intermediate size will get deeper into the airways and deposit there by hydrophilic interactions or electrostatic forces. Ultrafine particles can reach the lowest part of the airways, the alveoles. They may be phagocytized by alveolar macrophages. (b) An inhaled anesthetic is transported with the air stream to the alveoles. It gets absorbed into blood according to its gas/blood partition coefficient. Uptake into the brain and the narcotic effect depend on the blood/lipid partition coefficient. A variety of physiological parameters have modulating effects (see insert). Analogous partition principles apply for many volatile organic solvents

## Density

The density of a material reflects the atom or molecular weight of its components.

*Gas* density sometimes plays a role in inhalation toxicology. For example, carbon dioxide that is formed by microbial activity in a pit may accumulate near the bottom, favored by the higher density (about 1.6-fold) of carbon dioxide compared to the mean density of air. Likewise, chlorine gas that is released from a defective tank tends to remain near the bottom of poorly ventilated rooms. When radon is emitted from building materials or from the ground, it tends to accumulate in poorly ventilated basements.

The density of fine and ultrafine particles will have an influence on the site of impaction or deposition in the airway system (upper airways, bronchi, or alveoli). The Stokes law describes sedimentation of particles in a fluid. It has been also used to describe the movement of inhaled particles in the bronchial airstream (Tsuda et al. 2013).

---

## Solubility

Solubility is the ability of a substance (solute) to dissolve homogeneously in another substance or medium (solvent). It has a key importance in toxicology. Above the critical concentration, saturation tends to occur and additional solute precipitates or results in a two-phase liquid system. The scale for solubilities ranges from very soluble to slightly soluble or insoluble.

### Solubility in Water

#### Hydrophilic Substances

Due to its polarity and its partial ionization in hydronium plus hydroxide, water is a universal polar solvent. Chemicals that dissolve well in water are termed hydrophilic. Solid hydrophilic substances that are brought in contact with water will be subject to the process of solvation, which is the interaction of water molecules with the surfaces of the solid substance (hydration). Nonionic substances, like monosaccharide molecules, will form hydrogen bonds between the hydroxyl groups of the sugar molecule and the surrounding water molecules, thus bringing the sugar in solution. In the case of salts, water molecules induce a solvation process that leads to a dissociation of the anions from the cations, both being freely dissolved in water.

#### Lipophilic Substances

Organic molecules that lack hydrophilic functional groups are lipophilic (hydrophobic) substances. They are, at best, very poorly soluble in water. Intermolecular chemical forces between the polar water molecules are much stronger than those between water molecules and very lipophilic organic molecules, and thus water will “exclude” the organic molecules. Therefore, solid lipophilic substances will not dissolve in an aqueous phase, and liquid lipophilic chemicals will form a water/lipid biphasic liquid system. Depending on composition, the latter can be a system with two completely separated phases or an emulsion (like milk).

### Solubility in Lipid Environment

Ethanol belongs to those substances that are miscible with water as well as with many organic solvents. Organic molecules that lack hydrophilic groups will be soluble in organic solvents but poorly soluble in water.

## **n-Octanol/Water Partition**

To characterize a test substance with regard to hydrophilic/lipophilic properties, the substance is introduced into a two-phase system consisting of water and an organic solvent that do not mix. The n-octanol/water biphasic system (Kramer et al. 2020) is simple and very common in pharmacology and toxicology. Low amounts of the test substance are added and its distribution between the two phases analyzed and expressed as partition coefficient ( $K_{ow}$ ).  $K_{ow}$  is a unitless number reflecting the ratio of the chemical concentration in the lipophilic phase compared to the aqueous phase. It provides no information about the maximum solubility of the agent in either phase.

## **Amphiphilic Substances**

Amphiphilic substances have a hydrophilic and a lipophilic part. In a two-phase system, they tend to form a thin interphase. Beyond a critical concentration, some amphiphilic substances (e.g., phospholipids) may form monolayered micelles or bilayered liposomes in aqueous solution; many pharmaceutical drugs belong to this group. The various members of the membrane transporter family (SLC22a) in intestine, liver, kidney, and other organs support cellular uptake and/or cellular release of amphiphilic substances and thus have a role in their absorption, elimination, and overall kinetics. Products of phase II biotransformation, like glucuronide- and sulfate conjugates, are amphiphilic and are readily eliminated via the canalicular membrane into bile. In blood, amphiphilic substances are bound to a considerable extent to serum albumin.

## **Virtually Insoluble Substances**

There exist substances that are very insoluble in aqueous as well as lipid environment. When ingested, such substances may pass through the length of the gastrointestinal tract unabsorbed and may be excreted unchanged. Barium sulfate is an example. Despite the toxicity of soluble barium compounds, barium sulfate can be used in gastrointestinal X-ray diagnostics because it is not absorbed.

Nevertheless, virtually insoluble substances are not generally harmless, e.g., when they are inhaled as fine particles (e.g., asbestos fibers) or when they accumulate in the environment (e.g., plastic particles or toxic metals).

## **Surface Adsorption**

Surface adsorption is the feature of a substance in a liquid or gaseous phase to reversibly bind to the surface of solid material. It has a great role in environmental toxicology of soils, because any substance that is applied to agricultural land or spilled on the ground may leak into the ground. Depending on its volatility and solubility, it will gradually be carried with rain water and by capillary forces into

deeper layers. It will adsorb via weak chemical forces on the surfaces of soil particles, usually in a reversible manner. The extent of adsorption depends on soil composition and affects the lag time until the substance is detectable in the ground water. The Langmuir adsorption model describes the physicochemical features of adsorption (van Elteren and Budic 2005).

Atmospheric particles tend to adsorb volatile chemicals, which changes particle features and may be of relevance for the toxicity of inhaled particles.

---

## Osmotic Activity

The organism tightly regulates the osmolarity of body fluids. The sodium-potassium pump in the cell membrane generates, within the cell, an isosmolarity of about 300 mosmolar. Erythrocytes will swell and burst due to osmotic shock when placed in water. But the human skin and mucosal surfaces are quite resistant to varying osmolarities of aqueous liquids. The luminal side of gastrointestinal epithelial cells is protected by an “unstirred layer,” mucous layer, and an acid microclimate. This, together with the ion pumps on the brush border membranes, enables the cells to maintain their osmotic environment even when the osmotic activity in the intestinal lumen changes after food intake.

Osmotically active agents such as albumin and sometimes dextrose are used in intensive care to expand a shrunken blood volume and for keeping the osmotic pressure in a physiological range, thus compensating for losses of the osmotically important blood proteins.

And intravenous mannose reduces cerebral edema due to its osmotic activity. Mannose also serves as osmotic diuretic.

---

## Volatility, Vapor Pressure, and Vapor Solubility

Volatile liquids and volatile solid substances release at their surface molecules that have the kinetic energy to evaporate into the gas phase. The tendency to evaporate at a given temperature and pressure is characterized by the “vapor pressure” of the substance, which is also relevant for the reverse reaction, the tendency of the vaporized substance to condense. Volatility and vapor concentrations are of paramount importance for exposure assessment in occupational situations, indoor air pollutions, and industrial accidents.

The equilibrium partition coefficient of a volatile substance describes its distribution between air and water according to Henry’s law, which is of relevance for the pulmonary absorption and organ distribution of volatile organic chemicals. Inhalation anesthetics belong to the best studied substance groups concerning the effects of vapor pressure and vapor solubility on one side and the pharmacokinetics on the other. The well-understood principles governing the behavior of inhalation anesthetics are generally applicable for many lipophilic volatile substances of concern in toxicology.

## Example Anesthetics

Most inhalation anesthetics are liquids at room temperature. They are added in a vaporizer device to the oxygen-gas stream at a certain concentration. The mixture is inhaled by the patient, and the anesthetic will be directed with the gas flow to the absorptive areas of the lung, the alveoli. There, the anesthetic substance has to travel across a space of about 0.8 micrometers consisting of the surfactant lipid layer, the alveolar cell layer, and the neighboring endothelial cell layer before entering the pulmonary capillary blood.

The blood/gas partition coefficient describes the relationship between the concentration of a gaseous substance in the lung alveoli and its concentration in blood under equilibrium conditions. It resembles the water/gas solubility coefficient (Henry's law constant) but deviates from that, due to binding of substances to blood components, notably albumin, lipoproteins, and cells. Very high solubility and strong binding of an anesthetic in blood may have the disadvantage that much of the anesthetic substance will not contribute to achieving pharmacologically effective levels. Once in the blood, the anesthetic will be carried with the circulation to peripheral organs, notably to the well-perfused brain (Fig. 2b).

The second requirement for an inhalation anesthetic is a high blood/oil partition coefficient, which enables it to cross the blood-brain barrier in sufficient amounts to induce a narcotic effect in the central nervous system. A high lipid (oil) solubility of an anesthetic agent is correlated to the potency to induce anesthesia (Pavel et al. 2020).

In conclusion, low solubility in blood is associated with rapid onset of anesthesia.

High solubility in oil is associated with a high "potency," though this type of potency seems to result from a combination of the described kinetic features and molecular mechanisms of action. Other volatile agents, like many organic solvents, follow similar kinetic rules, although their anesthetic efficiency is much lower or missing.

## Example Mercury

The volatility of mercury provides a problem for human health. Beauty ointments that are traditionally used in some countries in Southern Europe to bleach the skin are composed of metallic mercury dissolved in fat. Mercury intoxications have occurred due to the application of these creams onto the skin. They can be diagnosed by mercury-related symptoms and by elevated mercury levels in human blood. It is assumed that absorption of mercury does not occur primarily via the skin route but rather after evaporation of mercury from the cream into the air and subsequent inhalation of the volatile metal by consumers and others in shared living rooms.

When mercury-amalgam fillings of teeth get old and start corroding, tiny amalgam particles will detach and be swallowed unnoticed. Because of the low solubility of mercury amalgams, gastrointestinal mercury absorption from swallowed particles will be quite low. Nevertheless, persons with several corroded amalgam fillings tend

to have increased mercury levels in their blood, compared to control groups. There is some evidence that this is caused by mercury vapor that is emitted from amalgam fillings and absorbed via the inhalation pathway.

## Environmental Relevance

When metallic mercury is spilled indoors and remains undetected, it will gradually evaporate and cause mercury contamination of indoor air. Volatility is also the precondition that allows for the known environmental transport of mercury over long distances. When it settles as sediment, it may get converted by marine and soil microorganisms to methylmercury, which is lipophilic and biomagnifies as toxic substance in the food chain (Fig. 3a). Volatility also plays a role for the risk of polychlorinated biphenyls in sealing materials. Even when applied to sealing joints on the exterior of a building, PCBs that tend to evaporate when the sealing material is exposed to direct sunshine, may enter the indoor air, sediment on indoor surfaces, and thus cause a continuing PCB exposure of persons in those buildings. Moreover, long-distance atmospheric transport causes a global spreading of PCB congeners (Fig. 3b).

---

## Viscosity

Viscosity of a toxic substance may provide serious problems. For example, sulfur mustard, a vesicant that is prohibited by the Chemical Weapons Convention, is a viscous, colorless liquid that, when a person comes into contact, sticks to skin and clothing, is difficult to remove or decontaminate, and will rapidly cause chemical burns.

Viscosity of atmospheric fine particles tends to have an influence on their agglomeration and on the adsorption of volatile substances. Inhaled low-viscosity particles enter deeper into the airways and lungs but get transported back by ciliary action more efficiently compared to particles with higher viscosity. The viscosity of air itself, which, contrary to liquids, increases with increasing temperature, also has an influence on the diffusion of fine particles.

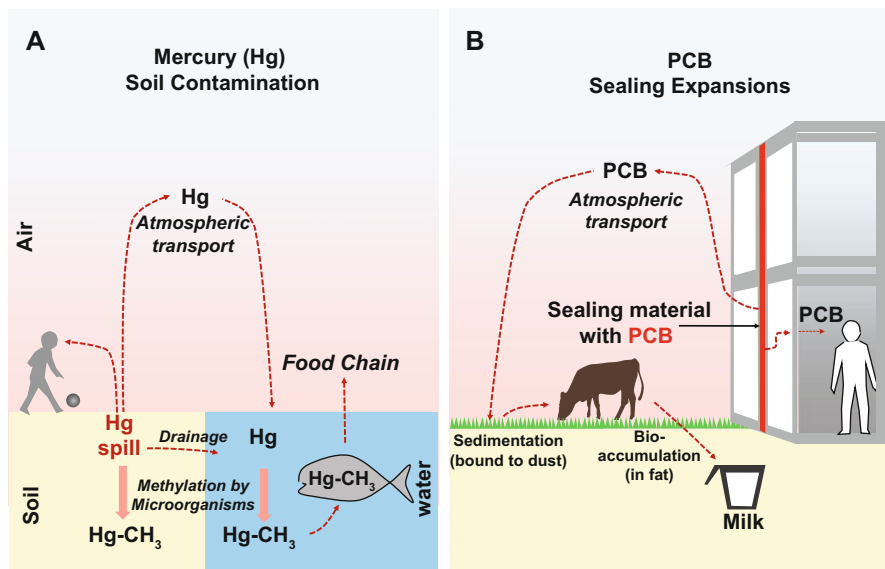

Blood has a higher viscosity, compared to water, due to the blood cells, plasma proteins, and lipoproteins. Increased blood viscosity is a risk for circulatory incidences. Hemodilution can be used therapeutically to correct its abnormal viscosity.

---

## Stability

Any marketed chemical is expected to remain stable during the shelf-life of the product, and higher stability is generally considered a sign of higher quality. Many materials, ranging from plastic foils to food ingredients, get stabilized by suitable additives. Pharmaceutical drugs must undergo long-term measurement of stability at

### Volatility and Pollution ( 2 Examples)

**Fig. 3** Volatility of persistent substances (examples). (a) Metallic mercury (Hg), contaminating the soil, will evaporate with time and cause increased Hg levels in the surrounding air, a possible danger for children. Mercury vapor may also undergo longer-range atmospheric transport and sediment on water. Mercury in the soil and mercury in aquatic systems gets metabolized by microorganisms to lipophilic, toxic methylmercury that tends to get enriched in the lipid fractions of the food chain. (b) Polychlorinated biphenyls (PCBs) in sealing expansions of exterior building walls tend to evaporate over months and years, notably under warmer temperature conditions. PCB vapor tends to enter the building and cause irreversible indoor contamination. Volatile PCBs may also undergo atmospheric transport, and, after sedimenting on the ground, they may be taken up with the feed by cattle and appear in milk

different temperature and humidity conditions to ensure that there will be no loss of activity and no formation of toxic derivatives during storage.

Metals in the environment are physically stable. Chemically, they may undergo oxidation/reduction reactions or get chelated and thus become solubilized; some are methylated by microorganisms (e.g., mercury). Asbestos in building material is quite stable but will corrode with time and release asbestos fibers into the air.

There exist also comparatively stable organic chemicals that decompose in the soil at only a very slow rate. Examples are benzo[a]pyrene and a range of chlorinated aromatic substances including the insecticide DDT, the PCBs, or PCDDs. This high stability in the environment is the cause of ecotoxicologic problems inherent to these persistent chemicals. The so-called throwaway societies will be confronted with a world full of chemical substances, trash, and plastic that do not readily decompose in the environment.

## Heat Sensitivity

Cooking, baking, and frying of food is associated with chemical changes that affect taste and appearance (e.g., Maillard reaction) but may be accompanied by formation of toxicologically relevant side products: Acrylamide occurs as a toxic side product of the reaction of amino acids with carbohydrates. When barbecuing meat, mutagenic and carcinogenic substances may be formed, including benzo[a]pyrene, carcinogenic nitrosamines, and Trp-P-1/ Trp P-2, the pyrolysis products of tryptophan. Eye-irritating acrolein forms when fat (triglyceride) is heated to high temperature; first, glycerol is released by hydrolysis and then dehydrated to acrolein.

## Mechanical Abrasion

The scraping off of material from a solid surface has a number of toxicological aspects, for example, in connection with release of materials from artificial joints and tooth fillings, the abrasion of allergenic nickel from accessories, or abrasion of soot from surfaces during skin contact. Standardized tests for studying abrasion resistance of materials are available.

## Photochemical Instability/Reactivity

*Ecotoxicology*: Sunlight-induced reactivity has several toxicologically relevant aspects:

Photosmog is the result of photochemical reactions among atmospheric components, with involvement of ozone, nitrogen oxides, and aldehydes, catalyzed partly on the surface of fine particles and resulting in formation of peroxyacetyl nitrate (PAN) as one of the irritants and lacrimation-causing agents (Fig. 4a). On the other hand, photochemical destruction plays a positive role in the inactivation of polluting organic chemicals on the surface of soil.

## Photosensitivity

*Phototoxicity* is associated with rapidly appearing skin sensation and blisters that occur, for example, after skin contact with the plant Giant Hogweed and its furanocoumarins, which penetrate the upper layer of the skin and form reactive products under the influence of light, damaging cellular molecules, including DNA, and causing photodermatitis. Sunlight-induced photosensitization and skin rashes are sometimes seen in patients taking certain drugs, such as chloroquine.

## Isotopic Instability

Radioactive isotopes behave chemically (in most cases) like the nonradioactive isotopes of the elements. Potassium in the earth crust and in living cells exists mainly

## Effects of Light and Heat (examples)

**Fig. 4** Effects of light and heat (examples). (a) Schematic drawing showing generation of photosmog by interaction of ambient oxygen with anthropogenic nitrogen oxides (e.g., from vehicle exhausts) and other volatile air pollutants under the influence of sunlight. Peroxyacyl nitrate and related products with airway- and eye-irritating effects are formed. (b) Waste incineration in the presence of chlorinated chemicals such as polyvinylchloride leads to the formation of polychlorinated dibenzodioxins (PCDDs) which get emitted into the outdoor air in cases of insufficient filtration. PCDDs are persistent organic pollutants. They may undergo long-range atmospheric transport, before sedimenting

as stable isotopes (K-39 and K-41). But a very minor fraction (0.01%) is radioactive K-40, which causes some unavoidable internal background radiation.

Medicine uses radioactive elements in diagnostics and in radiotherapy. Moreover, radiolabels (C-14, H-3, and many others) introduced at specific positions of organic molecules are used in pharmacology and toxicology in order to investigate toxicokinetics and biotransformation of the agents.

## Flammability

Flammability is a safety problem in itself. Some substances are subject to auto-ignition; others start burning at the flash point and continue burning at a temperature beyond the fire point. Apart from the direct threat for property and life, a fire has serious toxicological aspects: As soon as a substance burns, gases will develop. For the most part, the oxidation products  $\text{CO}_2$  and  $\text{CO}$  are formed, together with smoke

of varying composition. Both gases are a danger to life, CO<sub>2</sub> causing dizziness and narcosis, and CO displacing oxygen from hemoglobin and producing anoxia.

Flame retardants are added to flammable materials to suppress ignition or slow down fire spreading; some of them act as radical scavengers, inactivating the highly reactive radicals formed in combustion, and thus suppress the chain reaction of heat-induced radical formation and heat production.

Plastic material undergoes thermal degradation under heat, either in the process of pyrolysis (in the absence of oxygen) or of oxidative degradation, leading to formation of volatile and particulate emissions into the air. When plastic material burns, CO<sub>2</sub> and CO are common combustion products. Burning organic material also releases irritants such as aldehydes. In addition, cyanide (HCN) may be produced from burning wool and polyurethane. The gases are acute health hazards. When polyvinylchloride (PVC) is present in a fire, hydrochloric acid (HCl) as well as polychlorinated dibenzodioxins (PCDD) tend to be formed. Emitted PCDD will subsequently sediment in the environment and may constitute a chronic exposure risk (Fig. 4b).

And when a larger container with a flammable toxic agent explodes in an incident, released gases and volatile substances may cause contamination and fatalities in the region, as was the case in the Bhopal accident in India, in 1984.

Acute exposure guideline values (AEGV) have been defined that are useful in such incidences to decide about adequate protection measures for the exposed population.

---

## Kinetics and Reaction Types

### Toxicokinetics

Toxicokinetics is the field that describes the time courses of appearance and disappearance of an administered substance in body fluids. The overall process involves rates and extents of absorption, distribution, metabolism, and elimination (ADME). Elimination kinetics describes the disappearance of the xenobiotic after it has reached its peak concentration in a body fluid. The decrease typically follows first-order kinetics. Biphasic and triphasic elimination curves may result from involvement of multiple metabolic pathways and elimination routes (bile, urine). As rule of thumb, one can often assume that a substance is quasi-eliminated after five half-lives (corresponding to 97% eliminated). Vice versa, when a substance is repetitively (e.g., daily) administered, 50% of maximal blood level will be reached after one half-life.

Ethanol is an exception, because its high levels in body fluids after a drink saturate the ethanol metabolizing enzymes, with the consequence that ethanol elimination is not exponential – but linear with time (zero-order elimination kinetics). ADMET (absorption, distribution, metabolism, elimination, toxicology) is a tool set, applying physiologically based toxicokinetic modeling in order to make predictions about toxicological relevance (Pozzan 2020).

## Interaction Types

The physicochemical subdiscipline “reaction kinetics” deals with the time courses of chemical reactivity. The subdiscipline “thermodynamics” deals with the energy requirements and the equilibrium state of a reaction. Both are important aspects of the molecular mode of action of toxic agents.

The mechanisms of adverse chemico-biological interactions depend on the chemical substance and its biological interaction partner. Highly reactive chemicals like mustards may covalently bind to biomolecules and destroy molecules and tissues. Toxic metals tend to bind to sulfhydryl groups and inactivate proteins. Free radicals that may arise during biotransformation of some substances or in the course of oxidative stress may covalently bind to biomolecules or initiate the process of lipid peroxidation, causing defects in lipid membranes. Such interactions are usually irreversible and analytically identifiable in the form of abnormal protein adducts, breaks in macromolecules, or lipid peroxidation markers.

Non-covalent chemico-biological interactions between the toxic substance and a ligand binding site of a receptor or enzyme are usually reversible, following the principles for inhibitors in Michaelis-Menten kinetics.

Only few toxic agents are suicide substrates that bind covalently to the active center of an enzyme; organophosphates belong to this group. Ligands of biological receptors tend to have more than one interaction site with the target protein, such as a lipophilic weak (van der Waals) bonding with a hydrophobic pocket plus electrostatic interactions plus hydrogen bonding, which together enable a precise steric positioning of the ligand within the binding site of the protein. Models about toxic modes of action of a substance tend to be a matter of scientific dispute before a decision about their relevance for toxicological risk assessment is made.

Chelation is a type of reaction, in which several weak interaction sites in an organic molecule bind a metal-cation in a cage-like manner. Chelators are used to treat patients who were diagnosed with metal intoxication; they mobilize the metal and enforce its elimination via the kidneys. Chelators are also used technically, e.g., to keep calcium soluble in washing machines in order to protect the machine and the textile. When entering environmental water systems, chelators have the tendency to mobilize toxic metals, but they also decrease essential metals required by aquatic organisms. Therefore, chelators have a relevance for aquatic toxicology.

In summary, physicochemical features of a substance are of great relevance for its characterization as a unique substance, its analytical detection, and its safety profile. The physicochemical properties provide essential and unique information, required for risk assessment, notably in the areas of exposure assessment, toxicokinetics, and ecotoxicology. They are a necessary but not a sufficient component in all kinds of toxicological risk assessment.

### Abstract

Toxicity is an inherent feature of many different types of chemical substances, such as acids/bases, heavy metals, chlorinated molecules, organic solvents or protein-toxins. Specific chemical structures tend to be associated with characteristic modes of chemico-biological interactions and respective adverse effects in the living organism. The principles of “intrinsic toxicity” are of considerable importance for risk assessment, notably when toxicity data of known substances are missing or incomplete. In cases of intoxication with an unknown substance, the pattern of clinical symptoms may be a key, guiding to the type of substance causing such adverse effects. This contribution illustrates the concepts of intrinsic toxicity from the viewpoints of both, chemical structure and biological effects.

---

## Introduction

Intrinsic toxicity reflects the ability of a substance to access biological targets (toxicokinetics) and to interact with target biomolecules and deteriorate biochemical pathways with an adverse outcome for health (toxicodynamics).

The term “intrinsic toxicity” has sometimes been used in a narrower sense to describe endogenously formed toxic products such as free hemoglobin (Simoni et al. 2009) or glucose-adducts (Szwergold 2005). Herein, the term “intrinsic toxicity” is used in a wider sense, considering structural features that are characteristically associated with a mode of adverse action, and providing examples for organ-related outcomes. It refers to the questions: What makes a substance toxic and how does an organism respond?

Intrinsic toxicity of a substance can be described in different ways: By structural features of the substance and its functional groups, by the biomolecular mode of action, and by the type of adverse effect in the living organism. Intrinsic toxicity of a substance is one cornerstone of overall toxic action, the other ones being intrinsic responsiveness of target organs, exposure, and dose (Fig. 1). Knowledge of the principles of intrinsic toxicity is essential for risk estimation and a key to predict or estimate adverse effects when no toxicity data are available. It is also the basis for the analogy principle and the read-across method in risk assessment. Nevertheless, each substance is unique, and the complete set of toxicokinetic and toxicodynamic information is needed to fully characterize its intrinsic toxicity in detail.

**Fig. 1** Intrinsic toxicity as major factor determining toxicity. Four parameters affect the outcome of a toxic interaction: intrinsic toxicity of the chemical, type of exposure, dose, and the specific response of the target organism

## Structure-Related Intrinsic Toxicity

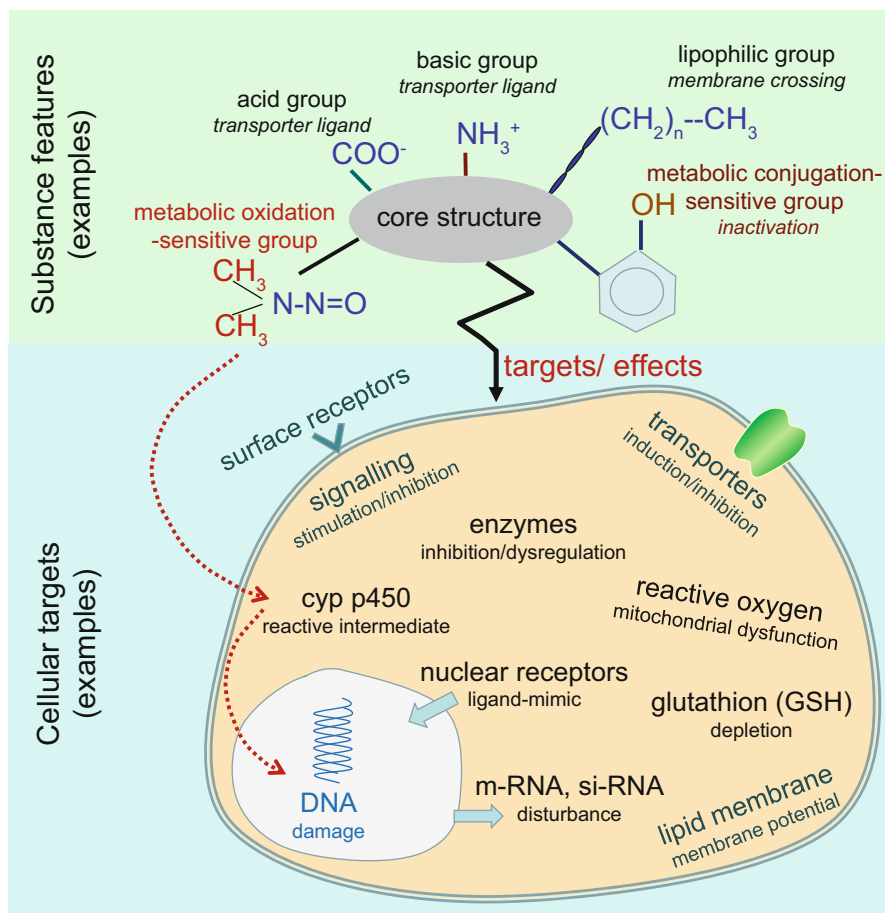

Intrinsic toxicity features are dependent on the structural components of a compound. Conceptually, one may consider a chemical substance as consisting of a core structure (atom, molecule, or particle) of a certain size, to which functional groups and side chains are attached (Fig. 2).

Size, lipophilicity, and cationic/anionic charge largely decide about absorption, distribution, and cellular uptake. Oxidation-sensitive side groups of the substance decide about the route and velocity of phase I metabolism, including generation of reactive intermediates with cytotoxic and genotoxic potential

## Toxicokinetic and Toxicodynamic Aspects

The structural composition is important for both toxicokinetics and toxicodynamics.

*Toxicokinetics:* In order to reach its target organ, a xenobiotic must get absorbed and carried with the circulation to its target cell. A long lipophilic side chain, introduced in a molecule, may enable it to cross organ barriers and biological

**Fig. 2 Substance features and common cellular targets.** Schematic drawing of the core structure and various types of functional groups of a model chemical substance (upper panel). Major cellular and biomolecular targets for toxic actions are shown in the lower panel

membranes. Carboxylic groups or amino groups may enable the substance to be transported by one of the families of membrane transporters, such as organic anion transporters (OAT), organic cation transporters (OCT), or ATP-dependent exporters (ABC-transporters). Some of the transporters support cellular uptake and others cellular elimination, and the overall process is an important determinant for the half-life of the active substance within a cell type.

Ingested dietary proteins are degraded in the gastrointestinal tract by proteases. In most cases, only short peptides and amino acids can get absorbed via the respective transporters. However, several toxin proteins have structural features that make them intrinsically resistant to such degradation and even allow them to cross the gastrointestinal barrier by endocytosis or related processes, favored when the epithelial lining is not completely tight.

Most xenobiotics undergo biotransformation mostly in the liver but also in extrahepatic drug-metabolizing organs like kidneys, gastrointestinal tract, and lung. Often hydroxyl groups are introduced by one of the cytochrome P450 isoenzymes through a mechanism whereby oxygen is transferred to the substrate in mixed-function oxidase reactions, involving NADPH as cofactor and yielding one or several different phase I biotransformation products. Phase I metabolism normally detoxicates xenobiotics; however, some xenobiotics are converted to reactive (intermediate) products.

Xenobiotics with a preformed hydroxyl group (e.g., naphthol) and hydroxylated phase I products are typically further converted in phase II biotransformation reactions (conjugation) often with glucuronic acid and sulfate. In most cases, conjugates tend to be less toxic. They exit liver cells via membrane transporters into bile or, alternatively, into blood with subsequent urinary elimination.

*Toxicodynamics:* The chemical reactivity in combination with the three-dimensional architecture of a substance is the basis for toxicodynamics. Figure 2 (lower panel) shows examples of molecular targets within a cell. Many toxic mechanisms are based on non-covalent interactions, often with an enzyme, a receptor, or membrane transporter. Such non-covalent interactions are usually reversible and directed quite selectively against a specific target molecule. Other toxic substances, such as corrosive agents or reactive metabolites of phase I biotransformation, tend to interact covalently and less selectively with surrounding biomolecules, producing cytotoxic damage, often including genotoxic DNA adducts and breaks, or initiate a destructive pathway like glutathione depletion, oxidative stress, or lipid peroxidation.

Though each chemical has its individual toxic footprint, there exist structural patterns that are associated with a specific toxic interaction. The following section provides some examples.

## Corrosive Substances

Ingestion of corrosive substances usually leads to a medical emergency (Kalayarasan et al. 2019). Strong **acids** and **bases** have an acute globally destructive effect on living tissue. On the molecular level, acids and bases interact with the functional groups of macromolecules and destroy their repulsive surface layer and intramolecular folding, thus resulting in denaturation and agglomeration of macromolecules. This results in cell death (necrosis) and destroys the fine structure of surrounding tissue. Strong bases tend to dissolve the denatured tissue and thus produce deeper lesions (liquefactive necrosis) that will later transform into scars and irreversible damage. Acids precipitate proteins in a way that may result in a protective layer of denatured material, thus self-limiting further destruction of the tissue below (coagulative necrosis).

The stomach provides an exception. The gastric proton pumps may generate an acidity of less than pH 2 in the gastric lumen. A healthy gastric and duodenal mucosa has a surprising ability to protect itself from self-destruction by secreting neutralizing bicarbonate and mucus to the mucosal surface. When this protection fails, an

ulcer may develop, and in case of a pathologic reflux of gastric acid to the esophagus, a reflux esophagitis may result.

The eyes are predisposed to damage by acid or alkaline spills, and the oral cavity, pharynx, and esophagus are at danger, when corrosive substances are swallowed.

Volatile acids, such as formic acid or concentrated sulfuric acid, are relevant as inhalative toxicants. When inhaled, they dissolve in the aqueous phase of the airway mucosa, which they acidify, thus causing irritation and damage. Likewise, volatile alkaline substances like ammonia dissolve in the aqueous phase of the airway mucous membrane, making it more basic, and are very aggressive to the airways when inhaled.

A different mechanism of corrosivity is exhibited by sulfur **mustards** (Ghabili et al. 2011), nitrogen mustards, and a number of organo-arsenic compounds (e.g., Lewisite). These substances are chemically very reactive; bind covalently to glutathione, protein, DNA, and other types of biomolecules; and thus are universally corrosive to exposed skin, airways, and, in general, any tissue. These substances are banned internationally by the Chemical Weapons Convention.

Numerous regulatory restrictions and warnings exist for corrosive substances. International pictograms are available to label containers that hold corrosive substances (GHS 2020).

## Short-Chain Aldehydes

Various short-chain aldehydes are volatile reactive chemicals with the potential to bind to biomolecules, thus irritating exposed body surfaces and airways already at low dose (LoPachin and Gavin 2014). Repeated exposure may lead to a sensitization, either via neurogenic inflammation or via allergic sensitization. An example is formaldehyde (Bernardini et al. 2020), which once constituted a widespread air problem indoors, often due to its release from urea formaldehyde foams used for insulation of houses, before stabilizers were commonly used that suppress formaldehyde release.

## Short-Chain Chlorinated Solvents

Carbon tetrachloride, chloroform, methylene chloride, trichloroethylene, and related halogenated aliphatic organic substances are volatile, lipophilic chemicals. They have a long history as solvents, vinyl chloride in addition as polyvinyl chloride precursor. Due to their lipophilicity, inhalation at the workplace causes stupefying and narcotic effects on the brain and side effects on the nervous system.

Many chlorinated solvents are readily biotransformed in the liver. This is usually accompanied by abstraction of a chlorine atom or, in the case of vinyl chloride, formation of an epoxide. Biotransformation tends to be associated with formation of reactive intermediates that are cell toxic and cause acute liver cell damage. Dichloromethane is metabolized to carbon monoxide which may cause carbon

monoxide intoxication. One pathway of trichloroethylene biotransformation is the conversion to trichloroacetic acid, a strong acid.

Chronic carbon tetrachloride exposure causes liver cirrhosis and liver cancer. Chronic vinyl chloride may cause a tumor of liver vascular walls (angiosarcoma). Dichloromethane is carcinogenic to the kidney. Additional targets exist. For example, chloroethane makes the heart more sensitive to catecholamines and arrhythmias.

Volatile short-chain chlorinated solvents tend to have a long half-life in the atmosphere and to affect air chemistry negatively.

In general, the intrinsic toxicity of these substances has several roots: Their small molecular size and the lipophilicity favor inhalative absorption and uptake into the brain, causing acute and chronic neurotoxicity. The genotoxicity of reactive intermediates constitutes a cancer risk. Many regulations exist, to restrict exposures of workers and the general population and to minimize release into the environment, though the latter is a continuing matter of discussion.

## Nitrosamines

Nitrosamine or *N*-nitrosamine is the name for substances with the general formula  $R_1R_2(N-N=O)$  where  $R_1$  and  $R_2$  represent alkyl or aryl residues which are attached to a *N*-nitroso group. When taken up in the body, most nitrosamines are metabolized by drug-metabolizing phase I enzymes. This generates instable intermediates, notably methyl cations (Fig. 3).

The lower panel shows the reaction sequence for dimethylnitrosamine. After hydroxylation by CYP2E1, the product decomposes spontaneously to finally form formaldehyde and a methyl cation, which is highly reactive, causing cell damage and genotoxicity

The reactive intermediates bind covalently to neighboring biomolecules, thus inactivating them. High acute doses of dimethylnitrosamine may cause fatal liver cell necrosis. Medium acute doses do not cause widespread necrosis but are associated with genotoxicity and may cause, after a latency period, appearance of pre-neoplastic islands in the liver and finally cancer of the liver and other organs (Robles 2014).

In addition, when secondary amines are ingested and get in contact with nitrite in the acidic environment of the stomach, there is the probability of endogenous nonenzymatic formation of nitrosamines (Fig. 3, upper panel). Pharmaceutical drugs that carry a secondary amine group need to undergo tests that make sure that they are no precursors of nitrosamine formation. Nitrosamine impurities in pharmaceutical drugs have occurred, e.g., in sarta-, metformin-, and ranitidine-containing products (WHO 2019). This is a danger signal for regulatory agencies that has led to warnings and recalls. According to the described synthesis principle, nitrosamines may also be formed as unwanted side products during some types of food processing. Threshold limit values for nitrosamines have been defined for various foods and beverages, e.g., certain types of dark beer often according to the ALARA principle (as low as reasonably achievable), or “below detection limit.”

**Fig. 3 Nitrosamine: formation and metabolic activation (schematic drawing).** The upper panel shows the reaction in acidic conditions of nitrite with a secondary amine (characterized by two organic residues) to form a nitrosamine. Nitrosamine formation may occur in the acidic environment of the stomach, when secondary amines (components of some nutrients, some drugs) react with nitrite

*N*'-Nitrosornicotine is a major tobacco-specific nitrosamine. It is generated by nitrosation of nicotine during tobacco curing, processing, and smoking.

Most nitrosamines are mutagenic and carcinogenic. The intrinsic toxicity of nitrosamines is due to the formation of reactive chemical species.

## Organophosphates

Acetylcholine is a major neurotransmitter substance in the brain, peripheral nervous system, and neuromuscular junctions. To terminate each pulse of acetylcholine-

mediated neurotransmission, acetylcholine released into the synaptic space gets inactivated rapidly by the enzyme acetylcholine esterase (AChE), which cleaves the ester bond of the molecule. In this catalytic process, the choline moiety binds to the “anionic site” in the catalytic center of the enzyme and the acetyl part of the molecule to the “esteric site.” Subsequently, acetylcholine gets cleaved. Choline is released and the acetate-enzyme bond gets hydrolyzed.

Organophosphate compounds bind with their phosphorus to a serine residue of the esteric site of the enzyme, resulting in release of a side group from the organophosphate. The remaining enzyme adduct does not dissociate readily. The resulting blockade of the enzyme is initially reversible, but later it may become irreversible during an “aging process.” Variants of the organophosphate side chains have been developed to enhance target specificity of biocidal organophosphates and to optimize their decomposition rate in the environment. Some (e.g., parathion) are used as insecticides. Molecular modifications led to highly efficient irreversible inhibitors of the enzyme that are potential warfare agents (e.g., sarin), prohibited by international convention.

Malathion lotion is approved in various countries for application on human skin to fight head lice. On the other hand, many fatalities worldwide are due to wrong usage or suicidal intake of organophosphate insecticides (Robb and Baker 2020). Warning pictograms and labels are of little help in the case of suicidal intention but very crucial in other cases and, together with recommendations for careful and correct handling, help to avoid intoxications.

## Phenylethylamines

Phenylethylamines are a class of psychoactive substances that share a common chemical core structure. They occur as endogenous neurotransmitters such as nor-adrenalin and dopamine or as plant-derived active substances such as ephedrine. Phenylethylamine analogues have been developed as therapeutic drugs (e.g., amphetamines) but also include illegal psychoactive drugs of addiction. The “cathinones,” characterized by a keto-group, represent a large and increasing group of novel psychoactive substances found on black markets, responsible for intoxications of drug users in many countries.

Any substance with phenylethylamine structure, which is seized by the police on the black market, is considered as a signal for clandestine use and potential intrinsic toxicity (depending on dose). Forensic experts tend to apply the analogy principle in situations, when the chemical identity of the substance has been determined, but no pharmacological and toxicological data are available.

## Aromatic Chlorinated Substances

Aromatic chlorinated substances became known as persistent organic pollutants (POPs) of high environmental concern. This group of substances includes insecticides like

dichlorodiphenyl trichloroethane (DDT) and technical oils containing mixtures of polychlorinated biphenyl congeners (PCBs), as well as a large group of congeners of polychlorinated dibenzofurans (PCDF) and polychlorinated dibenzodioxin (PCDD). The latter are not produced for technical applications but may occur as side products during synthesis of the wood preservative pentachlorophenol and during incineration processes when chlorine is present, notably waste incineration. Many of the congeners of PCBs and PCDDs were found to be very resistant to metabolism, thus cumulating in human fat tissues over many years. They are also quite resistant to environmental breakdown and thus bioaccumulate in the food chain, notably in animal fat, milk, egg yolk, and the final consumer, the humans, notably in mother's milk. The congeners have on the whole the same toxic endpoints but different strengths of adverse effects (see Sorg 2014). Toxicity equivalency factors (TEFs) are assigned to each congener, thus allowing to calculate the total risk, on the basis of the measured exposure dose of each congener. The use of DDT as insecticide was stopped almost worldwide not least because it cumulates in the environment and is suspected of tumor-promoting activity.

The intrinsic toxicity of many chlorinated aromatic POPs is due to their accumulation in the food chain, very long half-life of many congeners, and a combination of various serious adverse effects. Regulation of POPs for the protection of human health is covered by the international Stockholm convention.

Many polycyclic organic substances are inducers of a number of drug-metabolizing enzymes, among them cytochromes P450 and glucuronosyltransferase. Aromatic hydrocarbons like benzo[a]pyrene and methylcholanthrene and chlorinated heterocyclic organic compounds, like PCDDs and DDT, are ligands of the arylhydrocarbon receptor (AhR). They bind to the receptor in the cytoplasm, which then associates with the protein ARNT (aryl hydrocarbon receptor nuclear translocator). The complex translocates to the cell nucleus and activates transcription of specific genes (Nebert, 2017).

One of the best known effects of AhR-receptor binding is the induction of cytochrome P450 in the liver. Animal treatment with such inducers causes an up to about eightfold increase of cytochrome P450 isoforms.

Various pharmaceutical drugs (classically phenobarbital) or ethanol may induce cytochrome P450 as well, however with different isoenzyme expressions compared to chlorinated POPs.

Induction of xenobiotic metabolizing enzymes has two types of consequences: First, it increases the rate of biotransformation of xenobiotics and therefore reduces circulating levels of xenobiotics, therapeutic drugs, and some hormones. Second, it accelerates formation of reactive intermediates of procarcinogens and may increase the risk of genotoxic damage. The "human cytochrome P450 (CYP) n-fold induction in vitro test method" (OECD 2014) provides further information.

## Lectins

Lectins are proteins that have a high affinity to glycoproteins on the outer surface of cell membranes. Lectins occur as natural ingredients in many plants. When lectin-rich beans are ingested without preceding heat denaturation, the lectins bind to

intestinal epithelial cells and cause gastrointestinal distress. One of the most toxic lectins is ricin, found in castor beans. When ingested, it gets in contact with mucosal surfaces and disturbs the exposed cells. Ricin is at the same time a nonbacterial AB toxin that can be taken up by endocytosis into cells, where it inhibits protein biosynthesis. Ricin is in the list of potential warfare agents.

## AB Toxins

AB toxins are bacterial toxins containing two protein subunits (Odumosu et al. 2010; Kumar et al. 2019). The B subunit (binding) binds to cell surface glycoproteins and enables the toxin to enter a cell via receptor-mediated endocytosis. In the target cell, the A subunit (active) exerts its adverse effect by inhibiting or activating a vital cellular pathway often due to its intrinsic enzymatic activity, thus causing cellular dysfunction and organ failure. Though AB toxins have this general mechanism in common, the various toxins differ with regard to their routes to their target cell types, molecular endpoints, and symptoms of intoxication. Here are some examples:

Cholera toxin is released during cholera infection in the intestinal lumen and taken up by intestinal epithelial cells, where it switches on the production of cyclic-AMP (c-AMP). This activates outward directed ion pumps, followed by secretion of large amounts of water into the intestinal lumen, thus causing diarrhea and possibly death due to extreme water- and electrolyte loss.

Quite differently, the AB toxin of botulinum known as botulinum neurotoxin (BoNT) specifically acts in neurons (Pirazzini et al. 2017). When BoNT A is inadvertently ingested with toxin-contaminated food, it is largely resistant to digestion by proteolytic enzymes. It is taken up via endocytosis in the intestine, and once in the blood and lymphatic system, it gradually enriches on high-affinity binding sites (BoNT-receptor) on presynaptic membranes of cholinergic neurons, mainly on the neuromuscular junctions, to which the B subunit (heavy chain) binds firmly. The two subunits of BoNT are then internalized into vesicle cavities, which recycle to the presynaptic space. On their way, the vesicles get acidified by a proton pump activity, the disulfide bridge between the two BoNT subunits dissociates, and the A subunit (light chain) finds access to the cytosol. There it exhibits a metalloprotease enzymatic activity, thus disabling proteins (SNARE proteins such as synaptobrevin) required to fuse the synaptic vesicle with the plasma membrane and to release acetylcholine. Thus, BoNT arrests further release of acetylcholine and therefore interrupts this neurotransmission (Fig. 4).

Botulinum toxin is considered to be the most toxic substance known and listed in international agreements of prohibited chemical weapons. Nonetheless, it can be used therapeutically under strictly controlled conditions to relax spasms and tensions of locally treated small muscles.

**Fig. 4** Simplified schematic drawing of a cholinergic motor neuron synapse and the effect of botulinum neurotoxin A (BoNT A). Botulinum neurotoxin (BoNT A) is a bichain protein, consisting of a heavy chain (H) and a light chain (L). The H-chain shows high binding selectivity for receptors on presynaptic membranes of motor neurons. The BoNT-receptor complex is endocytosed. The vesicle gets acidified by an ATPase, which induces release of the L-chain into the cytosol. The acidified vesicle takes up acetylcholine (ACh). The cytosolic L-chain has protease activity; it cleaves and inactivates SNARE-proteins that are required to fuse the synaptic vesicles with the presynaptic cell membrane. This way, BoNT A causes a long-lasting arrest of ACh release and inhibition of muscle activities

Tetanus toxin exhibits a similar molecular mechanism of action on neurons but is transported in a different way by retrograde axonal transport to the spinal cord, where it inactivates inhibitory interneurons, resulting in spastic paralysis.

The A-unit of diphtheria toxin has ADP-ribosylation enzyme activity that is directed toward the ribosomal elongation factor EF-2. Diphtheria toxin thus inhibits protein synthesis, causing potentially life-threatening acute disease.

Anthrax toxin consists of three subunits. The B subunit is responsible for cellular uptake of the protein complex. One of the two A subunits (lethal factor) has peptidase activity that inactivates MAPKK enzyme, a key regulatory kinase involved in stress-mediated cell survival. The other A subunit possesses adenylate-cyclase activity and disturbs cellular signaling. Working together, they cause cell death (apoptosis).

AB toxins share a number of intrinsic toxic features, which makes them very different from other substances. They are well suited as model to demonstrate that

intrinsic toxicity comprise both kinetic and dynamic aspects: (1) escaping complete intestinal digestion, (2) targeting specific cell types with high affinity, (3) resistance to cellular proteolysis, and (4) exhibiting highly selective destructive enzyme activity.

The field of AB toxin-producing organisms is within the responsibilities of microbiology. It includes prevention of growth of the respective bacteria (e.g., cholera, botulinum) in the human environment, active vaccination to prevent infections (e.g., diphtheria), and antitoxin treatment of intoxicated individuals.

AB toxins can be expected in the future to serve as an archetype for the development of novel therapeutics that target specific cell types and molecular functions.

## Dust, Fine, and Ultrafine Particles

Airborne dust consists of particles of varying sources, diameters, and chemical composition. Larger dust particles tend to sediment according to their mass and size. Ultrafine particles and nanoparticles tend to behave like gas. House dust is rich in tiny textile fibers, dander, and hair. It also contains various amounts of allergens of house mites and mold. Street dust contains abrasions of tires, brakes and road materials, vehicle exhausts, and more.

When airborne dust is inhaled, penetration depth is inversely correlated to particle size. Larger dust particles sediment on the walls of the nose, pharynx, and upper section of the bronchial tree and will usually be cleared by the ciliated epithelium. Inhaled fine particles move deeper, ultrafine particles, and nanoparticles can reach the deepest, oxygen-absorbing tissue of the lungs, the alveoli. In the lung alveoli, ultrafine particles may initially get phagocytized by alveolar macrophages. Poorly soluble particles that are not cleared from the lung tend to cause chronic adverse lung effects, sometimes pulmonary cancer.

There is good evidence that the number of inhaled particles is more relevant for pulmonary toxicity than particle mass (Kwon et al. 2020). However, many additional parameters will co-determine toxicity such as particle shape, surface area, surface charge, solubility, degradability, and presence of soluble toxic components (see Oberdörster and Kuhlbusch 2018). There seems to be an association between airborne particles and cardiovascular disease.

Risk assessment with regard to chronic toxicity is difficult even for single particle types, such as crystalline silica. It is even more difficult with regard to multicomponent particles formed in combustion processes or urban dust that is composed of different particle types from many different sources. Due to their surface activity, these tend to agglomerate and/or undergo photochemical reactions with oxygen, nitrogen oxides, and volatile chemicals in the air. A detailed characterization of urban airborne particles will have to include a battery of methods, such as cascade impactor, particle counters, electron microscopy, and analytical chemistry.

The common intrinsic toxic characteristics of ultrafine particles are (1) airways and lungs as primary targets, (2) inflammation in the airways, and (3) pulmonary accumulation of particles.

## Metals and Metal Compounds

Metal toxicology is an extraordinary complex field (see also: Nordberg et al. 2014; Kozłowski et al. 2014) for several reasons. First, a number of metals are essential components of the human organism and can hardly get classified as inherently toxic agents, although elevated levels of essential macrominerals and trace minerals may cause disease under certain pathologic conditions. Second, metals of higher order in the periodic system exist as inorganic and organic compounds, in different oxidation states, each having specific toxicokinetic and toxicodynamic features. Third, it is sometimes not clear if metalloids, like arsenic, should be considered as metals or nonmetals. Fourth, the route of uptake (oral, inhalative, dermal) affects the severity and type of toxicity. Fifth, various metals are stored in the organism over a longer period and thus may accumulate, often unnoticed.

### Essential Metals

Within the organisms, levels of the macrominerals sodium, potassium, calcium, and magnesium are well kept within a physiological range. Nevertheless, due to increased intake or biological dysregulation, body overloads may occur causing disorders or disease, e.g., sodium (edema and hypertension), potassium (cardiac arrhythmias), calcium (decreased neuronal activity), or magnesium (confusion and others).

Likewise, the levels of trace minerals (e.g., iron, manganese, copper, and zinc) are tightly controlled in the organism. This is extremely important, as seen in the case of iron.

Free iron is toxic to cells under oxidative stress, because iron<sup>2+</sup>/iron<sup>3+</sup> cycling is associated with the formation of aggressive hydroxyl radicals according to the Haber-Weiss reaction. The organism has a number of mechanisms to keep levels of free iron in a narrow range: Intestinal iron absorption is downregulated when sufficient iron is present. Nonfunctional iron in blood plasma is tightly bound to transferrin. Iron uptake into cells occurs via iron-specific membrane transporters in a hepcidin-regulated manner. Excess iron is stored in the core of iron-rich ferritin particles, surrounded by a protein shell. Functional iron in the heme group of hemoglobin and cytochromes is tightly bound as central atom in the porphyrin complex.

Presently, it is undecided whether chromium is an essential mineral. Here we focus on a different aspect, namely, the effect of the oxidation state of chromium on toxicity. Chromium (VI) compounds are carcinogenic (Wang et al. 2017). They may enter cells via the sulfate-anion membrane channel. Within the cell, chromium (VI) is reduced to highly reactive chromium (V) and (IV), which catalyze the formation of reactive oxygen species resulting in DNA damage. In contrast, chromium (III) compounds are unable to enter cells and are not associated with carcinogenicity.

## Nonessential Metals

Many metal compounds of higher order in the periodic system with a specific density above 5 (“heavy metals”) have in common that they either tend to interact with amines, sulfhydryls, or carboxylic groups of biological macromolecules or possess a catalytic activity, thus deteriorating biological functions (Rajkumar and Gupta 2020). Beyond such general modes of action, each metal compound has its own characteristic toxicity pattern. Here follow some examples:

Metal toxicity can only occur when the metal (or metal-containing compound) is bioavailable. For example, **barium sulfate** is used in gastrointestinal X-ray diagnosis as contrast medium. It is highly insoluble and virtually nonabsorbable in the intestine. In contrast, soluble barium compounds are readily absorbed, cause hypokalemia, and are associated with cardiac toxicity.

Cadmium sulfide is virtually insoluble in water and not much absorbed after oral intake, whereas soluble cadmium species or inhaled cadmium compounds are toxic causing acute liver damage and chronic kidney disease and are classified as carcinogens. Tobacco smoking is a relevant source for cadmium intake. Cadmium at elevated levels is in part bound to the metal-binding protein metallothionein.

Lead inhibits the enzyme aminolevulinic acid dehydratase and thus depresses heme synthesis. Moreover, it is very neurotoxic and has various additional targets of toxicity. It tends to accumulate in the organism. The organic derivative tetraethyl lead, formerly used in large amounts as antiknock agent for petrol to improve engine performance, is a volatile liquid that is readily absorbed via the inhalative and dermal routes. This substance is primarily neurotoxic.

Mercury had in the past many technical and medical applications but was gradually abandoned and banned in most items due to its chronic toxicity that varies with its chemical form. Metallic mercury is volatile; when inhaled, it is sufficiently lipophilic to get absorbed and to cross the blood-brain barrier, where it gets oxidized by enzymes and retained in the brain for years, causing neurotoxicity. Mercury salts have adverse effects on various organs, depending on the type of salt. Methylmercury is neurotoxic and embryotoxic.

Thallium intoxications, when survived, are characterized by the loss of hair.

Osmium tetroxide is a volatile, lipid soluble liquid. It interacts with various types of biomolecules, such as double bonds of phospholipids. When airborne, it causes damage of the eye and airways. It is considered to be the most toxic metal compound.

This section so far has shown that each metal has its individual type of toxicity. Nevertheless, there are some common aspects relevant to the concept of intrinsic toxicity:

- Elevated exposures to metals and their compounds may constitute a health risk.
- Metals can be analyzed by atomic absorption spectrometry.

- Patients with metal intoxication receive metal-chelating agents as treatment to enforce elimination.
- Once in the environment, metal atoms will persist.

To protect humans from toxic metal exposures, numerous national and international recommendations, guidelines, and limit values have been defined, for virtually all regulated areas, including food, drinking water, toys, cosmetics, pharmaceuticals, soils, and sewage sludge; it would be beyond the scope of this chapter to give references. At the same time, new semiconductors and catalysts bring new types of metals (e.g., platinum-group metals as catalysts) into the environment, for which the long-term toxic consequences are not yet clear.

---

## Target-Related Toxicity

### Prologue: Damage and Repair

An understanding of the mode of action of a toxic substance is of scientific interest but has also practical regulatory consequences, such as decisions to ban or tightly regulate a chemical or group of chemically related substances that pose a high risk.

Some toxicants, e.g., the organophosphates, deteriorate just a single type of enzyme, thus causing dysfunction and sometimes death of the organism. Other toxicants are universally reactive chemicals (e.g., mustards) that form covalent bonds with many types of cellular molecules and thus cause cell death in the exposed tissue.

There exist two types of cytotoxicity-induced cell death: When ATP synthesis and basic biochemical pathways of a severely damaged cell are still functioning, the cell initiates programmed cell death (apoptosis) (Elmore 2007). One of the apoptosis pathways is triggered in a multistep pathway by release of cytochrome c from the mitochondrial membrane. In the process of apoptosis, the cell starts degrading its contents in an ordered manner and releases local mediators that attract neighboring cells to migrate toward the injured area. Proliferation of nearby organ-specific stem cells finally replaces lost cells by newly formed daughter cells (not in all tissues).

In contrast, massive cytotoxic damage rapidly leads to unordered lysis of cells (necrosis) and release of debris. Tissue damage after necrosis tends to be more complex than after apoptosis, involving inflammation to remove the cell debris.

Depending on the severity of damage and type of toxic injury, repair may ultimately result in full tissue regeneration or defective healing. Defective healing involves inflammation, whereby immune cells degrade cell debris. They also send out signal substances that may attract fibroblasts. This may lead to an irreversible replacement of functional organ cells by connective tissue. Repair velocities vary among tissues. Skin and mucous membranes have a rapid tissue repair capacity, but neuronal cells only a very restricted ability for cell recovery or renewal. Knowledge of such pathobiological processes is important for understanding tissue alterations, induced by either single acute exposure or repeated chronic lower-dose exposures.

## Molecular and Organ Level

Intrinsic toxicity can be seen not only from the viewpoint of the toxic agent (as shown above) but also from the viewpoint of organ-specific adversities.

### Membrane Potential and Neuronal Activity

#### Resting Membrane Potential

The resting membrane potential of cells is maintained by the sodium/potassium ATPase activity in the cell membrane that shuffles potassium ions from the extracellular space into the cell in exchange to sodium ions. However, potassium ions tend to leak back into the extracellular space, and the concomitant outward-directed positive charge is the origin of the cell's resting membrane potential. The sodium/potassium pump is inhibited by the digitalis poisons of the foxglove. Intoxication leads to nausea, vomiting, and multiple other CNS effects. The heart muscle is particularly sensitive. Depending on other factors such as plasma-potassium and noradrenalin, higher doses of ouabain, digitoxin, etc., cause potentially fatal cardiac arrhythmias.

Gramicidin integrates into biological membranes as a transmembrane pore that allows small cations to cross the membrane uncontrolled; valinomycin is an ionophore that shuttles potassium ions from one side of the membrane to the other. These are just examples for adverse interactions that cause a collapse of the membrane potential.

#### Nerve Conductance

Nerve systems contain a variety of different cell types. Among them, the nerve cells (neurons) play the key role, since they are electrically excitable and can conduct electrical impulses. Their cell bodies have dendrites and long axons that extend to other nerve cells, sensory neurons, and the musculoskeletal system. Neuronal information is propagated via an electric pulse (action potential) along the membrane of the axons (neuronal conduction) and via chemical transmission (neurotransmission) across the junctions (synapses) between communicating neurons. Acute neurotoxicity is usually due to stimulation or inhibition of either mechanism.

*Action potential:* The action potential is generated by voltage-gated ion channels in the membrane of nerve cells, notably for sodium, that are opened when an excitation or an action potential impulse arrives, thus depolarizing the membrane and propagating the impulse. Thereafter, the channels close rapidly.

Here are some examples for adverse reactions: Tetrodotoxin, the poison of the puffer fish, as well as saxitoxin, a substance that is responsible for paralytic shellfish poisoning, are blockers of the voltage gated sodium channel, resulting in an inability to propagate an action potential.

In contrast, aconitine, the alkaloid of the plant monkshood, keeps the voltage-gated sodium channel open, even after termination of an action potential, inducing a domino effect on potassium and calcium fluxes that may result in release of

acetylcholine into the synaptic space. Pyrethroids also keep the channel in the open state, thus paralyzing insects.

### Cardiac Long QT Syndrome

Cardiac action potentials are not initiated (though affected) by nerve activity but initiated by the autonomous cardiac pacemaker. The impulse is started and propagated by myocardial cells, which constitute the electrical conduction system of the heart. Deviations from “normal” can be diagnosed in the electrocardiogram. Various therapeutic drugs affect the ion fluxes by interaction with sodium and potassium ion channels. This causes a change of conductivity, visible as long QT syndrome in the electrocardiogram (ECG), thus increasing the risk of cardiac arrhythmias (Lester et al. 2019). It is therefore generally recommended to analyze such risks early during drug development or, when prescribing such medications, to control the patient’s ECG.

### Neurotransmission

Neurotransmission across chemical synapses can be adversely affected by many substances that increase or decrease neurotransmission. Adverse (activating or inhibiting) interactions with neurotransmission of acetylcholine (ACh), for example, include these mechanisms:

1. ACh release into the synaptic space (e.g., BoNT inhibits).
2. Binding to the postsynaptic ACh receptor (e.g., neonicotinoids activate, whereas atropine inhibits).
3. ACh degradation (e.g., organophosphates inhibit).
4. Choline reuptake (e.g., hemicholine inhibits).

Since neurotransmitter receptors exist in various subtypes that are heterogeneously distributed within the functional areas of the central nervous system, each substance that affects that network tends to exhibit its peculiar pattern of psychotoxic and neurotoxic symptoms.

Additional mechanisms of neurotoxicity exist. For example, a case of contamination of the synthetic opioid-mimetic MPPP (“1-methyl-4-phenyl-4-propionoxypiperidine”) with MPTP (“1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine”) has been described. The latter is converted in the brain by monoamine oxidase to the neurotoxic agent MPP<sup>+</sup> and induces Parkinson’s disease (Langston 2017).

Moreover, many acutely neurotoxic agents are chronically neurodegenerative; ethanol is a simple example. In conclusion, substances belonging to different chemical classes may cause adverse effects on neuronal transmission.

## Reproductive and Developmental Effects

*Reproductive toxicology* deals with genotoxic effects and chromosomal aberration in germ cells as well as non-genotoxic adverse effects on viability and count of sperm cells. *Developmental toxicology* deals with tissue development and differentiation of the embryo/fetus and disturbances by toxic and teratogenic substances. For the

safety of the pregnant women and the developing child, protective regulations are essential. Here we enumerate some of the challenges associated with the detection of adversely acting substances.

First, teratogens such as thalidomide adversely interact with specific tissue differentiation regulating morphogens that are often active only during a very short time period, sometimes just one day.

Second, the developing brain is very susceptible to damage by neurotoxic agents (e.g., ethanol, methyl mercury, neuroactive drugs) transferred from the mother to the child; intellectual deficits may become evident at birth or later in childhood.

Third, an adverse effect to the embryo may arise indirectly from substances that affect hormones or the placental sufficiency of the pregnant woman.

Fourth, oocytes of females are formed already in the embryo. Each egg then remains in an arrest state until its ovulation. This poses a risk of cumulative genotoxic damage, while at the same time oocytes have less DNA-repair capacity compared to diploid cells. The two-generation test aims at detecting adverse effects that become visible in the second generation (see also OECD testing guidelines 414, 415, 416, and 443 (OECD 2020) and ICH test guideline S5 (ICH 2020)).

### **Irritation**

Irritation is a disorder, usually seen on skin, conjunctivae of the eyes, and mucous membranes of the respiratory tract and the gastrointestinal tract, disappearing soon after termination of exposure. Nerve endings carry sensor biomolecules (TRPV, transient receptor potential vanilloid) capable of binding many types of irritating substances; capsaicin is a prototype. Ligand binding initiates a local neurogenic inflammation, including a pain signal to the brain and a signal for local attraction of white blood cells, thus causing inflammation at the contact site. Tear gas acts via the TRPV receptors in irritating exposed epithelia of eyes and upper airways.

Low levels of a corrosive substance may cause a simple irritation, while higher doses are corrosive. Chronic tissue irritation can have further-reaching consequences, including the long-term formation of neoplasms.

### **Sensitization**

Sensitization results from priming exposures that activate the immune system to become responsive and reactive to subsequent exposures, which then cause an allergy. The mechanism involves binding of the substance to biomolecules, detection of “foreign” epitopes by specialized cells of the immune system, and expansion of lymphocyte clones that produce corresponding antibodies or carry antibody-related molecules on their surface directed against the foreign molecule. After an initiating sensitization processes, the immune system is triggered to fully develop an allergic reaction when subsequent exposures to the substance occur.

In daily life, sensitizations are often induced by proteins. However, chemically reactive small molecule substances may also become sensitizers when binding cellular proteins; the substance-protein complex then may constitute an epitope that is recognized by the immune system as “foreign.”

Sensitization tests *in vivo* like the local lymph node assay (OECD 2010) and *in vitro* skin sensitization tests (OECD 2018) can detect early immunological and cellular response parameters that are associated with sensitization. Regulations in food safety are aimed at banning known allergic materials for use as food additives. However, for persons who have an allergy to a component of natural food, e.g., of nuts, fish, milk, or the wheat ingredient gluten, a clear labeling and declaration of the ingredients of food products is a necessary and reasonable regulatory solution that helps affected individuals to avoid the allergen.

### **Genotoxicity, Mutagenicity, Carcinogenicity**

*Genotoxicity* is the feature of a substance to produce changes in DNA, such as DNA strand breaks, adducts, and frameshifts, as well as chromosomal aberration and breakage. Genotoxicity can be studied *in vivo* by investigating chromosomal changes (clastogenicity, aneuploidy), DNA fragmentation or nucleotide adducts, or *in vitro*, like in the bacterial mutagenicity tests. The latter is usually performed in the presence of a liver microsomal system to convert the test substance to its phase I metabolites, including any reactive intermediate with genotoxic/mutagenic properties (see respective OECD test guidelines for chemicals (OECD 2020) and ICH test guidelines for pharmaceuticals (ICH 2020)).

Depending on severity and location within the DNA strand, genotoxic effects may cause acute cell death (necrosis or apoptosis), or the cell may survive and repair the damage or survive with a mutation. In the latter case, the final outcome will depend on the type of the affected cell:

- (a) Fully differentiated organ cell: The damage tends to remain locally restricted.
- (b) Organ stem cell: The mutation may proliferate to daughter cells within the organ/tissue. Chemically induced cancer develops as a process that starts after an initial genotoxic DNA damage (initiation) in an organ stem cell and proceeds stepwise via promotion and progression.
- (c) Germ cell: The mutation can get proliferated to the next generation.

Genotoxic carcinogens are thought to have no zero risk threshold. But non-genotoxic tumor-promoting agents like some hormones (e.g., estrogens) and endocrine disruptors (Del Pup et al. 2016) are thought to have a threshold, below which there is no risk.

Since carcinogenesis is a complex multistep biomolecular process that develops over time, affected by hereditary – and many other influences, the proof for an intrinsic carcinogenicity of a substance usually requires long-term (two years) studies in animals. When interpreting data of animal carcinogenicity studies, one should be aware that high doses of a substance are often applied, sometimes in a subtoxic dose range, which might induce cytotoxicity-related changes and tumor promotion. A full pattern of the toxicokinetics helps to interpret mechanisms and results. When animal experiments don't provide clear dose-response relationships, notably in the low-dose range, extrapolation methods help to define a probable risk level.

Epidemiological findings are very valuable when there is a stable association between exposure levels and the incidence of a human tumor type. But solid information is available only for a restricted number of mainly “old” substances. Epidemiological findings are often equivocal, not least because of mixed exposures, varying exposure levels, and other influencing factors.

## **Liver as Target Organ**

The liver is the body’s “sewage plant” for endogenous catabolic products and xenobiotics. Following intestinal absorption, it takes up nutrients and xenobiotics from the portal blood (hepatic first pass clearance), or from the circulation; modifies the substances chemically, to detoxify them; and releases the products both back to the blood and via membrane transporters (exporters) of the canalicular membrane into primary bile. Depending on the type of intrinsic toxicity, the liver may respond with different kinds of injury. Here follow some examples.

### **Intrahepatic Cholestasis**

Intrahepatic cholestasis is characterized by reduced bile flow, often induced by pharmaceuticals, which either inhibit exporters or deteriorate bile flow by lowering bile fluidity or inducing an inflammation that compresses bile canaliculi. Reduced bile formation and bile flow result in elevated levels of xenobiotics and bilirubin in the blood (Sundaram and Bjornsson 2017).

### **Drug-Induced Autoimmune Hepatitis**

This rare event may be induced by some drugs such as nitrofurantoin or halothane, which in the course of their hepatic metabolism form neo-antigens, probably due to protein-binding of their reactive intermediates. Upon repeated exposure, a then sensitized immune system may handle such adducts like (auto)antigens, potentially causing liver cell necrosis and inflammatory infiltration.

### **Liver Cell Necrosis**

This type of hepatotoxicity is often the result of cytochrome P450-dependent biotransformation of xenobiotics that generates reactive intermediates, which then cause damage to liver cells. Examples are carbon tetrachloride, dimethyl nitrosamine, and aflatoxin. At high acute doses, they cause acute liver cell necrosis; chronically they are associated with the risk of liver cirrhosis and liver cancer.

Acetaminophen is a safe analgesic, when used according to prescription. A therapeutic dose is conjugated with glucuronic acid and sulfate; only a small portion is metabolized by cytochrome P450 enzymes that produce reactive intermediates, which normally are readily detoxified by conjugation with glutathione. However, excessive overdosing saturates the glucuronidation and sulfation pathways. The surplus of reactive intermediates then depletes hepatocellular glutathione (a major cellular antioxidant) and binds to proteins, thus causing liver cell death, sometimes

with fatal outcome (McGill et al. 2012). Overdosing acetaminophen is a major cause of drug-induced liver failure in the USA and Great Britain.

The poisonous mushroom “death cap” contains amanitin and several related cyclic oligopeptides that together are named amatoxin. These heat-resistant peptides are absorbed in the intestine and accumulated in liver cells, where they inhibit the enzyme RNA polymerase II and thus hepatic protein synthesis. The continuing loss of vital cellular proteins results in liver cell necrosis and often death after about two days. The other toxin of the “death cap,” phalloidin, is poorly absorbed, but when injected, it is taken up by liver cells, associates with F-actin, and thus inhibits the dynamics of the cytoskeleton.

### **Fatty Liver**

Ethanol is a major causative factor for fatty liver. Ingested ethanol gets oxidized in the liver (and other organs) to acetaldehyde and subsequently to acetic acid, which is converted to acetyl-CoA. The oxidation reactions deliver NADH/NADPH. The reaction products are substrates/cosubstrates for triglyceride synthesis. Fat droplets may transiently get stored in liver cells, thus expanding liver volume, initially without symptoms, but chronically often associated with lipid disorders and a risk for progressive liver disease.

### **Liver Cirrhosis**

Liver cirrhosis develops as a long-term response to severe or repeated hepatotoxic exposures (e.g., ethanol, carbon tetrachloride) and other causes. It is characterized by a shrinking liver volume, replacement of liver cells by connective tissue, and disturbed liver architecture.

### **Liver Cancer (Hepatocellular Carcinoma)**

Primary liver cancer may develop as a consequence either of massive short-time exposure or of chronic low-level exposure to substances that are genotoxic or converted to genotoxic metabolites in liver cells, such as aflatoxin or nitrosamines. Tumor promoters such as ethanol, chlorinated aromatic hydrocarbons, and viral infections tend to speed up the appearance of a tumor.

### **Hepatic Encephalopathy**

A partly damaged liver has a reduced capacity to detoxify catabolic products and xenobiotics. This leads to accumulation of neurotoxic substances such as ammonia as well as metabolic products of intestinal microbiota that are insufficiently eliminated by a damaged liver, thus exerting narcotic effects.

---

## **Role of Individual Susceptibility**

Intrinsic toxicity is the potential of a substance to produce an adverse effect. However, whether a toxic effect occurs may depend on additional conditions, such as individual sensitivities. Regulations covering an entire population just to protect

few susceptible individuals are sometimes not feasible. In such cases, regulations may provide recommendations and information that help the susceptible individuals to avoid the adverse exposures (e.g., pharmaceuticals package insert).

### **NSAID-Induced Ulcer Disease**

Nonsteroidal anti-inflammatory drugs (NSAID) are used for pain control, often chronically. Many individuals tolerate recommended doses without gastrointestinal problems. But some individuals, notably the elderly and those under stress, may develop a gastroduodenal ulcer (Hunt and Yuan 2011). This is in part due to the intrinsic inhibitory effect of NSAIDs on prostaglandin synthesis, whereby the gastro-protecting effects of prostaglandins are decreased (e.g., blood flow, mucous secretion, bicarbonate secretion).

### **Asbestos, Cigarette Smoke, and Lung Cancer**

Asbestos exposure is a risk for lung cancer and for mesothelioma. Smoking is a high risk for lung cancer. Asbestos workers who smoke have an explicitly potentiated risk to develop lung cancer compared to nonsmoking asbestos workers (Klebe et al. 2019).

### **Gluten and Celiac Disease**

Celiac disease is an inflammatory reaction of the intestinal mucosa triggered by gluten of wheat and structurally related proteins of other cereals (Lerner et al. 2017). It involves the following mechanisms: Gliadin molecules are poor substrates for gastric and intestinal proteases. When the intestinal barrier is compromised, they can gain access to the subepithelial tissue, where they get deaminated by tissue transglutaminase. As side product of this catalytic process, protein adducts may be formed. These are identified by the adaptive immune system of predisposed individuals as “foreign” neo-antigens, inducing sensitization, local inflammation, and an autoimmune response with production of antibodies. When exposure continues after the initial sensitization, the now inflamed mucosa loses its barrier function as well as the ability to efficiently absorb nutrients. Gluten is categorized as food allergen. An essential help for individuals with celiac disease is the labeling of gluten-containing and/or gluten-free food products.

### **Alpha-1 Antitrypsin Deficiency and Lung Function**

Alpha-1 antitrypsin is an endogenous inhibitor of overshooting, tissue damaging protease activity, notably in the lung. The pulmonary form of the genetic disorder

“alpha-1 antitrypsin deficiency” is associated with accelerated aging of the lung (emphysema) and airway hypersensitivity toward inhaled irritating chemicals and smoke.

## Iron and Iron Storage Disease

In hereditary hemochromatosis, severalfold more iron tends to be absorbed from food than in normal conditions. The iron overload causes liver disease and other disorders. This reveals the intrinsic toxicity of iron, when the normal tight biological regulation of iron levels fails.

## Age-Dependent Sensitivities

*Fetus:* Ethanol readily distributes across the blood-placenta barrier, so that the developing fetus and its neuronal system are exposed to ethanol in drinking pregnant women, sometimes with the outcome of an irreversible fetal alcohol syndrome of the offspring, characterized by deficits in physical and mental capabilities.

*Newborns:* Opiates and opioids taken by pregnant women may cause acute respiratory depression and withdrawal syndromes after delivery.

*Children:* The metal lead and its compounds are more toxic in children compared to adults, because children absorb the metal more efficiently and their developing brain is more susceptible to the intrinsic neurotoxicity of lead compared to adults.

*Elderly people:* Organ function declines with age. This is evident with heart function, lung function, liver function, and kidney function and associated changes of blood circulation. So elderly people are more susceptible to substances with the intrinsic toxic feature of inhibiting oxygen transport by hemoglobin (e.g., carbon monoxide) or oxygen utilization for ATP production in mitochondria (cyanide). As renal glomerular filtration and hepatic drug-metabolizing capacities decrease with age, dosing of many pharmaceutical drugs must be adapted to avoid overdosing.

## Poor Metabolizers

Due to the polymorphism of cytochrome P450 isoenzymes, the metabolic rate of some substances varies considerably (Leeder 2015) even among healthy young individuals. Poor (slow) metabolism of a substance may be associated with excessive or prolonged effects of pharmaceuticals. An example is the unusually strong decline of blood pressure after repeated intake of the antihypertensive drug debrisoquine that is metabolized by cytochrome P450 2D6. Slowly metabolizing individuals tend to accumulate various drugs (e.g., amitriptyline) with the risk of overdosing and side effects. Genetic deficiency of plasma cholinesterase causes delayed metabolism of the muscle relaxant succinylcholine that is used in anesthesia.

## Summary

Knowledge of intrinsic toxicity concepts may support the risk manager to anticipate the hazard of a chemical for which no toxic profile is known. Such knowledge helps the clinical toxicologist who is confronted with certain symptoms of an intoxicated patient, to make assumptions about the substance that produces such symptoms. The intrinsic toxicity concept is the basis for the analogy principles (chemical-structure analogy and biological effect/symptom analogy) and for bridging approaches that are used to estimate toxicities in situations where toxicological information is incomplete or missing.

## Abstract

Most xenobiotic compounds which require regulation undergo metabolic alterations in the human organism which frequently differ from those occurring in nonhuman species and in in vitro experimental test systems. Some of these differences are fundamental, including the complete absence of metabolic steps which are crucial for the toxicity of the compound under consideration. Examples of crucial species differences in toxicity-related xenobiotic metabolism include MeIQx (2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline), aflatoxin B1, and vinyl acetate which are discussed in this chapter.

## Fundamentals

Most xenobiotics do not remain unchanged in the human organism (and in other organisms), but rather are metabolized (Oesch-Bartlomowicz and Oesch 2007). The change in chemical characteristics of the thereby produced metabolites as compared with the chemical characteristics of the corresponding parent compounds usually leads to changes in both, the desired properties, for example, therapeutic efficacy, and also in undesired properties, that is, xenobiotic metabolism usually is toxicologically not neutral, but rather leads in most cases to toxication or detoxication of the respective compound (for an overview see Oesch-Bartlomowicz and Oesch 2007). Thereby xenobiotic metabolism becomes one of the most important factors controlling the toxicity of the respective compound. This, in turn, makes xenobiotic metabolizing enzymes to control factors for xenobiotic toxicity. These xenobiotic metabolizing enzymes drastically differ quantitatively and in many instances even qualitatively between animal species, organs, cell types, developmental stages, and physiological states such as health and individual diseases, most often even between strains and genders (for a succinct review see Hengstler and Oesch 1999). For an extrapolation of toxicity findings in experimental systems to humans, cognizance of differences in xenobiotic metabolizing enzymes between the systems used and humans is therefore critical.

Quantity and also chemical identity of the formed metabolites depend on many factors. This complexity leads to difficulties to predict from experimental systems which metabolites and how much of them will be generated in humans. Difference in xenobiotic metabolism between species is one of the factors which most profoundly limit the extrapolation of toxicological results obtained in experimental systems to humans (for a comprehensive review see Hengstler et al. 1999). The later considerations in this chapter will therefore especially take this interspecies parameter into account. However, in order to be comprehensive, it must also be stated that in addition to these crucial species differences, further important differences exist also within a given species. This includes genetic differences in xenobiotic metabolism between strains and between individuals. In humans genetic polymorphisms in xenobiotic metabolizing enzymes known to-date account for up to 40% of cytochrome P450 (CYP) dependent xenobiotic metabolism (Modak 2010). The generally used pharmaco-/toxicokinetic default uncertainty factor of 3.2 to account for human interindividual differences in the extrapolation of toxicity data to human may need to be enlarged if it does not encompass human polymorphisms from poor to extensive metabolizers of the xenobiotic compound in question (Schroeder et al. 2011). Moreover, differences caused by different gene expressions during development and disease states drastically influence xenobiotic metabolism, most profoundly if the liver, the organ responsible for the largest portion of the mammalian xenobiotic metabolism, is involved. In addition, environmental factors, nutrition, and drug treatment can profoundly modulate xenobiotic metabolism by enzyme induction or repression, activation or inhibition (for an overview see Oesch and Arand 1999; updated version in German: Arand and Oesch 2019). These numerous factors may interact with each other, generating a high complexity of xenobiotic metabolism

control and consequent toxicities. For instance, very early on, it had already been shown that differences in nutritional status profoundly influenced drug metabolizing enzymes induction (e.g., by DDT) and the consequent toxicity of a third compound (e.g., carbon tetrachloride) (McLean and McLean 1966).

In order to improve the water solubility and excretability of xenobiotics, the organism most often uses conjugation with endogenous water-soluble building blocks such as glutathione, glucuronic acid, or sulfate. Such conjugations need the preexistence of suitable substituents in the xenobiotic compound in question which, if not preexisting in the parent compound, first have to be introduced or liberated. This step in xenobiotic metabolism is called phase I, and the subsequent conjugation is called phase II (the then frequently following active excretion of the generated water soluble metabolite from the cell of origin is often called phase III).

The Phase I metabolites possess at the site to be conjugated electrophilic (such as epoxides,  $\alpha,\beta$ -unsaturated carbonyls) or nucleophilic (such as hydroxyl, sulfhydryl, amino, carboxyl) structural components. Depending on their relative chemical reactivities, electrophilic moieties can have high toxicological potential by reacting with nucleophilic moieties of endogenous compounds. This is toxicologically most significant if the electrophilic moieties modify the structures of macromolecules such as proteins, RNA, and – especially important – DNA. The latter potentially leads to significant genotoxicity. In contrast to this, nucleophilic metabolites usually do not covalently react with endogenous molecules and therefore usually are toxicologically less problematic. However, they can, in some cases, have affinity to receptors and thereby lead to desired therapeutic or undesired toxic interactions.

The conjugating phase II reactions in most cases lead to a large increase in the water solubility of the compound in question, to its efficient excretion and to termination of its biological activity, be it beneficial (therapeutic) or undesired (toxic). However, some important exceptions exist. For instance, some glucuronides (e.g., of morphine) possess high biological activities; some conjugates (e.g., of vicinal halogenated alkanes) with glutathione possess higher genotoxic potential than the parent compound (for an overview see Oesch-Bartlomowicz and Oesch 2007).

The enzymes catalyzing phase I reactions include oxidoreductases and hydrolases. Oxidoreductases relevant for xenobiotic metabolism include cytochromes P450 (CYP), flavin-containing monooxygenases (FMO), monoamine oxidases (MAO), and cyclooxygenases (COX). In most cases these oxidoreductases introduce oxygen into xenobiotic molecules or abstract hydrogen or electrons. CYPs are quantitatively especially often involved in xenobiotic metabolism. Thus, two-thirds of the top 200 drugs prescribed in the United States (year of survey: 2002) are cleared through metabolism that involves CYPs (Williams et al. 2004). Further important xenobiotic metabolizing oxidoreductases include dehydrogenases and reductases such as alcohol dehydrogenases (ADH), aldehyde dehydrogenases (ALDH), and carbonyl reductases. They abstract or add hydrogen atoms. Diverse xenobiotic metabolizing hydrolases catalyze the hydrolysis of esters, amides, glucuronides, sulfates, or epoxides.

In the phases II reactions electrophilic substrates are conjugated by glutathione S-transferases (GST), nucleophilic substrates by UDP-glucuronosyltransferases (UGT), sulfotransferases (SULT), N-acetyltransferases (NAT), acyl-CoA-aminoacid-N-acyltransferases, and methyltransferases (for an overview see Oesch and Arand 1999; updated version in German: Arand and Oesch 2019).

A correct prediction of toxicity is especially important in cases of long latencies such as cancer, since a wrong prediction leads to accumulation of numerous irreversible damages before the error becomes manifest. For such toxicities, electrophilically reactive metabolites are especially important which frequently have a short life span and are formed in low quantities. For such cases, cognizance of reactive metabolites and xenobiotic metabolizing enzymes responsible for their control (formation, detoxication, sequestration into alternative pathways) is especially important. Examples of some important electrophilically reactive metabolites and xenobiotic metabolizing enzymes involved in their control are given in Table 1. An important consequence of the fact that quantitatively minor metabolites may be responsible for toxic (especially for genotoxic) effects is that species-specific divergent pathways leading to such minor but toxicologically important metabolites may become crucial. When a human-only metabolite is not formed in the experimental species chosen for toxicity testing, an incomplete xenobiotic safety assessment may result leading to an underestimation of toxicological risk. The FDA/CDER guidance on safety testing of drug metabolites (U.S. Department of Health and Human Services 2008/2009) therefore states that a unique human metabolite must itself be tested for toxicity when the metabolite level reaches >10% parent systemic exposure at steady state.

Some overall approximations in relatively high similarities of some xenobiotic metabolizing enzymes or their response to exogenous stimuli between certain experimental animal species and humans may be attempted. Although the different animal models have many differences in the ligand-binding domain of the

**Table 1** Reactive metabolites: Some important prototypes

Parent compounds	Reactive metabolites	Enzymes involved in the control
Aromatic/olefinic hydrocarbons	Epoxides	Cytochromes P450 Glutathione S-transferases Epoxide hydrolases

Vicinal dihaloalkanes	Episulfonium ions	Glutathione S-transferases

respective nuclear receptors involved in the control of xenobiotic metabolizing enzymes induction compared with humans (Mohutsky et al. 2010; Evans and Mangelsdorf 2014), induction responses compared with humans appear to be most similar in rats and mice for CYP1A; in rats, mice, and pigs for CYP3A; in monkeys for CYP2C; and in dogs for CYP2D (Martignoni et al. 2006; Zuber et al. 2002; Bogaards et al. 2000). However, some exceptions of outstanding practical importance highlight the fact that a priori acceptance of these overall relatively high similarities may be dramatically misleading for an individual xenobiotic compound under consideration. Thus, rifampicin does not induce CYP3A in rats or mice, but does so in humans (leading to unwanted pregnancies in combined use of contraceptives and rifampicin) and in rabbits (Kocarek et al. 1995; Back et al. 1988). Inversely, pregnenolone-16 $\alpha$ -carbonitrile (PCN), which strongly induces CYP3A in rats and mice, causes no induction in humans or rabbits, and CYP3A induction by 5 $\alpha$ -pregnane-3,20-dione is seen only in humans and mice, but not in rats or rabbits (Mohutsky et al. 2010). For improved predictions animal models have been genetically modified in which some nuclear receptors controlling induction of a xenobiotic metabolizing enzyme of that species has been knocked out and replaced by the corresponding human gene (Ma et al. 2007; Scheer et al. 2008; Gonzalez et al. 2015).

---

## Examples of Metabolism Associated Toxicity

Having discussed the basic aspects of drug metabolism the following chapter will focus on examples of compounds where drug metabolism plays an important role for risk assessment. Usually risk assessment is based on animal experiments. For identification of acceptable human exposures, NOAELs (see ► [Chap. 1, “Aims and Mission of Regulatory Toxicology”](#)) from laboratory animals are used and multiplied with safety factors. Usually this procedure identifies exposure levels that are safe for humans. However, working with safety factors, for example, a fixed safety factor of 10 to consider possible interspecies differences of metabolism, may under certain circumstances lead to mistakes. This is the case when interspecies differences in metabolism between humans and the relevant animal species are huge. To illustrate this problem, some examples of well-characterized compounds will be discussed in the following paragraphs (from: Hengstler et al. 1999 and Hengstler et al. 2003 and references cited therein). It should be considered that they represent extreme and rare cases. Nevertheless, they are important to illustrate how mistakes in risk assessment can be avoided.

---

### MelQx (2-Amino-3,8-Dimethylimidazo[4,5-f]Quinoxaline)

MelQx represents an intensively studied heterocyclic amine found in fried as well as cooked meat. It is formed by a heat dependent reaction between muscle creatinine and amino acids. MelQx is a strong colon carcinogen in rats and mice. However, it

**Fig. 1** Activation of the heterocyclic amine MeIQx (2-amino-3,8-dimethylimidazo-(4,5-f)quinoxaline) to a mutagenic metabolite by liver microsomes of humans, rats and cynomolgus monkeys. The dashed line shows the number of spontaneous revertants in the Ames test (Davis et al. 1993; review: Hengstler et al. 1999)

does not cause colon cancer in cynomolgus monkeys. Therefore, a critical question is whether human risk assessment should be based on the rodent or monkey data. Because of the small evolutionary distance, one might be tempted to favor the monkey for this purpose. However, a relatively simple experiment demonstrates that in this case risk assessment must be based on the more susceptible rodents. An Ames mutagenicity test using microsomes from livers of human, rat, and cynomolgus monkeys as a metabolizing system reveals major interspecies differences. Human and rat microsomes strongly activate MeIQx to a mutagen, whereas microsomes from cynomolgus monkeys are almost inactive (Fig. 1). This corresponds to the mechanism of metabolic activation of MeIQx to a carcinogenic nitrenium ion (Fig. 2). Human and rat cytochrome P450 1A2 form a hydroxylamine that is further metabolized to a reactive N-acetoxy-ester. In contrast, cynomolgus monkeys lack an activity corresponding to human or rat cytochrome P450 1A2. However, it should be considered the cynomolgus monkey represents an exception with respect to MeIQx metabolism. Even other monkey species, such as marmosets, form the hydroxyl amine from MeIQx and are therefore susceptible to its carcinogenic effect. In conclusion, humans are similarly susceptible to MeIQx induced carcinogenicity as rats and do not represent a resistant species, such as cynomolgus monkeys. Therefore, risk assessment must be based in this case on the more susceptible species.

## Aflatoxin B1

Aflatoxin B1 is one of the most potent liver carcinogens for humans and rats. However, the TD50 (the dose that induces tumors in at least 50% of the animals) shows large interspecies differences, ranging between 1 and 6  $\mu\text{g}/\text{kg}/\text{day}$  for different rat strains, whereas even doses of 2000  $\mu\text{g}$  AFB1/ $\text{kg}/\text{day}$  did not yet cause liver tumors in 50% of the C57/BL6 mice. Therefore, the interspecies differences between rats and mice are larger than a factor of 1000, a difficult scenario for human risk assessment.

**Fig. 2** Mechanism of metabolic activation of MeIQx to a DNA binding nitrenium ion by cytochrome P450 1A2 and N-acetyltransferase 2. Humans and rats efficiently form the hydroxylamine. However, cynomolgus monkeys lack a corresponding activity

To study whether humans are as susceptible to AFB1 as rats or rather as resistant as mice, genotoxicity assays were performed using liver microsomes of all three species as a metabolizing system (Fig. 3). Sister chromatid exchanges (SCE) in human lymphocytes were analyzed as a genotoxic endpoint. Incubation of AFB1 (10  $\mu\text{M}$ ) with liver microsomes of all three species caused a clear increase in SCEs when NADPH was added to the incubation mixture, whereby NADPH acts as a cofactor of the cytochrome P450 mediated metabolic activation of AFB1. However, metabolic activation by mouse liver microsomes was stronger compared to human and rat. It should be considered that lower AFB1 concentrations (only 1  $\mu\text{M}$  for mice compared to 10  $\mu\text{M}$  for human and rat) were used. This seems to be in contrast to the aforementioned carcinogenicity studies where mice appeared to be more resistant than rats. However, this discrepancy could be explained by an additional experiment

(Fig. 3). In microsomal preparations, the cofactors of phase II metabolism, such as glutathione (GSH), are too diluted to allow an *in vivo* like phase II metabolism. Therefore, GSH and cytosol of the corresponding species (containing, e.g., glutathione-S-transferases) were added to the microsomal incubations. These experiments showed a strongly reduced SCE induction when mouse cytosol was added (Fig. 3). In contrast, addition of cytosol and GSH did not reduce genotoxicity of human and rat microsomal incubations. Therefore, mouse liver microsomes have a higher capacity to activate AFB<sub>1</sub> to a genotoxic species compared to humans and rats. On the other hand, the cytosolic compartment of mice also shows a higher capacity to detoxify AFB<sub>1</sub>.

Today, the mechanisms underlying these observations are known. Activation of AFB<sub>1</sub> to a genotoxic carcinogen, namely, AFB<sub>1</sub>-exo-8,9-epoxide, is catalyzed mainly by cytochrome P450 1A2 and 3A4 (human). The extremely efficient inactivation of AFB<sub>1</sub>-exo-8,9-epoxide in mouse liver cytosol is catalyzed by the glutathione-S-transferase isoenzyme mGSTA3-3 (synonym: mGST-Yc). In contrast, humans and rats do not express phase II enzymes with a similarly high capacity to detoxify AFB<sub>1</sub>-exo-8,9-epoxide.

An adequate technique for identification of the interspecies difference in AFB<sub>1</sub> susceptibility is analysis of DNA adducts in primary hepatocytes (Fig. 4). While an approximately similar extent of DNA adducts was formed in human and rat hepatocytes, the corresponding data of mice were below the detection limit. Finally, the glutathione conjugation capacity can directly be analyzed, illustrating the low capacity of human liver cytosol to detoxify AFB<sub>1</sub>-8,9-epoxide compared to mice (Fig. 5). In conclusion, humans are more susceptible to AFB<sub>1</sub> mediated carcinogenesis than mice. Therefore, human risk assessment in this case should be based on rat data.

---

## Vinyl Acetate – The Relevance of Practical Thresholds

The examples of MeIQx and AFB<sub>1</sub> have illustrated the importance of basing risk assessment on toxicity data of species that resemble the human situation. This is particularly relevant in case of huge interspecies differences of metabolic activation or detoxication. A further important aspect for risk assessment is the dose response relationship at low *in vivo* relevant doses. In this chapter, we discuss the example of vinyl acetate to illustrate the relevance of threshold mechanisms. Similar principles can be applied to acrylonitrile and 1,3-butadiene which also are produced in large amounts. Vinyl acetate is carcinogenic in rats and mice. After oral administration only tumors of the oral cavity, esophagus and forestomach have been observed. Inhalation studies with rats led to tumors of the olfactory epithelium. Therefore, vinyl acetate represents a typical “site of contact carcinogen.” Vinyl acetate is known to induce DNA protein adducts, chromosomal aberrations, and sister chromatid exchanges. Therefore, it represents a genotoxic carcinogen. Nevertheless, metabolism and mechanism of action of vinyl acetate show some relevant differences compared to MeIQx and AFB<sub>1</sub> that should be considered for risk assessment.

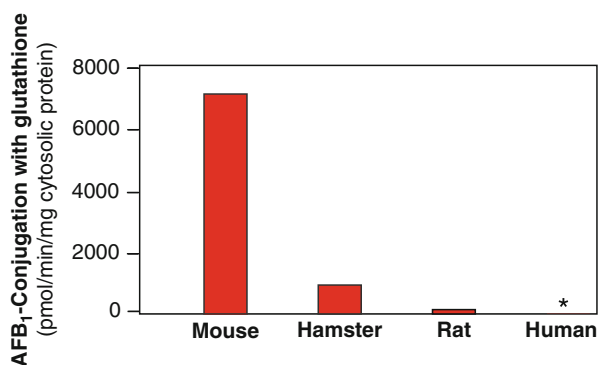

**Fig. 3** Influence of phase I- and phase II-metabolism on the genotoxicity of aflatoxin B<sub>1</sub> (AFB<sub>1</sub>), as evidenced by the sister chromatid assay in human lymphocytes. Venous blood of a volunteer was incubated with AFB<sub>1</sub> in the presence of human (first chart), mouse (second chart), or rat (third chart) liver microsomes. Concentrations of 10 μM AFB<sub>1</sub> were used for incubations with human and rat microsomes. For incubations with mouse microsomes, only 1 μM AFB<sub>1</sub> was used since higher concentrations were no longer in the linear concentration-effect range. First column: negative controls with microsomes, but without the co-factor NADPH. Second column: influence of phase I metabolism in the presence of microsomes and NADPH. Third column: combined influence of phase I metabolism and glutathione-S-transferases in presence of microsomes, NADPH, cytosol, and 2.5 mM glutathione. Forth column: negative control, with the same conditions as for the third column but using heat inactivated cytosol (Wilson et al. 1997; review: Hengstler et al. 1999)

Importantly, vinyl acetate is rapidly metabolized to acetaldehyde and acetic acid. This reaction is catalyzed by carboxyl esterase and aldehyde dehydrogenase. Acetaldehyde can cause DNA-protein crosslinks and finally chromosomal aberrations at high concentrations. Acetaldehyde represents the only genotoxic metabolite of vinyl acetate. The parental compound is not genotoxic. Also, the second metabolite, acetic acid, may contribute to vinyl acetate cytotoxicity by decreasing the pH value. Decreases of the pH value of less than 0.15 units usually remain without toxic

**Fig. 4** DNA binding of  $^3\text{H}$ -aflatoxin  $\text{B}_1$  in cultivated hepatocytes of humans (three donors), rats (Sprague Dawley, male and female), and mice (CD-1, male) after incubation for 24 h (Cole et al. 1988; review: Hengstler et al. 1999). (\*, Below detection)

**Fig. 5** Conjugation of aflatoxin  $\text{B}_1$ -8,9-epoxide (generated by incubation with microsomes) with glutathione by cytosol of livers from mice, hamsters, rats or human (Slone et al. 1995). (\*Below detection limit)

consequences. However, a further decrease in pH may cause cytotoxicity and replacement proliferation. This will promote carcinogenesis resulting from acetaldehyde induced DNA lesions.

For risk assessment, it is important to consider that both metabolites of vinyl acetate, acetaldehyde, as well as acetic acid also are endogenously formed in the organism. Acetaldehyde is formed in threonine metabolism. Endogenously, acetaldehyde is present in concentrations of approximately  $0.3 \mu\text{g}/\text{ml}$  blood. Exposure to vinyl acetate at levels that increase acetaldehyde and acetic acid within the endogenously occurring range does not induce tissue damage or carcinogenesis, which will be shown below. Therefore, it can be concluded that the organism has established protective mechanisms that avoid tissue damage at physiological levels of both vinyl acetate metabolites. Exposure to vinyl acetate should be acceptable if the resulting increase in acetaldehyde and acetic acid at the highest exposed cells of the organism is lower than endogenously formed concentrations.

Although the aforementioned theoretical considerations may seem plausible, the assumption of a "practical threshold" is only acceptable when proven by experimental data. Dose response experiments for vinyl acetate induced carcinogenicity

**Fig. 7** Five critical steps on path to cancer induced by vinyl acetate in the olfactory epithelium (from: Hengstler et al. 2003). Panel 1: Concentrations of acetaldehyde in the basal cells of the olfactory epithelium, the cells of origin of nasal tumors. Panel 2: Reduction of pH in relation to vinyl acetate exposure. Reduced pH is responsible for cytotoxicity in the olfactory epithelium (panel 3), which causes replacement proliferation (panel 4) and finally promotes induction of nasal tumors (panel 5)

mechanisms. Vinyl acetate exposure of 600 ppm will lead to a concentration of 12.4  $\mu\text{g/ml}$  acetaldehyde in basal cells (step 1). The pH value will decrease by 0.49 units (step 2) which will cause degeneration of the olfactory epithelium (step 3) and will lead to replacement proliferation (step 4) of basal cells. Therefore, all steps critical for carcinogenesis are active at 600 ppm vinyl acetate. This leads to a clear increase of tumor incidence (Fig. 7). The model demonstrates that the mechanisms critical for carcinogenesis (steps 1–4) become active only when threshold concentrations of acetaldehyde and acetic acid are exceeded. These threshold concentrations will only be exceeded when vinyl acetate exposure occurs above certain levels (Fig. 7). In conclusion, two metabolites, acetaldehyde and acetic acid, are responsible for the toxic and carcinogenic effects of vinyl acetate. Both metabolites also occur endogenously. Only above certain threshold concentrations carcinogenicity can be expected. Therefore, risk assessment of vinyl acetate has to take into account quite different principles as for, for example, aflatoxin B<sub>1</sub> or heterocyclic amines where similar threshold mechanisms are not known.

## Abstract

Controversy on toxicological dose–response relationships and extrapolation of an incidence to low dose can be the consequence of misleading data presentation, diverging mechanistic understanding, or lack of differentiation between a continuous response variable, such as any concentration of a biomarker, and an incidence derived from a binary response (yes or no?) in individuals (dichotomous variable). In this chapter, we address respective issues and illustrate them with examples for genotoxicity, mutagenicity, and cancer incidence. The rate of any interaction of a toxicant with a biological target molecule at low dose is proportional to its concentration. Linear extrapolation is therefore a reasonable default for rates of first-line interaction in the low-dose range. In toxicity testing however, (i) we do not measure rates of interactions but concentrations of biomarkers, and (ii) we deal with a dose range that usually expands to overt toxicity. Deviation from linearity is observed with increasing dose whenever saturation, inhibition, or induction of a process involved comes into play.

## Introduction

A nonmonotonic shape of the dose–response curve may be observed as a special case of nonlinearity, if a background measure in untreated controls is decreased at low dose but increased at high dose. A dose response can appear as a threshold if two processes that affect the background level in opposite directions cancel each other out. A mathematical threshold, where there is no effect at all up to a defined breakpoint of the dose–response “curve,” cannot be advocated for any continuous response measure. We use computational modeling to characterize how competing influences that are dominant over different dose ranges combine to generate different shapes. The situation is different for an incidence of a defined effect, e.g., a diagnosis of cancer. On an individual level, the response is given by a binary “yes or no.” For dose response, each individual has its own “threshold dose” to switch from “no cancer” to “cancer”; the dose–incidence “curve” represents a staircase of individual threshold doses and reflects the tolerance

distribution in the examined population. Extrapolation to low dose therefore follows differences in individual susceptibility and cannot be predicted by the mode of interaction between toxicant and biological target. For complex endpoints of toxicity such as cancer, individual susceptibility is determined by numerous genetic and in-life factors, such as enzymatic activation and detoxification of endogenous and exogenous carcinogens, DNA repair, or cell cycle control. Multiplicative combination of the individual activity of these factors and application of the central limit theorem of statistics suggests that the tolerance distribution – and with this the dose–incidence relationship – is approximated by a cumulative normal curve against  $\log(\text{dose})$ . Using this model for a dose–incidence extrapolation, the cancer risk drops faster than by linear extrapolation, the more we approach dose zero. In the last section, we combine a mechanistically supported nonmonotonic dose response with individual differences for the rate of the underlying counteracting processes. Monte Carlo simulations indicate that a non-monotonic shape of a dose response for a biomarker, determined as an average of a dose group, does not exclude a monotonic shape for some individuals. An observation of a nonmonotonicity in animals cannot be carried over by default to a dose–incidence response in a human population.

## Dose–Response Curve in Textbook

The usual representation of a dose–response relationship is the cumulative normal distribution against the logarithm of the dose (Fig. 1). It is based on the finding that a lognormal curve often provides a good fit to data of different types of response variables. This holds for continuous response variables such as any rate of a process

**Fig. 1** Typical sigmoid shape of dose–response curves in textbooks of pharmacology and toxicology for different types of response variables, using a logarithmic scaling of the dose axis. *Left* (continuous response variables): ligand–receptor binding (*B*) and receptor-mediated response (*W*, “Wirkung”) as a function of the logarithm of the ligand concentration (*substance A*). *Right* (dichotomous variable): incidence of a therapeutic effect (*E*) or of death (*L*) shown as a function of  $\log(\text{dose})$ . (Reprinted with permission from Aktories/Förstermann/Hofmann/Starke, *Pharmakologie und Toxikologie*, 9. Auflage 2005, Abb. 1–4 and 1–7, Urban & Fischer, München)

**Fig. 2** Three shapes of dose–response curves that could be interpreted as indicating some type of “*threshold*”: linear–sublinear (a nonzero slope at low dose, bending up at an undefined threshold), mathematical threshold ( $slope = 0$  up to a defined breakpoint dose), and nonmonotonic dose response ( $slope < 0$  below the “threshold”). (Reprinted with permission Lutz and Lutz 2009)

or concentration of a biomarker, as well as for an incidence of a defined effect, which is based on a binary (yes-or-no) response in individuals.

For an extrapolation to background (dose zero), the logarithmic dose scaling may be misleading because the sublinear appearance at the low-dose end may be interpreted as indicating a threshold. For an appropriate discussion of dose–response curves, it is crucial to understand (i) the consequences of logarithmic scaling of the dose axis and (ii) to clearly define the term “threshold.”

Figure 2 shows that “threshold” could mean different things (Lutz and Lutz 2009). One curve starts with a positive but statistically insignificant slope and bends up at the “threshold dose”; the second is a mathematical threshold that is defined by an initial slope zero, followed by  $slope > 0$  at some breakpoint; and the third has an initially negative slope, which results in a nonmonotonic shape over the whole dose range. We will later discuss mechanism and conditions that may lead to the different types of “threshold.”

### The Logarithm “Catch”

First of all, we must caution against the use of a logarithmic scale for the dose axis in connection with a discussion of dose–response extrapolation (Lutz et al. 2005). Problem #1: Since  $\log(0)$  is indefinite (“ $-\infty$ ”), the response measure of

**Fig. 3** Logarithmic representation of the dose axis distorts the straight line of a linear dose response into a threshold appearance. All three representations show the same linear dose–response relationship  $y = 5 + 10 \cdot x$ . *Left:* arithmetic dose scale; *center:* log scale spanning one factor of ten for dose; *right:* log scale spanning seven factors of ten down to dose  $10^{-6}$

the control group at dose zero cannot be plotted in the same graph together with the treated groups, and visual inspection of the dose range of extrapolation to background is not possible. Problem #2: Logarithmic scaling of the dose axis distorts a straight line (“linearity”) into a threshold-like curve. Figure 3 shows different representations of the same linear function  $y = 5 + 10 \cdot x$ . An arithmetic scale is used for the left panel. The center panel uses a logarithmic scale and spans doses between 0.4 and 4. A sublinear shape is seen. The right panel spans six orders of magnitude down to dose  $10^{-6}$ . The dose groups that show an increase above control are compressed into one factor of ten and appear with a steep slope. Such a delusive appearance of a threshold still shows up in publications. It is easily generated by the use of doses that are many orders of magnitude below the no-observed-effect level.

The low-dose part of the sigmoid shape shown for receptor–ligand binding ( $R + L \rightarrow RL$ ) in Fig. 1b is another example of the result of logarithmic dose scaling.

**Fig. 4** Low-dose part of receptor–ligand (RL) complex formation as a function of ligand concentration  $[RL]/[R_{tot}] = [L]/([L] + K_D)$  for the dissociation constant  $K_D = 1$ , shown on a logarithmic scale (*left*; as used in Fig. 1) and on an arithmetic scale (*right*)

The underlying function  $[RL]/[R_{tot}] = [L]/([L] + K_D)$  is not sigmoid but a hyperbola, and linearity is a good approximation at low concentration of ligand  $[L]$ . Figure 4 shows this function on a logarithmic and an arithmetic scale (left and right panel, respectively). Note that Michaelis–Menten kinetics of enzyme reactions follows the same function. This also means that the rate of enzymatic product formation is approximately proportional to the substrate concentration at concentrations below the Michaelis constant.

## Conclusions

The fact that logarithmic scaling of the dose axis provides good data fit by a cumulative normal distribution, data both for continuous variables and for incidences (dichotomous variable), is misleading in two ways. On the one hand, the sublinear appearance of the low-dose part can mimic a threshold even for a linear dose response; on the other hand, it is suggestive of the misconception that the sigmoid shape of a dose–incidence relationship adheres to the same principles as a dose response for a continuous variable.

---

## Continuous Response Variables

### Linearity as Default Extrapolation for Rates of First-Line Interactions

Many biomarkers measured in toxicity testing are concentrations, e.g., products of physical or chemical interaction of a toxicant with a biological target (binding to a receptor or an enzyme; reaction with protein or DNA). According to the law of mass action, the rate of interaction is approximately proportional to the concentration of the reaction partners at low dose. Linear extrapolation is therefore an appropriate default for the low-dose end. This includes situations of complex metabolic

**Fig. 5** Two-step formation of a guanyl-7-adduct in DNA by the carcinogenic mycotoxin aflatoxin B<sub>1</sub> via metabolic activation to the chemically reactive epoxide. *Up- and down arrows* indicate competing processes of detoxification

activation where the toxic reaction product is the result of multiple steps and includes competing reactions. In Fig. 5, the mycotoxin aflatoxin B<sub>1</sub> (AFB<sub>1</sub>), a potent hepatocarcinogen, is shown to react with the seven-position in guanine to form the respective promutagenic DNA adduct. Metabolic activation to the chemically reactive, electrophilic epoxide (in brackets) is a necessary intermediate step. The up-and-down arrows indicate that a number of concurrent reactions (other pathways of elimination; reaction with other nucleophiles, e.g., water or glutathione) take place. All reactions – toxification as well as detoxification – are approximately proportional to the concentration of the reactant as long as capacity-limited processes are not approaching saturation.

Considering extrapolation of a biomarker to low dose, it means that reducing the dose by a given factor is expected to result in a reduction of the biomarker by the same factor. For DNA-adduct levels, for instance, this also means that the rate of formation cannot drop to zero at any low dose. A mathematical threshold for a dose response as shown in Fig. 2 is therefore not possible. As an example of linearity down to the ng/kg dose range, DNA adducts in the liver of rats treated with [<sup>3</sup>H]AFB<sub>1</sub> of high specific radioactivity decreased in a dose-proportional manner for all treatment scenarios at dose levels below 100 ng/kg per day (Fig. 6).

### Deviation from Linearity Due to Saturation of Processes that Modulate Biomarker Levels

Toxicity studies usually include dose levels beyond the range of proportionality for the reaction rates that determine the response measure. Deviation from linearity is therefore the rule rather than the exception. For biomarkers of genotoxicity, one important mechanism that results in sublinear deviation of the dose response for mutation is saturation of DNA repair. Figure 7 shows the formation of a GC → AT base-pair substitution mutation resulting from methylation of guanine at the O<sup>6</sup>-position (G\*). The full process of mutagenesis requires two rounds of DNA replication. It starts with mispairing of G\* with thymine (T) at the first round, followed by

**Fig. 6** Linear dose–response relationships at the low-dose end for [ $^3\text{H}$ ]aflatoxin B $_1$ -DNA adducts in rat liver. Single and multiple daily oral dosing, as well as application in drinking water (DW) for up to 56 days. Note the *double-log plot*: slope = 1 for all *full lines* are indicating proportionality between dose and response, i.e., linear dose response

the correct pairing of T with adenine (A) in the second round. Repair is possible at all stages of the process. At low dose, i.e., at slow rate of DNA-adduct formation, repair may be proportional to the damage, so that mutation rates stay low. The resulting slope of the dose-mutant frequency relationship is positive, but may not be significant. With further increase in dose, repair will become saturated, which results in a steep increase in slope for mutant formation.

Superposition of the rates of formation and repair of DNA are shown schematically in the left panel of Fig. 8. It shows a linear dose response for the rate of DNA-adduct formation (dashed line) and a saturation curve for DNA repair (dotted line). The difference between the two curves (adduct formation minus repair; full line) assumes a sublinear shape for the dose response for mutagenicity.

This situation is considered the mechanistic basis of a threshold-like dose response for the mutagenicity of ethyl methanesulfonate (EMS) in mice. The respective data had been collected in the follow-up of a drug contamination by this ethylating agent (Lutz 2009). Figure 9 shows the induction of lacZ mutants in MutaMouse<sup>®</sup> treated daily for 28 days with EMS. At low dose, DNA ethylation was probably repaired almost as rapidly as it had been formed. When the enzymatic

**Fig. 8** *Left panel*: schematic representation of the superposition of a dose linear increase for adduct formation (*dashed line*) by a saturable rate of DNA repair (*dotted line*). The result is a sublinear curve for mutant frequency as a function of dose (*full line*). *Right panel* (includes background DNA damage at dose 0): The slope for exogenous adduct formation is the same as in the *left panel*. The repair activity is assumed to be induced (steeper slope at low dose) and active also on background adducts. Superposition results in a nonmonotonic dose response for mutant frequency

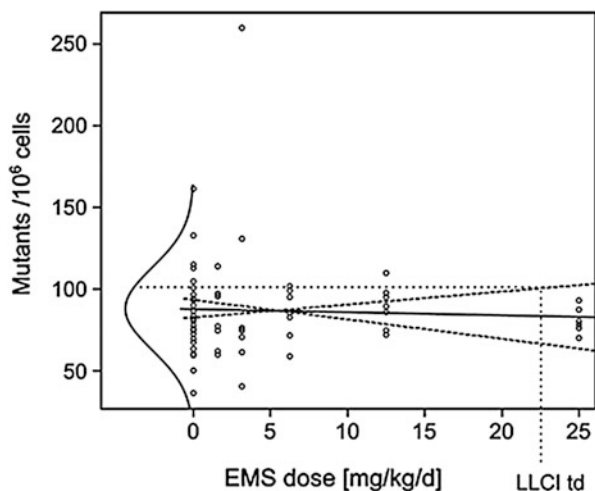

**Fig. 9** Dose response for lacZ mutant frequency in bone marrow cells of MutatMouse™ treated daily for 28 days with ethyl methanesulfonate (EMS;  $\text{CH}_3\text{-SO}_2\text{-O-CH}_2\text{-CH}_3$ ). Circles represent individual mice. The *full line* indicates the best fit by a hockey stick model; the *dashed line* represents the lower limit of a two-sided 90% confidence interval for the respective breakpoint (23 mg/kg per day). (Reprinted with permission Lutz and Lutz 2009)

DNA repair came into saturation with further increase in DNA ethylation, the dose–response curve for mutant induction bent upward. A hockey stick threshold model provided much better fit to the data than a linear dose response and showed a lower limit of a 90% confidence interval for a hypothetical breakpoint at 23 mg/kg per day (dashed line) (Lutz and Lutz 2009).

### Nonmonotonic Shape if Background Is Reduced at Low Dose

In view of the general understanding that both adduct formation and repair are approximately proportional to low dose and the fact that repair always lags somewhat behind, one would expect minute, though positive slope for mutant induction also below the “threshold dose.” In our example, however, linear regression of the mutant frequency data shown in Fig. 9 below the “threshold” shows a slightly negative slope (Fig. 10). It appears as if treatment of the mice with ethyl methanesulfonate below the putative threshold dose had resulted in a minute reduction of the background mutant frequency. If true, how could this be explained mechanistically?

DNA methylation of guanine by S-adenosyl methionine forms an important part of promutagenic background DNA damage. In view of the high mispairing

**Fig. 10** Linear regression of the dose–response data below the threshold dose for lacZ mutant induction by ethyl methanesulfonate shown in Fig. 9 (see respective legend for experimental details). The best estimate of the slope is imperceptibly negative (*full line*). *Dashed lines* indicate the limits of a 90% confidence interval for the slope. The *horizontal dotted line* connects the upper bound of the regression at the threshold dose to the variance of response in control animals shown as a normal distribution. (Reprinted with permission Lutz and Lutz 2009)

potency of  $O^6$ -methylguanine, inducible repair has evolved to limit this dangerous type of DNA damage. The negative slope could therefore be explained by the hypothesis that  $O^6$ -ethylguanine, a DNA adduct similar in structure to  $O^6$ -methylguanine, induced DNA repair even at lowest doses of EMS. If the induced repair was not only active on DNA ethylation but also on background DNA methylation, one could explain the negative slope for mutant frequency. Over a wide dose range then, a nonmonotonic shape appears because of saturation of the induction of repair.

This hypothesis is illustrated schematically in the right panel of Fig. 8. It differs from the schema in the left panel in that it includes a background DNA damage and exhibits a steeper initial slope of repair due to additional induction of repair by DNA ethylation. Superposition of the linear dose response for the formation of adducts by the saturable rate of repair now results in a nonmonotonic shape for total DNA damage.

### Confidence Limits on Low-Dose Effect and Comparison with Background Variation

While linear regression shows a negative, while not statistically significant, slope as best fit to the data, the true slope could also be positive or more negative. This is indicated in Fig. 10 by the dashed lines that show upper and lower limits of a

90% confidence interval for the slope of the linear regression. The question now is whether induced mutant frequency at the threshold dose of 23 mg/kg per day would be of concern if the upper limit of the confidence interval for the slope were true. This can be discussed on the basis of a comparison of the hypothetical increase in mutant frequency with the variation in background observed in the 27 control mice. The horizontal dotted line in Fig. 10 intersects at percentile 72 of a normal distribution fit to the data points, which allows the conclusion that even a statistically unlikely positive slope for mutant frequency would vanish within less than one standard deviation of the background variation.

## Conclusions

The dose–response curve for continuous response variables of early biomarkers of toxicity is the result of a superposition of a number of processes that contribute to the response measure. Each single process shows a monotonic dose response that is approximately linear at low dose and usually saturates with increasing dose. Superposition of the contributing dose responses results in sublinear or supralinear deviation from linearity. If one of the processes reduces the background response level, a nonmonotonic shape may also be observed. A mathematical threshold, where slope zero changes at a defined breakpoint of the curve to slope  $> 0$ , can hardly be explained by a biologically based mechanism. For practical purposes, however, i.e., to provide an estimate and its confidence limits for the point of transition, a simple statistical threshold model such as the hockey stick model might be useful.

## Mechanistic Background of Nonmonotonic Dose Response

Several scenarios that can give rise to nonmonotonic dose responses had been addressed before publication of the EMS data (Conolly and Lutz 2004):

1. Formation of cyclic AMP as a function of the binding of phenylisopropyladenosine to adenosine receptors: Data showing a nonmonotonic shape are explained by the antagonistic action of the adenosine receptors A1 and A2, given the differences in ligand affinity and efficacy of signal transduction. A1: antagonistic, high affinity, low efficacy; A2: agonistic, low affinity, high efficacy.
2. Androgen-mediated gene expression: Combined exposure to native androgen and a synthetic analog interacts competitively at the androgen receptor to form a series of homo- and heterodimers with differing abilities for promotion of gene expression.
3. DNA adducts and mutation: Induction of repair also repairs DNA damage due to a background process. This theoretical example in fact predicted the observations for ethyl methanesulfonate and lacZ mutant induction in transgenic mice discussed above.

**Table 1** Examples of nonmonotonic dose response for processes that are dominated differently over different dose ranges. Response is below background at low dose and returns to background (for androgen-mediated gene expression) or is above background (other three examples) with increasing dose (Conolly and Lutz 2004)

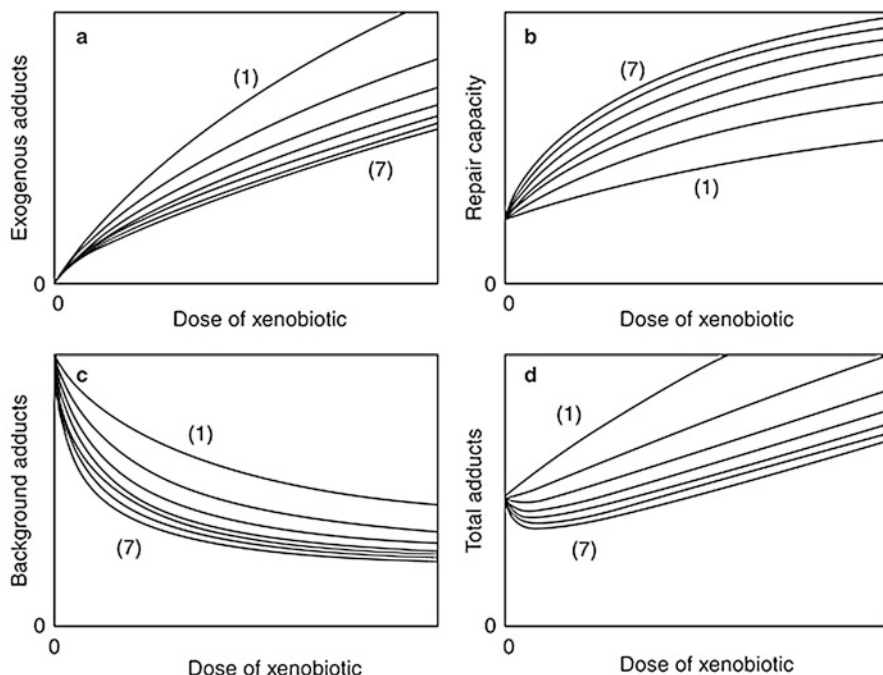

Endpoint	Toxicant or ligand	Dominant influence at low dose	Dominant influence at high dose
Activity of adenylyl cyclase: Formation of cAMP	Phenylisopropyladenosine	Adenosine A1 receptor	Adenosine A2 receptor
Androgen-mediated gene expression	Hydroxyflutamide (in the presence of dihydrotestosterone)	Homodimers (dominant at low and high dose)	Heterodimers (dominant at mid-dose)
Total DNA damage (endogenous plus exogenous)	DNA adduct-forming agent	Induction of DNA repair	Exogenous DNA adducts
Mutation	DNA adduct-forming agent	Cell cycle checkpoint	Exogenous DNA adducts

4. Cell cycle checkpoints: DNA damage activates checkpoints in the cell cycle. Long-duration checkpoints provide additional time for DNA repair before DNA replication can fix the damage as a mutation.

The four examples, though diverse, are all characterized by the presence of more than one influence on the shape of the dose–response curve, with each influence being dominant over a different range of doses (Table 1).

It is possible within these four examples to distinguish two classes of mechanisms that give rise to nonmonotonic dose response. The latter two examples involve adaptive responses of the exposed tissue – induction of DNA repair and activation of cell cycle checkpoints. The first two examples – modulation of adenylyl cyclase activity and androgen-mediated gene expression – do not involve adaptation. Rather, they reflect constitutive biology. Adaptation requires some amount of time, hence any appearance of a nonmonotonic dose response has a temporal aspect – nonmonotonicity will not be seen if the interval between exposure and measurement of the relevant endpoint is too brief. For risk assessment, we are usually concerned with longer-term exposures, so that nonmonotonic responses on all kinds of adaptation must be considered relevant.

Computational modeling can be used to characterize how these influences combine to generate different dose responses, including nonmonotonicity (Conolly and Lutz 2004). This involves “parameter sweeps” where the value of the key parameter is varied across a range to produce a corresponding set of dose–response curves. As an example, for nonmonotonicity due to induction of DNA repair, a sweep on the parameter “induction of DNA repair” was conducted (Fig. 11). When the efficacy of induction is low (panel B; level 1), the dose–

**Fig. 11** Modeling dose–response relationships for DNA adducts as a function of dose of an exogenous mutagen (a), modulated by different levels (1–7) of repair induction (b). (c) Decrease of background DNA adducts due to the induced repair. (d) Total adducts (background plus exogenous) obtained by superimposition of (a) and (c). (Reprinted with permission Conolly and Lutz 2004)

response curve for total adducts is monotonic (panel D, showing the sum of exogenous and background adducts). High levels of induction (levels 4–7) generate nonmonotonic curves of increasing degree. Interestingly, an intermediate efficacy (level 3) leads to a dose–response curve where, at low dose, the increase in the adduct burden due to the xenobiotic is closely balanced by the induction of repair capacity, resulting in a threshold-like curve.

It is tempting to speculate that this result explains the data for ethyl methanesulfonate and lacZ mutation (see Figs. 9 and 10). The data are consistent with an intermediate efficacy for induction of a repair process that acts on both the background burden of promutagenic DNA damage and the damage due to ethyl methanesulfonate. Differentiation between (i) a monotonic curve with a shallow slope  $> 0$ , (ii) a seeming threshold, and (iii) a weakly nonmonotonic curve must be based on plausible mechanistic considerations. Data fitting by different models may find the statistically best fit, but this is no proof of the true shape of the dose response.

Similar results are obtained for the other three cases listed above (Conolly and Lutz 2004). Sweeping on a key parameter leads from a monotonic dose response, through an intermediate, threshold-like regime to a clearly nonmonotonic response.

These results suggest that the conditions, under which nonmonotonicity arises, may be only subtly different from those generating monotonic responses. It possibly involves no more than a quantitative difference in one of the background components of the effect under study.

## “Incidence” as a Different Type of Response Variable

### A Dose–Incidence Relationship Reflects Differences in Susceptibility

The risk of an exposure-related increase in a defined disease is measured as an incidence in a group of animals or humans. Each individual can either manifest this effect (“yes”; response value 1) or not show the effect (“no”; value 0). The incidence is given by the fraction or percent of responders in the group and increases with dose.

Figure 12 shows a hypothetical example of the dose–incidence relationship for the effect of alcohol on a group of ten humans. The yes-or-no criterion of toxicity is defined as the loss of balance to keep walking straight on. The group is given increasing volumes of wine at weekly intervals, and the test is made after 15 min. The graph shows that one individual manifested the adverse effect already when the dose increased from 100 to 150 mL. At the other end of the dose response, it took

**Fig. 12** Representation of a dose–incidence relationship for the effect of alcohol on a group of ten individuals. Dose steps: 50 ml of wine. Each individual has its own threshold dose range to lose balance

more than 400 mL to knock out the most tolerant individual. In other words, the threshold dose for the most susceptible individual was somewhere between 100 and 150 mL; the threshold dose for the most tolerant individual was between 400 and 450 mL. The resulting “curve” therefore represents the distribution of susceptibility (or tolerance) of the individuals in the group exposed.

The problem of risk extrapolation to low dose therefore boils down to the question about whether individuals in a large population show a lower threshold dose than observed in a small group of ten. In order to answer this question, we must investigate the criteria that are responsible for differences in susceptibility. For our example of tolerance of the acute effect of alcohol on the equilibrium, the most important criterion is the volume of distribution for ethanol. Since this is largely determined by the body weight, the most susceptible individual was probably a slim female, the most tolerant a heavy male. Other factors that you may mention are stomach content at the time of drinking (rate of absorption) and habituation to alcohol. Knowledge of the type of interaction of alcohol with its biological target(s), on the other hand, does not help predict the shape of the curve in the dose range of extrapolation. Information on the molecular mode of action is of interest only in the search of factors that may modulate the susceptibility. This limitation of the usefulness of mechanistic information for dose–incidence relationships is not commonly recognized.

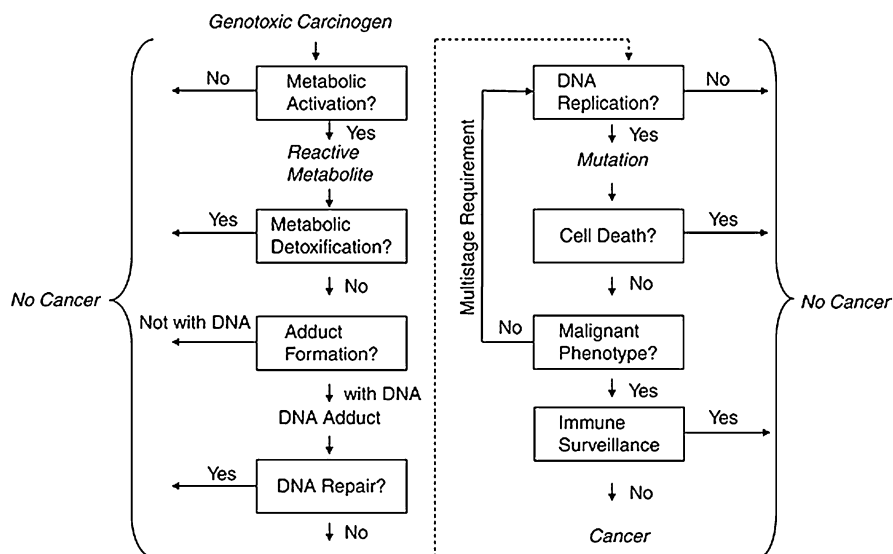

## Conclusions

As opposed to the situation of continuous response variables of biomarkers, a dose–incidence relationship is not a smooth curve but a flight of steps that represents the sequence of individual threshold doses to switch from “no” to “yes.” The flight of stairs reflects the tolerance distribution in the respective group of individuals. Mode of action does not account for the shape of the dose–incidence relationship, but its knowledge may help define susceptibility factors, characterize and model their distribution in the population, and identify susceptible groups and individuals.

---

## Chemical Carcinogenesis and Cancer Incidence

Tumor induction is a complex process with numerous modulatory factors that determine the individual’s probability to manifest the disease after carcinogen exposure. Figure 13 shows a number of factors in rectangular boxes that express important interindividual differences: metabolic activation of a carcinogen, metabolic detoxification, rates of DNA repair and replication, inheritance of activated cancer genes or inactive tumor-suppressor genes, and immune surveillance, to name a few. How should these factors and activities be combined to result in a susceptibility expressed as an individual threshold dose? An example with two factors could illustrate the approach. Assume two individuals who differ by a factor of two for both the rates of detoxification of the aflatoxin epoxide and of repair of the respective DNA adduct. As a consequence, the rate of mutation will be four times as high in the individual with the lower activity for detoxification and DNA repair. In order to generate the same rate of mutation for both individuals, the aflatoxin dose has to be reduced by a factor of four for the more

**Fig. 13** Schematic representation of the process of chemical carcinogenesis by a genotoxic carcinogen. The boxes show factors for which individuals express different activity, which modulates the rates of the steps towards the manifestation of cancer

susceptible individual. As a conclusion, for quantitative combination of susceptibility factors, individual rates have to be multiplied.

## Multiplicative Combination of Susceptibility Factors Results in a Lognormal Distribution

The central limit theorem of statistics states that *sums* of a large number of independent random variables are approximately normally distributed. The Galton board (1889) shown in the top left panel of Fig. 14 illustrates the principle, for the simplest situation of the sum of ten binary variables, where balls that can fall either to the left or to the right (Limpert et al. 2001). *Multiplicative* combination of the ten variables calls for different shapes of the triangles, as illustrated in the top right panel of Fig. 14; the distribution now has a positive (right) skew. The bottom panels demonstrate that logarithmic transformation of the x-axis reverts the right skew to the symmetry of the normal distribution defined by its mean and a *multiplicative* standard deviation.

To implement these findings for a discussion of a dose–cancer incidence relationship means that the x-axis represents the dose axis; balls represent human individuals with different threshold doses of carcinogen to get cancer. The binary factors chosen for the Galton board obviously do represent the world of biology. The factors that modulate the rate of chemical carcinogenesis as shown in Fig. 13 can assume different types of distribution and variance. It will be a future task to collect the respective information

**Fig. 14** *Top*: the Galton board (1889). Physical models illustrating the central limit theorem of statistics. *Left*: additive superposition of ten “good or bad” random susceptibility factors. *Right*: multiplicative superposition of factors, which generates a right-skewed distribution. *Bottom*: using a log scale, the *right* skew (*left* panel) converts back to the normal distribution (*right* panel). (Reprinted with permission Limpert et al. 2001)

in the human population. The larger the number of factors and the larger their variances, the larger will the multiplicative standard deviation of the lognormal distribution become.

## Extrapolation of a Dose–Cancer Incidence Relationship

### It Is Time for a Revival of the Lognormal Distribution for Cancer Risk Extrapolation

The first model employed by the US regulatory agencies to estimate a cancer risk at low dose utilized the Mantel–Bryan procedure (Mantel and Bryan 1961). Starting from animal data and considering a wider variability in the human

**Fig. 15** Dose–cancer incidence relationship following on a lognormal susceptibility distribution. Carcinogenic potency  $TD_{50} = 1$  (incidence 0.5 [50%] at dose 1). Multiplicative standard deviation  $\log_{10}(10) = 1$ , i.e., a dose-reduction factor of 10 results in an incidence reduction by 1 standard deviation (Mantel and Bryan 1961). The extrapolated cancer incidence for dose 0.1, 0.01, 0.001, and 0.0001 is 0.16, 0.023, 0.0014, and 0.00003, respectively (see also Table 2)

population, the susceptibility was suggested to follow a normal distribution against  $\log_{10}$  (dose) with a conservative multiplicative standard deviation of 10 (called “slope 1” [ $\log_{10}$  of 10]). In other words, reduction of the dose by a factor of ten was assumed to result in a decrease of the incidence by one standard deviation. The approach was abandoned because of the uncertainty associated with the assumption on the slope and because of arguments of the stochastic aspects of carcinogenesis.

Dose–response data for tumor incidence in humans are very limited. For lung cancer incidence as a function of cigarette smoking, the data available for British physicians were analyzed using different models, including a lognormal distribution. Best fit was achieved with a multiplicative standard deviation of 5.75 (Whittemore and Altshuler 1976). The drop in risk for drop in dose for this particular example is therefore steeper than when using the default assumption of Mantel and Bryan.

The dose–cancer incidence curve that follows a lognormal susceptibility distribution is shown in Fig. 15. As starting point it assumes a dose of 1 for a 50% tumor incidence; the drop in risk with drop in dose follows the conservative assumption of Mantel and Bryan. The graph shows the respective drop in risk from 0.5 to 0.16 (16%) with the first step in dose reduction by a factor of 10 and a reduction from 16% to 2.3% by another factor of ten. The graph does not allow visual assessment of the cancer risk with further decrease in dose. Table 2 provides this information down to  $10^{-5}$  times the  $TD_{50}$ , both for the Mantel–Bryan

**Table 2** Low-dose extrapolation of cancer incidence in a population of 100,000. Comparison between a linear and two lognormal dose–response relationships with different standard deviations. Assumptions: tumorigenic potency:  $TD_{50} = 1$  dose unit; dose-reduction factor: 10

Dose	Linear extrapolation		Lognormal extrapolation multiplicative SD = 10 ( $\log_{10}$ probit slope 1)		Lognormal extrapolation multiplicative SD = 5.75 ( $\log_{10}$ probit slope 0.76)	
	Incidence in 100,000	Risk reduction factor	Incidence in 100,000	Risk reduction factor	Incidence in 100,000	Risk reduction factor
1 ( $TD_{50}$ )	50,000		50,000		50,000	
0.1	5,000	10	15,865	3	9,412	5.3
0.01	500	10	2,275	7	425	22
0.001	50	10	135	17	4	107
0.0001	5	10	3	45	0.007	558
0.00001	0.5	10	0.03	110	0.000002	2987

assumption and the human lung tumor data for smokers. Comparison with a linear extrapolation allows the following conclusions: At relatively high-dose levels in the range of 0.1 times the  $TD_{50}$ , linear extrapolation drops faster than the lognormal extrapolations. The ranking reverses with every further dose step towards zero. At dose 0.0001 times the  $TD_{50}$ , for instance, linear extrapolation predicts a much higher incidence than following the lognormal curve postulated for lung cancer in smokers.

## Tolerance Distribution Versus Stochastic Modeling

Knowledge on susceptibility factors for the rate of carcinogenesis as shown in Fig. 13 has increased dramatically in the last few decades. Major advances can be noted for the inheritance of mutant “cancer genes” of individual differences for DNA repair and metabolic activation and detoxification. The use of tolerance distribution models for cancer risk extrapolation therefore deserves a revival. Yet, a number of aspects of the process of chemical carcinogenesis may keep a stochastic element. For instance, the question of whether a DNA adduct is formed in a critical gene (oncogene or tumor-suppressor gene) or in an innocuous gene will not be fully predictable on an individual level.

## Conclusions

A dose–cancer incidence relationship for a given population is predictable to the extent of our knowledge of the distribution of individual risk factors. Confidence limits will have to be widened to account for remaining stochastic aspects. These limitations do not invalidate the general statement that linear extrapolation of a treatment-related excess cancer risk to background incidence is inappropriate.

## How to Incorporate a Nonlinearity of an Experimental Biomarker in a Dose–Incidence Relationship?

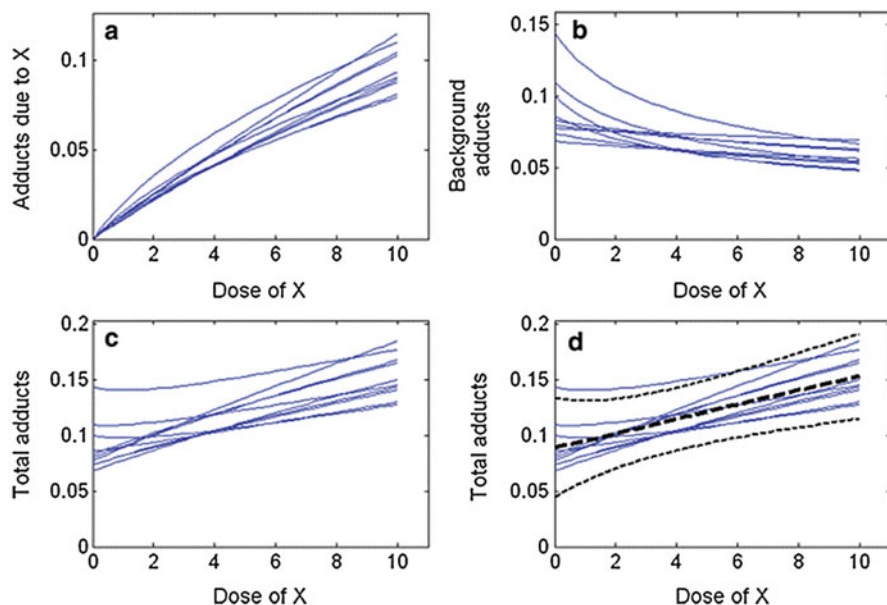

The threshold-type dose response shown above for mutant induction in mice treated with ethyl methanesulfonate (Figs. 9 and 10) leads us to the question how this knowledge can be used for a dose–incidence curve for humans exposed to this genotoxic agent. Since a dose–incidence curve is not directly dependent on mode of action but follows the distribution of tolerance within the population, the question must be addressed whether the factors that result in the deviation from linearity in the transgenic mice also operate in the human population. How is the activity of the protective factor(s) distributed among individuals? In the particular case of repair of DNA ethylation, it will be important to investigate whether there are individuals that may not benefit from this type of DNA repair and its induction.

Since DNA methylation is one of the most critical types of background DNA damage, an individual with little or no respective repair would probably accumulate lethal mutations already during fetal development. It could therefore be assumed that all newborn are able to repair DNA methylation to an extent required for survival and show a nonlinear dose response for exogenous DNA ethylation. Whether there is even a nonmonotonic shape as shown as an average response in mice will depend on the distribution in the human population of the inducibility of repair activity.

## Monte Carlo Simulations to Differentiate the Dose Response for a Population Average Versus Individuals

Our model for induction of DNA repair is based on a normal distribution for the parameter that determines the efficacy with which DNA damage due to the xenobiotic induces DNA repair. Monte Carlo sampling allows prediction of dose–response curves for individual members of a population (Fig. 16). The four panels show how individuals in a population can differ in their response to genotoxicant exposure, given interindividual variation in ability to induce DNA repair. All types of dose–response curves are seen: monotonic, seeming thresholds, and nonmonotonic. Note that the mean and the lower confidence limit are monotonic, while the 95% upper confidence limit on the mean response is nonmonotonic. Similar results are obtained for the Monte Carlo version of the model predicting how activation of cell cycle checkpoints affects the rate of mutation (Conolly et al. 2005).

While computational studies and simulations are theoretical and while we know of no dataset that actually shows different behaviors of dose response in human individuals, we do think that the results suggest mechanisms by which individuals within a population may have quite different susceptibilities to xenobiotic stressors.

**Fig. 16** Monte Carlo simulation with ten runs to generate dose–response curves for ten individuals who vary in their ability to induce DNA repair capacity. (a) Formation of DNA adduct from xenobiotic as a function of dose. (b) Background (endogenous) DNA adducts as a function of the dose of X. (c) Total DNA adducts (endogenous plus exogenous). (d) Same as (c) plus *dashed lines* to show the *upper* and *lower* 95% confidence limits and the mean for the population. (Reprinted with permission Conolly et al. 2005)

## Conclusions

A nonmonotonic shape of a dose response shown for a population average does not exclude a monotonic shape for subpopulations or individuals. This limitation holds both for a dose response of a continuous biomarker and for a dose–incidence relationship. Nonmonotonicity cannot be considered a default for a population unless there are convincing arguments that all individuals meet the same quantitative criteria for the underlying modulatory factors.

## Abstract

A health risk for an individual due to an exposure to a hazardous substance depends upon the properties of the substance, the amount of the substance, and the susceptibility of the individual. If an individual is susceptible to a particular hazardous substance only the amount of the substance determines the risk resulting from the exposure to this substance. In the case of local effects the concentration of the hazardous substance in the environment and the duration of the contact determine the risk, with the exception of allergic reactions where the susceptibility is more significant. In the case of systemic effects only the internal exposure or dose is relevant for the risk. Therefore, it is important for the marker of exposure to be a good surrogate for the dose in the target organ. If appropriate methods are available a biological monitoring is more significant for risk assessment as compared to ambient monitoring. If biomarkers of effect are available not only the general but also the individual risk can be assessed.

**Introduction**

Risk assessment is the quantification of the likelihood that a quantitatively defined exposure of an individual (or a group of individuals) to a given chemical might result in some adverse health effects. The probability depends on three elements: the risk factor itself (hazard or hazardous substance), the level and duration of exposure, and the individual susceptibility.

This can be described with the simple equation:

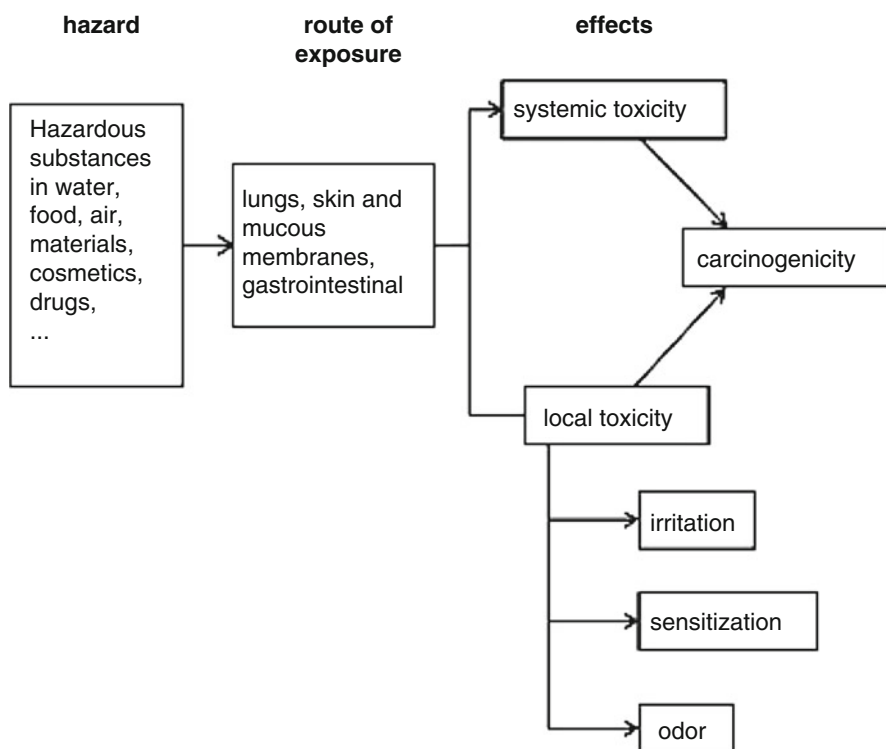

$$\text{Risk} = \text{Hazard} \times \text{Exposure} \times \text{Susceptibility}$$

The equation states that for an existing level of risk to be present, each of the three components must be different from zero (Manno et al. 2010). A risk assessment needs information about the hazard and the susceptibility and must be based on a valid exposure assessment.

Exposure assessment requires a monitoring of the concentration of the hazardous substances in the air or in materials, or the concentration of the substances or their metabolites in the body fluids of exposed persons. For this purpose it is necessary to use analytical methods which have been tested for reliability and practicability. An appropriate internal quality assessment as well as an external quality assessment of the applied methods is essential to assure the accuracy and the comparability of results. For example, the international program of the German External Quality Assessment Scheme (G-EQUAS) provides proficiency testing for most of the human biomonitoring parameters, which are commonly used for the assessment of the human exposure to chemicals (Göen et al. 2012).

If scientifically based threshold limits in water, food, or air are available the exposure assessment is often used in terms of a risk assessment for human health. This means that in cases where the threshold limits are exceeded it would result in a concrete risk to the individual. This is best possible for local effects caused by the hazardous substance. For a systemic effect, however, this would be justified only when the measured value in water, food, or air is a good surrogate for the effective dose in the human body.

Hazardous substances from the environment come into contact with the human body via mucous membranes, skin, lungs, and the gastrointestinal tract. The critical toxicity of a hazardous substance can be its local toxicity or its systemic toxicity (Fig. 1).

**Fig. 1** Hazards and effects

---

## Local Toxicity

### Irritation

Exposure of persons to hazardous substances can cause irritation or erosion of the skin or the mucous membranes. These effects depend on the characteristics of the hazards and their concentration in the environment. At workplaces the concentration of a hazardous substance in air is of importance. Many occupational exposure limits for hazardous substances in air are based on irritative effects seen in man or in animals. For these hazards a time-weighted average threshold limit value (8 hours) would not be protective. Therefore, either short exposure threshold limit value for a 15-minute period or, in the case of a substance with a very high irritative potential, even ceiling threshold limits are evaluated. A guidance on how local irritancy data should be incorporated into risk assessment procedures, particularly with respect to the derivation of occupational exposure limits (OELs) has been published by Brüning et al. [2014](#).

## Sensitization

Allergies caused by chemical substances affect mostly the skin (contact eczema, contact urticaria), the respiratory passages (rhinitis, asthma, alveolitis), and the conjunctiva (blepharconjunctivitis). The kind of allergy is mainly determined by the chemical properties of the substance.

The development of a contact allergy of the delayed type is determined by several factors like the sensitization potential resulting from the chemical properties of the substance, the exposure concentration, the size of the exposed skin area, the duration and manner of exposure, the genetic disposition of the person, and, last but not the least, the state of the tissue with which the substance makes contact (DFG 2020). Therefore, apart from the concentration, susceptibility is also significant for skin sensitization. The size of the skin area correlates with the number of dendritic cells in the skin which come into contact with the allergen and, thus, also influences the risk of sensitization. A quantitative dermal exposure assessment that is valid is very difficult to do (Ness 1994) and not practicable for a routine exposure assessment. As the sensitization depends on the concentration of the substance there are ceiling concentrations for many allergens (e.g., formaldehyde, Nickel, fragrance) in consumer products. This should prevent sensitization; however, for already sensitized individuals the risk of an allergic reaction remains.

The allergic reactions of the airways and conjunctiva which take the form of bronchial asthma or rhinoconjunctivitis mostly involve reaction of the allergen with specific IgE antibodies and belong to the manifestations of the immediate type. Most respiratory allergens are macromolecules, mainly peptides or proteins. But low molecular weight substances can also produce specific immunological reactions in the airways. Allergic reactions of the immediate type can also cause systemic reactions and even anaphylactic shock. The development of allergies of the respiratory passages, like that of contact allergies, is dependent on a number of factors. In addition to the substance-specific potential for causing sensitization, the exposure period and the genetically determined disposition of the exposed person play a decisive role. Particular attention should be drawn to atopic diathesis which is characterized by an increased susceptibility to atopic eczema, allergic rhinitis, and allergic bronchial asthma with increased IgE synthesis (Schnuch et al. 2002). But the concentration of the allergen in air is very important for sensitization (Drexler et al. 2000) as well as for the provocations of symptoms (Drexler et al. 1999). So far it has been possible to evaluate health based threshold limit values only for a few allergens (isocyanates, flower).

For individuals who are already sensitized the individual susceptibility is very significant for the risk assessment. At least for the high molecular type-1 allergens persons with the so-called atopic diathesis have a considerably higher risk for sensitization than non-atopic individuals. After sensitization the hazards cause the allergic symptoms only in sensitized individuals. For non-sensitized individuals the susceptibility is zero, and according to the equation mentioned in the beginning of the text, the risk, therefore, is zero independent of the exposure.

## Local Carcinogenicity

Carcinogenic substances can cause the risk of a systemic or a local cancer (e.g., asbestos, cadmium for lung cancer). In the case of a local cancer risk only the concentration in air is relevant for the extent of the hazard. It is, however, very important to differentiate between the total dust and the inhalable dust fraction which can enter the alveoli. Only the inhalable fraction of the dust is the fraction which is relevant to health. The aerodynamic diameter determines the fraction which enters the thorax (thoracic fraction). Some of the smaller solid particles and droplets are deposited in the tracheobronchial region or in the alveolar region. For this reason it is not enough to measure only the mass ( $\text{mg}/\text{m}^3$  or ppm). The number of particles and their geometry are also very important for the resulting health risk (DFG 2020).

---

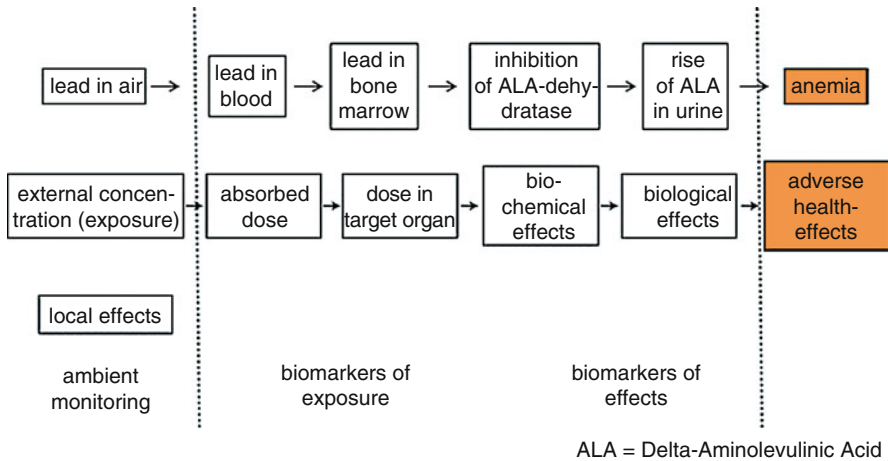

## Systemic Toxicity

For hazardous substances which cause a systemic toxicity the quantification of biomarkers of exposure is a better surrogate than the quantification in food, water, materials, or air because only the amount of the hazardous substance which is incorporated into the body is relevant for the dose. The amount of the hazardous substance incorporated is very difficult to assess based only on the values in food, water, and other materials because the question as to how much of the hazardous substance is released and how much is absorbed can never be answered correctly. This is even true for hazardous substances in air because the amount of ventilation, the distribution of the hazardous substance during the time period, and the local distribution have a relevant influence on the dose. Also at work places it is often the additional skin contact which can be quantified only by means of a biological monitoring that is relevant.

In Fig. 2 the course of an externally caused health effect, for example, a lead induced anemia is shown. A part of the hazardous substance is absorbed from the environment and can be quantified as the internal exposure, like lead levels in blood in the above example. The amount which gets into the target organ correlates in most cases with the internal dose like lead in blood and lead in bone marrow. Early biochemical effects like the inhibition of the delta aminolevulinic acid (ALA) can be compensated without a biological effect. Chronic or intensive exposures result in initial biological effects (rise of ALA in urine) before the adverse health effect (anemia) is seen.

Biomarkers of exposure are the concentration of either a substance or its metabolites. There are various methods for analysis of hazardous substances in biological materials that have been published (DFG 2010). Important for the correct interpretation of the results is among others the knowledge of the half-life of the parameter which could be in the range of a few minutes (e.g., some solvents in blood) to many years (e.g., PCB, dioxins).

Detectable effect parameters like protein adducts and DNA adducts are also biomarkers of exposure as long as they have no role in the pathogenesis. The most

**Fig. 2** Monitoring hazards and effects

commonly used protein adducts are hemoglobin adducts. The number of adducts with the amino acids in the hemoglobin is so low that the adducts do not influence the function of the hemoglobin. The advantage of the use of hemoglobin adducts is their half-life. Taking into account the life span of erythrocytes the hemoglobin adducts are used to assess the exposure during the last 3 months before the blood sampling. DNA adducts are biological target dose markers which reflect the exposure of the last 10 days before the sampling (Henderson et al., 1989).

Another advantage of the adduct biomarker is that one can estimate the proportion of the toxic metabolites. As a rule, it is the metabolite that is produced in phase 1 metabolism and not the hazardous substance itself that is responsible for the carcinogenic effect and for the formation of the hemoglobin adducts. Persons with a high activation (phase 1 metabolism) and a low deactivation (phase 2 metabolism) rate are more susceptible resulting in a higher cancer risk. For example, aromatic amines are activated by hydroxylation and deactivated by acetylation. The hydroxylated metabolite is excreted with the urine and forms the carcinogenic agent in the bladder. Under the same exposure conditions persons with a higher rate of acetylation have lower hemoglobin adducts and a lower risk of developing bladder cancer as compared to those with a low rate of acetylation.

Biomarkers of exposure quantify the dose whereas biomarkers of effect indicate early biochemical or functional alterations including a wide array of biological responses, ranging from physiological adaptation to disease. They represent a heterogeneous group of indicators and have different applications depending on the toxicological significance (Manno et al. 2010). The quantification of CO-Hemoglobin as biomarker of an exposure to carbon monoxide and the acetylcholine esterase activity as a biomarker of an exposure to inhibitors of this enzyme are well-known examples. Other endpoints, such as proteins in urine of subjects exposed to nephrotoxic solvents or metals, have been largely used as early indicators

of biological effect. This application requires, of course, that the target organ and preferably also the mechanism of chemical toxicity be known. Effect biomarkers used as early predictors of clinical disease can improve health risk assessment and contribute to implement new effective disease prevention in occupational and environmental settings, but they must be first validated. Validation also involves the clarification of the biomarker's toxicological significance, which means its relation with the chemical's mechanism of action and its ability to detect or predict a specific toxic effect (Manno et al. 2010).

Biomonitoring is used successfully in many environmental exposure studies either for the assessment of the current exposure of hazardous substances (Schwedler et al. 2017) or of the discovering of time trends of the exposure (Göen et al. 2018). In occupational studies, in addition to recording exposure, clinical parameters are usually also examined to determine health effects and the No Observed Adverse Effect Level (NOAEL).

Biomonitoring has also become an important instrument in routine diagnostics for physicians. In the field of occupational medicine, biomonitoring is the most important tool to assess the individual's exposure to specific chemicals, to characterize exposure pathways, and to assess potential individual risk factors. It is increasingly recognized that compliance with a limit value in the air for certain hazardous substances cannot exclude an unacceptably high exposure of workers (e.g., for lead), so that only the determination in biological material is the basis for health protection.

## Abstract

Risk characterization is the final step in the risk assessment process. All scientific data are summarized, reviewed, and evaluated in an integrated manner. Risk characterization should provide a clear description of the potential risk and outline the strengths and weaknesses of the whole risk assessment process. This includes a description of all assumptions and uncertainties of applied procedures, as well as a delineation of how the decision-making process.

**Introduction**

The goal of risk characterization is to provide decision makers with all the information necessary to take risk management actions in a logical and clear manner. The main question to be answered here is “Which effects, in the sense of a possible occurrence of a harmful effect, or in the sense of an increased risk, respectively, are linked with a certain given or expected exposure?” Typical risk management questions that require answers in the process of risk characterization are outlined in the text box below. The risk manager should have an understanding of, and a feel for, how exact risk predictions are, as well as to where the data described lie in the continuum from actual human data to data extrapolated from animal studies or in vitro experiments.

**Some Risk Management Questions to Risk Characterization**

1. What is the bottom line/final conclusion of the risk assessment?
2. Does the risk assessment provide sufficient information to justify regulatory action?
3. What is the range of uncertainty that characterizes the calculated exposure and the extrapolated number of potentially exposed individuals? Do we know if the calculated exposure corresponds to the actual one? Does the actual (or expected) exposure constitute a health (or environment) problem?
4. Which lacking data could give rise to criticism of the risk values or the risk management options?
5. Are there ongoing studies that could, eventually, provide lacking critical data in reasonable time?
6. Did the risk assessment undergo a peer-review process? If yes, by whom? What was the outcome?
7. Is there a possibility of “zero risk”? Was this really excluded?
8. Which key parameters drove the outcome of the risk assessment?
9. If studies were excluded from the risk assessment, which consequences did this have on its outcome? Why were these studies not considered?

It is also very important to identify vulnerable population groups or subgroups that are at particular risk under certain circumstances. An increased vulnerability could be the consequence of a higher exposure or an increased susceptibility. An example of an elevated exposure is that of population groups that consume very high amounts of fatty fish. Such groups may ingest higher amounts of, for instance, dioxins, polychlorinated biphenyls, methyl mercury, and other persistent compounds that accumulate in fat tissue. Children, in particular small children, constitute a group

with higher vulnerability towards a number of risk factors, since their organ systems and their physiological defense mechanism against toxic compounds are still not fully developed.

---

## Elements of Risk Characterization

### Hazard Characterization

Hazard characterization, the description of the potential to harm, requires an interpretation of all data on the toxicity and the dose–response relationship (Dybing et al. 2002).

While hazard identification is the process of determining whether exposure to a toxicant can cause an adverse health effect by assessing and integrating all the available information that may be in vivo studies, in vitro studies, in silico (QSAR, read across, etc.), epidemiological studies, and control clinical studies on humans, the objective of hazard characterization is to document the relationship between dose and response.

In the case of epidemiological studies, for example, it must be clarified if the exposed and control groups have been appropriately selected, if the length of the observation was adequate, if latent effects and confounding factors have been fully considered, if a causal relation between exposure and effect seems logical, and if the level of exposure/dose was adequately captured.

With experimental animal data, the main issue is about the integrity of the studies conducted. Here, a number of factors play a crucial role, among others if the studies have been conducted according to GLP principles (and if not, if an adequate and reproducible operative approach has been applied and described), how the choice of the test species and strain was made, the number of animals per dose group, the choice of dose or exposure levels, and the intervals between repetitive exposures, as well as the duration of the experiment. Often there are no data on certain endpoints. In such cases, it is important to evaluate, based on the existing information, to what extent the missing studies might change the outcome of the risk assessment.

At the onset, information concerning the completeness and the quality of the database is assessed. Studies are evaluated with respect whether or not they have been conducted according to accepted scientific and ethical principles and if they have been adequately assessed and documented.

An important step in hazard characterization is the identification of the critical effect (or critical effects). In some instances, several toxic endpoints are observed. The decision as to which of these effects can be considered as critical (and there may be more than one) depends on the severity of the respective toxicological endpoint and the exposure/dose level at which it first occurs. Eventually, more than one such endpoint needs to be considered, especially when particular toxic outcomes affect particular population groups as is the case with developmental toxicity.

When conducting hazard assessment, a distinction is often made between toxic effects that have a threshold of toxicity and those that show an effect at any

observable exposure level regardless of how low it is (nonthreshold effects). In the first case, it is assumed that the exposure must exceed a certain level before a toxic effect is manifested. Consequently, a “safe” maximal exposure can be calculated, below which damage is not likely to occur.

In the second case, it is assumed that an effect would occur at every exposure, be it so low. In such cases, the probability of a damage (e.g., 1 in 1,000,000) is often calculated for extremely low doses using a variety of mathematical models. Such an approach is mainly applied in the case of genotoxic carcinogens. Modern approaches to risk assessment suggest that such a differentiation is artificial and that all data should be treated in the same manner.

Hazard identification should, to the extent possible, include a description of the mode of action or, if data are available, the exact mechanism of action.

Usually, as the dose increases, the measured response also increases. At low doses, there may be no response. The adverse effect that occurs at the lowest dose is selected as the critical effect for risk assessment (e.g., Acute Reference Dose (ARfD), Lowest or No-Observed-Adverse-Effect-Level (LOAEL/ NOAEL), or ideally BMD limit (BMDL) see) which serves for the derivation of a health-based guidance value (Margin Of Exposure (MOE) or Tolerable Daily or Weekly Intake (TDI/TWI)) (Table 1).

The concept of an ADI was introduced in 1961 by the Joint FAO/WHO Expert Committee on Food Additives (JECFA). Expressed in milligrams of additive per kilogram body weight, it is the dose, if consumed on a daily basis over a lifetime that would cause no adverse effects. The ADI/ TDI approach has been applied to toxic substances including non-genotoxic carcinogens. ADIs and TDIs are derived by dividing a surrogate for the threshold/points of departure by a standard uncertainty factor (UF) of a 100-fold (see paragraph below).

**Table 1** Reference points and Health Based Guidance Values

Reference point (RPs)	Health-Based Guidance Value (HBGV)	Risk characterization
Benchmark Response (BMR)	Acceptable Daily Intake (ADI)	Margin of Exposure (MOE)
Lowest Benchmark Dose (BMDL)	Tolerable Daily Intake (TDI)	Risk Characterization Ratio (RC)
Benchmark Dose (BMD)	Acute Reference Dose (ARfD)	Hazard Quotient (HQ)
No Observed (Adverse) Effect Level (NO(A)EL)	Reference Dose (RfD)	Margin of Safety (MOS)
Lowest Observed (Adverse) Effect Level (LO(A)EL)	Derived-No-Effect-Level (DNEL)	Population at Risk
No Observed (Adverse) Effect Concentration (NO(A)EC)	Derived-Minimal-Effect-Level (DMEL)	
Lowest Observed (Adverse) Effect Concentration (LO(A)EC)	Population Adjusted Dose (PAD)	

According to EFSA, tolerable upper intake level (UL) is defined as the maximum level of total chronic daily intake of a nutrient (from all sources) judged to be unlikely to pose a risk of adverse health effects to humans. “Tolerable intake” in this context highlights what is physiologically tolerable and is a scientific judgment as determined by assessment of risk, i.e., the probability of an adverse effect occurring at some specified level of exposure. ULs may be derived for various life stage groups in the population. However, the UL is not a recommended level of intake. It is an estimate of the highest level of intake which carries no appreciable risk of adverse health effects. To establish whether an exposed population is at risk requires a risk assessment to determine what is the fraction (if any) of the population whose intake exceeds the UL and the magnitude and duration of the excessive intake (EFSA 2006).

The BMD is defined as a dose level, derived from the estimated dose–response curve, associated with a specified change in response, the Benchmark Response (BMR) (e.g., 0.1%, 1%, 5%, or 10% incidence). The BMDL is the lower confidence bound and is often used as the reference point, e.g., for a BMR of 5%, the BMDL05 can be interpreted as follows: a dose for which the response is likely to be smaller than 5% and for which where the term “likely” is defined by the statistical confidence level, usually 95% confidence (EFSA 2009; Muri et al. 2009) (Fig. 1).

Especially for acute toxicity, the acute reference dose approach (ARfD) as defined by the Joint FAO/WHO Meeting on Pesticide Residues (JMPR) is being applied to pesticides. The ARfD of a chemical is “an estimate of the amount of a substance in food and/or drinking water, normally expressed on a body weight basis, that can be ingested in a period of 24h or less without appreciable health risk to the consumer on the basis of all known facts at the time of the evaluation” (JMPR 2002).

## Uncertainty Factors

The uncertainty factor of a 100-fold takes into account interspecies differences and human inter-individual variability. This UF allows for interspecies differences and human variability and has been subdivided to take into account toxicokinetics and toxicodynamics with even values of 100.5 (3.16) for the human aspect. Ultimately, such refinements allow for chemical-specific adjustment factors and physiologically based models to replace such uncertainty factors (Dorne 2010). Intermediate to chemical-specific adjustment factors are pathway-related uncertainty factors which have been derived for phase I, phase II metabolism and renal excretion. Pathway-related uncertainty factors are presented here as derived from the result of meta-analyses of toxicokinetic variability data in humans using therapeutic drugs metabolized by a single pathway in subgroups of the population. Pathway-related lognormal variability was derived for each metabolic route. The resulting pathway-related uncertainty factors showed that the current uncertainty factor for toxicokinetics (3.16) would not cover human variability for genetic polymorphism and age differences (neonates, children, the

**Fig. 1** Key concepts for the BMD approach, illustrated using hypothetical continuous data (EFSA 2017a). (The observed mean responses (triangles) are plotted, together with their confidence intervals. The solid curve is a fitted dose–response model. This curve determines the point estimate of the BMD, which is generally defined as a dose that corresponds to a low but measurable change in response, denoted the benchmark response (BMR). The dashed curves represent, respectively, the upper and lower 95% confidence bounds (one sided) for the effect size as a function of dose. Their intersections with the horizontal line are at the lower and upper bounds of the BMD, denoted BMDL and BMDU, respectively. It should be noted that the BMR is not defined as a change with regard to the observed mean background response, but with regard to the background response predicted by the fitted model. This distinction is important because, in general, the fitted curve does not hit the observed background response exactly (so that adding the BMR to the observed background response will in general not provide the correct intersection with the dose–response at the BMD). In the Figure, the BMD corresponds to a 5% change in response relative to background ( $BMR = 5\%$ ). The fitted curve yields an estimated background response of 8.7, and a 5% increase of that equals 9.14 ( $= 8.7 + 0.05 \times 8.7$ ). Thus, the BMD05 of 21.50 is obtained from the intersection of the horizontal line, at a response of 9.14, with the fitted dose–response model. In this example, the BMDL05 has a value of 18)

elderly). Latin hypercube (Monte Carlo) models have also been developed using quantitative metabolism data and pathway-related lognormal variability to predict toxicokinetics variability and uncertainty factors for compounds handled by several metabolic routes. For each compound, model results gave accurate predictions compared to published data and observed differences arose from data limitations, inconsistencies between published studies, and assumptions

during model design and sampling (Dorne 2010). Ideally, chemical-specific adjustment factors (CSAFs) derived from physiologically based toxicokinetic–toxicodynamic models are established (e.g., assessment of cadmium) (Amzal et al. 2009; EFSA 2009).

## Other Approaches

When a quantitative dose-response relationship cannot be defined, a semiquantitative or qualitative analysis will have to be done. More specifically, in the absence of adequate human and animal toxicological data, structure-activity relationship data can also provide useful insights into the prediction of toxicokinetics of the chemical in the body and an indication of its toxicity for groups of structurally related chemicals or individual chemicals and can include the threshold of toxicological (TTC) approach (EFSA and WHO 2016).

The principle of Threshold of Toxicological Concern (TTC) has been developed and is now used by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in their evaluations. Establishing an accepted TTC would benefit consumers, industry, and regulators, since it would preclude extensive toxicity evaluations when human intakes are below such threshold, and direct considerable time and cost resources towards testing substances with the highest potential risk to human health (Kroes et al. 2000).

## Exposure Characterization

As the Swiss physician Paracelsus stated in the sixteenth century, “all substances are poisons; there is none which is not a poison. It is the dose which determines a poison.”

In characterizing exposure, it is important to start by describing the applied exposure assessment methods, as well as their strengths and weaknesses. If different approaches to exposure assessment were employed in parallel, a comparative assessment of all of them should be presented.

Exposure characterization should include a description of all exposure sources and the contribution by all relevant environmental media (air, water, food, soil) to the total exposure. While the total exposure must be determined, it may be important under certain conditions to consider exposures related to different routes (e.g., inhalation and ingestion) separately. This is particularly important in cases where different toxicological effects are observed following exposure via different routes. Furthermore, it is important to consider all environmental compartments that lead to an exposure (such as the workplace or the general environment) separately when determining and describing the overall exposure.

Finally, it is crucial to determine the exposure of particularly vulnerable groups of the population and to identify all such groups that are subject to higher exposure levels.

## Uncertainty and Variability

Although, ideally risk assessments would be based on a more than adequate knowledge base, in reality it is not always the case. This means that all risk estimates are uncertain to some degree. To address this, the risk assessor should always consider the uncertainties and variabilities in the calculations.

In the process of risk assessment, uncertainties may stem from the lack of data or because extrapolations are necessary. These must be identified in the risk characterization. In addition, variability aspects must be fully considered, be they between individuals or between particular groups of the population. A good risk characterization will address and describe both aspects.

Questions related solely to uncertainty are those that address a lack of knowledge or information. Examples include the eventual need (due to lack of data) for extrapolation from short- to longer-term exposures (e.g., from subchronic to chronic exposure), the extrapolation from lowest dose that results in an adverse effect (lowest observed [adverse] effect level, LO[A]EL) to the highest dose that shows no adverse effect (no observed [adverse] effect level, NO[A]EL). This category of pure uncertainty aspects also includes all deficiencies of the database, for example, the lack of certain studies. Such studies could be ones linked to certain exposure duration or ones that assess certain toxic endpoints (e.g., studies on neurotoxic or reproductive effects). In such instances, it is critical to evaluate to what extent the missing information could change the overall assessment and to provide a clear and logical description of such an evaluation. This requires appropriate experience and often a knowledge of the mechanism of action, besides information on exposure and toxicokinetics. Generally, with increasing information the certainty of the risk assessment increases as well (Fig. 2).

The dose that causes an effect can vary from one person to the next depending on factors such as genetic differences, preexisting medical conditions, etc. Similarly, Exposure varies from one person to the next depending on factors such as working

**Fig. 2** Precision of a risk estimate as a function of available information. The more data are available, the lower the uncertainty around the risk estimate

conditions, life conditions, geographical food habits, etc. Questions related to both uncertainty and variability are encountered in cases where interspecies extrapolation is necessary. This is the case, for example, when the health risk to humans is evaluated based on data from animal experiments. The variability between individuals in a given population group (intraspecies variability) also plays an important role. In both cases, the variability encompasses aspects of toxicokinetics and toxicodynamics, including, *inter alia*, the contact rate, uptake or absorption, general systemic availability, systemic elimination, active site concentration, physiological parameter changes at site of effect, and the functional reserve capacity. Aspects of variability must all be fully considered in the risk characterization process.

When assessing the potential for risks to people, toxicology studies generally involve dosing of test animals as a surrogate for humans. Since we don't really know how differently humans and rats respond, EFSA and other international organizations often use an uncertainty factor to account for the aforementioned differences (interspecies differences). Additional consideration may also be made for differences within the tested animals such as the sex, the age, etc. (intraspecies differences).

In certain cases, special issues may play a role in risk characterization. In the case of persistent compounds that bioaccumulate, such as PCBs, dioxins, and persistent chlorinated pesticides, risk characterization should rather be based on the total body levels over exposure time (body burden) rather than on the external exposure or a dose over a limited period of time. With these compounds, it is also important to consider that an exposure *in utero* is not only related to an eventual exposure during pregnancy, but rather on the body burden of the mother at that time. Another example is that of substances that show cumulative effects, such as cholinesterase inhibitors, which exert their toxic effects through a common point of action.

## Weight of Evidence

When the scientific question is relatively simple and can be addressed directly, then a straightforward assessment with the steps described in this charter can be conducted to reach an outcome.

In many assessments, however, questions may need to be subdivided to yield more directly answerable questions and a weight of evidence assessment needs to be conducted (see ► [Chap. 6, "Toxicological Risk Assessment"](#)). The weight of evidence has three core steps: Assembling the evidence, weighing the evidence, and weighing the relative support for possible answers to the question (after EFSA [2017b](#)).

## Transparency of the Process

In risk characterization, the whole process of risk assessment must be clearly outlined, and all elements necessary for decision-making on managing potential risks sufficiently

described. In this respect, information on the scope of the risk assessment (why was it conducted?) on the extent and quality of the database, as well as on the date of the last literature search were conducted. Furthermore, it must be stated if, and if yes why, adjustment or uncertainty factors were used. Finally, all elements of the decision process must be described, including the mechanism of peer review.

## Abstract

Risk evaluation is the step within the risk analysis process that links risk assessment (the final step of which is risk characterization) with risk management. This intermediary step is mostly not explicitly mentioned, or it is seen as a preliminary step in risk management. The goal of risk evaluation is to link exposure levels with corresponding risks and to identify sources of uncertainty in the scientific data used.

**Introduction**

Based on the outcome(s) of the risk assessment, options for risk management need to be developed and evaluated for the decision-making process. Risk management covers all actions and decisions as to whether or not, and, if yes, how certain risks should be eliminated or reduced. Options and strategies developed for their possible implementation can be of regulatory, economic, informational, or technological nature. They need not to be mutually exclusive. In order to reach adequate and rational decisions, a risk must be seen in the context of other risks and evaluated considering various different factors.

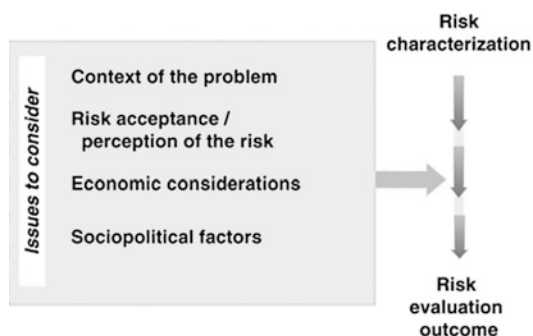

Good risk management decisions should follow certain principles. Thus, the problem must be discussed within its health or ecological context and should consider the views of all those who would be affected by possible decisions. Such decisions must be based on a balanced scientific assessment and build on a full analysis of different regulatory and nonregulatory options for action. They must lead to a reduction or an elimination of the risk under consideration and be implementable in a rapid and efficient manner and with the support of all relevant stakeholders. Actions must, indeed, be proven to affect the risk to be minimized or eliminated. They should offer the possibility for being revised or changed if new information becomes available that would justify it.

---

**Elements of Risk Evaluation**

To allow for sound risk management decisions to be reached, risk evaluation should offer ways to eliminate or reduce the risk(s) under consideration that fulfill certain criteria. Risk evaluation should be based on scientific, technical, and economic data of the highest possible quality. It should take account of the mostly existing context of multiple risks. Recommended actions must be technically, politically, and economically feasible and should offer clear advantages with regard to cost. They should give preference to prevention and place innovation in the center of the decision-making process. Finally, they should take account of sociopolitical aspects. Some elements of risk evaluation are discussed in more detail in other chapters of this book. In this chapter, the main aspects of risk evaluation will be briefly discussed and relevant terms will be explained (Fig. 1).

**Fig. 1** Issues to consider within the framework of the risk evaluation process

## Context of the Risk Problem

A risk cannot be evaluated in an isolated manner. Often, a risk factor, for example, a chemical substance, has several sources that contribute to the overall exposure. In such cases the risk should be evaluated within the “multiple source context.” The risk evaluation must consider the contribution by each of these sources to the overall exposure in order to permit the development of effective risk management options that will, indeed, reduce the risk. The question here is mostly about the point of intervention that would achieve the most effective protection.

An exposure to the same risk factor could occur through different environmental media (e.g., air, water, drinking water). One example is lead. Human exposure is via air (inhalation; the main sources here are car exhaust emissions if lead-containing petrol is used, lead-containing paint, and various industrial processes), via drinking water (ingestion, e.g., in the case of lead water pipes), via food (ingestion, mainly through the use of lead-containing food cans), as well as via direct exposure through the use of lead-containing cosmetics (e.g., dermal exposure). A risk evaluation must therefore also consider exposure through all relevant environmental media (“multi-media context”).

The source of one risk factor might also release other substances that may pose an additional risk. Dioxins, for example, are encountered as food contaminants (e.g., in fish), often in combination with, *inter alia*, polychlorinated biphenyls, and methyl mercury. The three compounds have all neurotoxic effects among other toxic actions. The combined effects must be considered jointly. In such cases, individual compounds should not be evaluated independently from accompanying exposures (“multifactor context”).

Finally, a risk must be evaluated in comparison to other risks in the same group of population. This is important in order to set priorities for action and to initiate actions which are most urgently needed first (“multiple risk context”).

## **Risk Acceptance**

The decision as to whether or not a risk is acceptable requires a judgment in the context of social, political, and economic aspects. Of special importance to the risk evaluation is the way society judges the particular risk under consideration and to what extent certain exposures would be tolerated. Risk acceptance depends to a large extent on the perception of risk. Risks are not always seen by the public in scientific terms but often also based on qualitative perception. Thus, risks are accepted if they are common and known, if they are easy to control, if their mode of action is known, if the exposure is voluntary, if the effects are immediately seen and do not affect future generations, and if potential effects are reversible and/or are not of catastrophic nature. Trust in responsible institutions, lack of media interest, and clearly visible economic benefits also increase risk acceptance. In general, risks are more accepted if they are easy to see and their control appears to be easily accessible. Thus, the risk of a nuclear reactor accident is judged to be higher than that of a motorcycle accident or that of smoking. Aspects of risk acceptance must therefore be clearly delineated and fully considered in risk evaluation. Risk comparisons may help in providing an objective view in this context.

## **Socio-economic Analysis**

Socio-economic analysis is a well-established method of weighing up the pros and cons of an action for society as a whole and need to contain a description of the risks as well as information on the health and environmental benefits, the associated costs, and other socio-economic impacts. In socio-economic analysis, one needs to analyze and document whether the socio-economic benefits of continued use of the substance outweigh the risks of continued use for human health and the environment.

## **Economic Factors**

An economic valuation provides important information for risk management. Economic considerations should therefore form an integral part of risk evaluation, including potential benefits which would be brought about through an improved health and environmental protection. In particular, two aspects should be looked at. The cost-benefit analysis considers economic and/or social gains emanating from a risk-producing process in comparison to its costs, which should also include those costs related to eventual damages to human health and environmental integrity. The cost-effectiveness analysis, in contrast, evaluates rather the “efficiency of a certain intervention” (e.g., a regulatory measure or a technological evaluation) in controlling a certain risk. Here, the expected economic and/or social benefit due to a certain proposed measure is quantified and compared to

the cost caused by such a measure. In both processes, the quantification of positive and negative effects on human health and the environment in economic/monetary terms is a major problem.

## **Sociopolitical Factors**

Risk management decisions are political in nature. Therefore, options developed in risk evaluation need to reflect social and political considerations. Among the questions to be addressed, the issue of other risks that occur concomitantly and need also to be managed figures prominently. In this context, different risks are evaluated in a comparative manner, and a rational weighting is performed. Often, it is necessary to assess which risks should be given priority in reaching risk management decisions and which can be addressed at a later stage, since it is difficult, if not impossible, to address all risk factors at the same time. This process of comparing risks and weighing risk management options is defined as “risk balancing.”

Sometimes, an action taken to control a given risk factor may lead to the appearance of new risks to health and/or the environment. Replacement of a chemical in a technological process with another, for example, can produce new risks. A practical example would be to abandon the disinfection of drinking water to avoid the risk due to chlorination by-products: the expected reduction of the health risks due to chlorinated organic compounds in drinking water would be linked to a significant increase in the risk of waterborne infectious diseases. Considerations of this kind fall under the term “risk-risk tradeoffs.” The main question to be addressed here is: “which risks do we take if we control another through certain measures?”

Another aspect of sociopolitical and ethical nature is that of “environmental equity.” In this context, considerations are made as to whether or not the population group(s) that benefits from a certain activity is the same as those who carry the risk. The aim is to avoid situations where a group carries all (or the larger part) of risk, without profiting from the risk-producing process, and that all benefits come to another group that carries no or a substantively lower part of the risk.

## **Uncertainty and Variability: Scientific and Economic Aspects**

Since risk evaluation is an intermediary step linking risk characterization with risk management, uncertainty and variability issues that emerged and were discussed in risk characterization must also be fully considered when developing options to minimize or eliminate risks. Problems that could be of relevance at this step could target scientific or economic aspects. Examples of scientific issues include the relevance of toxicological studies under real-life conditions (risk prediction), the possibility to detect and consider differences in susceptibility among exposed populations, as well as the identification of highly exposed groups. In addition, questions concerning realistic exposure scenarios and on interactions between different risk factors may be of relevance. Economic problems include the difficulty of

quantifying health and environmental aspects from an economic point of view. Other issues target the inconsistency of economic analyses and the uncertainties connected with it, as well as the inadequacy of methods to validate the advantages of potential risk management actions for human health and the environment.

---

## Outlook

Aspects described in this chapter are within the context of evaluating a given risk in the context of other risks and with consideration given to risk acceptance, as well as political and economic factors. Such considerations constitute a judgment of the characterized risk in connection with the development of control options as a prerequisite for managing the risk. Risk evaluation, thus, has a bridging function between the pure science and the political decision-making process. Even though this step is not explicitly included as a separate process in the usual risk assessment and risk management paradigms, risk evaluation is an important basis for decisions. Modern approaches to risk analysis, such as the one proposed by the US National Research Council in 2009, promote a more integrated approach to risk assessment and management, during which questions related to risk evaluation are addressed from start (problem formulation) to end (risk management), ensuring stakeholder involvement and risk communication throughout.
